"*To the solid ground*
Of Nature trusts the mind which builds for aye."—WORDSWORTH.

THURSDAY, MAY 2, 1889.

THE NEW CODE AND SCIENCE TEACHING.

THE new Code of the Education Department[1] is now lying on the table of the House of Commons, and never, since the famous proposals of Mr. Mundella, has there been so much stir among those interested in primary instruction as at the present moment. The reason is not far to seek. For some years a Royal Commission has been sitting and taking evidence, and it has produced several bulky Blue-books during the course of the past year. It was known that the Commission was divided into a majority and minority who were strongly opposed to one another on certain questions of policy. This has found expression in lengthy reports and contradictory recommendations; but, to the satisfaction, if not to the surprise, of educationists it is found that on purely educational matters there is an almost perfect unanimity between the two sections. It was therefore a matter of deep interest to see how, and to what extent, these recommendations, signed by every member of the Commission, would be embodied in the proposed Code of 1889.

At the outset it may be well to remark that there are several alterations in this Code which are almost universally allowed to be improvements. But it is conceived in a spirit of compromise, and perhaps no party is entirely satisfied with it. The only point we have to consider is the aspect of the Code towards the teaching of natural science.

It may be convenient to group our observations under different headings.

I. The direct changes proposed in the teaching of science. These are almost confined to one or two modifications in the geographical schedule, and to a provision that "Scholars of any public elementary school may attend science classes held at any place approved by the inspectors." This may be very useful in towns, especially as it will admit of the formation of central laboratories or work-rooms similar to the present cookery centres.

II. The proposed changes which will tend to facilitate the teaching of science. There are four subjects of instruction which are termed "class-subjects": English (including grammar, composition, and repetition of poetry), Geography, Elementary Science (a progressive course of object-lessons), and History; together with Needle-work for girls. Only two of these class-subjects can be taken for examination, and, under the old Code, "English" must necessarily be one of those chosen. The consequence of this is, that "Elementary Science" has never got a footing in our schools, for even where two class-subjects are taken, they are nearly always English and Geography, or English and Needle-work. The supremacy of English is now to be put an end to, so that any teacher may now take Elementary Science, if he or she should prefer it, and earn a grant.

The enormous waste of time and patience in making little children, even in our infant-schools, learn the spelling of common words, is to be reduced. The inspector is to give no dictation exercises to boys and girls under the second standard. This will give more time for object-lessons and other valuable modes of instruction.

Some relaxation of the literary requirements are also made in the case of evening schools.

The present system of payment by results is to be so modified that the cramming in the three R.'s will not be so profitable, and there will be more chance for intelligent teaching. One of the matters also to be taken into account by the inspector in assessing a school, is the provision of "apparatus," though this need not necessarily have anything to do with what scientific men would call by that name.

These proposed changes are in the right direction, but the value of many of them will largely depend upon how they are understood. There is a singular want of clearness in some of the clauses. The annual "Instructions to inspectors" have not been yet drawn up, and indeed it is very improbable that they will make their appearance until after the Code has become law. It is quite possible to take away with one hand what is given with the other. The present agitation is therefore of great importance

[1] "Code of Regulations, with Schedules, by the Right Honourable the Lords of the Committee of the Privy Council on Education." (Eyre and Spottiswoode.)

not merely in getting modifications of the Code when discussed in Parliament, but in inducing the Education Department to give their inspectors such instructions as shall secure that the greater liberty of teaching should be a reality; that the ominous word "repetition," introduced into one or two paragraphs may not become "English" in disguise; and that the spelling of the second standard should not involve a laborious preparation of the younger children.

III. These alterations bearing on the teaching of science fall far short of what the Royal Commissioners unanimously recommend. The report of the majority states that "some elementary instruction in science is only second in importance to the three elementary subjects:"—namely, reading, writing, and arithmetic, and it places among subjects regarded as essential, "geography (especially of the British Empire); lessons on common objects in the lower standards leading up to a knowledge of elementary science in the higher standards." It adds, "That geography, if properly taught, is a branch of elementary science, which should not be separated from the other branches, and might well be taught along with object lessons, in accordance with the recommendations of the Royal Commission on Technical Instruction"; "that the curriculum in the ordinary elementary schools might often include not only instruction in the elementary principles of science, but also, in certain standards, elementary manual instruction in the use of tools, and in higher schools and evening schools this work might be carried still further"; "that, in making future appointments to the office of inspector, it would be desirable, in regard to a larger proportion of them than at present, to give special weight to the possession of an adequate knowledge of natural science." The members of the minority express themselves, if possible, more strongly; and make such additional remarks as, "We are of opinion that, after the children have left the infant school, transitional methods should be adopted, which will develop their activity and train their powers by drawing in all cases, and by such other means as, for instance, modelling, or the collection and mounting of botanical specimens."... "If science is to be well taught, care should be taken, that where the ordinary teachers are not qualified, specially trained teachers should be employed." In respect to technical schools they say, "These schools, which should be the crown and development of elementary education, should be in touch and close sympathy through their management with our elementary school system."

IV. The proposals of the new Code also fall far short of what the principal School Boards are attempting. Spirited efforts are made in Birmingham, Manchester, Sheffield, Brighton, and other provincial towns, in establishing higher elementary schools with useful scientific teaching. The London Board determined from the commencement that object-lessons leading up to science subjects should be given in all its schools. It has repeatedly contended for the official recognition of such lessons; and it has lately sent a memorial to the Education Department asking that the regulation, at present in force in the infant schools, that, in assessing the grant, regard should be had "to the provision made for simple lessons on objects and on the phenomena of Nature and of common life," should be extended to the boys' and girls' departments.

The reforms decided upon by the London Board last year with the view of making the teaching more experimental and practical, and not so much a matter of book-learning as a development of intelligence and skill (see NATURE, vol. xxxvii. p. 577), are being gradually put into operation.

It has also for some years carried on a few classes for manual instruction in the use of tools with good success, but its efforts in that direction have been nearly paralyzed by the disfavour of the Legislature. This seems a necessary step towards the technical education which is now loudly called for (see Sir Henry Roscoe's lecture, NATURE, vol. xxxviii. p. 186); but in the new Code we look in vain for a word of encouragement.

Some of the larger Boards have carefully provided good instruction in natural history, and in the fundamental principles underlying mechanical, physical, and chemical science, for their pupil-teachers, though that does not appear upon the Government schedule.

V. What is wanted is a far more liberal recognition of the claims of science in elementary education. At present, object-lessons or certain sciences are, no doubt, recognized by the Code; but it is merely as an additional subject of instruction not comparable with the literary subjects which are considered essential, and which occupy the great bulk of the scholars' time. The knowledge of Nature is, in fact, totally neglected in hundreds or thousands of elementary schools, especially in country districts, where it would appear to be even more important than in towns. A boys' or girls' school can obtain the highest credit in the inspector's report, and the highest possible grant of money, without its scholars having ever heard of animal or plant, or of those materials of the world, or of those natural forces, with which the scholars will have to deal all through their lives. And what is perhaps still more anomalous, those pupil-teachers who are possibly expected to give object-lessons in their schools are never examined in natural history by the Department, and may gain a high place in their examinations without the least knowledge of any kind of natural science.

It seems most desirable that every little child who enters our schools should be led to observe and inquire; its curiosity and activity should be encouraged and directed; only when its senses have been made acquainted with things should it be introduced to the words by which they are called, first orally, then in writing or print. It should proceed from the concrete to the abstract, The works of the Creator are as worthy to be studied as the words of men, and should hold as high a place in any school curriculum.

The reply of the Department to such requests as these will probably be, We cannot assume that the teachers are capable of teaching or the inspectors of examining science. No doubt there is that difficulty. But many of them are capable, and they are all presumably intelligent men, who would easily learn what might be required of them. Special teachers of science also exist, and special examiners might be appointed. It may not be possible to insist on all these reforms at once, but at least encouragement should be held out to them, instead of the disappointing uncertainties of the Code now before Parliament.

J. H. GLADSTONE.

THE NATIONAL SCIENCE MUSEUM.

IT is now fifteen years since the Duke of Devonshire's Commission, in its fourth Report, made the following recommendations:—

"With regard to *the Scientific Collections of the South Kensington Museum*, we recommend:

"9. The formation of a collection of physical and mechanical instruments; and we submit for consideration whether it may not be expedient that this collection, the collection of the Patent Museum, and that of the Scientific and Educational Department of the South Kensington Museum, should be united and placed under the author ty of a Minister of State.

"With regard to *Provincial Museums*, we recommend:

"10. That, in connection with the Science and Art section of the Education Department, qualified naturalists be appointed to direct the collection of specimens in order to supply whatever deficiencies exist in the more important Provincial Museums; and also in order to organize typical museums, to be sent by the Department of Science and Art into the provinces to such science schools as may be reported to be likely to make them efficient instruments of scientific instruction.

"11. That a system of inspection of Provincial Museums be organized with a view of reporting on their condition, and on the extent to which they are usefully employed, and whether the conditions of the loan or grant from the Department of Science and Art have been fulfilled."

It is quite in accordance with the general way in which scientific matters are treated by the British Government that practically nothing has been done to give effect to these recommendations. Committee after Committee has been appointed, but it would seem more to give an excuse for delay than anything else. But the apathy of the Government was not shared by H.M. Commissioners for the Exhibition of 1851, for some time afterwards they offered a large site on their estate, and a building to be erected at a cost of £100,000, if the Government would undertake its maintenance for the purposes named in the recommendations. Even this munificent offer was declined.

Again we hear that another Committee has been appointed. Its sailing orders are not known, but whatever they may be, it seems desirable to again place on record after an interval of fifteen years that part of the Report in question which relates to the inquiry intrusted to the Committee. The Report was the result of much and patient inquiry and deliberation (the Commission worked for five years), and that the competence of the Commission may not be doubted after this lapse of time, we give the names of the Royal Commissioners: the Duke of Devonshire, Sir John Lubbock, Sir James P. Kay-Shuttleworth, Dr. W. Sharpey, Prof. T. H. Huxley, Prof. G. G. Stokes, Prof. Henry J. S. Smith, and Mr., now Sir, Bernhard Samuelson. Mr. J. Norman Lockyer was the secretary of the Commission.

THE COLLECTIONS AT SOUTH KENSINGTON.

64. The South Kensington Museum is administered by a Director who is responsible to the Lords of the Committee of Privy Council on Education.

65. Though, from special circumstances, the art collections of this Museum have been, up to the present time, most developed, it has contained, from its earliest days, several collections of a scientific nature. Those at present existing are:—

(1) The food collection.
(2) The animal products collection.
(3) The structure and building materials collection.
(4) Models of machinery, ships, and military and naval appliances.
(5) Collections illustrating economic entomology and forestry.
(6) Collections illustrating fish culture.
(7) The educational collections.
(8) The Patent Museum.

66. *The Food Collection.*—This collection, which was commenced in 1858, has been formed with a view to showing, first, the chemical composition of the various substances used as food; secondly, the sources from which all varieties of food are obtained; and, thirdly, the various substances used for adulteration, and the best methods of detecting them.

A duplicate collection of the chemical analyses of food is used for circulation among country schools, and large descriptive labels are supplied to the managers of country museums who may apply for them.

67. *The Animal Products Collection.*—This collection was established by the Commissioners for the Exhibition of 1851, who observed that, whilst the public possessed, in the Museums of Kew and Jermyn Street, collections illustrative of the economic applications of mineral and vegetable substances, there was no representation of the uses of the animal kingdom. The collection consists of animal substances employed in textile manufactures and clothing; substances used for domestic and ornamental purposes; pigments and dyes yielded by animals; animal substances used in pharmacy and in perfumery; and the application of waste matters, together with illustrations of the processes of manufacture.

We have been informed that, for want of space, this collection has been but little developed of late years.

68. *Construction and Building Materials Collection.*—This collection had its origin in a large number of models and specimens which were presented to the Commissioners for the Exhibition of 1851 at its close. In 1859 the collection had become so extensive from gifts, especially from the Exhibitions in London and Paris, that the classified Catalogue formed a most useful book of reference on the subject, and was largely sold as such.

The collection consists of the following objects:—building stones; marbles and slates; cements and plasters; bricks of every description; tiles for roofing, flooring, and wall decoration; terra-cottas; drain-pipes; asphalte and bitumen; iron and metal work; woods applicable to building purposes; glass, and its application; models of buildings and construction; paper-hangings; *papier-mâché* work; architectural drawings and plans.

69. In connection with this Museum, numerous experiments on the strength of materials have been carried on, the results of which have been published in the Catalogues.

70. *Models of Machinery, Ships, and Military and Naval Appliances.*—This collection consists principally of models of marine engines, ships, and guns. But there are also specimens and models of machinery of a different character, such as the Jacquard loom, the Whitworth measuring machine, and the Babbage calculating machine.

71. *Collections illustrating Economic Entomology and Forestry.*—A collection of economic entomology is now in course of formation. It is intended to enable the public to distinguish insects injurious to man from those that work to his advantage, and to illustrate the best means of destroying those which are injurious, or of mitigating the ravages committed by them.

This collection, in its relation to forestry, contains specimens of the various kinds of timber attacked by insects, the insects themselves in various stages of growth, and the appearance of the foliage and bark when attacked. The best known means of destroying the insects are also indicated.

72. *Collection illustrating Fish Culture.*—This collection illustrates the artificial breeding of fish, the protection of rivers, methods of capture of fish, &c. All or nearly all the collection belongs to Mr. Buckland (Inspector of Salmon Fisheries). It is on loan to the Museum.

73. *The Educational Collections.*—These collections comprise: (1) a library of books bearing on education in which education in science is largely represented; and (2) a collection of school furniture and fittings, philosophical instruments, apparatus for scientific and other instruction, specimens and diagrams of natural history, including mineralogy and geology, and other educational appliances, such as drawing materials, &c.

74. The origin of the library and collections is due to an Educational Exhibition formed by the Society of Arts, and held in St. Martin's Hall in the summer of 1854. When this Exhibition closed, many of the contents, English and foreign, were placed by the exhibitors at the disposal of the Society, and a strong desire was expressed that it should become a permanent institution. The collection thus formed was offered to and accepted by the Government.

75. The chief manufacturers of educational appliances and publishers of school books have largely contributed, and numerous gifts have been received from foreign Governments, especially at the close of the Exhibitions of 1862 and 1871. In consequence of the great demand for educational works on scientific subjects, the vote for purchases has of late years been largely expended in strengthening the library and collections in this direction.

76. Special collections of apparatus for teaching the various branches of science have lately been formed. Duplicate sets of these are circulated in the country.

77. The total number of books and pamphlets in the library exceeds 30,000.

78. A reading-room, ill-adapted and much too small for the purpose, as it has been stated in evidence, is attached to the library. It is open during the same hours as the Museum, and is chiefly frequented by students, teachers, clergymen, school-managers, and others who wish to consult special books, or to become acquainted with the best educational works on the various subjects.

79. *The Patent Museum.*—In connection with the South Kensington Museum, but under the control of the Commissioners of Patents, there is also a Patent Museum, consisting of a collection of patented and other inventions, ill-accommodated in a building which is much too small for the proper display of the objects. The collection belongs partly to the Commissioners of Patents, partly to the Commissioners for the Exhibition of 1851, and partly to private persons: it contains many most interesting specimens, especially a series illustrating the history of the steam-engine from its earliest days.

Proposed Additions to the Scientific Collections of the South Kensington Museum.

80. We consider it our duty to point out the striking contrast afforded by the British Museum collections, dealing with biology, geology, and mineralogy; the Jermyn Street collections, dealing with geology (scientific and economic), mineralogy, mining, and metallurgy; the Kew collections, dealing with botany, on the one hand; and, on the other hand, the collections in the Scientific Department of the South Kensington Museum (including the Patent Museum), where alone has any attempt been made to collect together, in a Museum, objects illustrating the experimental sciences.

81. While it is a matter of congratulation that the British Museum contains one of the finest and largest collections in existence illustrative of biological science, it is to be regretted that there is at present no national collection of the instruments used in the investigation of mechanical, chemical, or physical laws; although such collections are of great importance to persons interested in the experimental sciences.

82. We consider that the recent progress in these sciences, and the daily increasing demand for knowledge concerning them, make it desirable that the national collections should be extended in this direction, so as to meet a great scientific requirement which cannot be provided for in any other way.

83. The defect in our collections to which we have referred is, indeed, already keenly felt by teachers of science. If a teacher of any branch of experimental science wishes to inspect any physical instrument not in his possession, as a teacher of literature would a book, or a teacher of biology would a specimen, there is no place in the country where he can do it.

84. We are assured by high authorities that, on the Continent, collections of scientific apparatus, when combined with lectures accessible to workmen, have exerted a very beneficial influence on the development of the skill of artisans employed in making such instruments.

85. Lord Salisbury, in evidence before us, has stated:—

"There is another point in which I think that the Government might give an advantage of an educational kind to scientific research. It would be desirable, if it were possible, to provide the means of giving scientific instruction to instrument makers. My impression is that their importance to the conduct of scientific research is scarcely sufficiently recognized by the public, and that it is, I will not say quite, but almost of equal importance, to have highly educated and cultivated scientific instrument makers, as to have highly educated scientific thinkers."

86. A valuable part of the instruction to which Lord Salisbury refers would be derived from the examination of collections in which the history and latest developments of each instrument could be studied with a view to its improvement or modification in any particular direction.

87. On this point we have received interesting evidence from Colonel Strange:—

"What is your opinion as to the need of a museum of scientific instruments, and apparatus, and machines, and tools used in the arts?—I think that that is a very important branch of the subject indeed. I need scarcely allude to the great importance that is attached to that on the Continent. The name of the Conservatoire des Arts et Métiers will suggest it at once, which is the very best evidence indeed that I could produce. I have often visited it with great interest and profit. Moreover, I believe there are several others in Paris, some of more recent establishment, of the same kind; I look upon that as a most necessary part of any scientific system. No scientific system can be complete without examples of the apparatus that are being used in all branches of science, both in England and abroad, and on that point I speak from experience of the great use that such a museum would be. . . . If there were a great museum, such as I suggest, containing all the new developments in instruments, and in machines and tools, to which I could resort, I should be able to introduce modifications with far greater confidence, and it would be an enormous assistance to me individually. I find very few persons who have really studied what I will venture to call the physiology of instruments and apparatus, and such persons would derive very great advantage, I think, from being able to go to an establishment where large collections of apparatus of different dates and the products of different minds were collected together in one view, some of which would contain some desideratum of which they were in search. I think, if they had such a collection to go to, it would materially aid them in the choice of the apparatus that they required, and would tend enormously to advance exact experiments. There is no doubt that some years ago there was no nation that could compete at all with England in such matters, but we have taught the rest of the world, and the pupil has now become somewhat in advance, in many directions, of his master. Also the spread of scientific education on the Continent has tended to the application of more sound principles of construction in such things than with us."

88. Although the question of the establishment of a Museum of Scientific Apparatus is more closely allied to the objects of our Commission than that of a Museum of Mechanical Inventions, we think it right to call attention to the proposals made by a Committee of the House of Commons appointed to report on the Patent Office Library and Museum.

89. That Committee gave, in the following terms, their conception of the nature of the "General Museum of Mechanical Inventions," the establishment of which they contemplated:—

"It appears to your Committee that the chief purpose of a General Museum is to illustrate and explain the commencement, progress, and present position of the most important branches of mechanical invention; to show the chief steps by which the most remarkable machines have reached their present degree of excellence; to convey interesting and useful information, and to stimulate invention."

90. With regard to the funds which would be necessary for the establishment of such a Museum on an adequate scale, the Committee, referring to a large sum which had accumulated from the fees paid by inventors (which fund, at the end of the year 1871, amounted to £923,741 8*s.* 11*d.*), stated that—

"Your Committee consider that the principal object of the fees payable under the provisions of the Patent Law Amendment Act, was to provide for the proper working of that measure, and not for the purpose of increasing the general revenue of the country. Without entering upon the question whether or not a claim exists to have the surplus exclusively devoted to the purposes of the Act of 1852, your Committee are of opinion that for the future the annual surplus revenue accruing from the operation of that Act should be so applied to the extent which may be necessary."

91. We agree with the Committee as to the general character of the objects to which the fund in question should be appropriated.

92. We consider that this fund, which is derived in great part from the applications of scientific principles to various uses in the arts and industries of the country, would be very properly spent in bettering some of the conditions on which invention and discovery depend: and we are of opinion that, among the uses to which such a fund could be most advantageously applied, the establishment of such a Museum of Scientific Apparatus as that which we contemplate would rank among the most important; and we are convinced that such a Museum would have a material influence upon the spread of scientific instruction throughout the country, and would therefore largely foster invention and discovery.

93. We accordingly recommend the formation of a collection of physical and mechanical instruments; and we submit for consideration whether it may not be expedient that this collection, the collection of the Patent Museum, and of the Scientific and Educational Department of the South Kensington Museum, should be united and placed under the authority of a Minister of State.

94. Whether this union be effected or not, we are of opinion that it is desirable that the scientific collections now placed at South Kensington should be subjected to a critical revision, with a view to restricting them to such objects as are of national interest or utility.

REPTILIAN ORDERS.

Catalogue of the Chelonians, Rhynchocephalians, and Crocodiles in the British Museum (Natural History). By G. A. Boulenger. New Edition. Pp. 311, Illustrated. (London: Published by the Trustees of the Museum, 1889.)

THE handsome volume before us deals, as its name implies, with all known existing forms of the three Reptilian orders of the Chelonians, Rhynchocephalians, and Crocodilians; but since the second group is represented only by a single species, while the number of Crocodilians comprises little more than a score of forms, the great bulk of the book is devoted to the Chelonians, and it will, therefore, mainly be this group to which our remarks will apply.

Previously to the appearance of this volume, the last systematic "Catalogue of Crocodilians and Rhynchocephalians" issued by the Museum was the quarto volume by the late Dr. Gray,[1] published in 1872; the next year having seen the publication of the revised list of Chelonians by the same author.[2] Without in any way wishing to disparage the labours of the late Keeper of the Zoological Department, to whose untiring energy the British Museum is so greatly indebted for its magnificent series of Reptiles, it is at once manifest that the present work is enormously in advance of any hitherto published, this advance being especially noticeable in the case of the Chelonians. Although in that order Dr. Gray figured a large number of skulls, yet the distinctive features afforded by this part of the skeleton were not accurately gauged from a taxonomic point of view, while the characters of the bony carapace, so far as they relate to the connections of the component bones with one another, were practically ignored. In this respect Mr. Boulenger has conferred a great boon, not only on the students of the Chelonia of the present day, but still more especially on those engaged in the study of fossil forms, who generally have to deal only with the more or less imperfect carapace and plastron. In almost every genus the author has caused at least one specimen to be stripped of its epidermal horny shields, so as to exhibit not only the impressions formed by the borders of these shields, but also the form and relations of the underlying bones which constitute the solid shell. And he has found that generic characters can be to a very large extent based on the structure of the skull, taken together with the form and relations of the bones of the shell; the contour of the neural bones of the carapace, and the relations of the suture between the humeral and pectoral shields of the plastron to the entoplastral bone being of especial importance. No less than seventy-three admirably-executed woodcuts serve to illustrate these osteological features, on which the taxonomy is so largely based; and by their aid the palæontologist may hope to clear up to some extent the affinities of the host of fossil Chelonians at present described under the vague terms of *Emys* and *Clemmys.*

The author proposes to divide the Reptiles treated of

[1] "Catalogue of Shield-Reptilia. Part 2. Emydosaurians, Rhynchocephalia, and Amphisbænians." (1872.)

[2] "Hand-List of the Specimens of Shield-Reptiles." (1873.)

in this volume into the following groups of higher than generic rank, viz.:—

Order **Rhynchocephalia.**
Fam. Hatteriidæ.

Order **Chelonia.**
Sub-order I. ATHECÆ.
Fam. 1. Sphargidæ.
Sub-order II. THEOCOPHORA.
Super-fam. A. *Cryptodira.*
Fam. 2. Chelydridæ.
3. Dermatemydidæ.
4. Cinosternidæ.
5. Platysternidæ.
6. Testudinidæ.
7. Chelonidæ.
Super-fam. B. *Pleurodira.*
Fam. 8. Pelomedusidæ.
9. Chelydidæ.
10. Carettochelydidæ.
Super-fam. C. *Trionychoidea.*
Fam. 11. Trionychidæ.

Order **Emydosauria.**
Fam. Crocodilidæ.

There are a few points in regard to the nomenclature of some of these groups where the author's views are at least open to question. This is especially the case with regard to the selection of the name Emydosauria to replace the almost universally accepted Crocodilia. The reason for the selection of this term appears to be, that it is the earliest. In common, however, with a large number of English zoologists, we (while deprecating the needless introduction of new ordinal names) hold that, although the enforcement of the rule of priority is, unfortunately, in most cases, obligatory as regards generic and specific names in order to avoid endless confusion, yet no such rule is necessary in respect to higher groups, where the name that has come to be generally used ought to be maintained. Then, again, the ungrammatically formed name Athecæ, for which Prof. E. D. Cope is responsible, should clearly have been amended to Athecata; while, since the name Thecophora—or, more correctly, Thecaphora—clashes with the same term employed for a group of Hydroid Zoophytes, we think the author would have been better advised had he followed his own article on Tortoises in the latest edition of the "Encyclopædia Britannica," and employed the term Testudinata in this sense. Finally, since the generic names *Hatteria* and *Sphargis* are rejected in place of the earlier *Sphenodon* and *Dermochelys* (which, by the way, should clearly be amended to *Dermatochelys*), we cannot follow the author in retaining the names *Hatteriidæ* and *Sphargidæ* for the families respectively represented by these two genera. If a family name means anything at all, it means a group of animals more or less nearly allied to a certain genus selected as the type, and it is therefore clearly illogical to call the *Sphenodon*-like reptiles *Hatteriidæ* when no such genus as *Hatteria* exists. Further, to show the absurdity to which this adherence to the rule of priority, in place of that of common-sense, in the case of family names might lead us, we have only to suppose that the name *Hatteria*, in place of being rejected as later than *Sphenodon*, had been rejected on account of being preoccupied by another form belonging to, but not the type of, a distinct family. In such case, we should have the family name *Hatteriidæ* for a group of animals which did not include the genus *Hatteria!* On these grounds we hold that the names *Sphenodontidæ* and *Dermatochelydidæ* should certainly replace *Hatteriidæ* and *Sphargidæ*.

In regard to the Rhynchocephalia, the author considers that its one existing representative indicates an extremely generalized type of reptile, of which the relations appear to be at least as close to the Chelonia as to the Lacertilia. In this respect, Mr. Boulenger departs very widely from the views of Prof. Huxley; and although we think he is undoubtedly justified in maintaining the Rhynchocephalia as a distinct order, yet we cannot overlook the circumstance that the Homæosaurian lizards of the Lithographic stone, which appear to be Rhynchocephalians, are most probably closely related to the ancestors of the Lacertilia.

The whole of the existing Crocodilians are included in a single family—against the three families adopted by Dr. Gray. The true Crocodiles are divided into *Crocodilus* and *Osteolæmus*, according to the absence or presence of a forward prolongation of the nasals to divide the anterior nares; while among the Alligators a similar feature serves to distinguish *Alligator* and *Caiman*. The *Crocodilus pondicerianus* of Gray is considered to be based upon a young specimen of *C. porosus*. The Gharial skull mentioned on p. 276 as having been obtained at Poonah would appear to be incorrectly labelled, as this reptile is unknown in Bombay.

Taking a brief general survey of the Chelonia, we think the author is fully justified in adopting Prof. Cope's division of the order into the two primary groups of Athecæ and Thecophora; the great difference in the structure of the skull, as exemplified by the absence of descending parietal plates in the former, being a character which is of itself apparently sufficient to uphold this division. We are aware, indeed, that Dr. G. Baur, of Newhaven, Conn., holds a precisely opposite view, and, in place of regarding the *Athecæ* as the most generalized type of existing Chelonians, looks upon them as an extremely specialized branch derived from the Cryptodiran *Chelonidæ*. There are, indeed, certain superficial, and probably adaptive, resemblances between these two types of marine turtles, but the fundamental differences are so great as apparently to render Dr. Baur's views untenable. And we should much like to ask that authority how he would explain the appearance of transverse processes to the dorsal vertebra of one of the extinct Athecæ on his own hypothesis of their phylogeny.

The three "super-families" into which the Thecophora are divided are, to a great extent, distinguished by the mode of flexure of the neck, by cranial characters, and by the relations of the pelvis to the shell. Certain very peculiar features in relation to the mandibular articulation, the tympanic ring, and the arrangement of the bones of the palate serve to distinguish the existing Cryptodira of the southern, from the Pleurodira of the northern hemisphere; but we have considerable doubts whether these characters will be found to obtain in the Mesozoic representatives of the group, and whether they are not rather acquired than archaic features. We should, indeed, have been glad to have an expression of the author's views as to the mutual relations from a phylogenetic point of view of the three groups of the Thecophora; because, if the separate nasals and parieto-squamosal arch of some of the Pleurodira be indicative of their more primitive organization, it would be pretty clear that the peculiar specialized character of the mandibular articulation can only be diagnostic of the later forms.

The Trionychoidea, or soft Tortoises, appear to show affinities to the Pleurodira in the structure of the palate; and here again we miss an expression of opinion as to the nature of this relationship. The peculiar chevron-shaped entoplastron, which is regarded as an important diagnostic feature of the group, was, we believe, first brought prominently to notice by Dr. Baur.

In regard to the families of the Cryptodira, the author follows Dr. Gray in regarding *Staurotypus* as nearly related to the *Chelydridæ*, but places it in a distinct family, of which *Dermatemys*, placed by Dr. Gray next the Batagurs, is taken as the type. *Cinosternum*, likewise placed by Dr. Gray in the *Chelydridæ*, is regarded as the type of another family, readily characterized by the absence of the entoplastral bone; while the *Platysternidæ* is likewise a family of which but one genus is known. The widest departure from the arrangement of Dr. Gray is, however, found in the case of the *Testudinidæ*, which is a very extensive family, embracing the *Emydidæ* of other writers, and no less than four other families of Dr. Gray's "Hand-List." The transition from one genus to another is, however, so gradual, as apparently to afford full justification for the new departure. Twenty genera of this family are recognized, all of which can be defined by characters of the skull and shell. We would especially note the disappearance of the well-known *Pangshura* of India in the genus *Kachuga;* and would also remark that, after its complex synonymy, the common European Pond Tortoise is finally to be known as *Emys orbicularis*. The genus *Testudo* is the largest in the whole order, comprising no less than forty-one species. Here it has been found that the division of the pygal, or supra-caudal, shield is a character commonly occurring in the typical *Testudo græca*, and consequently *Testudo emys*, which, on this account was made the type of the genus *Manuria*, and has attained an unfortunate notoriety owing to the controversy regarding *Scapia*, is included in the type genus. The *Chelonidæ*, or Turtles, are divided into the genera *Chelone* and *Thalassochelys*, each of which is represented by two species. And here we may notice the wise discretion of the author in refusing to recognize a host of so-called species based on features which may well be regarded as merely indicative of varieties. The members of this family, it may be remarked, are the only existing Thecophora in which the temporal fossæ are completely roofed over by bone; and since a more or less complete approximation to this feature occurs in many Mesozoic types, this bony roof may perhaps be regarded as indicative of direct affinity with some of these early types. In the Pleurodira the first two families are distinguished from one another by the presence or absence of a mesoplastral bone, as well as by well-marked cranial features, while the third family, represented only by the aquatic *Carettochelys* of New Guinea, has no epidermal shields on the shell. This remarkable form, it may be observed, is one of the few desiderata in the collection of the Museum.

In the Trionychoidea, all of which are included in the family *Trionychidæ*, the author has, we believe for the first time, pointed out characters by which the skull of the typical forms, in which the hyoplastral remains distinct from the hypoplastral, can be readily distinguished from that of the group typically represented by *Emyda*, and characterized by the fusion of the above-mentioned bones. In the diagnosis of the genera *Trionyx*, *Pelochelys*, and *Chitra* on p. 241, we meet with the following sentence, viz. "outer extremities of the nuchal bone overlying the second dorsal rib." This sentence, when contrasted with the corresponding diagnosis of the three following genera, strikes us as liable to lead to confusion; and the sentence would be better if it read "outer extremities of the nuchal bone overlying the rib supporting the first costal bone." It appears, indeed, that the first dorsal rib of Chelonians is aborted, and carries no costal bone, or plate, so that the first costal bone is supported by what is really the second rib. We may perhaps be pardoned for pointing out that the term "*straight* angle," mentioned in the fifth line from the bottom of p. 251 does not, at first sight, suggest the idea of a "*right* angle," for which, we presume, it is meant.

Scarcely any systematic work can nowadays escape criticism, but in our judgment the system adopted in the present volume appears to be one which in the main ought to meet with very general acceptation, and we heartily congratulate the author on the completion of a very laborious task in a manner which deserves the thanks of the students both of recent and fossil Chelonians. R. L.

THE HISTORY OF ANCIENT CIVILIZATION.

The History of Ancient Civilization. By the Rev. J. Verschoyle, M.A. (London: Chapman and Hall, 1889)

THE title of this book is somewhat misleading. One is led to expect from it a history of the growth of civilization from its earliest stages to its various developments among different nations or races, and of the relation of one form to another. But instead of this we have an account of the characteristic civilization of certain selected nations when at their best, with very little to indicate any relation between them. The nations whose civilization is described are the Egyptians, the Babylonians, and Assyrians; the Jews, Phœnicians, Aryans, and Persians; the Greeks and the Romans. The two latter are treated very fully, occupying about three-fifths of the whole. There can be no question that the information conveyed would be very useful to a student of ancient civilization, but he would immediately ask for more. If he had any intention of studying the question from a scientific point of view, he would not be content with isolated facts, but ask for the connection between them. Indeed, one of the most conspicuous features of the book is the complete absence of any scientific method; its merits must be appreciated entirely from the literary standpoint, especially in connection with the history and literature of Greece and Rome.

In any scientific history of civilization, the first stages, in which from rough stone implements men passed to the arts of drawing, sculpture, and the manufacture of pottery, and so to the invention of bronze and the erection of megalithic buildings, are surely of too much interest to be dismissed in a sentence or two, with an illustration of a "flint spearhead" of very peculiar appearance. To what races these men might belong we do not learn from our author, who, after observing that "modern science has also directed its attention to the subject of races and anthropology, and has issued in studies which have not, however, yet resulted in a decisive conclusion," dismisses all other races in eighteen lines, and springs on us the "white race," "whose first habitation was the highlands of Asia." "It was there that, after the deluge chronicled in the legends of all Eastern nations, mankind dispersed, and formed the three chief branches of the white race—the families of Ham, Shem, and Japhet." Thus we learn nothing about the remarkable and early civilization of the Chinese, on the ground that "the information respecting it is not sufficient." We are not, therefore, surprised that the author dismisses America with the single sentence, "In America, the copper or red race has continually receded before the Europeans, and cannot be counted amongst the civilized races." He apparently thinks there has never been but one race in America, and forgets the ancient civilization of the Aztecs, and that of the race which they themselves succeeded; and we cannot therefore hope that he will throw any light on the home of that remarkable people who carved the idols of Easter Island, or erected the megaliths of Tonga.

In the chapter on Egypt there is much interesting though somewhat disconnected information; but those who think that the arts and sciences are amongst the most important parts of civilization, will perhaps scarcely be satisfied with the statement that "the scientific theory, which would consider the pyramid a kind of observatory, is quite unfounded."

The materials for the description of the civilization of the cities of Mesopotamia are so rich that the chapter which deals with it cannot fail to be interesting; it is only to be desired that the relations of the Accadians, Babylonians, and Assyrians, and their several conditions, had been made more clear, and the great length of time, as in the case of the Egyptians, over which the same type of civilization continued, pointed out. Indeed, one of the remarkable features of ancient civilization, which has an important bearing on the antiquity of man, is its slow progress.

The account of Eastern civilization, or that of the Aryans and Hindus, is very defective. Indeed, we have little more than a short account of the tenets of Brahmanism and Buddhism, and no mention of their art, though many of the Hindu stupas and topes date back before the Christian era. There is some fair description of Persian and Phœnician civilization, but there is nothing about the Phrygians. The rock tombs of Asia Minor are unnoticed, and Troy is only mentioned in relation to the Greeks.

In contradistinction to this, the treatment of Grecian and Roman history is superabundantly full, as one sentence will show. "The 'epithalamium' of Mallius is probably his best work, always excepting his charming lyrics to Lesbia." If a notice of so little known a poet forms part of the history of ancient civilization, it is difficult to see why the omissions above enumerated should occur.

In a word, the whole subject is unequally treated; there is a bias towards classical learning, which, in spite of the useful information given, prevents the book from being in any sense a scientific history.

OUR BOOK SHELF.

Board School Laryngitis. By Greville Macdonald, M.D. Lond., Physician to the Throat Hospital, Golden Square. Pp. 31. (London: A. P. Watt, 1889.)

NUMEROUS as are the evils to which the Board School system is alleged to have given rise, we have before us yet another indictment to add to the list. This time, however, it is the teachers, and not the scholars, who compel our interest. Dr. Macdonald claims to have identified certain changes in the vocal apparatus of Board School teachers, of both sexes, of so definite a character as to enable him to state with certainty from the appearance of the throat that the patient belongs to that long-suffering class.

A varicose condition of the superficial vessels of the vocal cords and a nodular hypertrophy of the free margins are the conditions to which he calls special attention. Of the latter condition he notes that it may occur without obvious inflammatory surroundings, and quotes Stoerk's reference to it under the name of "singers' nodules." He does not, however, mention the Viennese laryngologist's explanation of them, which, in the present connection, is interesting. Stoerk claimed that these nodules were the direct result of an improper use of the voice, whereby a part only of the vocal cords was set in vibration. The nodules made their appearance at the spot intervening between the vibrating and the motionless parts of the cords, usually the junction of the anterior third with the posterior two-thirds.

Board School teachers, uninstructed for the most part as to the use of the voice, depressed by the close and often foul atmosphere of a crowded schoolroom, choked with the chalk from their blackboards, and often compelled to scream to make themselves heard above the din of an unruly class, are beset with every condition which predisposes to inflammation and over-straining of their vocal apparatus.

Dr. Macdonald suggests remedies for such a state of things, for the consideration of the ruling powers, and intimates that local treatment alone is of any avail in dealing with the changes to which he calls special attention. The varicose vessels he would destroy with the galvano cautery, and the nodules with the forceps. The monograph is written in a fluent and readable style, and treats of a subject which deserves the serious attention both of lay and professional readers. Possibly the interest of the latter class would have been more keenly aroused had the author appended a little more information as to the extent of his experience. He tells us that the Board School teachers consult him in increasing numbers, and that his success in treatment has been remarkable, but he does not quote cases, or offer any statistical record, by which his professional brethren may compare his experiences with their own in the same line of practice.

The pathological conditions to which he would affix such an attractive title are not by any means unknown as a consequence of chronic laryngitis in other walks of life, and something more than mere assertion must be offered before they can be generally accepted as the peculiar product of the Board School system.

E. CLIFFORD BEALE.

A Treatise on Elementary Algebra and Algebraical Artifices. By Saradaranjan Ray, M.A. Two Vols. (Calcutta: S. K. Lahiri and Co., 1888.)

THE work under review is also Part II. of "A Course of Elementary Mathematics." Vol. I. comprises those portions of elementary algebra usually to be found in modern text-books up to the chapter on proportion. Vol. II. includes chapters on variation, theory of equations, elimination, binomial theorem, and properties of logarithms, as well as many others; but those mentioned will suffice to show the general scope. The author gives the object he has had in view: "To create in beginners a taste for algebra, and to show them the utility and application of algebraical artifices." In achieving this desire he has met with some degree of success. The language employed is simple and clear. The proofs in many instances are interesting. We question the advisability of placing the binomial theorem and properties of logarithms at the conclusion of a work which contains biquadratic equations. At least an elementary chapter upon the former subject should precede the theory of equations, while a discussion of logarithms would be of great use in its development.

We notice one very important omission: the multinomial theorem finds no place in these volumes. This is much to be regretted, for the chapter on permutation could have introduced it in an elegant and suggestive manner. Again, we notice that the subject of series is scarcely touched upon. One would hope in a work of this scope to find a short chapter which would include reversion of series. However, there are many excellent features in the book. Chapters on "Consistency and Sufficiency," and on "Identities and Equalities," are novel and gratifying. The pages concerning arithmetical and geometrical progressions are original and inspiring; for example, the student is taught the meaning of the sum of n terms of a progression when n is negative, and is shown that both arithmetical and geometrical progressions possess the common property that two successive terms are connected by a linear relation; from this point of view the series are then further examined.

There are many examples, as a rule well selected, with occasional hints to show the learner that a little ingenuity will often overcome particular difficulties. There are a few occurrences of faulty printing, and some misprints which do not appear in the errata.

The students of our Eastern dependency are in possession of a book by one of their own countrymen who is a thorough master of his subject.

LETTERS TO THE EDITOR.

The Sailing Flight of the Albatross.

IN NATURE, vol. xxxix. p. 230, the late Mr. William Froude, in a letter to Sir William Thomson, on the subject of the "Soaring of Birds," gives a short account of the well-known and often discussed sailing flight of the albatross; and says that after long consideration the only explanation which presented itself to his mind was, that the birds use the upward current caused by the lifting of the air from the bottom of the trough to the level of the crest of an advancing wave. Mr. Froude by a rough calculation—the waves being supposed 10 feet from hollow to crest—concludes that an upward current of 3 feet per second may be caused in this manner, and states that the bird's movements were often in accordance with this explanation, though it was often impossible to affirm or deny the accordance.

Having had many opportunities of observing the flight of the albatross, I cannot think this explanation the true one. I have often seen albatrosses sailing when the sea appeared as flat as a table, with the exception of the small waves caused by a light wind. This seems fatal to Mr. Froude's explanation, which requires waves of considerable size. As Mr. Froude observed, the birds often sail along the crests of waves. It seemed to me that they were sometimes using the current diverted upwards by the wave, just as on land birds use that diverted by hedges, river-terraces, &c.

I will first give a description of the flight of these birds, as I observed it when on board steamers running between Australia and New Zealand, which are nearly always followed by numbers of birds; and then attempt an explanation. The sailing flight is never to my knowledge done in a calm. I once observed the effect of a gradually diminishing wind on their flight. The steamer was going about nine knots. When the wind, which was very nearly aft, became one or two knots slower than the steamer, the birds, which had hitherto kept their wings perfectly steady, began to flap at intervals which became shorter as the wind lessened, and when it ceased they flapped almost without intermission, and soon ceased to follow the vessel.

The birds go through a series of movements which are related to the direction of the wind. Starting from near the surface, they rise in a slanting direction against the wind, to a height which varies with the strength and direction of the wind. The average seemed to me about 20 feet. Then comes immediately a turn half round in a rather large circle, followed at once by a rapid descent down the wind. They then take a longer or shorter flight in various directions, almost touching the water. After that another ascent in the same manner, and so on, repeating the series of movements *ad libitum.* The interval of time between the ascents evidently depends on the direction of the wind with regard to the course of the vessel. When the wind is ahead, and the birds' velocity through the air great, being necessarily greater than the wind's velocity plus that of the steamer, the interval is short. When the wind is abaft the beam, and the birds' velocity much less, the interval is usually much longer. As a general rule, there is a rough proportion as to the favourableness of the wind and the length of time between successive ascents. Also, when the wind is favourable and not strong they do not rise so high as in a strong and adverse wind.

The explanation I have to give of the movements above described depends upon the well-known fact that the velocity of the wind at the surface is diminished by friction, so that its velocity increases with the height, the *rate* of increase being greatest near the surface. Prof. Osborne Reynolds found by experiment that the wind's velocity over a grass meadow at a height of 8 feet was double that at 1 foot.[1] Over the sea, when there is enough wind to roughen the surface, the drag on the lowest stratum is probably greater than over a grass meadow, on account of the motion communicated to the water. This effect of friction makes clear the object of the ascents against, and the descents with, the wind. For, as a bird rises, he enters currents of wind which increase in velocity with the height, in a direction contrary to his own motion, so that the loss of velocity consequent on rising, and which would take place in still air, is partly—or perhaps, when the wind is strong, wholly—made good. The bird thus gains energy of position, which is converted into energy of motion by descending. A bird's ascent against the wind may be compared with the ascent of a particle up an incline, while the incline itself is accelerated in a horizontal direction opposite to that of the particle's motion, thereby enabling it to reach a height greater than that due to the initial velocity. The albatross does not go on rising until his velocity is nearly exhausted, but makes a half-turn at great speed previous to his descent. Thus the quickness of the ascent, with, as Mr. Froude says, scarcely if any apparent loss of speed, is explained. By making a slanting descent with the wind, the bird carries with him the velocity of the faster-moving wind of the high level into the slower-moving wind near the surface; and thus increases his velocity through the air, to which is to be added that due to his fall. Thus, if resistance is left out of account, the bird's velocity since he began to ascend would have been increased by twice the difference in the velocity of the wind near the surface, and at the height to which he rises. And as the power of overcoming resistance varies as the square of the velocity, the addition of several feet per second to the bird's already high velocity is equivalent to much more energy than is lost in the few seconds occupied by the rise, turn, and fall;

[1] "On the Refraction of Sound by the Atmosphere," by Prof. Osborne Reynolds. Read before the Royal Society, April 23, 1874.

so that there is a clear gain, which may be expended in flight until the speed is so much reduced that it is necessary to increase it by another ascent.

The reason is clear why, when following a steamer against the wind, the birds are compelled to repeat at short intervals the movements by which speed through the air is gained, and why, when the wind is favourable, the intervals are longer. The great length of these intervals just mentioned seems to me the difficult point in the theory. It cannot be proved that the speed acquired by the movements described is sufficient for such long flights between the ascents as are sometimes seen, under conditions where there is no suspicion of upward currents near the surface. Our knowledge of the resistance of the air to such complex surfaces as the wings of birds is, I believe, almost nothing; and even if we knew, without doubt, the true explanation of the manner in which the energy lost by resistance is renewed, we might find it hard to apply it to all cases, unless we had some real knowledge of the supporting power of the air, and the horizontal resistance at different velocities.

I have sometimes seen a number of albatrosses sailing in a peculiar manner, the wind being at right angles to the course of the steamer. They ascend against and descend with the wind, turning alternately right and left, so as to describe an undulating line, not far behind the stern. A number of them sometimes do this for hours, while others are sailing in various directions farther off. It is curious that the common sea-gulls of New Zealand (*Larus dominicanus*), which have become to a great extent land-birds since the country was colonized, may be sometimes seen making their way over flat country in the same manner as the albatrosses just described—that is, at right angles to the wind, and turning alternately right and left, and nearly touching the ground at each descent. Their success in doing the sailing flight is, however, imperfect, as they seem compelled to flap their wings a few times during the second half of each ascent. Perhaps future generations of gulls may improve. No doubt some muscular exertion is saved by this mode of progression. The foregoing theory of the sailing flight of the albatross shows, I think, the action of a *vera causa*, which, as far as I know, has not been noticed before. A. C. BAINES.

Christchurch, New Zealand.

Note on *Ragadia crisia*.

MR. W. L. DISTANT, in his admirable "Rhopalocera Malayana," calls attention to the recent appearance of *Ragadia crisia* in the Malay peninsula. As I have had opportunities of studying the habits of the species in what seems to be one of its head-quarters, it may be desirable to record the facts.

Mr. Distant writes as follows:—"One of the most peculiar facts in relation to this butterfly seems to be its almost recent appearance in the Malay peninsula, or at all events its first capture there by collectors. I did not meet with it myself when collecting at Province Wellesley, nor did I subsequently receive it in numerous collections derived from the peninsula. In 1883, however, the species seems to have been common from Penang to Singapore. I first received two specimens captured on Penang Hill, and sent to me as a new species; others shortly followed from Province Wellesley, with the remark of an experienced collector that the species was quite new to the locality; and almost simultaneously the Indian mail brought me more examples from Sungei Ujong, Malacca, and Singapore. My friend Mr. Logan also sent me an example with the comment, 'a very rare butterfly not known to collectors here.'

"Capt. Godfrey, who also captured the species at Sungei Ujong, described it as being found in low undergrowth in the forest, where, especially in the early morning, I several times met with it. Its flight is weak and feeble, but it cleverly eludes pursuit by threading its way through tangled brushwood" ("Rhop. Mal.," p. 421).

Mr. W. B. Pryer, in his joint paper with Mr. Distant ("Rhop. Northern Borneo," *Ann. Mag. Nat. Hist.*, January 1887, p. 49), describes it as "rare, under almost thick forest shade." In ten years' collecting in North Borneo he has only met with a few specimens, not more than a dozen, nearly all of which he saw at Silam, on the coast of the district I write about.

I find it to be the very commonest butterfly in the dense forest of the centre of Darvel Bay Peninsula, on the east coast of British North Borneo.

I first saw the insect in the deep forest between Lamag on the River Kinabatangan and Itok Batu on the River Segama, about 120 miles inland. It was not common, but I always saw one or two daily. Since then Mr. Pryer has taken it higher up the River Kinabatangan, some 250 miles up stream. The butterfly is still quite rare on the coast, the only specimens having fallen to Mr. Pryer's net.

Last year I made an exploration through the forest from the River Tinkyo in Darvel Bay to the head-waters of the River Segama. Within four miles of the coast, in the alluvial flat of the River Tinkyo, the species was seen daily, but was far from common. As soon as we touched the mountain country it began to grow common, and from 600 feet to 2500 feet above sea-level it was the commonest butterfly in the deep forest.

Capt. Godfrey's description of its habits agrees with mine, except in one particular. He found it most plentiful in early morning. I was always in the jungle from soon after dawn to near dusk, and found it appeared about 9 o'clock in the morning, and was on the wing till about 4 o'clock in the afternoon.

It has the feeblest (and wickedest) flight of any butterfly known to me. I never saw it rise six feet above the ground, and it flaps slowly along, apparently with effort, its wings not stiff but bending with each stroke. It *looks* a certain capture; but this, as Capt. Godfrey found, is delusive and elusive. It keeps just above the low bushes from two to three feet high, and sneaks in among them most exasperatingly. It seems to do this deliberately, and will rather circuit round an opening made by a fallen tree than cross the small opening. It is often seen flying in rain.

As a rule it is quite solitary, it being rare to see two at once, and it is not at all bold or pugnacious.

Its wings are so soft that it often crumples in the wet, and it is almost impossible to set it during the rainy season, the wings relaxing in a few hours, though it may have been a week on the setting-board.

From February to October it was equally common. I then came out of the forest. It probably flies all the year round.

It is one of the few true forest species, and avoids the sunshine.

I do not know whether the insect is common elsewhere, and can offer no suggestion as to why it should be spreading from this part, though it is undoubtedly creeping coastwards. The eastern part of North Borneo is untouched primæval forest, the only clearings being on the coast and river-banks, and these are small. The country where *Ragadia* abounds is quite uninhabited, and it is difficult to see how the food-plant (unknown) could have been taken thence to the Straits Settlements. Then too, in Borneo at any rate, it would avoid clearings.

Leaving this question for future observers to solve, we now know that in one part of the interior of North Borneo *Ragadia crisia* is very common, and it is extending its area.

SYDNEY B. J. SKERTCHLY.

Spherical Eggs.

PROF. ALDIS will find references to the history of this ancient question in an article by Mr. W. Walton in the *Quarterly Journal of Mathematics*, vol. ix. p. 79, where it appears as Leslie Ellis's problem of the thirsty crow. "A thirsty crow flew to a pitcher and found there was water in it, but so near the bottom he could not reach it. Seeing, however, plenty of small, equal spherical pebbles near the place, he cast them one by one into the pitcher, and thus by degrees raised the water up to the very brim and satisfied his thirst. Prove that the volume of water must have been to that of the pitcher in a ratio not less than $3\sqrt{2} - \pi : 3\sqrt{2}$." References are supplied in the article by the Rev. Dr. Luard to Pliny's "Natural History," book x. chapter 43, "De Corvorum Intelligentiâ"; Plutarch, "De Solertiâ Animalium; and Ælian, "De Naturâ Animalium." Consult also Tait's "Properties of Matter."

Thus in an aggregation of closely-packed equal spherules the unoccupied space is $1 - \frac{1}{6}\pi\sqrt{2}$ of the whole volume.

We may verify this experimentally by comparing the weight of a given volume of small lead shot with the weight of an equal volume of lead; theoretically the densities should be as π, to $3\sqrt{2}$.

On a larger scale, the question may be studied in the piles of spherical shot formerly to be seen in our forts and arsenals. Whether we begin piling the shot in horizontal layers, in triangular order, or in square order, the internal molecular arrangement of the spheres is the same; but the square order in the horizontal layers is preferred, as it is then possible to build the pile on a rectangular base, finishing off at the top with a ridge of balls in single file, the sloping faces all showing the spheres in triangular order.

Suppose a bag, impermeable to water, is filled with lead shot, placed in an hydraulic press, and subjected to great pressure. The lead spheres will be flattened against each other in regular cell structure into a solid mass, each sphere being changed into a *rhombic dodecahedron*; and in this manner the form of the cell of the bee has been considered as arising in a natural manner by Mrs. Bryant, D.Sc., in a paper read before the London Mathematical Society, vol. xvi., "On the Ideal Geometrical Form of Natural Cell-Structure." The plane surfaces of separation also form a possible arrangement of the films of a mass of soap-bubbles; but the instability of the corners where six edges meet modifies the soap bubble arrangement to the form investigated by Sir W. Thomson in the *Acta Mathematica*.

April 27. A. G. GREENHILL.

Name for Unit of Self-Induction.

A NAME for the unit coefficient of self-induction is much wanted. No one is satisfied with secohm, and yet it seems making its way; by reason, no doubt, of Ayrton and Perry's ingenious commutating arrangement for helping to measure it. It is an unpleasing name, and it is too big a unit. The name quad, which I formerly suggested, is on further consideration still less satisfactory for permanent use, because it emphasizes unduly the accident that *in electro-magnetic measure* self-induction happens to be a length. One looks forward to the time when all distinction between electrostatic and electro-magnetic measures shall vanish by both ceasing to be; and at that not far-distant time, names emphasizing the present arbitrary state of things will be anachronisms, as well as stumbling-blocks to beginners. I beg to suggest that a milli-secohm shall be called a *vo*. It is a short and harmless unmeaning syllable not yet appropriated. It should be its own plural. The unit of conductivity is already styled a *mo*; and 8 vo will look well alongside 12 mo. "Vo-meter" is short and satisfactory. A unit of magnetic induction will then be the vo-ampere; and this, being of a size convenient for dynamo makers, may be hoped to replace their abominable mongrel unit "Kapp-lines."

The vo in electro-magnetic measure is 10 kilometres, and hence a vo ampere per square decimetre is a magnetic field of a thousand C.G.S. units, and might be called a "Gauss." For lightning-conductor work the natural unit of self-induction will be a milli-vo, or 10 metres of electro-magnetic measure.

Grasmere, April 16. OLIVER J. LODGE.

Hertz's Equations.

PERMIT me to add a line of explanation of my letter on this subject, printed in NATURE, vol. xxxix. p. 558. I intended no criticism of Hertz's general result, but merely to draw attention to the necessity of rejecting all solutions of the equation in Π which made the force (Z) infinite for points on the vibrator.

Berkswell, April 24. H. W. WATSON.

A NEW PEST OF FARM CROPS.

DURING the past three or four years, in the examination of plants affected by various injurious worms and Arthropods, and of the soils in which such plants grew, I have from time to time been led to suspect that certain small species of *Oligochæta* were concerned in damaging, if not ultimately destroying, several species of cultivated plants. With a view to converting suspicion into proof, experiments on isolated growing pot-plants have been carried on.

Within the past few weeks I have received, through the kindness of Miss E. A. Ormerod, additional evidence of a striking character, which induces me to place the main facts on record.

In the spring of 1885, Miss Ormerod forwarded to me for inspection two small white *Oligochæta*, 1½ inch long, received by her in soils from the roots of plants. In reporting on them I replied that it did not seem very probable that they could seriously injure the plants.

In April 1888, an inquiry reached me as to the nature and means of prevention of a serious attack of "small white worms" destructive to pot and green-house plants. On being placed in communication with the observer, the Rev. William Lockett, Rector of Littledean, I received from him a box of soil taken from his affected flower-pots, and much valuable information in answer to a series of questions put by me. The soil itself contained some hundreds of the white worms described; and the detailed information all pointed to these worms as the cause of many serious losses which had been sustained.

The worms were Enchytræidæ, of the genus *Enchytræus*, apparently near to *E. Buchholzii*, Vejd. I took three plants, a sunflower, a geranium, and a tradescantia, and had them re-potted in carefully examined sifted earth; when they were well established, I put fifteen of the worms into each pot, and left them to be tended by the gardener. I kept a number of the worms in soil which was alternately wetted and dried at regular intervals. They all kept alive and vigorous; when wet to complete immersion they were most active, when dried they remained quiescent, apparently dried up, and difficult to discover.

After two months, the sunflower drooped and bent over, and examination showed the roots and rootlets dead and the stem rotting. Within the decaying stem some of the Enchytræidæ were found alive and active. The other two plants are still living, but it will be shown that the number of worms supplied them was too small. Mr. Lockett lost spiræas, vegetable marrows, fuchsias, gloxinias, and many other plants, and the dead roots often contained in and around them many hundreds of worms to each plant. Both in his garden and a neighbouring ash-heap he found an abundance of them.

I was on the point of repeating my experiments this spring with various seedlings, when I received by the kindness of Dr. Gilbert, of Rothamsted (at the suggestion of Miss Ormerod), a quill with two or three specimens of worms of the same genus. Mr. John J. Willis, the superintendent of the field experiments at Rothamsted, in sending them described them as obtained from a field of clover "with a good plant except across one portion of the field, where all the plants were dying off," the small worms occurring at the roots of the clover along with larvæ of *Sitones* and wire-worm. "There is scarcely a plant that has not one or more of these creatures attached." Mr. Willis has been good enough to send me several communications on the subject, and a supply of the worms, living and in spirit. Much of his information is interesting, as that the more decayed the root, the larger the number of worms; that even healthy plants harbour a few specimens; that the worms seem sometimes to enwrap the rootlets with their coiled body. He hears of other fields of clover in a similar condition apparently to those at Rothamsted. I have a quantity of detailed information, but to summarize it, there appears to be but little room for doubt that these small *Oligochæta* are one cause of the decay of the clover at Rothamsted, as they were of the many varieties of garden plants at Littledean.

The Enchytræidæ have not hitherto, so far as I can learn, been accused of causing serious injury to plants. Vejdovsky, in his "Monographie der Enchytræiden," says, "Die Enchytræiden bewohnen trockene und feuchte Erde, süsses und salziges Wasser, Sümpfe und morsches Holz." In what manner they directly injure the plant remains to be observed—probably by sucking the fine root-hairs. Under observation the pharynx is rapidly everted and withdrawn in the act of feeding. I have so far recognized two species. If, as seems not improbable, further corroboration should be forthcoming, we may find that we have to add to the list of enemies of the clover plant from which it so mysteriously suffers, these unsuspected Oligochætes. The discovery, though fraught with so little satisfaction to the already burdened agriculturist, can hardly fail to prove of interest to the zoological student of farm pests.

ALLEN HARKER.

Royal Agricultural College, Cirencester, April 10.

RAIN CLOUDS ON LAKE TITICACA.

THE cloud system here, 12,500 feet above sea-level, is so beautiful, and seems to throw so much light on the formation of one particular type of shower, that I venture to send diagrammatic sketches of two excellent specimens of cloud-building over rain.

I have never seen cumuloform clouds so perfectly developed as on this lake. Whether the height above the dust and haze of lower levels makes the blue sky darker than usual, or whether the temperature is such that the cumulus is composed of snow-flakes instead of water-drops, the contrast between the sky and cloud is much greater than usual.

The sketches were taken on a showery day, and the clouds were visible simultaneously in different directions. The type of shower is not unknown at home, but there much complication arises from the almost constant existence of cyclonic cloud systems.

Certain features are common to both pictures. Nearest the earth, appears a more or less conical-shaped space *r*,

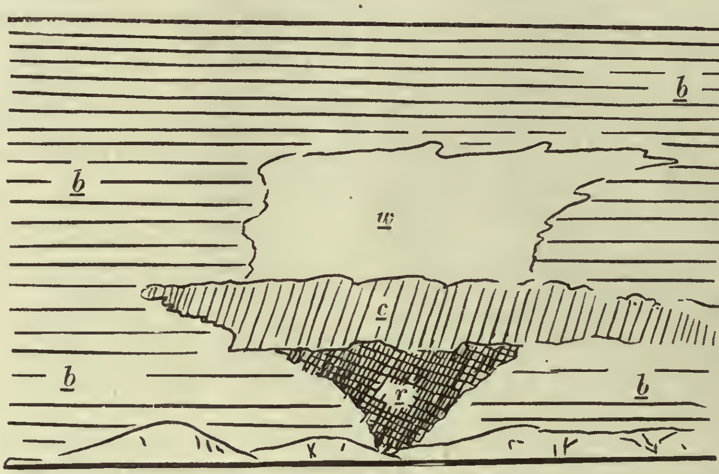

FIG. 1.—*b*, blue sky; *c*, flat-topped mass of dark cloud, rounded components; *r*, rain; *w*, white cloud, tending to flatten out and to cirrify.

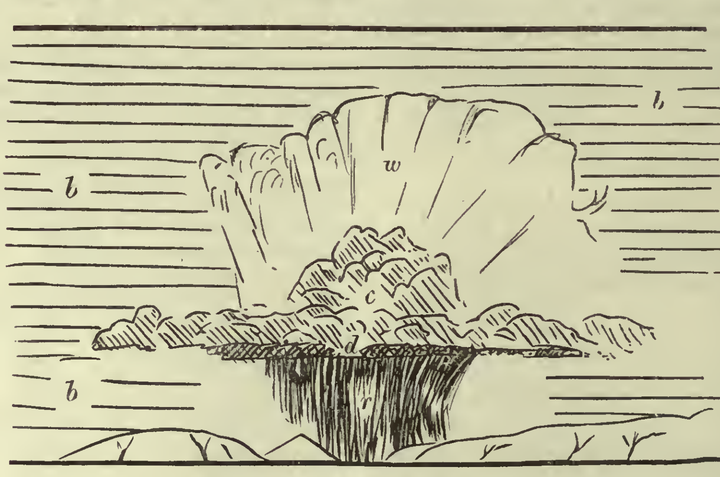

FIG. 2.—*b*, blue sky; *c*, dark cumuloform cloud, flat-topped at edges; *d*, dark belt; *r*, rain; *w*, white cloud, tending to flatten and to cirrify.

of uniform inky blackness, where rain is falling. Above, and stretching laterally some distance beyond the rain, is a belt of dark cloud, *c*, curiously flattened at the top; but the outlines are always *rounded*, and there is no trace of linear or hairy structure. In Fig. 2 a mountainous rocky cumulus rises above the flat dark mass *c*; and as the rain could be seen falling, I have indicated that appearance in the sketch.

In both, a white cloud, *w*, of remarkable shape and structure, rises above the dark mass *c*. Sometimes, as in Fig. 1, this cloud is nearly uniform in structure, but exhibits a tendency towards hairy structure at the edges. Other times, as in Fig. 2, the white cloud *w* shows traces of cumuloform structure of a very peculiar type. Instead of round, rocky lumps, the white cloud is composed of long, straight, fingery masses of cumulus, with a tendency to fibrous or hairy structure, and radiating slightly outwards from the base, like the head of a cauliflower. I have endeavoured to suggest this appearance by the straight lines, drawn through *w*, in Fig. 2; for the real structure defies delineation with pen or pencil.

In all cases, the top of *w* is more or less flat, and the whole diffuses outwards, sideways, or edgeways, rather than upwards. As the shower breaks up, *w* seems to be left as a middle-level layer of strato-cirrus.

The whole shower is surrounded by blue sky, there is no cirrus at a higher level; and while the low cloud *c* moves from north-east, the white cloud *w* may be coming either from north-east or more probably from north-west.

The puzzling nature of cloud perspective makes it very difficult to interpret the appearance of these clouds. There can be little doubt that the lower clouds, *c*, are the product of the condensation of rising columns of air; but while the somewhat cumuloform structure of *w* ought also to indicate an upward motion, the flat top, and outward diffusion, would suggest a more horizontal motion. I cannot therefore suggest any rational explanation of the building of these shower clouds; and the true nature of this phenomenon will only be discovered when the theodolite is used to determine whether *w* lies vertically or horizontally in the blue sky.

RALPH ABERCROMBY.

Lake Titicaca, February 28.

A FLAT FISH NURSERY.

PROF. EWART submitted the following report at a recent meeting of the Scotch Fishery Board:—

"I have to report that I recently discovered in the inshore waters what might best be described as a flat fish nursery. This nursery, which is about five miles in length, and from two to four miles in width, stretches along an exposed and only slightly indented shore, where the sea rises during spring tides from sixteen to twenty feet. The bottom of this area consists chiefly of fine sand, covered here and there with large patches of the common sea-mat (*Flustra*); the average depth is about four fathoms. When a small beam-trawl (with a net having meshes small enough to capture all the fish over two inches in length) was carried over the bottom parallel to and at a distance of about half a mile from the shore, large numbers of small flat fish were invariably secured. On one occasion as many as five hundred and sixty of these small fish were taken in less than an hour, and at all times the 'take' was large, and usually from 80 to 85 per cent. of the small flat fish were under two and a half inches in length. Some distance from the shore the takes were smaller, and on one occasion the trawl only secured twenty-three small fish, when used in about ten fathoms of water, some seven miles from shore. Along with the small flat fish, there were usually a few small round fish, a number of shrimps—sometimes over, sometimes considerably under one pint—numerous hermit and other crabs, and large quantities of *Flustra*. As it may be possible to materially increase the fish supply by affording protection to the young fish, I hope to be able ere long to report that other similar nurseries have been found, and also as to whether flat fish during their earlier stages of growth frequent the inshore in preference to the offshore waters.

"I have also to report that Mr. Scott (who in January last secured many thousands of plaice eggs floating in the open sea over a shoal of spawning plaice) has recently come across a large shoal of spawning haddocks which were apparently resting on the bottom at a depth of about 30 fathoms some fifteen miles off the coast of Banff. The surface waters over the shoal were crowded with haddock and cod eggs at nearly all stages of development. At a single sweep Mr. Scott with his tow-net secured nearly half a million eggs, while the trawlers were capturing hundreds of the spawning fish that were resting on or moving about near the bottom."

NOTES.

THE annual *conversazione* of the Royal Society will be held on Wednesday, May 8.

AT a meeting of the American Academy of Arts and Sciences on April 10, in Boston, the Rumford Medals were presented to Prof. Albert A. Michelson.

WE regret to have to record the death of Mr. R. Stirling Newall, F.R.S., at the age of seventy-seven. Mr. Newall's name was well known in connection with the invention and manufacture of wire rope and telegraphic cables. Just before his death he offered as a gift to the University of Cambridge the 25-inch refracting telescope which he had constructed some years ago.

THE Civil Service Estimates for the year ending March 31, 1890, show that a sum of £41,221 will be required for the maintenance of the Natural History Museum, South Kensington, for the present financial year. The corresponding sum in the Votes last year was £40,934. The principal increase is under the head of "Purchases and Acquisitions," for which the sum asked is £4700 instead of £3700. On the other hand, there is a decrease of £915 under the head of "Furniture and Fittings." The remaining heads do not show any material variation.

DR. LENDENFELD'S "Monograph of the Horny Sponges," which the Royal Society are about to publish, is now nearly through the press. It will consist of about 950 pages of text and over 50 plates.

WE have received the Report of the Mason Science College, Birmingham, for the year ended February 23, 1889. It is hardly creditable to Birmingham that the authorities of such an institution as this should still have to complain of a deficiency of income. Although the amount of the deficiency compares very favourably with those in former years, the Council feel that the economies they have been forced to adopt in order to decrease the difference between income and expenditure seriously impair the College work by hampering the Professors, especially those who have laboratories under their charge and require costly apparatus to illustrate their teaching.

PROF. H. G. SEELEY, to whom a sum was assigned from the Government Grant for a research on the Permian or Trias Reptilia, has been spending his Easter recess in St. Petersburg and Moscow. The officers and professors of the Academy, the University, and the School of Mines at St. Petersburg have shown him every attention, and his work in the museums appears likely to lead to important results.

MUCH excellent work has been done by the London Geological Field Class, which is carried on under the direction of Prof. H. G. Seeley. The Report relating to the excursions during the summer of 1888 shows that the work is conceived in a thoroughly scientific spirit, and that it cannot fail to exercise a most wholesome intellectual influence on all who take part it. This year, on account of Prof. Seeley's projected visit to South Africa in July, the class will begin its labours earlier than usual. The first excursion will take place on May 4. Many persons interested in geology ought to take advantage of this opportunity for the study of the country around London, and we are glad to learn that the secretaries have received the names of more subscribers than they have received at the same date in any previous year.

MR. DUTHIE, the Government Botanist for Northern India, who has been at work with Dr. King, of the Howrah Botanical Gardens, in classifying the plants collected by him when attached to the Black Mountain Expedition, has now been directed by the Government to make a special study of the grasses and fodders of Upper India.

THE *Times of India* says that the Sukkur Bridge, which has been constructed over the Indus, has now been opened. At Sukkur the river is very rapid, but the large island of Bukkur, standing about midway in the stream, was of great assistance in carrying out the plans. There are thus two bridges, one from Bukkur to the left bank, the other from Bukkur to the right bank. The latter consists of three spans, the longest of which is 278 feet; the former, known as the Sukkur Bridge, is in length between the abutments no less than 790 feet. Two cantilevers, 310 feet long, one from each side, were erected, and the intervening space of 200 feet was crossed by a girder. There was thus a space between the pillars of 820 feet, which is said to be the largest span of any rigid bridge in the world. The weight of the span is 3300 tons. The bridge was sent out in pieces from the works of Messrs. Westwood, of Poplar, and now, sixteen months after the arrival of the materials from England, it is practically complete.

A CORRESPONDENT writes to us about a "find" which, he thinks, may prove to be of some interest. At Hornsey, near Turnpike Lane, an excavation—about 18 or 20 feet wide, and about 20 feet deep—is being made in connection with a new pumping-station. In cutting into the clay, the men have come upon large fragments of a white substance, in the inside of which are what appear to be "the vertebræ of some animal." Our correspondent expresses a hope that some one competent to form an opinion about the matter will "take a run down to Turnpike Lane" (near the Great Northern station at Hornsey), and examine the objects which he believes to be fossils. After the present week, he says, there will probably be no opportunity of seeing the clay in the state in which it was when the objects were removed from it.

AT the meeting of the Scientific Committee of the Royal Horticultural Society, on April 23, Mr. W. T. Thiselton Dyer presented a note from Mr. Scott, the Director of the Meteorological Office, relating to the "useful" temperature as reckoned in "day degrees," and to the amount of sunshine since January 1 of the present year, as compared with recent years. The present season, it seems, has been much better than the last, except as regards the amount of sunshine, in which there is not much improvement.

SIR JAMES HECTOR has issued the Meteorological Report for New Zealand, containing observations for the years 1883 and 1884. Returns have been published since 1853, but since the year 1880 the number of stations has been greatly reduced, in favour of current weather reports ; the principal stations are now only four in number. With the view of enabling daily weather reports to be issued by the press throughout the colony, with the least possible expense, a series of twenty typical isobaric charts were prepared and are shown in the Report. Each represents a certain type of weather and bears a distinguishing number, which is telegraphed to the leading journals, so that when the number for the day is quoted, the diagram can be printed, and, although not absolutely correct, it is of great assistance in making known the general condition of the weather. The Report also contains some valuable returns from stations in the Fiji group of islands.

A NEW amine, methyl-ethylamine, $C_2H_5(CH_3)NH$, has been obtained by Drs. Skraup and Wiegmann, by the action of alcoholic potash upon morphine. Not only is the actual preparation of this hitherto unknown amine of importance in itself as completing a series of isomers of the formula C_3H_9N, but the fact of its derivation from morphine also throws considerable light upon the constitution of that alkaloid. It has been shown by several chemists that morphine, $C_{17}H_{19}NO_3$, is a derivative of phenanthrene, $C_{14}H_{10}$. As a methyl and an ethyl group have now been extracted in the form of an amine, it appears very likely that these groups are present in morphine, replacing two hydrogen atoms of phenanthrene and probably attached to nitrogen. If this be so, morphine may turn out to be the iso-nitrile of a substituted phenanthrene, and it remains now for future work to test the truth of this, and to determine the positions and functions of the oxygen atoms. In the latter connection, it was found in the course of this investigation that, in addition to the volatile amine, a second substance of phenol-like properties was also formed, but great difficulties were met with in its purification. In the actual experiments, morphine was heated for about five hours at 180° C. with ten times as much of a twenty per cent. solution of potash in alcohol. A volatile substance of amine-like odour was evolved, and was driven over by means of a current of coal gas into dilute sulphuric acid. The filtered acid solution was then supersaturated with soda and the purified amine distilled over in steam into a standard solution of hydrochloric acid. It was only found possible to eliminate from the morphine in this way about 50 per cent. of its nitrogen. The concentrated hydrochloric acid solution deposited crystals of a hydrochloride, and the solution also gave with platinum chloride crystals of a platino-chloride melting at 208°. Analysis of this latter salt showed that the amine present possessed the empirical formula C_3H_9N. There are four possible isomers of this formula, three of which, trimethylamine, propylamine, and isopropylamine, have been prepared ; and methyl ethylamine, which has hitherto been unknown. The hydrochloride yielded the base itself, by action of the strongest potash, in the form of a clear liquid of intense amine odour, unlike, however, that of trimethylamine. The properties of its salts were also found to exclude the possibility of its being propyl- or isopropylamine, so an attempt was made to prepare synthetically the only other possible isomer, methyl-ethylamine. This was successfully accomplished by heating methyl iodide with a mixture of 30 per cent. ethylamine solution and alcohol in a sealed tube at 100° for three hours. The product was distilled as far as possible in steam, the residue decomposed with potash, and the remainder of the volatile amines driven over in steam. The aqueous solution of the mixed distillate was then shaken with ethyl oxalate, and successive products were obtained, on concentration, of diethyl oxamide, acid ethylamine oxalate, and, lastly, the oxalate of the sought-for base, methyl-ethylamine. This salt, when recrystallized, melted at 154°, like the oxalate prepared from the amine derived from morphine ; and from it the hydrochloride, platinochloride, gold chloride, and free base were prepared, in every case the products being identical with those prepared from the base of morphine.

MESSRS. SMITH, ELDER, AND CO. have issued a third edition of Darwin's work on "Coral Reefs." To this edition Prof. Bonney contributes an appendix, giving an account of recent speculations—about which there was lately so much discussion in NATURE—as to the origin of coral reefs.

A CHEAP edition of Darwin's "Journal of Researches into the Natural History and Geology of the Countries visited during the Voyage of H.M.S. *Beagle* round the World," has been published by Mr. Murray. The portrait of Darwin which appeared in the NATURE series of "Scientific Worthies" is prefixed to this edition.

MESSRS. CHARLES GRIFFN AND CO. have published a sixth edition of "A Pocket-book of Electrical Rules and Tables for the use of Electricians and Engineers," by John Munro and Andrew Jamieson. The work has been thoroughly revised, and enlarged by about 120 pages and 60 new figures.

SOME valuable contributions towards a Flora of Caithness, by J. F. Grant and Arthur Bennett, have been reprinted from the *Scottish Naturalist*. The number of species and varieties that are admitted for the county of Caithness is over 600, a fair number, the authors think, considering the physical features of the county. Caithness has about 80 species that have not yet been found in Sutherland, and about the same number not yet found in the Orkneys.

THE Smithsonian Institution has issued six lithographs illustrative of the anatomy of *Astrangia Danae*. The plates were drawn by Mr. Sonrel, in 1849, under the direction of Prof. Agassiz, who intended to prepare a complete memoir on the subject. Mr. J. Walter Fewkes has written an explanation of the plates to make them available to students of marine invertebrates.

A NEW number of the *Internationales Archiv für Ethnographie* has been issued. It consists of Parts I. and II. of the second volume; and the contents, as in every preceding number of this excellent periodical, are full of interest for students of ethnography. There are three long articles—all in German. In the first, Dr. F. von Fuschan gives an instalment, carefully illustrated, of a paper on an amusement popular in Turkey, corresponding to the magic lantern. The second is an elaborate essay, also illustrated, by Dr. H. Schurtz, on knives made in various parts of Africa for the purpose of being thrown. In the third article, Mr. R. Parkinson, of New Britain, brings together many valuable ethnological facts relating to the inhabitants of the Gilbert Islands.

THE "Uses of Plants," by Prof. G. S. Boulger, which is about to be published by Messrs. Roper and Drowley, is a manual of economic botany, having special reference to vegetable products introduced during the last fifty years. It enumerates all vegetable substances in use in England as food, materia medica, oils, gums, rubbers, dyeing, tanning, and paper-making materials, fibres, timber, &c., both home-grown and imported; and there are short essays on the recent progress of vegetable technology in its various branches.

IN a Report lately received, Mr. W. Fawcett, Director of Public Gardens and Plantations, Jamaica, gives an interesting account of a visit of a few days to the Cayman Islands during May 1888. In an appendix he gives a list of the plants he collected, for the determination of which he expresses indebtedness to the authorities at Kew. "From this list," says Mr. Fawcett, "it will be seen that about 20 per cent. of the species are found more or less throughout the tropics. They are such as one might expect to find on any tropical island. It is interesting to note that one of the ferns (*Acrostichum aureum*) which is found growing to a height of 6 to 10 feet in swamps in Jamaica and throughout the tropics, was one of the first plants to establish itself on the Island of Krakatão, where the terrible volcanic disturbance completely destroyed every vestige of plant life. On its shore was also found the fruit of another plant occurring in the Cayman Islands, viz. the almond tree (*Terminalia Catappa*)."

AT a recent meeting of the Royal Asiatic Society of Japan, a paper was read by Dr. Seymour on the hygiene of Japanese houses, in which he disproves the common idea that dwelling-houses in that country are very unhealthy. A Japanese house, is, on the whole, suited to Japanese life. The extreme airiness of the structure prevents the charcoal fires doing the inhabitants any injury. Its chief defects can be easily remedied. The boarding of the floor can be made more close-fitting; ventilating panels should be used; the ceilings could with advantage be higher, and the drainage should be well looked after. Amongst foreigners there is distinctly more illness in brick and stone houses than in the wood or frame houses, on account of the damp remaining in the walls of the brick houses while it dries up almost immediately in the others. The remarkably small infant mortality amongst the Japanese shows that their houses are healthy and suited to their modes of life.

MR. F. A. HERON has been appointed an Assistant in the Zoological Department of the British Museum, not in the Geological Department, as stated (by a printer's error) in NATURE, vol. xxxix. p. 590.

THE additions to the Zoological Society's Gardens during the past week include two Macaque Monkeys (*Macacus cynomolgus* ♂ ♀), from India, presented by Mr. J. G. Mackie; two Caracals (*Felis caracal*) from Bechuanaland, presented by Captain Treville Cookson; a Ring-tailed Coati (*Nasua rufa*) from South America, presented by Mr. William Shiell; a Long-eared Owl (*Asio otus*), European, presented by Mr. Thomas B. Butler; three Orbicular Horned Lizards (*Phrynosoma orbiculare*) from Mexico, presented by Mr. T. H. Collins; a Rhesus Monkey (*Macacus rhesus* ♀), four Concave-casqued Hornbills (*Dichoceros bicornis* ♂ ♂ ♀ ♀) from India, a Crowned Hornbill (*Anthracoceros coronatus*) from Malabar, a Nepalese Hornbill (*Aceros nepalensis*) from Nepal, deposited; a Peacock Pheasant (*Polyplectron chinquis* ♂) from British Burmah, a Squacco Heron (*Ardea ralloides*) from Southern Europe, purchased; a Yellow-footed Rock Kangaroo (*Petrogale xanthopus* ♀), a Derbian Wallaby (*Halmaturus derbianus* ♀), born in the Menagerie.

OUR ASTRONOMICAL COLUMN.

THE APRIL METEORS.—Few of the April meteors appear to have been visible this year. They were watched for by Prof. Herschel at Croydon, Mr. Denning at Bristol, Mr. Backhouse at Hurworth (near Darlington), Mr. Monck at Dublin, and other observers. The shower of Lyrids was but weakly represented, and meteors generally were scarce. Several conspicuous ones were, however, recorded from the secondary streams of the April epoch. On April 20, at 10h. 16m., a meteor equal to Sirius was seen between Corvus and Virgo by Mr. Backhouse, and at the same time Prof. Herschel recorded a second-magnitude in Perseus. A comparison of the two paths shows the objects to have been identical, and the heights of the meteor at its beginning and end points, as computed by Prof. Herschel, were 50 and 46 miles respectively (over Derbyshire), which is much lower than usual. The radiant-point was at $301° + 34°$. Another brightish meteor was seen on April 21, at 10h. 16m., by Prof. Herschel and Mr. Denning, and its heights were from 76 miles above a point near Newport, Monmouthshire, to 60 miles near Brecon. The radiant was at $217° - 2°$, near μ Virginis. A fine meteor, quite equal to Venus, was observed at Bristol on April 27, at 8h. 51m., slowly descending in Hercules. Its path was from about $218° + 49\frac{1}{2}°$ to $249° + 32\frac{1}{2}°$. It left a trail of sparks as it fell, and its lustre fluctuated in a remarkable manner.

THE WHITE SPOT ON SATURN'S RING.—Prof. Holden reports that a careful examination of the ring of the planet with the great Lick equatorial on several evenings from March 2 to March 24 has resulted in the detection of no abnormal appearance in it. A kind of yellowish deformation or lump was indeed noticed close to the shadow on two or three occasions, but it proved to be due partly to bad definition, for it was only seen when the air was unsteady, and partly to contrast, for a similar appearance was produced in any part of the ring by the use of an occulting bar.

THE VARIABLE X CYGNI.—Mr. Yendall gives a new determination of the elements of this variable in *Gould's Astronomical Journal*, No. 191. Discovered by Mr. Chandler in 1886, it has proved a variable of very interesting character, and its light changes still require much study. The rise from minimum to maximum is generally sharp, but the interval varies much in length, the range being from 3·3 days to 8·7 days; the mean interval being 6·9 days. The curve is flat at minimum, and from these two circumstances Mr. Yendall has confined himself to the use of the maxima alone in the determination of his new elements. The decrease from maximum to minimum shows a remarkable halt, sometimes a positive rise, almost important enough to be considered a secondary maximum. Lastly, the magnitude touched at the extreme points of the curve varies from epoch to epoch, but with a general correspondence between the two phases, a bright maximum being accompanied by a bright minimum, and the contrary. A connection between the duration of the rise and the brightness at maximum has not yet been established. The elements given by Mr. Yendall are—

1886 October 10d. 6h. 11·8m. Camb. M.T. ± 52·3m. + 16d. 9h. 36m. 51s. ± 2·3s. E.

PHOTOGRAPHIC DETERMINATION OF THE BRIGHTNESS OF THE STARS.—No. 7 of vol. xviii. of the *Annals of the Harvard College Observatory* details the progress of the researches in stellar photography carried on at that institution by the assistance of the Bache fund, the particular direction in which the inquiry is being carried on being the determination of stellar magnitudes by means of photography. The present work is concerned with the determination of the brightness of the stars in three particular regions, each with special qualifications for the functions of standard stars; viz. 1000 close circumpolar stars, 420 stars in the Pleiades, and over 1100 equatorial stars. These three catalogues have been prepared with great care; the errors of the different photographic plates fully examined, and the relation of photometric to photographic magnitude investigated. The work therefore forms a most necessary and valuable introduction to a complete survey of the heavens on the same method. The instrument used was the Voigtländer photographic doublet, of 8 inches aperture and 44 inches focal length, so that the scale of the photographs was that of the atlas of the *Durchmusterung*, 2 centimetres to a degree. The images of the stars obtained on the plates were of different kinds, the clock sometimes being employed to drive the telescope when the stellar images were points or disks, sometimes the clock was stopped when trails were obtained, sometimes the clock was used but trails produced through the polar axis of the telescope not being parallel to that of the earth; indeed the adjustment of the polar axis was made in this way. The standard for measuring the stellar points was a photograph of the Hyades, the plate being exposed six times with exposures of 3 seconds, and 3^2, 3^3, to 3^6 seconds respectively. For measuring trails a plate was exposed to the polar region, and the aperture of the telescope varied to correspond to successive differences of a magnitude. The result of the careful and independent measurements of the plates showed that the measures of a skilled observer of the same star disk or trail did not vary on the average by so much as a tenth of a magnitude; so that if the errors due to the photographs themselves can be eliminated the photographic method of determining stellar magnitudes is at least as efficient as the best photometric methods. The comparison of the diurnal with the clock trails showed that the correction for declination to be applied to the former was only half 2·5 log cos δ, the value it should have had if the chemical action due to a certain amount of energy was independent of the time during which it acted.

The first of the three catalogues given in this work is that of the stars within 1° of the pole. Rectangular co-ordinates are given with the stars, instead of R.A. and declination. Of the 1009 stars included, 947 are within one degree radius from the pole, and nearly all are above the fifteenth magnitude. The catalogue of the Pleiades includes all of Wolf's stars between 3m. preceding, and 2m. following Alcyone, and 30′ north and 15′ south of that star with a few apparently overlooked by Wolf. The equatorial catalogue contains the stars within 2° of the equator. Ten different fields were photographed on each plate, one being exposed on the meridian, eight others right and left at intervals of 40m. hour angle, and the tenth on the polar region. A comparison of the results obtained brings out some interesting points. Tempel, at Marseilles, observing the Pleiades with a 4-inch telescope, reached fainter stars than Wolf at Paris with 12 inches aperture. The behaviour of photographic lenses of different apertures shows that to double the aperture is to command two additional magnitudes; to treble it, two and a half. A 24-inch aperture should, therefore, grasp stars below the seventeenth magnitude. A comparison of the photographic magnitudes with the Cordoba Catalogue, and the *Durchmusterung* gives distinct maxima for the residuals in the Milky Way, showing that the Catalogue magnitudes are too faint near the Galactic stream where stars are numerous.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1889 *MAY* 5–11.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on May 5

Sun rises, 4h. 26m.; souths, 11h. 56m. 32·0s.; daily decrease of southing, 5·1s.; sets, 19h 27m.: right asc. on meridian, 2h. 50·7m.; decl. 16° 23′ N. Sidereal Time at Sunset, 10h. 22m.

Moon (at First Quarter on May 8, 7h.) rises, 7h. 57m.; souths, 16h. 17m.; sets, 0h 35m.*: right asc. on meridian, 7h. 11·7m.; decl. 22° 41′ N.

GEOGRAPHICAL NOTES.

THE discovery is announced of a new mouth of the Zambesi, forty-five miles south of the Quaqua, on which Quillimane is situated. The name of the river is Chindé. As we know already of a Chindé River which joins two of the principal mouths of the Zambesi, the probability is, not that a new mouth has been discovered, but that an already known mouth has been more completely explored. The Chindé, it seems, has a channel some 500 yards wide, with three fathoms of water at the lowest, and is therefore expected to afford a clear waterway to the main Zambesi.

FOR the last few years Baron Nordenskiöld has been engaged on a work of great importance in the history of geography, and especially of cartography. He has been collecting from the archives of various European countries specimens of the earliest printed (as distinguished from manuscript) maps, and some of his finds are really original discoveries. These he intends to reproduce in a great atlas with accompanying text, in which, among other things, he will describe and discuss the various editions of Ptolemy; of these he has formed a unique collection. The work will appear both in a Swedish and an English edition.

THE country of Oklahoma, about which we have heard so much during the past fortnight, is in the very heart of what is known as the Indian Territory, which lies between Kansas on the north and Texas on the south. Although on the Survey maps of the United States it seems to be well watered, the actual results would show that the water is not well distributed. It is traversed by the Canadian and Cimarron rivers, and between them are found on the map a perfect network of streams. The area of Oklahoma is a little over 3000 square miles, equal to about one-twentieth of the total area of the Indian Territory; the number of Indians in the latter is about 80,000.

IN an article in the May number of the *Fortnightly Review*, by Mr. F. C. Selous, the well-known South African hunter and explorer, we find a useful account of Mashonaland, around which at present there is so much interest. No man knows the country so well as Mr. Selous, who during the past ten years has traversed it in all directions. Mashonaland lies to the north-east of the Matabele country, and is described as a land of perennial streams, where thirst is an unknown quantity. The high plateau, which is of very great extent, forms the watershed between the Zambesi to the north and east, and the Limpopo and the Sabi to the south; it is from 4000 to 4600 feet above sea-level. Nearly the whole of it is magnificently watered by a network of running streams, the springs supplying which well out from the highest portions of the downs, so that an enormous area of land could be put under irrigation. The whole year round a cool wind blows almost continuously from the south-east, a wind which in the winter months becomes so cold that it may well have its origin among the icebergs of the Antarctic seas. The country, Mr. Selous assures us from his own experience, is admirably adapted for European occupation and labour. The soil is rich and fertile, and from the facilities for irrigation enormous quantities of wheat could be grown. Although the highest and healthiest parts of the country are very open, still one is never out of sight of patches of trees. Besides the high plateau of Mashonaland, the whole of which is over 4000 feet above sea-level, extending along the watershed for a distance of over 200 miles from the Matabele country to the source of the Hanyane and Mazoe Rivers, with a breadth of from sixty to one hundred miles, there is a vast extent of country lying to the south, east, and north-east of the plateau, well-watered and fertile, having an altitude of from 3000 to 4000 feet. These plateaus are of much ethnological interest, as giving shelter to the very few remnants of the peaceful Mashonas that have escaped extermination at the hands of the bloodthirsty intruders, the Matabele.

Mr. Selous leaves England for the Cape to-morrow. It is possible that he may be compelled to lead a prospecting party up the Zambesi. Should this not be the case, he is likely to proceed northwards beyond the Zambesi to the Garenganze country, west of Lake Bangweolo, and thence make either for the source of the Lualaba, which he will endeavour to follow down until it broadens out into the Congo.

M. J. Taupin, Professor in the College of Interpreters at Saïgon, has completed an important exploration in the lower Laos country. Starting from Saïgon in October 1887, M. Taupin, after visiting the Siamese province of Siem-Reap, and photographing the numerous Khmer remains in that province, notably those of Angkor, crossed the forests of the lower Laos, to Ubon, where he resided several months. Among other things he has obtained a knowledge, at least summary, of the Laotian language and writing, the only graphic-alphabetic system, it is stated, on which we have no positive information. The language, M. Taupin states, is spoken by four million people. He has surveyed about 1000 kilometres of rivers and watercourses not found on any map, besides making many important corrections. He has made many notes on natural history, and experimented with the culture of European plants. The meteorology and anthropology of the country, moreover, received much attention at his hands.

At the next meeting of the Geographical Society, on May 13, the evening will be mainly occupied with a discussion of Mr. Stanley's letters, in which several well-known African authorities are likely to take part.

Captain Binger, a French explorer, has succeeded in filling up one of the blanks on the map of Africa. Starting from the banks of the Niger, he penetrated the country of Kong, amid many dangers and sufferings.

THE HENRY DRAPER MEMORIAL.[1]

The researches which constitute the Henry Draper Memorial have consisted for the last three years in the photographic study of the spectra of the stars. While this subject will continue to be the principal one under investigation, Mrs. Draper has decided to extend the field of work undertaken, so as to include the study of the other physical properties of the stars by photography. As will be seen from the detailed statement below, the first research undertaken is now rapidly approaching completion, the plans for the study of the southern stars have been matured, and this study will soon be begun; the detailed study of the spectra of the brighter stars is making progress, and a large piece of photometric work will soon be undertaken with a new telescope. The progress made in each investigation will now be described, as in previous Reports.

1. *Catalogue of Spectra of Bright Stars.*—The Bache telescope, which has an 8-inch photographic doublet as an objective, is used for this work. The photographs cover the entire sky north of $-25°$, with exposures of about five or ten minutes. About 28,000 spectra of 10,800 stars have been examined, including nearly all stars visible in Cambridge of the seventh magnitude or brighter. The Catalogue is now nearly ready for the printer, the final copy having been prepared as far as 14h. in right ascension.

Nearly the entire time of three or four computers has been devoted during the past year to this work. The intensity of about 15,000 of the spectra has been measured, completing this part of the research. Much time has been spent in checking and verifying the results. All the positions have been checked and brought forward to 1900 two or more times independently. All discordant measures have been re-examined, and a search has been made for possible error when bright stars are omitted or very faint ones inserted. Seven thousand two hundred notes have been made on the various stars in the Catalogue. Each note has an appropriate number which permits it to be entered in its proper place. Most of these notes relate to additional lines contained in these spectra besides those by which the type is determined. The position and intensity of these lines is estimated. A portion of them have been reduced to wave-lengths. The printing of the Catalogue might have been already begun but for the difficulty of deciding how the different types of spectra should be distinguished. The classification used for visual observations fails to indicate many differences obvious in the photographs. On the other hand, the photographic portions of spectra of Types II. and III. are nearly identical. The photographs also show many stars whose spectra are intermediate between those of the typical stars which have determined the usual classification. A system has, however, been adopted which permits all differences detected in the photographs to be described in the printed volume.

Thirteen spectra were found on these plates which could not be identified with stars. Three of these proved to be due to Mars, one to Vesta, three to Jupiter, four to Saturn, and two to Uranus. Accordingly all the exterior planets bright enough to be detected in this way appear on these plates.

The measures of the intensity of the spectra form a very important portion of this work. Since the same part of the spectrum is measured in each case, the true relative energy is determined. That is, the same result is obtained as if the measures of rays of the same wave-length were made by any other method, as photometrically by the eye, by the thermopile, or by the bolometer. The colour of the star will be indicated by the extent of the spectrum, which is also noted. For the first time, therefore, we shall have a photometric Catalogue in which the error due to the colour of the star is eliminated. A preliminary determination of the accordance of the results derived from different photographs of the same star shows that the average value of the residuals will be about 0·16, which is the same as the corresponding quantity for the Harvard Photometry. The number of stars is more than twice that contained in the latter Catalogue.

2. *Catalogue of Spectra of Faint Stars.*—In November 1888, the photographs required to cover the sky north of the equator were nearly finished. It was expected that in two months the observations would be completed. The telescope, which was the same as that used in the previous research, was, however, wanted for photographing the Solar Eclipse of January 1, 1889. It was accordingly sent to Willows, California, where it was mounted, and the greater portion of the remaining photographs were taken there. It was then sent to Peru, as will be described below. The few remaining photographs, including the repetition of those found on further examination to be unsatisfactory, will be taken in Peru.

3. *Detailed Study of the Spectra of the Brighter Stars.*—The 11-inch refractor with one, two, or four large prisms over its objective has been employed in this work throughout nearly every clear night, until stopped by the morning twilight; 686 photographs have been taken, most of them with an exposure of two hours. With our present photographic plates about 570 stars north of $-30°$ are bright enough to be photographed with one prism, 170 of them with two prisms, and 87 of them with four prisms. To obtain the best possible result some of the photographs must be repeated many times. The difficulty is increased by the invariably hazy appearance of the lines in some spectra, like that of α Aquilæ, which was at first attributed to poor definition of the photograph. It is expected that the work will be completed during the next year by original or repeated photographs of 228 stars with one prism, of 64 with two, and of 12 with four. In general, stars as bright as the

[1] "Third Annual Report of the Photographic Study of Stellar Spectra conducted at the Harvard College Observatory," Edward C. Pickering, Director. (Cambridge: John Wilson and Son, University Press, 1889.)

fourth magnitude can be satisfactorily photographed with one prism, the spectra obtained being about an inch long. Fainter stars, if of a bluish colour, give sufficiently distinct images, in some cases good results being obtained with stars of the seventh magnitude. For example, fourteen stars in the Pleiades are well photographed with this apparatus. With four prisms much longer spectra are obtained and many more lines are visible. But certain differences in the character of the spectra are better shown with the smaller dispersion. Numerous photographs have been taken of the variable stars *o* Ceti and β Lyræ. The changes in the spectrum of the latter star seem to be undoubted, those of *o* Ceti, if any, to be slight. Various peculiarities in the spectra of individual stars have been detected. One photograph of ζ Ursæ Majoris shows the K line distinctly double, and others show it single. Many photographs will be required to determine the law of its variation, if this is due to changes in the star itself. Bright lines were detected in the spectrum of ϕ Persei, putting it in a class in which only two or three other stars are known to fall. In the double star β Cygni the two components have spectra of different types, an important consideration in the theories regarding their formation. The brighter component is of the second type, the fainter of the first.

Ordinary photographic plates are not sensitive to rays of much greater wave-length than the F line, or 486. By staining the plates with various coal-tar products the range of sensitiveness may be greatly extended. With erythrosin the spectrum extends to the wave-length 590. The sodium line D is distinctly seen to be double in the photographs of α Boötis and α Aurigæ. Various experiments were also made with cyanin, but the plates were not sufficiently sensitive to give good results. The entire length of the spectrum with four prisms, including the portion obtained by erythrosin, is about six inches and a half.

A beginning has been made of the measures of the positions of the lines in the spectrum. A scale of fortieths of an inch has been ruled on glass, and the positions of the lines read off with the aid of a magnifying-glass. Twelve of the photographs of α Canis Majoris have been studied in this way. The spectrum of this star is traversed by the hydrogen lines, which are strong, and by other lines which are so faint that they are only visible when the dispersion is large and the definition good. The catalogue thus formed contains about 320 lines. The average deviation of the measures of the same line on different plates is about 0·05 of a millionth of a millimetre, or 0·05 cm. on the scale of Ångström's map. If the line occurs in the solar spectrum these measures will generally identify it. In other cases the exact position must be determined by a dividing engine. If a line can be distinctly seen, its wave-length can probably be thus determined with as great accuracy as that of the position of the solar lines on the map of Ångström. In the spectrum of α Boötis 140 lines are visible between the D and F lines.

The classification of this large number of spectra is a matter of no little difficulty. Slight differences exist in many stars, and certain stars appear to hold an intermediate position, so as to render a rigorous division into classes impossible. On the other hand, many stars appear to have identical spectra. The first step will be to arrange the stars in groups, and then compare the best defined spectra of different groups. A minute discussion and the measurement of wave-lengths will be necessary only in the investigation of a comparatively small number of spectra.

4. *Faint Stellar Spectra.*—The 28-inch reflecting telescope constructed by Dr. Draper was assigned to this work. During the first six months of the year a careful study was made of this problem, and the difficulties encountered bore evidence of the skill of Dr. Draper in obtaining good results with this telescope. The best method of using this instrument seemed to be a modification of the form first tried by Dr. Draper,—a slit spectroscope from which the slit had been removed. The rays from the mirror were rendered parallel by a concave lens which replaced the objective of the collimator. As this lens had the same focal distance as the objective of the observing telescope, it was not necessary that either should be achromatic. After long trials with this and other forms of apparatus, a spectrum was at length obtained showing good definition. As the results were not better than those described above, and the instrument, from its size, was slow in operation, the experiments have not been carried further.

5. *Catalogue of Spectra of Bright Southern Stars.*—The 8-inch Bache telescope remained in California until February 2, 1889, and was then sent to Peru to continue research No. 1 on the southern stars. The sky from $-25°$ to the south pole will be covered, and the resulting photographs sent to Cambridge and reduced, as in the case of the northern stars. The advantages of discussing all stars from the north to the south pole according to one system are very great, and are here secured for the first time in so extensive an investigation. If no unforeseen difficulty arises, the photographs will all be completed during the next two years.

6. *Catalogue of Spectra of Faint Southern Stars.*—Research No. 2 will also be extended to the south pole simultaneously with the observations required for No. 5. It is expected that these photographs also will be completed in two years.

The Bache telescope described above has proved an extremely convenient instrument for various purposes. Besides the spectroscopic researches already mentioned, several other investigations have been undertaken with it, some of which will be found in the Memoirs of the American Academy, vol. xi. p. 179, and the Harvard Observatory Annals, vol. xviii. Nos. iv., vi., and vii. Owing to its short focal length it possesses many advantages over photographic telescopes of the usual form. With exposures of an hour and a half more stars were photographed in the Pleiades than are given in the engraving accompanying the Annual Report of the Paris Observatory for 1886, although that work was based on photographs taken by the MM. Henry with exposures of three hours and a telescope having an aperture of 13 inches. Nearly twice as many stars were photographed in this region as were visible with the 15-inch telescope of the Harvard College Observatory. The short focus of the telescope also gives it especial advantages for photographing nebulæ. Twelve new nebulæ were thus discovered in a region where but eighteen were known before. Various other investigations, such as a determination of the law of atmospheric absorption, have been undertaken with the aid of this telescope. It has been so persistently used in spectroscopic work that the other researches have been neglected, especially those in which very long exposures were required. Its removal to Peru now cuts it off for some time from such use on the northern stars. Accordingly, Mrs. Draper has procured a similar lens, which is now in the hands of the firm of Alvan Clark and Sons for retouching and mounting. Several important researches will be undertaken with this instrument. Photography is now used in so many departments of astronomy that a general investigation of the photographic brightness of the stars seems desirable. A plan has been proposed by which a single plate will contain photographs of a number of regions one degree square, but in different portions of the sky. Thus a series of standard faint stars will be photographed, which can all be measured, and reduced to the same scale. One or more photographs of the vicinity of the north pole will be taken on each plate, and thus serve to correct the results obtained on different plates. It is proposed in this way to secure a series of standards of stellar magnitude at intervals of about five degrees. A third lens of similar form, having an aperture of four inches, will be attached to the telescope, with which photographs on a smaller scale, but five degrees square, will be taken simultaneously. These photographs will cover the entire sky, and it is proposed to measure the photographic brightness of all stars of the seventh magnitude, or brighter, which are represented on them. This investigation will have a special value in connection with the photometric measures of the spectra described above. It is hoped also to photograph the entire northern sky by means of the 8-inch telescope, with exposures of an hour. Each plate covers a region nearly ten degrees square, of which the images in the central five degrees square are satisfactorily in focus. One of the regions containing standard stars will appear in the centre of each plate. By such a series of plates the photographic brightness of any stars brighter than the fifteenth magnitude can be determined on a uniform scale. The faintest stars photographed will be nearly a magnitude fainter than the limit proposed by the Astrophotographic Congress, so that all plates included in that work can be reduced to a uniform system. The advantages of such plates for studies of the distribution of the stars and other similar investigations are obvious.

From the above description it appears that the field of work of the Henry Draper Memorial, as now extended, is almost boundless. The problems to be investigated relate to the fundamental laws regulating the formation of the stellar system. Questions of such importance should be discussed on a sufficiently large scale, or the results of the discussion will soon be superseded by a repetition of the work. The liberal provision made for the Henry Draper Memorial permits the investigations to be planned on a scale which is likely to avoid such undesirable duplication of work.

GRÜNWALD'S MATHEMATICAL SPECTRUM ANALYSIS.

THE following interesting criticism of Dr. Grünwald's recent work on the mathematical spectrum analysis of various of the elements, by Joseph S. Ames, of the Johns Hopkins University, appears in the February number of the *American Chemical Journal* :—

"Dr. Anton Grünwald, Professor of Mathematics in the Technical High School at Prague, has given his theory of spectrum analysis in the following papers :—(1) 'Ueber das Wasserspectrum, das Hydrogen-, und Oxygenspectrum,' *Astronomische Nachrichten*, No. 2797, 1887, and *Phil. Mag.*, xxiv. 354, 1887; (2) 'Math. Spectralanalyse des Magnesiums und der Kohle,' *Monatshefte für Chemie*, viii. 650, *Wiener Sitz. Berichte*, 2 Abth. xcvi., 1887; *Phil. Mag.*, xxv. 343, 1888 (abstract); and (3) 'Math. Spectralanalyse des Kadmiums,' *Monatshefte für Chemie*, ix. 956.

"His aim is to discover relations between the elements by tracing connections between their spectra, and thus to arrive at simpler, if not fundamental, 'elements.' He considers the lines in the spectra of two substances, say A and B. If he finds a group of lines in the spectrum of A, which, on multiplication with a simple numerical factor, give line for line a group in the spectrum of B, he assumes that A and B have a common component. This factor, which transforms the one group into the other, is, he says, the ratio of the volumes occupied by the common constituent in unit volume of the two substances. Thus, let *c* be common to A and B, and let it occupy the volume [*a*] in unit volume of A, and [*b*] in unit volume of B; then the factor which transforms that part of the spectrum of A due to *c* into that of B, also due to *c*, is [*b*]/[*a*]. It is not difficult to find relations between the spectra of different substances; and, accepting Dr. Grünwald's hypothesis as to the transforming factor, we can deduce formulas for the elements. For example, in the hydrogen spectrum there are two groups of lines, [*a*] and [*b*], which, when multiplied respectively by $\frac{19}{30}$ and $\frac{4}{5}$, give corresponding groups in the spectrum of water, and, since in water hydrogen occupies $\frac{2}{3}$ of the volume, we have the equations

$$[a] + [b] = 1$$
$$\tfrac{19}{30}[a] + \tfrac{4}{5}[b] = \tfrac{2}{3}$$
$$\therefore [a] = \tfrac{4}{5}, \quad [b] = \tfrac{1}{5}$$

which gives hydrogen the composition ba_4. For reasons which depend upon solar physics, Grünwald calls the substance *a* coronium, and *b* helium. Further, he says that all the lines in Hasselberg's secondary spectrum of hydrogen can be changed into water-line by multiplying by $\frac{1}{2}$; which shows, according to his theory, that the modified molecule H^1 occupies in H_2O half the volume it does in the free condition. He finds that oxygen has the composition $H^1 b_4 (b_4 c_5)_5$, where *c* is a new substance. In his last paper, however, Dr. Grünwald states that he has proved *c* to be nothing but *a* in a different state of compression.

"He adopts the spectrum of water, *i.e.* of the oxyhydrogen flame, as a standard, and is then able to give various criteria by means of which the primary elements *a* and *b* may be recognized. Among them are the following: If λ is the wave-length of any line produced by *a* as it exists in hydrogen, $\frac{19}{30}\lambda$, $\frac{3}{4}\lambda$, $\frac{56}{75}\lambda$ will each be the wave-lengths of any line of the water-spectrum, and if λ is the wave-length of any line produced by *b* as it exists in hydrogen, $\frac{4}{5}\lambda$ will be the wave-length of a line of the water-spectrum. Applying his criteria to magnesium, carbon, and cadmium, he finds that they are made up entirely of *a* and *b* in various states of compression. For instance, one group of lines in the cadmium spectrum is transformed into a group of *b* by the factor $\frac{2}{3}$, another group is identical with a group of *b*, and so on. But the group of lines of *shortest* wave-length is transformed into a group of *b* by the factor $\frac{7}{6}$; and cadmium falls in the seventh row of Mendelejeff's table. Similarly, the group of lines of shortest wave-length of zinc is transformed into a group of *b* by the factor $\frac{5}{4}$, and zinc is in the fifth row of the table. Dr. Grünwald finds in this a general law which he verifies in the cases of Al, Si, Fe, Cu, Zn, As, Sr, Ag, Cd, In, Sn, Sb, Te, Ba, Au, Hg, Tl, Pb, and Bi. He further connects the lines of greater wave-length with the substance *a*; and, as in all cases so far tried all the lines can be deduced from these two substances, he is led to believe that *all the so called elements are compounds of the primary elements a and b*.

"It is unfortunate that Dr. Grünwald has not published a complete list of the lines characteristic of *a* and *b*, for until this is done his theory cannot be accurately tested. There are two distinct questions to be answered: (1) Are there any numerical relations connecting the spectra of the elements? and if so, (2) what is the meaning of the fact? Cornu, Deslandres, and others have long since answered the first question for us, but whether Dr. Grünwald's answer to the second is correct or not depends upon the completeness with which the numerical relations hold for the *entire* spectra of the substances. It is here that Dr. Grünwald's work can be criticized.

"As noted above, the spectrum of the oxyhydrogen flame is used to test the existence of lines belonging to *a* and *b*. By far the most accurate and complete determination of this spectrum is that of Liveing and Dewar (Phil. Trans. 1888); but this does not always answer Dr. Grünwald's purposes. In the B. A. Report for 1886 there is a provisional list of lines of the water-spectrum, which he often uses, although the wave-lengths have since been corrected. Further, if other lines are necessary, they are found by halving the wave-lengths of the secondary spectrum of hydrogen. Many lines thus determined are actually present in the water-spectrum; but why are not *all* there? Dr. Grünwald says it is because the amplitude of vibrations of parts of the molecule can be so changed, owing to the presence of other substances, that the intensity may increase or diminish, or become too faint to be observed. To this argument there is absolutely no answer. In some cases, too, the average of two wave-lengths is used as a criterion of a wave-length of *b* which falls between them! And as a last resort, if the necessary wave-length cannot be found in the water-spectrum by any of these means, it is put down as 'new,' and is called an 'unobserved' line. As just shown, Dr. Grünwald easily explains why the strongest lines in the spectrum of an element, cadmium for example, when 'transformed' into water-lines, may be faint, and *vice versâ*. But how does he account for the fact that double lines are not transformed into double lines? This seems to me a fundamental objection. The concave-grating gives the only accurate method of determining the ultra-violet wave-lengths of the elements; and, as a consequence of not using it, most of the tables of wave-lengths so far published are not of much value. So Grünwald's error here may be great. And, besides, when we consider that in the water-spectrum as given by Liveing and Dewar, without the help of the secondary spectrum of hydrogen, there is on the average one line for every two Ångström units, it would be remarkable indeed if any law could not be verified. This is strikingly shown in the first group of the cadmium lines. Here 6742 and 6740 are two readings for the wave-lengths of the *same* line, as made by two observers; yet Grünwald finds a water-line for each of them!

"The fact that there are exact numerical relations connecting the spectra of different elements does not afford a proof of Grünwald's hypothesis; and until the above difficulties are removed the evidence is against it. But, even granting it, how do we know that *a* and *b* are not themselves compounds? In the second group of cadmium lines there are nineteen lines which can be transformed into *b* lines; *b* has many other lines; so at the most this only shows that cadmium and *b* have a common constituent unless, of course, the absence of the other cadmium lines is accounted for in Grünwald's own way of varying intensity.

"The lines of the spectrum of any substance, as carbon or iron, seem to fall into definite series or groups; and the wave-lengths of the lines in these groups can be expressed by formulas, as is well known. All that the fact of there being a connection between the spectra of different substances seems to show is, then, that there may be a formula common to many elements, as Kayser and Runge have recently found. And all that this means is that the molecules of those elements vibrate in general according to a similar law."

ON THE FORMATION OF MARINE BOILER INCRUSTATIONS.[1]

IN the older forms of marine boilers, sea water was almost universally employed; but with the introduction of high-pressure tubular boilers the amount of deposit was so serious, and the difficulty of removing it so great, that it became imperative to use distilled water. It is found, however, that the trouble has

[1] A Paper read at the thirtieth session of the Institution of Naval Architects, by Prof. Vivian B. Lewes, F.C.S., F.I.C., Royal Naval College, on April 11, 1889.

only been transferred from the steam boilers to the distilling apparatus, and that constant breakdowns of the latter necessitate the introduction of sea water into the boiler to eke out the supply of distilled water from the condensers.

The waters at present in use in marine boilers may be classified as—

(1) Sea water, (2) distilled water, (3) mixtures of sea water with distilled or fresh water.

In this paper the nature and causes of the deposits are studied in each of these cases.

Fresh water contains about twenty to fifty grains per gallon of dissolved solids, principally consisting of calcium carbonate, held in solution by carbonic acid present in the water, whilst sea water contains about 2300 grains per gallon, consisting principally of sodium chloride, together with magnesium salts and calcium sulphate. The wide difference in composition between fresh and sea water is also shown in the deposits formed by them. Analyses show that with fresh water the incrustation may be looked upon as consisting principally of calcium carbonate; that with a mixture of fresh and salt water the deposit consists of nearly equal parts of calcium carbonate and calcium sulphate; whilst the sea water gives practically calcium sulphate.

A deposit of calcium carbonate only, separates out as a soft powder, which remains suspended in the water for some time, and can fairly easily be removed from the boiler on cleaning; whilst calcium sulphate as formed in the boiler separates out in a crystalline form, and binds the deposit into a hard mass, so hard in fact that it requires the aid of a chisel and hammer to detach it from the plates and tubes, an operation which is extremely injurious, and tends to shorten the life of the boiler.

Calcium sulphate is much more soluble in a saline solution such as sea water than it is in fresh water, but its solubility rapidly decreases (1) on concentration of the saline solution, and (2) with increase of temperature and pressure.

Sea water having a density of 1·027 was evaporated, and analyses made at different densities with the following results:—

Saline Constituents per Cent.

Density ...	1·029	1·05	1·09	1·225
Sodic chloride	2·6521	4·4201	7·9563	23·8689
Calcic sulphate ...	0·1305	0·2175	0·3915	none
Calcic carbonate ...	0·0103	0·0171	none	none
Magnesic carbonate ...	0·0065	0·0032	none	none
Magnesic chloride ...	0·2320	0·3865	0·6960	2·0880
Magnesic sulphate ...	0·1890	0·3150	0·5670	1·7010

So that on concentrating sea water at ordinary atmospheric pressure, three distinct stages may be traced:—

(1) Deposition of basic magnesic carbonate;

(2) Deposition of calcic carbonate with remaining traces of the basic magnesic carbonate and hydrate; and, finally,

(3) Deposition of the calcic sulphate.

If the sea water be heated and concentrated above a density of 1·225, the salt commences to crystallize out.

These experiments show that if sea water be boiled merely under atmospheric conditions, it would be quite possible, by taking care that its density does not rise above a certain point (1·09) to prevent the deposition of the calcium sulphate; but any such regulation of density is rendered abortive by the fact that pressure and consequent raising of the boiling-point acts upon the calcium sulphate in solution in exactly the same way as concentration, as it is found that this substance is perfectly insoluble in either sea or fresh water at a temperature of 150° C. In the present high-pressure boilers, even if the sea water be mixed with a hundred times its volume of distilled water, so as to reduce its density very low, deposition of calcium sulphate still occurs.

Analyses of several specimens of deposits from boilers where sea water was used, showed that in all cases there were two distinct layers—(1) a hard crystalline deposit on the sides of the tubes, consisting of nearly pure calcium sulphate in the form of "anhydrite"; (2) a softer portion resembling alabaster in the interior, consisting of calcium sulphate, with about 6 per cent. of magnesic hydrate.

The presence of magnesic hydrate in boiler deposits is supposed to be due to the mutual decomposition of water and magnesic chloride, later experiments have shown, however, that when magnesic chloride and calcium carbonate mutually react upon each other, soluble calcium chloride and magnesium hydrate are formed; this explains why calcium carbonate is never found, except in very small quantities in marine boiler deposits.

When distilled water only is used, a slight coating is formed, practically consisting only of organic matter, whilst if at any time through a break-down in the distilling apparatus sea water is mixed with the distilled water, a thin and very hard scale of calcic sulphate is formed. An incrustation of this character gave on analysis:—

Calcic sulphate	90·84
Magnesic hydrate	0·75
Sodic chloride	1·41
Silica	0·85
Copper carbonate	1·11
Oxides of iron and alumina	0·24
Organic matter	2·96
Moisture	1·84
	100·00

This scale is of great interest from the presence in it of the carbonate of copper. It is well known that distilled water has a far greater solvent effect upon metals than a water containing salts in solution, and it is quite conceivable that the distilled water from the surface condensers attacks the brass and copper tubes and fittings, and deposits the copper on the tubes of the boiler, although in only small quantities; and it is interesting to note that the green spots due to the presence of the copper are all on the under side of the scale—that is, in contact with the metal of the boiler tubes, showing that in all probability it had been deposited, as suggested, from the water in the boiler, and in contact with the iron would set up local galvanic action and tend to produce pitting.

The importance of preventing boiler incrustation, and thereby saving the enormous waste of fuel and injury which it entails, has not been without influence on the minds of inventors, and almost every conceivable substance, from potato-parings to complex chemical reagents, have from time to time been patented for this purpose, but have failed more or less for marine boilers, because either they have had an injurious effect upon the metal of the plates, or else have produced an enormous bulk of loose deposit, which, although easily cleaned out if the various parts of the boiler were accessible, and if it were only being used intermittently, yet in a marine boiler continuously working, rapidly chokes the portions between the tubes.

For these reasons, no treatment of the sea water in the boilers themselves is practically possible, and with high-pressure tubular marine boilers the water must be either condenser water, made up to the required bulk with distilled water, as is at present done, or else the condenser water must be augmented by sea water specially prepared for the purpose in a separate apparatus before being supplied to the boilers.

If the engines of a vessel are in good condition, she will approximately require 1 ton of water per 1000 horse power per twenty-four hours, to make up the volume of the condenser water to the amount required for the boilers, so that, even supposing the engines not to be in good order, and considerable waste to take place, 10 tons per diem would be an outside allowance for even very large vessels. To obtain this amount of treated sea water the author proposes an arrangement, full details and diagram being given in the original paper.

The sea water, containing 40 pounds of soda crystals to the ton is heated up under pressure in a separate apparatus by passing through the solution superheated steam. Under these conditions the precipitated mixture of calcium and magnesium carbonates becomes very dense and settles very quickly. The water is then forced through filtering frames into the hot well of the boiler and is then ready for use. The whole process is effective and rapid, and simple arrangements are made for flushing out the apparatus, after each batch of water.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The courses of science lectures this term are as numerous as usual, but present few noteworthy features. Mr. Gardiner gives a general course of Botany, while Mr. Darwin is conducting the course of Elementary Biology (Plants), the lectures being given in the Archæological Museum Lecture Room. Prof. Macalister is lecturing on the History of Human

Anatomy, a subject on which a brief volume from his pen would be very acceptable. Prof. Foster's course is on the Physiology of the Senses this term.

Among the numerous courses of demonstrations in the Cavendish Laboratory we may note those of Mr. Wilberforce on Dynamo-Electric Machines (Alternating Current Generators and Transformers).

Two lectures will be given in the Literary Schools on June 4, and June 8 at 2.15 p.m., by Dr. Francis Warner, on the Study of Mental Action and the Classification of Pupils according to their Brain Power.

LONDON.—The following appointments of Examiners in various branches of Science in the University of London were made on Wednesday, April 24:—Prof. Hill and Dr. Larmor as Examiners in Mathematics and Natural Philosophy; Prof. FitzGerald and Mr. Glazebrook as Examiners in Experimental Philosophy; Dr. Pole and Sir John Stainer as Examiners in Music; Prof. Tilden as Examiner in Chemistry; *Prof. H. E. Armstrong, F.R.S., as Examiner in Chemistry; Prof. Bower and Prof. Ward as Examiners in Botany and Vegetable Physiology; Mr. Sedgwick as Examiner in Comparative Anatomy and Zoology; *Sydney J. Hickson as Examiner in Comparative Anatomy and Zoology; Prof. Boyd Dawkins as Examiner in Geology and Palæontology; *Prof. Charles Lapworth, F.R.S., as Examiner in Geology and Palæontology. The asterisks denote new appointments. The gentlemen to whose names no asterisks are prefixed held the same appointments last year.

SCIENTIFIC SERIALS.

American Journal of Science, April.—Contributions to meteorology, by Elias Loomis. In this paper, which was read before the National Academy of Sciences, November 14, 1888, the chief subjects discussed are the relations of rain areas to areas of high and low pressure. From these studies it appears generally that no great barometric depression with steep gradients ever occurs without considerable rain; that in great rain-storms the barometric pressure usually diminishes while the rainfall increases; that the greatest depression of the barometer generally occurs about twelve hours after the greatest rainfall; that a great rainfall is favourable to a rapid progress of the centre of least pressure. It also appears that in Great Britain the amount of rain with a falling barometer is twice that with a rising barometer; but this ratio diminishes rapidly eastwards, the precipitation in Central Europe being greater when the barometer is rising than when it is falling.—The sensitive flame as a means of research, by W. Le Conte Stevens. These experiments, which take as their starting-point Lord Rayleigh's memoir on "Diffraction of Sound" (Proceedings of the R. Institution, January 20, 1888), tend to show that the sensitive flame is not applicable for purposes of exact measurement, though it is much more nearly so than has been generally supposed. Without its aid it would have been impossible to establish the important analogies here shown to exist between light and sound.—The Denver Tertiary formation, by Whitman Cross. In this paper a succinct account is given of the newly determined Tertiary formation about the Denver district, Colorado, which had hitherto been assigned to the Laramie Cretaceous. Although of limited geographical extent, this formation possesses features of special importance in several respects. The vertebrate remains here occurring present some very remarkable associations, which appear to be in direct conflict with all past observations.—Events in North American Cretaceous history illustrated in the Arkansas-Texas division of the south-western region of the United States, by Robert T. Hill. Here are embodied the results of the author's investigation of the stratigraphic and palæontological conditions in the northern and eastern termination of the Texas Cretaceous, which are brought into relation with the corresponding formations in the Gulf and Western States.—The distribution of phosphorus in the Luddington Mine, Iron Mountain, Michigan, by David H. Browne. The results are here given of some 3000 analyses of ore from the Luddington Mine made during the last three years by the author while acting as chemist to the Lumberman Mining Company. Although no generalizations are attempted, these analyses tend to throw much light on one of the most difficult problems in the chemistry of iron ore—the distribution, throughout the vein, of Bessemer ore, and its relation to the formation of the deposit.—Papers were contributed by C. S. Hastings, on a general method for determining the secondary chromatic aberration for a double telescope objective, with a description of a telescope sensibly free from this defect; by G. Baur, on Palæohatteria, Credner, and the Proganosauria; and by O. C. Marsh, on some new American Dinosauria, with a comparison of the principal forms of the Dinosauria of Europe and America.

Bulletin de l'Académie Royale de Belgique, March.—On the discovery of some fossil remains of mammals anterior to the diluvium at Ixelles near Brussels, by Michael Mourlon. These deposits, brought to light in August 1888, were all found at a lower level than that of the rolled Quaternary gravels, and at some points were overlain by several beds of undisturbed shingle. They include remains of the cave bear, of *Elephas antiquus*, of *Bison priscus*, *Bos primigenius*, the hare, *Equus caballus*, and a smaller equine species here described under the name of *Equus intermedius*, altogether forty four individuals, representing five known and four not yet determined species, and presenting a general resemblance to the mammalian fauna of the English forest-bed.—On the physical properties of the free surface layer of a fluid, and on the contact layer of a fluid and a solid, by G. Van der Mensbrugghe. The experiments here described lead to results opposed to the capillary theories of Laplace and Poisson; they further show that the theory of Gauss is intimately associated with the surface tension of fluids, one leading inevitably to the other, and confirming the author's previous conclusion that the demonstrated existence of tension justifies the theory of Gauss.—Note on a theory of the secular variation of terrestrial magnetism deduced from experimental data, by Ch. Lagrange. Several arguments are advanced in support of the author's new hypothesis that the secular magnetism of the earth is due to a magnetic potential interior and not exterior to the surface of the globe. The solid globe itself is thus regarded as a magnet, or a solenoid—that is, as a magnetic body properly so called, or as a conductor traversed by circular currents.—A paper is contributed by P. De Heen on the determination of the theoretic formula expressing the variations of volume experienced by mercury with the changes of temperature.

Rendiconti del Reale Istituto Lombardo, March 28.—Influence of the digestive juices on the virus of tetanus, by Prof. G. Sormani. A series of experiments are described, which the author has carried out on rabbits, guinea-pigs, rats, and dogs, from which are drawn the following conclusions: (1) the flesh of animals dying of tetanus may be consumed with impunity; (2) the bacillus of tetanus swallowed by carnivorous and herbivorous animals passes through the system without causing death or any special disturbance; (3) the gastric juices of herbivorous animals neither kill, nor diminish the virulence of, the bacillus; (4) an animal may with impunity swallow a quantity of the virus ten thousand times more than would suffice to kill if introduced by hypodermic inoculation; (5) the facts here determined throw some doubt on the accepted theory that the effects of tetanus are due to the absorption of poisonous alkaloids derived from the bacillus.—G. Somigliana contributes a paper on differential parameters, explaining a process by which they may be formed, and demonstrating the invariability of those of the first order. Certain relations, either new or more general than those hitherto studied, are also established between the parameters of the first and second orders.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, April 4.—"The Ferment Action of Bacteria." By T. Lauder Brunton, M.D., F.R.S., and A. Macfadyen, M.D., B.Sc.

The chief objects of this research were, (A) to discover whether microbes act on the soil upon which they grow by means of a ferment; and (B) whether such a ferment can be isolated, and its action demonstrated on albuminoid gelatine and carbohydrates, apart from the microbes which produce it, in the same way that the ferments of the stomach and pancreas can be obtained apart from the cells by which they were originally secreted.

The microbes used were Koch's spirillum, Finkler's spirillum, a putrefactive micrococcus, scurf bacillus, and Welford milk bacillus (Klein).

The results of the inquiry were as follows:—

(1) The bacteria which liquefy gelatine do so by means of an enzyme.

(2) This enzyme can be isolated, and its peptonizing action demonstrated, apart from the microbes which produce it.

(3) The most active enzyme is that formed in meat broth.

(4) Acidity hinders, alkalinity favours, its action.

(5) The bacteria which form a peptonizing enzyme on proteid soil can also produce a diastatic enzyme on carbohydrate soil.

(6) The action of the diastatic enzyme can be demonstrated apart from the microbes which produce it.

(7) The diastatic enzyme has no effect on gelatine, and *vice versâ*.

(8) The microbes, for purposes of nutrition, can form a ferment adapted to the soil in which they grow.

(9) The putrefactive micrococcus gave negative results.

Linnean Society, April 18.—Mr. Carruthers, F.R.S., President, in the chair.—In view of the approaching anniversary meeting, the following were appointed auditors:—For the Council, Dr. John Anderson and Mr. Jenner Weir; for the Fellows, Mr. T. Christy and Mr. D. Morris.—The President called attention to a valuable donation of books on fishes, including the celebrated work of Bloch, recently presented to the Society's library by Mr. Francis Day, who, he regretted to say, was lying seriously ill at Cheltenham; upon which a cordial vote of sympathy and thanks was unanimously accorded.—Mr. J. R. Jackson, Curator of the Museum, Kew Gardens, exhibited specimens illustrating the mode of collecting at Ichang, China, the varnish obtained from *Rhus vermicifera*, so largely used by the Chinese and Japanese for lacquering. He also exhibited some Chinese candles made from varnish seed-oil.—On behalf of Mr. Henry Hutton, of Kimberley, some photographs were exhibited, showing the singular parasitic growth of *Cuscuta appendiculata* on *Nicotiana glauca*.—Dr. Cogswell exhibited specimens of vegetables belonging to four different families of plants, to illustrate the symmetrical development of rootlets.—Prof. Martin Duncan exhibited, under the microscope, and made remarks upon, the *sphæridia* of an Echinoderm.—Dr. Masters gave a summary of a paper on the comparative morphology and life-history of the Coniferæ, a review of the general morphology of the order based upon the comparative examination of living specimens in various stages of development. These observations, made in various public and private "pineta," supplemented by an examination of herbarium specimens, demonstrated the utility of gardens in aid of botanical research. The mode of germination, the polymorphic foliage, its isolation or "concrescence," its internal structure, the arrangements of the buds, the direction and movements of the shoots, were all discussed. In reference to the male and female flowers, the author described their true nature, tracing them from their simplest to their most complex or most highly differentiated condition; and showed that, so far as known, the histological structure and development were essentially the same throughout the order. Various special forms, such as the needles of *Pinus*, the phylloid shoots of *Sciadopitys*, and the seed-scales of *Abietineæ*, were described, and their significance pointed out. The phenomenon of enation with the correlative inversion of the fibro-vascular bundles in such outgrowths was considered in relation to the light it throws upon certain contested points in the morphology of the order; the chief teratological appearances noted in the order were detailed, and their significance discussed; the various modifications were shown to be purely hereditary or partly adaptive, and dependent on permanent or intermittent arrest, excess, or perversion of growth and development, and to various correlative changes; lastly, the polymorphic forms of the so-called genus *Retinospora*, suggested that in studying them we might be watching the development and fixation of new specific types.

Chemical Society, April 4.—Dr. W. J. Russell, F.R.S., President, in the chair.—The following papers were read:—The rate of dissolution of metals in acids, by Mr. V. H. Veley. The dissolution of copper in a solution of potassium bichromate acidified with sulphuric acid was investigated as affording a case in which no gas was evolved as such. The copper was employed in the form of metallic spheres which by various mechanical devices were rolled about continuously and regularly in the acid liquid, and the products of the changes continuously removed from the immediate neighbourhood of the metal. The author finds (1) that if the temperature be varied between 21° and 41° in an arithmetical proportion the amount of chemical action varies in a geometrical proportion; (2) that if the amount of sulphuric acid be varied in an arithmetical proportion between the limits of 41·3 and 23·5 grammes per litre, the amount of change also varies in an arithmetical proportion; and (3) that the amount of change is at first considerably increased by increase of proportion of potassium bichromate, but the effect afterwards gradually diminishes to *nil*, at which point the bichromate can be considered to be so much inert material: the amounts used varied from 22·1 to 66·3 grammes per litre.—Note on the interaction of metals and acids, by Prof. H. E. Armstrong. When a metal forming an element in a voltaic couple is dissolved, the rate of dissolution is in accordance with Ohm's law, $C = E/R$: and this should apply also to the case in which a metal is dissolved without any precaution being taken to arrange it as an element of a couple, as the action is conditioned by the formation of, and takes place within, "local circuits." The changes attending the dissolution of metals may, therefore, in a certain sense be said to be purely electrical in the first instance; yet within recent years it has been argued by various chemists that the phenomena are only in part electrical and in part chemical—whatever this may mean. The author discussed the various phases of such changes, and criticized the conclusions arrived at by Spring and Aubel and others. Referring to Mr. Veley's experiments Prof. Armstrong expressed the opinion that the results were in no way commensurate with the labour expended in obtaining them: although by introducing bichromate polarization by hydrogen had been prevented, its use had introduced complications which made the analysis of the results impossible; in fact the information likely to be obtained from such experiments was not of the kind required in the present state of chemical science. Thus the proof obtained that a copper sphere dissolved uniformly in a mixture of sulphuric acid and bichromate was but a proof of the efficiency of the stirring apparatus: such would necessarily be the case, as the values of E and R remained almost unchanged throughout the experiment owing to the relatively small proportion of the agents used up. In the course of his reply Mr. Veley mentioned that he had had occasion to verify Dr. Russell's observation that silver is not dissolved by nitric acid free from nitrous acid, to which reference had been made, and stated that in experiments with copper and nitric acid he had observed that the action took place at first more slowly, and only attained a maximum rate when a certain small amount of nitrate was formed. Prof. Armstrong remarked that this was a really important observation, proving that the dissolution of copper in nitric acid was dependent on the presence of a third substance—perhaps cupric nitrate.—A zinc mineral from a blast furnace, by Mr. J. T. Cundall.

Zoological Society, April 29.—Sixtieth Anniversary Meeting.—Prof. Flower, C.B., F.R.S., President, in the chair.—In the Report of the Council on the proceedings of the Society during the year 1888, it was stated that the number of Fellows on January 1, 1889, was 3076, showing a decrease of twenty-eight as compared with the corresponding period in 1888. The total receipts for 1888 had amounted to £24,025 10*s.* 8*d.*, showing an increase of £922 15*s.* 2*d.*, as compared with the previous year. The receipts from admissions to the Gardens had risen from £12,138 to £13,284. The ordinary expenditure for 1888 had been £21,439 16*s.* 4*d.*, which was £2436 less than the corresponding amount for 1887. Besides this, an extraordinary expenditure of £700 had been incurred, which had brought up the total expenditure for the year to £22,139. The sum of £1000 had been employed in repayment of a temporary loan from the bankers, and a further sum of £1000 had been devoted to the diminution by that amount of the debt on the Society's freehold premises, which now stood at £7000. After deducting these payments from the income of 1888, and adding to it the balance of £1158, brought over from the previous year, a balance of £1043 was carried forward for the benefit of the present year. The usual scientific meetings had been held during the session of 1888, and a large number of valuable communications had been received upon every branch of zoology. These had been published in the annual volume of Proceedings for 1888, which contained 717 pages, illustrated by thirty-two plates. Besides this, Part 7 of the twelfth volume of the Society's quarto Transactions, illustrated by eight plates, had been issued. The volume of the "Zoological Record" for 1888, containing a summary of the work done by British and foreign zoologists in 1887, had been issued early in the present year. It had been edited by Mr. F. E. Beddard, the Prosector to the Society. An important event in connection with the Library during the past year had been the receipt from the executors of the late Madame Cornély, widow of the late M. J. M. Cornély, an old and valued corresponding member of the Society, of a valuable library of zoological books. The Cornély Library consisted of about 840 volumes, of which 256 were new to the Society's Library, and many of these were rare and difficult of acquisition. In the Gardens in Regent's Park, the work during the past year had been entirely confined to repairs and renewals, which, however, had kept the staff of workmen busily engaged. The visitors to the Gardens during the year 1888 had been altogether 608,402, the corresponding number in 1887 having been 562,898. The number of animals in the Society's collection on December 31 last was 2290, of which 666 were Mammals, 1280 Birds, and 314 Reptiles. Amongst the additions during the past year nine were specially commented upon as of remarkable interest, and in most cases representing species new to the Society's collection. About thirty-one species of Mammals, seventeen of Birds, and two of Reptiles had bred in the Society's Gardens during the summer of 1888.—The Report having been adopted, the meeting proceeded to elect the new members of Council and the officers for the ensuing year. The usual ballot having been taken, it was announced that Lieut.-Colonel the Lord Abinger, C.B., Mr. Henry A. Brassey, Mr. Henry E. Dresser, Lieut.-General Sir H. B. Lumsden, K.C.S.I., and the Lord Arthur Russell, had been elected into the Council in place of the retiring members; also that Mr. Walter Morrison, M.P., elected into the Council since the last anniversary, had been re-elected in place of the late Surgeon-General L. C. Stewart (deceased); and that Prof. Flower, C.B., F.R.S., had been re-elected President; Mr. Charles Drummond, Treasurer; and Mr. Philip Lutley Sclater, F.R.S., Secretary to the Society for the ensuing year.

PARIS.

Academy of Sciences, April 15.—M. Des Cloizeaux, President, in the chair.—Researches on the thionic series, by M. Berthelot. The author describes a new method recently discovered by him, by means of which he has succeeded in measuring the heat of formation of nearly all the terms in the thionic series, such as the dithionic, trithionic, tetrathionic, and pentathionic acids. The method consists in oxidizing the salts of the thionic acids, previously dissolved, by means of bromine dissolved either in water, or, better, in bromide of potassium. For acids formed by the union of the same element combined in multiple proportions of oxygen there is in most cases a certain proportion between the liberated heat and the combined oxygen, a law already indicated by Dulong.—Experiments on putrefaction and on the formation of manures, by M. J. Reiset. Detailed descriptions are given of the critical experiments briefly referred to by the author in his recent communication on this subject. He also deals with a serious objection that has been raised against his general conclusion regarding the liberation of nitrogen during the process of putrefaction.—Movement of cyclonic storms in the various regions of the globe, by M. H. Faye. A general survey is given of the salient features of these phenomena in the North Atlantic, the Bay of Bengal, the Arabian Sea, the Indian Ocean, the China Sea, and Japan waters—that is, in the regions where they have been most carefully studied. The author insists on the essential identity of all their main characteristics; everywhere the same rapid trajectory from the equator towards one or other of the poles; the same manner of gyration narrowing towards the base round about vertical axes; the same progressive expansion frequently developing phenomena of varied segmentation far from the equator; the same independence of local climatic conditions pointing to their common origin in the upper atmospheric regions, and showing that these violent disturbances do not belong exclusively to the science of meteorology, but are the grandest terrestrial manifestations of the mechanics of fluids, acting in conformity with the simple theory already, on several occasions, announced by the author.—Observations of Barnard's new comet, March 31, made at the Observatory of Algiers with the 0·50 m. telescope for the period April 4–10, by MM. Trépied, Rambaud, and Renaux.—On the specific heat of sea water at different degrees of dilution and concentration, by MM. Thoulet and Chevallier. The measurement of the specific heat has been executed according to M. Berthelot's method with water taken on the Fécamp coast, sometimes pure, sometimes with distilled water added, and sometimes concentrated by evaporation, the determination both of the densities and of the specific heats being made at the temperature of 17°·5 C. The calculations here worked out explain the enormous influence exercised by the sea in regulating the climates of the globe.—On the intensity of telephonic effects, by M. E. Mercadier. In continuation of his previous note (*Comptes rendus*, cviii. p. 737) the author here describes his further experiments with aluminium and copper diaphragms. The effects produced with these are found, under like conditions, to be far less intense than with iron diaphragms, the chief cause of the difference being the very slight specific magnetism of the former as compared with the latter. On the other hand, the *quality* of the effects produced by the aluminium and copper diaphragms is very remarkable, as they give the *timbre* of sounds and of articulate speech far better than iron.—Researches on some new metallic sulphides, by MM. Arm. Gautier and L. Hallopeau. In continuation of the already described studies (*Comptes rendus*, cvii. p. 911) on the action of carbon-di sulphide on the argillaceous earths, the authors have been led to examine its action on various metals at a red heat. The sulphides thus produced include those of iron, manganese, and the silicate of manganese described in this paper, and of nickel, chromium, lead, and aluminium, which are reserved for a future communication.—On the heat of combustion of some organic substances, by M. Ossipoff. The author has undertaken a series of experiments for the purpose of determining the heats of combustion of certain organic bodies not yet studied from the thermic standpoint. He has already completed the study of cinnamic, atropic, and terebic acids, all of which are described in the present paper.—Bacteriological researches on the disinfection of hospitals, dwellings, &c., by gaseous substances, and especially by sulphurous acid, by MM. H. Dubief and I. Bruhl. From these experiments it appears that gaseous sulphurous acid has a destructive effect on germs contained in the air, especially when saturated by the vapour of water; that it acts mainly on the germs of bacteria, and that when employed in the pure state for a prolonged period it may prove fatal to germs even in the dry state.

April 23.—M. Des Cloizeaux, President, in the chair.—On the theory of the capture of periodical comets, by M. F. Tisserand. The object of this paper is to supply a rigorous proof of the theory, based on Laplace's study of Lexell's comet, that the influence of Jupiter, acting on a comet with parabolical orbit, may under certain conditions transform its course to an elliptical orbit analogous to those of the group of periodical comets. Some of the formulas here worked out agree very well for two of Tempel's comets and for that of Vico; but full details are reserved for the next issue of the *Bulletin Astronomique*.—Memoir on the ravages caused to agriculture by the cockchafer and its larva, by M. J. Reiset. The results are described of the measures that have been taken in France for the destruction of this pest since the year 1866. A detailed account is appended of its remarkable biological transformations, and instances given of its surprising vitality, surviving complete immersion in water for over four days, and when buried to a depth of 0·40 metre in the earth remaining in a state of suspended animation for 150 days.—Observations of Barnard's new comet, March 31, made at the Observatory of Paris (equatorial of the east tower), on April 19, by Mdlle. D. Klumpke; at the same Observatory (equatorial of the west tower), on April 18–19, by M. G. Bigourdan; and at the Observatory of Bordeaux with the 38 cm. equatorial, on April 20, by M. G. Rayet. During these observations the comet generally presented the appearance of a slight nebula with a nucleus of the fourteenth magnitude.—On magnetic rotatory polarization, by M. Vaschy. It is shown that M. Potier's recent hypothesis (*Comptes rendus*, March 11, 1889) on the action of the ether on ponderable matter offers a remarkably simple explanation of this phenomenon. On the other hand, it lends no support to Ampère's theory regarding molecular currents.—On the initial mode of deformation of the ellipsoidal crust of the earth, by M. A. Romieux. M. Daubrée's well-known experiments serve as the basis of a theory of the original crumpling and folding of the terrestrial crust, which is here worked out with illustrations. M. Romieux considers that, although now far removed from that initial deformation, the globe still retains many traces of its effects as here described. Thus, the Pacific Ocean, a vast and very ancient equatorial basin, acting in opposition to a continental mass with its more recent depression of the Central Mediterranean, is supposed to have impelled by successive spasmodic pressures three or four zones of folding against the resisting mass of the North Pole.—On the combinations of ruthenium with nitric oxide, by M. A. Joly. Continuing his investigations on this subject (see *Comptes rendus*, cvii. p. 994), the author here adds a considerable number to the compounds of ruthenium with nitric oxide. They comprise a compound of nitric oxide with the trichloride, $RuCl_3(NO) + H_2O$, and with the sesquioxide, $Ru_2O_3(NO)_2 + 2H_2O$, both remarkably stable bodies, resisting the action of water, of bases and acids, and decomposing only at a temperature above 300° C. It is suggested that analogous nitrous combinations might be formed with rhodium, and with osmium. In a future communication M. Joly proposes to show that the substances described by Fritsche and Struve, under the names of osmanosmic or osmiamic acid and of osmiates, have a constitution similar to that of these compounds of ruthenium. — Researches on the richness of wheat in gluten, by MM. E. Gatellier and L. L'Hote. A series of experiments are described by which the same wheat (white Victoria) is made to yield increasing proportions of gluten. The increase largely depends on the rotation of crops and on the proportion of nitrogen to phosphoric acid contained in the manures.—Papers were contributed by M. J. Janssen and Colonel Gouraud on Mr. Edison's improved telephone, full details of which have already appeared in the English scientific journals. The proceedings concluded with the following phonographic message sent by the President to Mr. Edison : "M. le Président et les Membres de l'Académie des Sciences adressent leurs félicitations à M. Edison pour les nouveaux perfectionnements qu'il a apportés à son phonographe, et espèrent le voir bientôt à Paris, à l'occasion de l'Exposition Universelle."

BERLIN.

Physiological Society, April 12.—Prof. du Bois-Reymond, President, in the chair.—Prof. Fritsch gave a brief account of the results he has obtained from the examination of the electrical organ of Torpedo which he has been carrying on for several years. Both Wagner and Remak had correctly made out that each plate consists of two layers, one dorsal and one ventral ; that the nerves are attached to the plate from the under side, and are distributed in branches over it ; and that the under surface of the plate is dotted. Very little further information as to the structure of this organ has resulted from the many investigations subsequent to those of the above-named observers. Prof. Fritsch then explained and set aside the views of the best-known observers, and summed up his own conclusions as follows. The lowest or marginal layer is composed of a layer, which is here and there discontinuous, of globules, which refract light very strongly ; between these the terminal fibres of the nerves make their way into the plate. The pallisade-layer, which some previous observers had described, has an existence in the form of a number of extremely fine filaments, which stand at right angles to the plate, but inasmuch as they are so fine as to be scarcely visible, nothing can for certain be made out as to their nature. Passing further in a ventral direction, globular structures are found in the lower plate, seated upon fibres which branch dichotomously ; these may perhaps be bulbous nerve-endings. Large nuclei lie between the ventral and dorsal layers. The dorsal or muscular layer contains extremely fine granules, arranged in rows at right angles to the surface. The above results were obtained by the application of the modified treatment with nitric acid. A series of photographs and drawings was exhibited in explanation of that which was described, and several preparations were shown under the microscope.—Prof. Preyer spoke on reflexes in the embryo. His researches extended over many classes of animals. As representing Mammals, guinea-pigs were chiefly used ; and for reptiles, snakes ; while in addition the embryos of fishes, frogs, mollusks, and other lower animals were also employed. But of all animals birds are most suitable for embryological observations, inasmuch as, with due precautions, the development of one and the same individual can be followed for a considerable time. Birds' eggs can be incubated in a warm chamber, and by removing a portion of the shell and replacing it by an unbroken piece from another egg, it becomes possible to follow the daily development of the chick and to experiment upon it. As early as the ninetieth hour of incubation, spontaneous "impulsive" movements may be observed, taking place apparently without any external stimulus as a cause, and at a time when no muscles or nerves have as yet been developed. After the occurrence of these spontaneous movements, and at the earliest on the fifth day of incubation, movements are observed to result from the application of mechanical, chemical, and electrical stimuli. In order to observe these the eggs must be allowed to cool down until all spontaneous movements have ceased. From the tenth to the thirteenth day more complicated and reflex actions occur on the application of stimuli, as, for instance, movements of the eyelids, beak, and limbs ; and if the stimuli are strong, reflex respiratory movements. These reflexes make their appearance before any ganglia have become differentiated. Prof. Preyer considered himself justified in concluding from this that ganglia are not essential for the liberation of reflex actions. He intends, on some future occasion, to give a more detailed account of these experiments, and of the conclusions which may be drawn from them. In the discussion which ensued the conclusions of the speaker were contested from many sides.

THURSDAY, MAY 9, 1889.

THE ESTATE OF HER MAJESTY'S COMMISSIONERS OF 1851.

UNDER this heading the *Times* has announced that "a Sub-Committee of the Commissioners, amongst the members of which are Lord Thring, Sir Lyon Playfair, Mr. Childers, M.P., and Mr. Mundella, M.P., held a meeting on Saturday last to adopt a final report upon the disposal of this Estate which should be submitted for the approval of the Royal Commissioners themselves." The Commissioners have determined to let out a considerable part of their Estate to house builders, and the Sub-Committee had before them, on Saturday last, tenders for building leases. If the Commissioners accept these tenders, they will add some £10,000 a year to their income. This notion of sacrificing the Estate to builders of private houses has been known for some months; and, with the view of demonstrating against so short-sighted, not to say utterly immoral, a policy, a Memorial has been framed and circulated. We have received a copy of it, and, entirely acquiescing in its object, we print it *in extenso*. It runs as follows:—

To His Royal Highness the Prince of Wales, K.G., &c., &c., President of Her Majesty's Commissioners for the Exhibition of 1851.

The Memorial from the undersigned on behalf of ____________ [Here fill in name of Chamber of Commerce, Corporation, Guild or Educational Institution.

SHEWETH

(1) That in the year 1851 a large surplus profit accrued after the conclusion of the Exhibition of 1851.

(2) That this surplus profit was for the most part expended by Her Majesty's Commissioners for the Exhibition of 1851 in the purchase of a considerable Estate of land at Kensington, for the erection of public institutions, and generally to benefit the country's Arts, Sciences, Manufactures, and Commerce.

(3) That various public institutions, such as the South Kensington Museum, the Training School of Science and Art, the Natural History Museum, the Royal College of Music, the Royal Albert Hall, and the Imperial Institute, have been or are in course of being built upon this Estate.

(4) That fine open spaces intervene between the various institutions, to provide for further extensions of them, and give them proper light and air.

(5) That Sir Lyon Playfair, M.P., as Secretary to Her Majesty's Commissioners, recently stated in the House of Commons that a large portion of these fine open spaces between the public institutions already named was to be leased for the erection of private houses and mansions.

(6) That, in the opinion of Your Royal Highness's Memorialists, this crowding upon the public institutions of private houses and mansions is adverse to the interests of Arts, Sciences, Manufactures, and Commerce, and foreign to the intentions of Her Majesty's Commissioners, publicly announced, when they purchased the land, and also subsequently.

(7) That, in the opinion of Your Royal Highness's Memorialists, this crowding upon the public institutions to benefit Arts, Sciences, Manufactures, and Commerce, of private houses and mansions is in conflict with the last public announcement in respect of the future of the Estate which H.R.H. the late Prince Consort made within six months of his lamented death.

Your Memorialists, therefore, respectfully pray that Your Royal Highness, as President of Her Majesty's Commissioners, will prevent the public institutions on the Estate of Her Majesty's Commissioners from being crowded upon by private houses and mansions, and will induce Her Majesty's Commissioners to preserve intact those unalloted portions of their Estate in order that they may be placed to the great public uses for which the Estate was destined by Her Majesty's Commissioners and their President, Your Royal Highness's illustrious father, the lamented Prince Consort.

The *Times*, commenting upon the effect of the Commissioners' scheme for filling up their Estate with private houses, says that "the irregular blocks of variegated private houses" will more or less overwhelm and hedge in "such National Institutions for Science and Art as the Estate may ultimately contain."

From time to time the Commissioners' various proposals for dealing with their Estate have been publicly criticized, with the useful result that such of the proposals as were in the nature of distinct departures from the original intentions set forth at the time the Estate passed into their keeping, have been modified or dropped.

Twelve years or so ago, some representatives of the original subscribers, whose aid in 1851 virtually placed a large portion of the surplus funds at the disposal of the Commissioners, urged that unallotted portions of the Estate should be sold to meet expenses in founding provincial galleries or museums for science and art. For good reasons, the Commissioners did not give way to these plausible representations. They said at that time that, under the guidance of the Prince Consort, "we purchased the estate to provide an *extensive site for the development of great institutions for the promotion of industrial art and science amongst the manufacturing population*." At this very time, and, as was stated in NATURE of May 2, p. 3, the Commissioners proposed certain conditions to the Government, under which they (the Commissioners) would raise £100,000 as a contribution towards erecting a Museum of Scientific Instruments, a Science Library, and Laboratories of Scientific Research and Instruction. This proposal, which was not entertained however by the Government of the day, contained provisions for keeping the main parts of the Estate free for the development of national institutions. The reasons for keeping the main portions of the Estate at liberty in this way have since remained every whit as strong as they were then. Indeed they are stronger than ever, in the face of Government action now being taken in respect of the "National Science Museum." But a malign influence supervened. It was but a week before Christmas last year, when Mr. G. Samuelson asked a question in the House of Commons, that Sir Lyon Playfair stated that Her Majesty's Commissioners for the Exhibition of 1851 were arranging to dispose of considerable plots of land on their Estate to house builders, in order that the Commissioners might increase their income by obtaining ground-rents from private houses, and that the Commissioners did not intend to publish their reasons for this. Is Sir Lyon Playfair's assurance in thus apparently setting public opinion at defiance to be ascribed to a sense of relief from further responsibility which he may have derived from his resignation of the secretaryship to the Commissioners?

There is no ambiguity in his statement as to the choking up of the Kensington Estate with private houses and mansions. The sites to be occupied by private houses are bounded on the north by the Albert Hall and the adjoining semicircular arcades or quadrants, on the east and west by portions of the galleries containing the Museum of Science and the India Museum, and on the south by the Imperial Institute. They form the gardens and terraces so well known to the public who flocked to the evening *al fresco* entertainments which were given in connection with the series of International Exhibitions recently held at South Kensington. The various public announcements issued by Her Majesty's Commissioners during the last thirty-five years conclusively show that this land was acquired for more useful and comprehensive purposes than those of speculative house builders.

Let us briefly refer to those announcements. On the close of the Exhibition of 1851, H.M. Commissioners found themselves the possessors of some £200,000. They were impressed with the fact that many public institutions founded to promote science and art had been "subject to the disadvantages of being placed in such a situation from the crowding of surrounding houses that they were without light or air, and had no convenient access." They therefore determined to purchase a large estate of unoccupied land, and in 1852 became the landlords of what has since been commonly known as the South Kensington Estate. For the ultimate use of this large property they proposed to trust to the "voluntary efforts of individuals, corporations, and authorities, to carry out the promotion of the different interests with which they are themselves connected." In their Report for 1856, the Commissioners, alluding to "the question of the site that has been purchased by us," show that, during the intervening years, "the great natural capabilities of the site have been properly developed by means of the construction of important lines of communication and other improvements; and that we are still occupied in taking the remaining steps requisite for perfecting the estate, and rendering it in all respects fit for the great national objects to which it is to be applied." Very shortly afterwards a large area of the Estate was leased to the Royal Horticultural Society. This was laid out as an ornamental garden surrounded by arcades and galleries. The late Prince Consort opened this garden in 1861. His Royal Highness made a speech on the occasion, in the course of which he said, "We may hope that at no distant day this garden will form the inner court of a vast quadrangle of Public Buildings rendered easily accessible by the broad roads which will surround them, Buildings where Science and Art may find space for development, with that light and air which are well-nigh banished from this overgrown metropolis." This was but six months before the death of the Prince. For some years the Prince Consort's superior policy in dealing with the Estate was respected and followed by Her Majesty's Commissioners. The Natural History Museum arose on the land at the south of the Horticultural Gardens. Galleries were built above and at the side of the long eastern and western arcades of the gardens; other galleries were erected between these gardens and the Natural History Museum. The Government secured a tenure of all these galleries as a temporary home in which the Government has placed the National Science Museum, the Collections of Historic Machinery, the India Museum, and the Collections of Modern Industrial Art. On the far north of the Estate was built the Royal Albert Hall: then followed the Royal College of Music. Later still sprang up the Technological Schools of the City and Guilds of London Institute. But with all this steady realization of the Prince Consort's far-seeing policy the Commissioners were not satisfied. Pleading necessity to find money for defraying the expenses of certain not over-wise experiments undertaken by them, they began to let land on the margins of their Estate for the erection of private dwellings. And the more prominent result of this is the beetling mass of mansions opposite Hyde Park, overshadowing the Albert Hall on one side, and frowning ominously upon the "inner court of the vast quadrangle" of the Estate. Then came the movement for an Imperial Institute. A great slice out of the "inner court" was allocated for this mysterious Institute, which is rapidly asserting its architectural entity. At this point in the development of the Estate, the Commissioners, it would seem, succumbed to the hopeless temptation of washing their hands of further trouble. And, as we have already stated, their present intention is to block up the remaining portion of the "inner court" with private houses and mansions, and thus disencumber themselves of any responsibility for institutions for science and art.

Now, an explanation, which has been offered, of this *volte face* on the part of the Commissioners is this. The subscriptions for the Imperial Institute are insufficient for its endowment. It must be remembered that the Imperial Institute is the outcome of the "Jubilee" loyalty. The possible utility of this Institute has been debated without success. To lay the foundation-stone, and to pay for a staff of subscription-touters and what not, during two years, have exhausted some £25,000 of its capital, which does not reach £300,000. The ingenuity of Lord Thring and Sir Lyon Playfair has, it is said, been accordingly taxed. Their united wits are credited with having proposed the sale to private house builders of the unallotted land as well as of portions of land already occupied by galleries containing the Science Museum and India Museum. The money thus realized, or most of it, is to go into the coffers of the Imperial Institute. Such are the statements made. If they are wrong, they should be contradicted.

Another minor incident which further exemplifies the Commissioners' attitude is the projected removal of the monument raised twenty-five years ago on their estate to commemorate the Exhibition of 1851. This monument is surmounted by a statue of H.R.H. the late Prince Consort. This too is to be swept away to make room for private houses.

WARREN DE LA RUE.

A PROMINENT and representative figure has just disappeared from scientific circles, whose absence will be deeply felt by the many eminent men with whom, for a long time, he had been associated. In the

Councils of our great Societies he was a man invaluable for his intelligence, for his persevering energy, for his promptness of resource, and for a generosity, princely, but discriminating. These words will at once suggest the regretted decease of Warren de la Rue. At the age of seventy-four, he can hardly be said to have died full of years; but assuredly Warren de la Rue died full of honours. He was almost, but happily not quite, the last of a generation or two, of men who, possessing ample pecuniary means in middle or early life, devoted the means and the life to the search for truth in Nature, each in his own line. The two Herschels, Wollaston, Babbage, Gassiot, Spottiswoode, and De la Rue are gone, and but few like to them still survive, linking us with the past. "The old order changeth;" and now the endowed and professional student of Nature is fast displacing the amateur. Nor need we altogether deplore it; for, after all, the Professor and the amateur belong to the same race of Englishmen; they have the same love of the quest for truth ardent within them; and in the case of the Professor there is now superadded the spur that comes from a sense of duty.

Warren de la Rue was born in 1815, and was the son of Mr. Thomas de la Rue, the founder of that eminent firm of manufacturing stationers in Bunhill Row who have rendered well-known services to social life by the production of numerous articles, unsurpassed in excellence in their particular craft. He first became known to the world at large by his newly-invented machine for the manufacture of envelopes, which was placed in the Great Exhibition of 1851, and formed one of the chief objects of attraction there. Not far from it lay a small photograph of the moon, taken by Bond with the Harvard refractor of 15 inches. It was comparatively, and from the circumstances of the times necessarily, but a poor performance, yet it held out the promise of future possibilities, and it certainly fired the hopes of De la Rue. It was to him what the itinerant telescope in the streets of Bath became to the elder Herschel, viz. the determining point of a future and illustrious career. Accordingly, we soon find him engaged in the construction of, what in the sequel has become, his historic reflecting telescope, having an aperture of 13 inches and a focal length of 10 feet. The mirror was figured and polished by his own hands, and the equatorial mounting of the telescope was completed in his manufactory at Bunhill Row, from his own designs. Here again our thoughts revert to the elder Herschel; but that great astronomer never approached the perfection either of the De la Rue mirror, or of the mechanism by which it was mounted and by which it was moved. It is, however, only just to say that much of this notable improvement was the natural outcome of the lapse of time and of the progress that had been made in the working of metal. The instrument was mounted in the suburbs of London, at Canonbury, in a small garden surrounded by houses. It was hither, when the day's work was done at Bunhill Row, that De la Rue retired at night; and here, by patiently waiting for a clear and serene atmosphere, an event of rare occurrence, and then only during the small hours of the morning, he finally succeeded in taking telescopic pictures of the planets Jupiter and Saturn, which it may not be too much to say remain still the equals of any subsequent delineations of the same planets. Of the Saturn picture, John Herschel was heard to say that he could die content if he could but once see the planet itself as beautifully defined. This great success at once placed him among the chief amateur practical astronomers of the day.

It was about this time that he associated himself with Owen, Quekett, Bowerbank, and others, in the formation of the Microscopical Society; and such were the keenness and exactness of his eyes and hand, that he soon became a chief referee for the performance of the wonderful microscopic objectives which then for the first time were produced by the skill of Powell and Andrew Ross.

His first essays in lunar photography were not so successful as he had anticipated: the collodion plates were deficient in rapidity, and his telescope, not being as yet provided with a clock movement, he was unable to keep the moon motionless in the field, even for the short exposure requisite to secure a photographic image. All this, however, was soon rectified. For, about the year 1857, he removed his residence and his telescope from Canonbury to Cranford, a village distant from London by some twelve miles west. There he provided his instrument with an admirable driving-clock, and applied what leisure he could get, sedulously to celestial photography; and there he secured the earliest substantial results of a method, which, at present, bids fair to revolutionize the processes of the most exact and refined astronomy. The photographs of the moon which he now obtained still remain works of art, which even the most skilful of recent astronomers find it difficult to emulate with success. He also made many attempts to photograph the solar disk; but owing to mechanical difficulties, connected with the necessarily infinitesimal duration of the exposure of the plates, his success was not great. He had hoped that, by treating the photographs stereoscopically, he might decide the true nature of sun-spots in respect of their being depressions or the reverse; but, although the evidence seemed greatly in favour of depression, the question can hardly be considered as photographically settled. His efforts in this direction ended in the construction of a small telescope for the Royal Society, with an object-glass of 3½ inches aperture properly corrected; and, with this photo-heliograph, numberless pictures of the sun were successfully taken at the Kew Observatory. This instrument has proved the parent of many others established in various parts of the world, so that at present scarcely a day passes without a record of the condition of the sun's disk. The arrangements for these observations of sun-spots are now constituted under the advice of the Solar Committee at South Kensington, and in due time no doubt important facts will be brought to light. All this is traceable to the little inconspicuous photograph deposited not far from the envelope machine in 1851; and in this way De la Rue became, and will ever be remembered as, the Father of Lunar and Solar Photography.

In 1860, De la Rue took this photo-heliograph with him on board the *Himalaya*, in connection with the memorable expedition to the Spanish Pyrenees, for the purpose of observing the total eclipse of the sun. He posted himself, with his whole battery of implements, at Riva Bellosa, in the valley of the Ebro, not far from Vittoria. He was successful in obtaining several photographs of the eclipse during its totality, which gave the promise of settling, once for all, the hitherto much-mooted question as to whether the red prominences belonged to the sun, or were attributable to a different origin. On his return home he devised a micrometer for the due measurement of these remarkable phenomena, and in conjunction with other photographs taken by Padre Secchi, at a station some 250 miles distant from Riva Bellosa, he succeeded in allocating these singular fiery prominences beyond question, in the gaseous envelope which surrounds the sun. The results of his researches were embodied in the Bakerian Lecture delivered before the Royal Society in 1862. Perhaps it is not too much to say that these efforts laid the foundation of that wonderful structure of solar physics which is daily enlarging our knowledge of the true nature of the sidereal universe.

In 1873 the Observatory at Cranford was dismantled, on the occasion of De la Rue's removal from his comparative seclusion there to his residence in London. The reflector, with all its numerous and valuable accessories, was presented to the University of Oxford, and by this noble gift it was enabled at length to establish an efficient Astronomical Observatory at a place of learning where Halley and Bradley had flourished and taught nearly two centuries before. The instrument was erected in completeness at De la Rue's sole expense, and for several years he defrayed the cost of the additional assistant necessary for its utilization.

Oxford has at no time been backward in acknowledging with gratitude all efficient services rendered in behalf of the studies of the place. Accordingly, on De la Rue was conferred the rare honour of the full degree of M.A., by which he became a member of Convocation, while New College also incorporated him among her Society of Wykehamists, and made him a member of their common room.

We have occasion to know that it was a source of gratification to De la Rue to feel assured that his generous gift was utilized to the full by his old friend the present Professor of Astronomy, and specially in the direction which himself had inaugurated. Moreover, when a few months ago he saw the marvellous results produced by Mr. Roberts in his photographic pictures of nebulæ, secured by a four hours' exposure, he gave directions for the additional mechanism requisite for the production, as he hoped and believed, of similar pictures by his own now ancient instrument. Such is the solidity of the original mounting, that at this moment it is finally placed on a par, in respect of accurate movement, with any known instrument; but he did not live long enough to watch the progress of the experiment. Nor does this end the catalogue of his gifts to the University. When he heard of the projected scheme inaugurated by Admiral Mouchez, the Director of the Paris Observatory, for completing a photographic chart of the entire sidereal heavens, he placed a considerable sum of money in the hands of the Vice-Chancellor in order to defray the cost of the large photographic telescope necessary for taking a part in this great enterprise. The University of Oxford is not an ephemeral institution, and De la Rue's acts of generosity will remain inscribed upon her annals.

While he was thus watching with intense interest the uses made at Oxford of the work of his renovated instrument, he was himself engaged in a new enterprise of his own. Whether the recollection of what his friend Gassiot had done some twelve years before at Clapham—how, when he returned from his City work in the early evening, he retreated down to his laboratory, furnished at incredible labour and expense, and there tried to investigate the nature and origin of the electric discharge, and especially the strangely beautiful luminous striæ observed in tubes partially exhausted, visited now and then, while at work, by Faraday and other kindred spirits—whether or not this may have been the inducing cause, certain it is that De la Rue became fascinated by the same phenomena, and enamoured with the same pursuit. Possibly through a like scientific contagion, Spottiswoode also, in due course of time, endeavoured to wrest the same secret from Nature's hands. For years these three men worked and persevered in hope. None of them wholly succeeded, and yet none of them wholly failed; each and all left finger-posts to guide some future and more fortunate research.

The space which can be here afforded to the memoir even of an illustrious man precludes more than a passing allusion to the honours and social distinctions which always accompany the efforts of a life such as Warren de la Rue's; and upon him they were accumulated in abundance. The abiding honour lies in the contemplation of the man. A career like his dignifies the daily life of a manufacturer, giving it an aim and an object apart from the accumulation of wealth; it humanizes, warms, and illuminates the absorbing abstraction of the solitary student; and it illustrates the fact of an Aristocracy of Nature.

THE PHILOSOPHY OF MYSTICISM.

The Philosophy of Mysticism. By Carl du Prel, Dr. Phil. Translated from the German by C. C. Massey. 2 Vols. (London: George Redway, 1889.)

WE own to a certain mistrust when we are asked to accept goods under a trade-mark of mysticism; just as we have a most Levitical desire to pass by on the other side when we encounter the latest lucubrations of the circle-squarer, the absolute harmony of Genesis and geology, or when the last new theory of the soul is extended before us, "All Danaë to the stars." Now the philosophy of mysticism contains the latest of soul theories, or rather it is an old theory—a very old theory indeed—which has been newly adapted and furbished up and fitted with the very latest adjuncts which the outskirts of modern science can supply, so that it is to all intents and purposes just as good as if it were altogether new and original. Do not let us be misunderstood: both author and translator act in the strictest good faith. There is no false pretence about the matter. The whole work is perfectly ingenuous. The antiquity of the central idea is not in dispute, but it is claimed for the author that he has essentially modified our conception of that idea, that he presents his matter from a new stand-point, which is enough in all conscience nowadays, and that he is the first to show, by systematic analysis and comparison, that somnambulism and its cognate states are not essentially abnormal or morbid, but are in truth a mere exaltation of ordinary sleep, that the faculties evinced in those states are incipiently manifested also in dream, and are even indicated, though still more indefinitely, in waking life. It is contended that in this way the whole dream-life is reclaimed from its presumed worthlessness for scientific and philosophical purposes.

A duality of person with a unity of essence is the theory which commends itself to Baron du Prel, and he has worked out with much skill and acumen the details of an hypothesis to which his evident earnestness induces us to accord a hearing even when we are compelled to dissent from his conclusions. This hypothesis will have none of science, falsely so called; it sets at nought the accepted views of the physiologist and the materialist, and is a new, if nebulous, gospel of transcendental existence and apparently limitless progression. Man's life is moulded by his conception of his relation to the world, and that conception the present work is to radically revise. Who can tell if in the twentieth century the acceptance of these mystical views may not transform the present eager, struggling, money-grubbing crowd into a fraternity of peaceful philosophers finding in the placid pleasures of catalepsy an efficient substitute for the excitement of a boom in copper and for the fevered gambling of the Stock Exchange?

The author is very hard in his strictures upon the feeble physiologist, the wicked materialist, and indeed upon the modern professors of science generally, whom he abandons to their "exact amusements," whilst he seeks "the true theory in the bare analysis of the process which takes place in memory," and it is really wonderful what a superstructure he raises on the basis of that analysis. His preliminary dig at contemporary men of science he follows up with cuts and thrusts at intervals, but his salient grievance is that one and all fail to conceive progress otherwise than on their existing plane, whereas true progress must be inevitably vertical. With the advent of experimental methods, we learn, the world of science believed itself to have discovered a means for the attainment of all available knowledge, but the belief is erroneous. Not only is science still very far from its goal, but with the completion of its existing tasks, new prospects will be opened in the vertical direction. Should science succeed in explaining the whole visible world, that explanation is only as to a *represented* universe, a secondary phenomenon, a mere product of our sense and understanding, leaving the true world untouched. The quality of our consciousness in its relation to that world has still to be considered, and by such a method alone can its true nature be in any degree discovered. The visible world undergoes qualitative changes in the generation of consciousness, for, since the vibration of ether is in consciousness light and atmospheric vibration sound, it is evident that we are not truly cognizant of things, but only of the modes in which our senses react upon them. Taking all which and much more besides into consideration, the author sums up the result of human thought on the world-problem by saying that "consciousness does not exhaust its object, the world," a remark somewhat analogous to that of the Danish prince who observed that "there are more things in heaven and earth than are dreamt of in our philosophy."

As the world is the object of consciousness, so is the *Ego* that of self-consciousness; and here, says the Baron, materialism still flatters itself with the hope of reducing all psychology to physiology. It is deceived: self-consciousness does not exhaust its object, but is as inadequate to the *Ego* as consciousness is to the world, and the *Ego* may as much exceed self-consciousness as consciousness is exceeded by the world. The degree of the excess, is, however, not absolutely constant, since, by the rise of consciousness in the biological process, the boundary between the conscious and transcendental worlds has been and will be continually displaced. Of being, other than representation, we know nothing, and spirit is the primary and the real, for were its perceptive faculty changed, the whole material world of representation would be transformed; a clear demonstration that the represented world is a mere creature of the spirit. Behind consciousness is the ultimate being of which that consciousness is but the reflection, and as this ultimate being is beyond consciousness the Baron terms it the unconscious. This unconscious may either lie immediately behind the physically conditioned consciousness, or may be so indefinitely removed as to allow of an intermediate root of conscious individuality which is only relatively unconscious for the organism of sense. The author finds such an intermediary in his so-called psychophysical threshold of sensibility, which is the shifting barrier between the unconscious and self-consciousness. He conceives a dualism of consciousness, the division of two "persons" in one subject, but his conception differs from the popular conception of the dualism of soul and body, of matter and spirit, of Nature and supernatural. This dualism of consciousness is, with him, an intelligence which emerges with clearness and power just in proportion to the cessation of the organic functions with which the consciousness of waking life is associated; the two halves of our consciousness, divided by the movable threshold of sensibility, forming the subject which is an organizing as well as a thinking principle. The hypothesis of transcendental individuality co-existent with the earthly life and constructive of the organism by which consciousness is (from the earthly stand-point) dualized, necessitates the doctrine of pre-existence. Transcendental individuality implies a distinction from personal consciousness, and that the soul is not wholly plunged in the successive bodies which it constructs; the personal consciousness with its *Ego* being the mere partial and temporary limitation of a larger self, the growth of many seasons of earthly life.

The state of the individual after death is not precisely defined, but is suggested by the similitude of the smaller of two concentric circles expanding to the larger; the circumference of the inner circle being the organic threshold of sensibility, which death removes altogether, as it is already partially removed in such analogous states as sleep, somnambulism, &c. As in preoccupation the mind is concentrated to a focus, and subsequently expands to the limits of consciousness, so is earthly consciousness in death expanded to the boundary limits of the true *Ego*.

Transcendental subjectivity provides for continuity of consciousness, but the experience and whole activity of one of our objective life-times will be assimilated for results independent of those proposed by the contracted *Ego*, which bear but a minute proportion to the gradually accumulated content of the whole individual. The personal *Ego* must be brought to the point of view of the transcendental subject to which the mere happiness of that *Ego* is indifferent. What to us as persons are but high ideal motives may be alone of interest to the larger self which only maintains the organic personality for its own purposes. Such is Mr. Massey's analysis of the master's views, and it must be obvious that on this showing matters are decidedly in favour of the higher *Ego* which has, so to speak, got it all its own way. But since that exalted essence is, according to its moral nature, a product of development, the greater morality is not always on its side, for were that the case, terrestrial existence would have no educational value, and it is comfortable, therefore, to learn that our moral consciousness in earth-life can erect itself against its larger self, and may thus enrich the latter by the moral fruits of mundane existence; the struggle which takes place between the divisions of the subject being analogous to the process of Nature in its endeavour to expel disease, and drive whatever is morbid in an organism to the surface, or, to put it baldly, a species of spiritual measles. Such a theory, it is contended, fits the progress of the individual into the progress of the race, avoiding the waste of energy involved in the conception that the former is sacrificed to the latter, and supplies a wondrous harmony in which pessimism is subordinated to optimism.

The author is erudite, and he hails from the Fatherland; it is therefore not a matter for surprise that somewhat Shandean theories are exposed in sentences of wondrous construction. With these Mr. Massey has manfully wrestled; but, in his commendable desire to play the part of a faithful translator, he has at times given us such specimens of Teutonic English "as she is wrote" as render the good Baron's mysticism ten times more mysterious. We have read and re-read a passage, and a dozen perusals have left us still in doubt whether the meaning which the author and translator intended to convey were really grasped. Fidelity may be carried too far. At other times he who runs may read, and the author expresses his sentiments with an ingenuous frankness, as when he writes that "every criticism will be welcome which is adapted to advance the subject and myself."

Assuming that we have mastered the Baron's theory, an assumption we hesitate to make, we may place it before such of our readers as prefer a crude simile to the technicalities of metaphysics, in an illustration derived from natural history. Those who have visited the rock-pools of our coasts must have noticed the amusing little hermit crab (*Pagurus bernhardus*), who ensconces his soft unarmoured tail in the temporary shelter of an empty shell. He wriggles into his self-chosen habitation, and holds on to it with the pinchers with which his tail is provided, until he voluntarily leaves it before the approach of death. The hermit crab is the unconscious whole whose tail is tucked into the shell of self-conscious existence. As he emerges from it, or retires more completely, the amount of crab within the shell varies, the threshold of sensibility is shifted, and the shell benefits or suffers accordingly. The development of the moral nature of the subject, and its fitness for higher re-incarnation, are likewise shadowed forth in the fattening of the crab's tail, and his search for a roomy whelk-shell in place of the restricted covering of the modest periwinkle. Or, once again, the threshold of sensibility may be likened to the lid of the box from which the Jack of memory leaps, and upon the closure of which forgetfulness ensues.

It may be readily imagined that the author does not ask us to accept his theories unproven, and he has collected a mass of curious information from the most varied sources. Some of his anecdotes are oases of entertainment, which will, we fear, be missed by readers who do not, as we have done, peruse the volumes from cover to cover. As instances of our meaning, we may cite the case of a weak-minded youth upon whom all instruction in languages and science was thrown away, but who, after a fall on the head, became distinctly clever, intellectual, and highly cultivated, quickly seizing what he had been taught in vain before—a demonstration of the value of a box on the ears in the case of a stupid boy; the girl who, in her waking life, was reminded of her self-imposed somnambulistic treatment by the vision of a squirt; the military author who entered the barracks to take charge of the watch, in obedience to a dreamed order which he conceived to be a reality (had the case been one of neglect of a real order which he believed himself to have dreamt, we fear the court-martial would not have admitted the plea); or the wife who, subject to conditions of alternating consciousness, resented the presence of her husband, whom she treated with maidenly reserve. To prove the existence of a transcendental measure of time which is totally different from the normal, we are told of a flea-bite which occasioned a dream, concluding with a stab in the part of the body upon which the insect operated; of a pinch on the thigh, which caused the sleeper to imagine himself bitten by a wild beast; of De Quincey's opium dreams, which appeared to him to extend over vast periods of time; and of Mahomet, who, having knocked over a pitcher of water when translated by the Archangel Gabriel, viewed all things in heaven and hell, and held ninety thousand conferences with the Deity, returning to his still warm couch before the contents of the pitcher were expended. A somnambulistic girl exclaimed, "Where am I? I am not at home in the head. There is a strange struggle between the pit of the stomach and the head; both would prevail, both see and feel." So you see that "transcendental physiological functions seem to be parallel with corresponding changes in the ganglionic system." Authorities jostle in kaleidoscopic confusion; the "Novum Organum" standing cheek by jowl with the Bhagavadgita and the Vedas; whilst Aristotle and Proctor, Plato and Mrs. Crowe, Habakkuk, Galen, Plotinus, L. Oliphant, Daniel, Darwin, Kant, Olcott, and scores of others, jostle each other in ill-assorted series, but each with his contribution to the mosaic of marvels. On such a catena of evidence are based the two volumes; and, in spite of their waywardness, there is a thread of argument running through them which it would be unfair to the author to sunder by attempting an imperfect *précis* of his work, had we even the heart to impose it upon our readers. It has been said that, sooner or later, all books come into the hands of those for whom they were written, and there is no special reason for an exception in this case because the evidence for what is really a very beautiful theory fails to carry conviction to us. Doubtless our "threshold of sensibility" has gone wrong in some unaccountable way, and we have not enough of the Subject on this side of it to estimate the pearls of transcendentalism at their true worth. To the true adept, the work will doubtless prove wholly acceptable, and the author may take comfort in the reflection that "on this globe we serve an end, the attainment of which cannot be hindered, though all mankind conspired against it."

OUR BOOK SHELF.

A Treatise on Chemistry. By Sir H. E. Roscoe, F.R.S., and C. Schorlemmer, F.R.S. Vol. III. The Chemistry of the Hydrocarbons and their Derivatives; or, Organic Chemistry. Part V. (London: Macmillan and Co., 1889.)

THE present and fifth part of the "Treatise on Organic Chemistry" is devoted to an account of the benzenoid compounds containing eight or more than eight atoms of carbon, and brings the subject down to the group of the terpenes and camphors, including india-rubber and gutta-percha.

The various compounds are, as the title of the work denotes, grouped about the hydrocarbons from which they are derived. Thus we have the styrolene group, the cumene group, the cymene group, and so on.

The present instalment of the work also describes numerous instances of the interesting class of benzenoid compounds containing closed lateral chains in the ortho-position, *i.e.* with the two ends of the chain attached to carbon atoms which in their turn are directly united with one another. Such compounds are, for example, the indoles, the indazoles, isatin, carbostyril, and coumarin.

The subject of closed-chain compounds has of late years possessed a peculiar fascination for organic chemists, and the reason of this is not far to seek; for, apart from the fact that many of the closed-chain derivatives of benzene, such as coumarin, isatin, and indole, either occur in nature or are the immediate derivatives of naturally occurring compounds, many chemists believe that various important problems in chemical statics may ultimately be solved by the study of these compounds. At present chemists do not altogether know why, for example, closed lateral chains of carbon atoms should occur only in the ortho-position, and never in the meta- or para-position; why such closed lateral chains never contain less than five or more than six carbon atoms; and why it has never been found possible to unite any single polyad atom to two contiguous (ortho) carbon atoms in benzene, whilst in paraffinoid compounds such a union may be effected. But when these questions have been answered, something will be known concerning the local distribution of the affinities of the ultimate atoms; and meanwhile the ingenious hypothesis of Van 't Hoff with regard to the position of the affinities in the carbon atom is a step in the right direction, and affords what is possibly more than a merely provisional answer.

The authors have also given a very full account of Wallach's interesting researches on the terpenes, and here, as elsewhere, the information is thoroughly up to date.

The instructive historical introductions prefixed to the descriptions of important compounds and groups of compounds, referred to in our notices of previous portions of the work, are continued.

Solutions of the Examples in a Treatise on Algebra. By Charles Smith, M.A. (London: Macmillan, 1889.)

THE value of such a book is great both to teachers and students. The former, as we have often pointed out, have scant leisure for working out the more elaborate questions which nowadays have place even in elementary treatises, or scarcely care to refer to their notes, which are never, unless they are exceptionally methodical men, to be found when wanted; the latter are, by means of such a work as the one before us, in a great measure rendered independent of outside aid. Though Mr. Smith's solutions are marvels of compressed diction in many cases, they yet are, we can certify from an extended examination of all parts of the subject, expressed with all the clearness required. In a few cases two solutions are given; this is an advantage, for often we have found the second solution very suggestive. We have, then, here an excellent corpus of solutions of questions, which have been considered by many competent judges to be well arranged and well calculated to draw out a student's powers in this part of mathematics. We have come across a few typographical errors (there is one on the last page), but they are in most cases easily detected on following out the solution.

Applied Mechanics. By D. A. Low. (London: Blackie and Son, 1889.)

THIS is an excellent little text-book, treating of those parts of the subject which the Science and Art Department require for the elementary stage. There are, however, specially marked articles which may be read by advanced students.

The author has taken, as the ground-work of the book, the notes which he has used for many years in his classes with much success. Much care has been taken with those pages relating to mechanism. The diagrams are especially good, and the descriptive portions accompanying them are clear and concise. A striking and most useful feature will be found in the unusually large number of examples following each chapter, typical examples also being worked out between the articles.

The last half-dozen chapters are devoted to the nature, use, and strength of materials used for purposes of construction, and the different kinds of stress to which they may be subjected. The syllabus issued by the Department for teachers in this subject, followed by the examination papers of recent years, is appended. The book is one which can be recommended, and will no doubt be well received by teachers and students alike. G. A. B.

Northern Afghanistan. By Major C. E. Yate, C.S.I., C.M.G. (Edinburgh and London: Blackwood, 1888.)

IN this volume the author has brought together a number of letters written from the Afghan Boundary Commission, and he explains that they are now published in a connected form as a sequel to his brother Captain A. C. Yate's book, entitled "England and Russia Face to Face in Asia." A large part of the work relates chiefly to matters of political interest; but there are also excellent descriptions of the various places which Major Yate visited, and of the people with whom he came in contact. His account of Herat and the shrines in the neighbourhood is particularly good; and Balkh, of which he gives a plan, he depicts concisely and clearly. Of the desert from Andkhui to the Oxus he says it is about as hot and wretched a country as he ever saw. In this desert, wherever a few inches of mud and water were left, he used to see the white-breasted pintail sand-grouse coming to drink in small numbers; but with that exception he saw no sign of game. Lizards of all sizes and colours were to be seen. A lizard, some 2 or 3 feet long—"of a yellowish colour with red stripes"—seems to have especially attracted Major Yate's attention. This animal "never tries to run away, but stands and hisses, distending its stomach to an abnormal size." The dog hates it cordially; and very naturally, for, when the dog is approaching to the attack in front, "the lizard suddenly brings his tail round and gives the unwary dog a most tremendous wipe across the side of the head." "The first interview between a dog and one of these animals is very amusing—the dog is always so utterly astonished at this unexpected attack on the lizard's part, and also so hopelessly wroth." We may note that in a pocket at the end of the volume there are two maps—a map of the north-west frontier of Afghanistan, and a sketch-map showing the routes traversed by the Boundary Commission during 1884, 1885, and 1886.

By Leafy Ways. By Francis A. Knight. (London: Elliot Stock, 1889.)

THIS volume is made up of "brief studies," which originally appeared as articles in the *Daily News*. The author's object is not to present scientific conclusions about Nature, but to convey some idea of the impressions which have been produced upon him by various elements of the external world. He is an ardent lover of everything in Nature that appeals to what may be called the artistic sense; and he has the secret of suggesting, by means of brief and simple descriptions, very vivid pictures of scenes in which he himself has found delight. No one who wants to be intellectually instructed should trouble himself to read the volume; but it will give much pleasure to persons who like to be reminded of some of the innumerable aspects in which the country reveals itself to sympathetic observers. The volume is prettily illustrated by E. T. Compton.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

On an Electro-magnetic Interpretation of Turbulent Liquid Motion.

THE equations of rate of increase of momentum F, components X, Y, Z, per unit volume of a liquid (density = 1) are—

$$X = \frac{du}{dt} + u\frac{du}{dx} + v\frac{du}{dy} + w\frac{du}{dz} + \frac{dp}{dx},$$

and corresponding terms for Y and Z. If the liquid be incompressible,

$$\frac{du}{dx} + \frac{dv}{dy} + \frac{dw}{dz} = 0.$$

Mulip ying this by u, and adding to X, we get—

$$X = \frac{du}{dt} + \frac{d}{dx}(u^2) + \frac{d}{dy}(uv) + \frac{d}{dz}(uw) + \frac{dp}{dx},$$

and similar ones for Y and Z.

It is at once obvious that these could be written down at once, for u^2, uv, and uw are the momenta per second carried into the element through its faces as in the kinetic theory of gases; and it is evident that the equation is the same as for a strained solid where these are the superficial normal and tangential forces.

If we now take the average values of these throughout any small region, and write for the average of $\frac{du^2}{dx} = \frac{\overline{du^2}}{dx}$, we have—

$$\overline{X} = \frac{du}{dt} + \frac{\overline{du^2}}{dx} + \frac{\overline{duv}}{dy} + \frac{\overline{duw}}{dz} + \frac{dp}{dx}.$$

Comparing this with Maxwell's stress in the ether, we must take ("Electricity and Magnetism," vol. i. § 105)—

$$\frac{\overline{du^2}}{dx} = \frac{d}{dx}\cdot\left(\frac{d\psi}{dx}\right)^2 - \frac{d}{dx}(Q^2 + R^2 - P^2) - \frac{d}{dx}(\beta^2 + \gamma^2 - \alpha^2),$$

$$\frac{\overline{duv}}{dy} = \frac{d}{dy}\left(\frac{d\psi}{dx}\cdot\frac{d\psi}{dy}\right) + \frac{d}{dy}PQ + \frac{d}{dy}\cdot\alpha\beta,$$

$$\frac{\overline{duw}}{dz} = \frac{d}{dz}\left(\frac{d\psi}{dx}\cdot\frac{d\psi}{dz}\right) + \frac{d}{dz}PR + \frac{d}{dz}\cdot\alpha\gamma;$$

adding these together, and comparing with the equation for X, we get—

$$\overline{X} - \frac{\overline{du}}{dt} - \frac{dp}{dx}$$

$$= \tfrac{1}{2}\frac{d}{dx}\left\{\left(\frac{d\psi}{dx}\right)^2 + \left(\frac{d\psi}{dy}\right)^2 + \left(\frac{d\psi}{dz}\right)^2\right\} + \frac{d\psi}{dx}\left\{\frac{d^2\psi}{dx^2} + \frac{d^2\psi}{dy^2} + \frac{d^2\psi}{dz^2}\right\}$$

$$+ P\left(\frac{dP}{dx} + \frac{dQ}{dy} + \frac{dR}{dz}\right) - Q\left(\frac{dQ}{dx} - \frac{dP}{dy}\right) + R\left(\frac{dP}{dz} + \frac{dR}{dx}\right)$$

$$+ \alpha\left(\frac{d\alpha}{dx} + \frac{d\beta}{dy} + \frac{d\gamma}{dz}\right) - \beta\left(\frac{d\beta}{dx} - \frac{d\alpha}{dy}\right) + \gamma\left(\frac{d\alpha}{dz} - \frac{d\gamma}{dx}\right),$$

and two similar ones involving Y and Z.

Now, assuming

$$-p = \tfrac{1}{2}\left\{\left(\frac{d\psi}{dx}\right)^2 + \left(\frac{d\psi}{dy}\right)^2 + \left(\frac{d\psi}{dz}\right)^2\right\},$$

and

$$\frac{d^2\psi}{dx^2} + \frac{d^2\psi}{dy^2} + \frac{d^2\psi}{dz^2} = 0,$$

$$\frac{dP}{dx} + \frac{dQ}{dy} + \frac{dR}{dz} = e,$$

$$\frac{d\alpha}{dx} + \frac{d\beta}{dy} + \frac{d\gamma}{dz} = m,$$

we get—

$$X - \frac{\overline{du}}{dt} = Pe + \alpha m - Q\left(\frac{dQ}{dx} - \frac{dP}{dy}\right) + R\left(\frac{dP}{dz} - \frac{dR}{dy}\right)$$

$$- \beta\left(\frac{d\beta}{dx} - \frac{d\alpha}{dy}\right) + \gamma\left(\frac{d\alpha}{dz} - \frac{d\gamma}{dy}\right),$$

and two other similar ones.

If we now *assume* as the relations connecting P, Q, R and α, β, γ with a velocity V—

$$V\left(\frac{dR}{dy} - \frac{dQ}{dz}\right) = \frac{d\alpha}{dt} \text{ and } V\left(\frac{d\gamma}{dy} - \frac{d\beta}{dz}\right) = -\frac{dP}{dt},$$

and the corresponding others, we get—

$$X - \frac{\overline{du}}{dt} = Pe + \alpha m + \frac{1}{V}\cdot\frac{d}{dt}(Q\gamma - R\beta),$$

which, if we suppose the motion steady, so that $\frac{du}{dt} = 0$ gives exactly the right expression for the mechanical force due to an electric charge, e, and a magnetic charge, m, and to an electric current with components $\frac{dP}{dt}, \frac{dQ}{dt}, \frac{dR}{dt}$.

In order to justify the assumed relation between α, β, γ and P, Q, R, compare with Sir William Thomson's equations of propagation of disturbance in a turbulent liquid (*Phil. Mag.*, October 1887, p. 342).

In his case everything is a function of y only, and in that case my equations become, when there is no mechanical force—

$$\frac{\overline{du}}{dt} = \frac{1}{V}\frac{d}{dt}(R\beta - Q\gamma),$$

$$= Q\frac{dP}{dy} - R\frac{dR}{dy} + \beta\frac{d\alpha}{dy} - \gamma\frac{d\gamma}{dy}.$$

Now under the circumstances contemplated, R and γ are not functions of y—

$$\therefore \frac{\overline{du}}{dt} = Q\frac{dP}{dy} + \beta\frac{d\alpha}{dy}.$$

If we now assume that during the passage of a disturbance of the kind $Q = \beta =$ constant, and they must be if

$$\frac{dP}{dx} + \frac{dQ}{dy} + \frac{dR}{dz} = \frac{d\alpha}{dx} + \frac{d\beta}{dy} + \frac{d\gamma}{dz} = 0,$$

we get—

$$\frac{d\overline{u}}{dt} = \frac{d}{dy}(PQ) + \frac{d}{dy}(\alpha\beta) = \frac{d}{dy}(PQ + \alpha\beta),$$

and consequently—

$$\frac{d}{dt}(R\beta - Q\gamma) = V\frac{d}{dy}(PQ + \alpha\beta).$$

Comparing this with Sir William Thomson's equation (34) we see that—

$$f = -\frac{R\beta - Q\gamma}{V}, \quad xzav(uv) = PQ + \alpha\beta).$$

Similarly, by calculating

$$\frac{d}{dt}(PQ + \alpha\beta) = Q\frac{dP}{dt} + \beta\frac{d\alpha}{dt}$$

$$= -QV\cdot\frac{d\gamma}{dy} + \beta V\frac{dR}{dy} = +V\frac{d}{dy}(R\beta - Q\gamma),$$

we reproduce Sir William Thomson's equation (49), if $V^2 = \frac{2}{9}R^2$, *i.e.* be $\frac{2}{9}$ of the average square of velocity of turbulency. This V is the velocity of propagation of the disturbance.

If we wish to identify this laminar motion of Sir William Thomson's with a simple wave propagation such as light consists of, we must take $Q = \beta =$ constant, and then the two equations are satisfied by—

$$\frac{dP}{dt} = -V\frac{d\gamma}{dy} \text{ and } \frac{d\gamma}{dt} = -V\frac{dP}{dy},$$

and

$$\frac{dR}{dt} = V\frac{d\alpha}{dy} \text{ and } \frac{d\alpha}{dt} = V\frac{dR}{dy},$$

no matter what Q and β are, and these are, of course, Maxwell's equations. There is nothing to settle which is the electric and which the magnetic disturbance, nor even which, f or $xzav(uv)$, is proportional to $R\beta - Q\gamma$, and which to $PQ + \alpha\beta$, but the consideration that electric currents and electrification are possible while magnetic currents do not exist, will probably decide a question of this kind. In Maxwell's simplest wave, P and γ only exist, and in this case, as I have assumed above, $xzav(uv)$ would correspond to electric, and f to magnetic disturbance. In Sir William Thomson's representation, $xzav(uv)$ is of the nature of a twist, and f of a flow, contrary to the usual notion that magnetic force is twisty. However, a flow cannot take place outwards continuously from a body, so that there seems a reasonableness in likening electrification to a twist. The fact that magnetism in matter rotates the plane of polarization sometimes to one side and sometimes to the other does not prove conclusively that it is a rotation: a flow might confer that property on matter.

In order to include the general case of a variable state, an interpretation of X, Y, Z, is required. Where no matter is present, we must assume—

$$-X = \frac{dp_1}{dx} + \frac{1}{2}\frac{d}{dx}(P^2 + Q^2 + R^2 + \alpha^2 + \beta^2 + \gamma^2), \text{ \&c.},$$

and in the steady state—

$$p_1 = -\frac{1}{2}(P^2 + Q^2 + R^2 + \alpha^2 + \beta^2 + \gamma^2).$$

When the state is not steady, we have, if

$$\frac{dP}{dx} + \frac{dQ}{dy} + \frac{dR}{dz} = e, \quad \frac{d\alpha}{dx} + \frac{d\beta}{dy} + \frac{d\gamma}{dz} = m,$$

$$X - \frac{d\overline{u}}{dt} = +Pe + \alpha m + \frac{d}{dt}\frac{(Q\gamma - R\beta)}{V}, \text{ \&c.}$$

We must assume that p_1 has no longer the above value; but by differentiating the first of these with respect to x, the second with respect to y, and the third with respect to z, we get—

$$\frac{dX}{dx} + \frac{dY}{dy} + \frac{dZ}{dz} - \frac{d}{dt}\left(\frac{d\overline{u}}{dx} + \frac{d\overline{v}}{dy} + \frac{d\overline{w}}{dz}\right)$$

$$= +\left(e^2 + P\frac{de}{dx} + Q\frac{de}{dy} + R\frac{de}{dz}\right) + \left(m^2 + \alpha\frac{dm}{dx} + \beta\frac{dm}{dy} + \gamma\frac{dm}{dz}\right)$$

$$-\frac{1}{2}\frac{1}{V^2}\frac{d^2}{dt^2}(P^2 + Q^2 + R^2 + \alpha^2 + \beta^2 + \gamma^2),$$

which is satisfied by $e = 0$, $m = 0$; or if e and m exist, by—

$$e^2 + P\frac{de}{dx} + Q\frac{de}{dy} + R\frac{de}{dz} = 0;$$

and

$$m^2 + \alpha\frac{dm}{dx} + \beta\frac{dm}{dy} + \gamma\frac{dm}{dz} = 0;$$

and

$$\frac{d\overline{u}}{dx} + \frac{d\overline{v}}{dy} + \frac{d\overline{w}}{dz} = 0, \quad \frac{d^2p_1}{dx^2} + \frac{d^2p_1}{dy^2} + \frac{d^2p_1}{dz^2} = 0;$$

and

$$\left(\frac{d^2}{dx^2} + \frac{d^2}{dy^2} + \frac{d^2}{dz^2} - \frac{1}{V^2}\frac{d^2}{dt^2}\right)(P^2 + Q^2 + R^2 + \alpha^2 + \beta^2 + \gamma^2) = 0,$$

which means that energy is propagated with a velocity = V, and so the assumed relations connecting P, Q, R, and α, β, γ, mean little more than that the initial state is stable.

This, I think, shows that, so far, the ether may be a turbulent liquid.

If we compare the dimensions of the quantities involved in the theory of motion of a turbulent liquid with those in the electro-magnetic theory, we find it convenient to put these latter dimensions into the following forms, as they are the same on the electro-magnetic and electrostatic systems.

Calling $[K^{\frac{1}{2}}\mu^{\frac{1}{2}}] = [V^{-1}]$, and density $[\rho] = [ML^{-3}]$, we can write—

Electric displacement	$= [K^{\frac{1}{2}}\rho^{\frac{1}{2}}V]$
Electric force	$= [K^{-\frac{1}{2}}\rho^{\frac{1}{2}}V]$
Magnetic displacement	$= [\mu^{\frac{1}{2}}\rho^{\frac{1}{2}}V]$
Magnetic force	$= [\mu^{-\frac{1}{2}}\rho^{\frac{1}{2}}V]$.

It is at once evident that the products of the force and displacement are, in each case, of the dimensions of the P^2, Q^2, R^2, α^2, β^2, γ^2, involved in the theory I have already given.

I think it would be well, perhaps, to introduce some new quantities of zero dimensions to define the polarization of the medium. It seems likely that the velocity involved in P must depend on how intensely the turbulency is polarized, and could therefore be measured by a quantity of zero dimensions multiplied by a measure of the turbulency. This measure would be $\rho^{\frac{1}{2}}V$, so that, for electrostatic energy—

$$P^2 = P_0^2(\rho V^2),$$

and for electro-magnetic—

$$\alpha^2 = \alpha_0^2(\rho V^2),$$

where P_0 and α_0 were of zero dimensions.

In order to introduce the effect of alterations in material, we may put these in the form—

$$P^2 = \frac{\rho P_0^2}{K\mu}, \qquad \alpha^2 = \frac{\rho\alpha_0^2}{K\mu},$$

and then the electric displacement will be—

$$= \sqrt{\frac{\rho}{\mu}}\cdot P_0,$$

and the electric force—

$$= \sqrt{\frac{\rho}{\mu}}\cdot\frac{P_0}{K};$$

while the magnetic displacement will be—

$$= \sqrt{\frac{\rho}{K}}\cdot\alpha_0,$$

and the magnetic force will be—

$$= \sqrt{\frac{\rho}{K}}\cdot\frac{\alpha_0}{\mu}.$$

If we call the six quantities $\overline{u^2}$, $\overline{v^2}$, $\overline{w^2}$, $\overline{vw}$, $\overline{wu}$, $\overline{uv}$, a, b, c, f, g, h, they are connected with the six quantities P, Q, R, α, β, γ, and the three undisturbed values of $\overline{u^2} = A$, $\overline{v^2} = B$, $\overline{w^2} = C$, by the equations—

$$a = A + P^2 + \alpha^2, \text{ \&c.}, \quad f = QR + \beta\gamma, \text{ \&c.}$$

In order to examine how these are related, take an ellipsoid defined by—

$$ax^2 + by^2 + cz^2 + 2fyz + 2gzx + 2hxy = d,$$

and we see that, if $A = B = C = R$, as is the case except in a crystalline medium, the ellipsoid is—

$$R(x^2 + y^2 + z^2) + (Px + Qy + Rz)^2 + (\alpha x + \beta y + \gamma z)^2 = d;$$

so that, if $Px + Qy + Rz = L$, $\alpha x + \beta y + \gamma z = \lambda$.

$L + i\lambda$ and $L - i\lambda$ are the imaginary circular reactions of the ellipsoid,[1] and consequently the intersection of L and λ, whose direction cosines are proportional to $Q\gamma - R\beta$, &c., is the major axis of the ellipsoid, when the above signs are attributed to L^2 and λ^2. As any ellipsoid can be expressed in this form by referring it to its circumscribing sphere and the corresponding planes of circular section, it is apparent that any polarized state of the turbulent motion can be built up of P, Q, R, and α, β, γ, polarizations. The axis of the ellipsoid mentioned above represents the flow of energy in the medium during the propagation of a disturbance.

I am inclined to think that Sir William Thomson's fear that diffusion would vitiate these investigations would be avoided either by supposing the turbulent liquid to consist of interlocked vortex rings, or of infinite intercrossing lines; and in either case a natural hypothesis would be that matter consisted of free vortex rings. GEO. FRAS. FITZGERALD.

Trinity College, Dublin, April 26.

[1] This was remarked to me by Prof. Lyle, of Melbourne, while I was recently speaking to him upon this subject.

The New Eruption of Vesuvius.

ON April 29, 30, and May 1, a constant series of explosions (*boati*) and rumblings accompanied by earthquakes, which shook the southern foot of Vesuvius, were very noticeable at Resina. About 2 a.m., on May 2, part of the new cone of eruption (formed during the last ten months) fell in, showing that the internal support of the lava column had been removed, in consequence of this filling the new dyke, the formation of which had given origin to the preceding sonorous and mechanical disturbances. On the same day at 3 p.m. the lava sank still lower in the conduit on account of the dyke reaching the surface at the upper part of the great cone. More of the eruptive cone crumbled in, and of course simultaneously a considerable outpour of lava took place from the dyke fissure which is situated on the south-east side of the great cone. This outflow soon formed a long tongue of lava reaching to the Pedimentina or lower.

My friend Mr. George Bidder, Jun., who is studying at the Zoological Station here, was fortunately able to visit the mountain yesterday (May 3), and much of the information in this letter I have to thank him for. Unfortunately the extremely bad weather has prevented the upper part of the mountain being examined, so that accurate information as to the position and length of the fissure has not been obtainable; I hope, however, to make the ascent to-morrow, and will then send a more detailed account for your next issue. So far as the facts at hand are available, it would appear that this eruption is of small importance, being an analogue of that of May 2, 1885, and that, therefore, the lava will hardly reach cultivated ground.

A short glimpse of the summit of the mountain this evening shows that much of the eruptive cone still exists, whilst the reflection from the flowing lava is much feebler than yesterday evening. Lastly, a single faint glimmer this evening at the vent demonstrates the fact that the lava has not sunk very deep in the chimney. The eruption, or more properly *disruption*, was coincident with a marked barometric depression.

Naples, May 4. H. J. JOHNSTON-LAVIS.

The Sailing Flight of the Albatross.

I have been much interested by the letter of Mr. A. C. Baines (NATURE, May 2, p. 9) upon this subject. In the year 1883 ("The Soaring of Birds," NATURE, vol. xxvii. p. 534) I suggested that the explanation of these puzzling performances might be found in the increase of wind with height. To take advantage of this, the bird must rise against the wind and fall with it; but, at the time referred to, I had before me only the observations of Mr. Peal, in Assam, on the flight of pelicans, in which this feature is not alluded to. In Mr. Baines's observations, the omission is supplied, and there seems little reason to doubt that the true explanation of the flight of the albatross has been arrived at. In the case of the pelican soaring to a great elevation, it is less easy to understand how the differences of horizontal velocity can be sufficient.

Reference may be made to a paper by Mr. H. Airy (NATURE, vol. xxvii. p. 590), in which the matter is further discussed. Similar views have also been put forward more recently by an American author, whose name I have, unfortunately, forgotten.

Terling Place, Witham, May 6. RAYLEIGH.

"Giphantia."

IN a curious little work, entitled "Giphantia," the full title of which I subjoin, there is, at pp. 95–98, a passage that may have some interest in connection with the early history of photography, and of which I therefore subjoin a copy.

The Camp, Sunningdale, April 29. J. D. HOOKER.

"Giphantia: or, a View of what has passed, what is now passing, and, during the Present Century, what will pass, in the World." Translated from the Original French, with Explanatory Notes. (London: Printed for Robert Horsfield, in Ludgate Street, 1761.)

"Thou knowest that the rays of light, reflected from different bodies, make a picture and paint the bodies upon all polished surfaces, on the retina of the eye, for instance, on water, on glass. The elementary spirits have studied to fix these transient images: they have composed a most subtile matter, very viscous, and proper to harden and dry, by the help of which a picture is made in the twinkle of an eye. They do over with this matter a piece of canvas, and hold it before the objects they have a mind to paint. The first effect of the canvas is that of a mirrour; there are seen upon it all the bodies far and near, whose image the light can transmit. But what the glass cannot do, the canvas, by means of the viscous matter, retains the images. The mirrour shows the objects exactly; but keeps none; our canvases show them with the same exactness, and retains them all. This impression of the images is made the first instant they are received on the canvas, which is immediately carried away into some dark place; an hour after, the subtile matter dries, and you have a picture so much the more valuable, as it cannot be imitated by art nor damaged by time. We take, in their purest source, in the luminous bodies, the colours which painters extract from different materials, and which time never fails to alter. The justness of the design, the truth of the expression, the gradation of the shades, the stronger or weaker strokes, the rules of perspective, all these we leave to nature, who, with a sure and never-erring hand, draws upon our canvases images which deceive the eye and make reason to doubt, whether, what are called real objects, are not phantoms which impose upon the sight, the hearing, the feeling, and all the senses at once.

"The Prefect then entered into some physical discussions, first, on the nature of the glutinous substance which intercepted and retained the rays; secondly, upon the difficulties of preparing and using it; thirdly, upon the struggle between the rays of light and the dried substance, three problems, which I propose to the naturalists of our days, and leave to their sagacity."

Geological Photography.

IN the report of the Annual Conference of Delegates of Corresponding Societies of the British Association (*vide* NATURE, vol. xxxix. p. 187), reference is made to the proposed appointment of a Committee to collect and register photographs of localities, sections, or other features of geological interest in the United Kingdom. Several Societies have already attempted local photographic surveys, but the need is felt to secure uniformity of action by all the Societies interested, and to arrange for the photographs to be available for teaching and other purposes when needed. In order that steps may be taken to arrange for the practical working of the proposed scheme at the forthcoming meeting of the British Association at Newcastle, I am desirous of invoking the kind aid of those of your readers who have interested themselves in the photography of local geological features (especially of typical and temporary sections) in favouring me with the following information:—

(1) A list of photographs already taken, illustrating given localities or sections; and

(2) The names of local Societies, or persons who are willing to arrange for a photographic survey for geological purposes in their district.

The information afforded me will be placed before the Geological Section of the British Association at their next meeting, and I trust to receive many offers of valuable assistance from different parts of the country. If copies of photographs are sent me they will be carefully kept for exhibition at the meeting. Several geological friends have favoured me with suggestions in regard to size of photograph, scales of height, length, and other details, which will all be carefully considered. Photography is now so popular and easy of accomplishment that there should be no difficulty in organizing local photographic surveys for the purpose I have indicated.

It was arranged at Bath that the delegates should get their Societies to think the matter over, and that I should meanwhile endeavour to prepare a list of local geological photographs already available for study. I am communicating with the Societies with this object, but your insertion of this letter will further aid me in directing attention to the subject over a wider circle than I am able to reach. OSMUND W. JEFFS.

12 Queen's Road, Rock Ferry, Cheshire, April 23.

Columnar Structure in Ice.

I HAVE just read Mr. James McConnel's interesting and important paper on the plasticity of ice (NATURE, vol. xxxix. p. 203), and as he remarks that it would be interesting to know whether the columnar structure he describes as occurring in the ice of the St. Moritz Lake has been observed in England, I venture to ask you to record the fact that I recollect seeing a precisely similar structure in the ice of the lake in Kew Gardens in February 1880. The phenomenon occurred *during a thaw* that preceded by a day or two the memorable snowstorm of that month, and the aspect of the ice, where it had been broken through, recalled to my mind that of the well-known fossil *Lithostrotion basaltiforme*, as it was built up of vertical columns, irregularly hexagonal in section, about a quarter of an inch in diameter and of equal length with the thickness of the ice, about 4 or 5 inches. If I remember aright, bright sunshine had been thawing the ice during the day. I made a note on the occurrence at the time, but as I came to India shortly after I do not know what has become of it.

T. D. LA TOUCHE,
Geological Survey of India.

Camp near Cherrapunji, Assam, March 4.

Brilliant Meteor.

I SEND you an account of a meteor I saw on Saturday evening last, thinking it may interest others as much as it has myself. I was lamp-signalling at the time (8.55 p.m.), and saw far the largest meteor I have ever seen. It was far brighter than any planet, or even than a good rocket. It seemed to start from the Great Bear, and fall in a north-east direction half-way to the horizon. I immediately stopped my message, and asked my companion (a mile distant) if he had seen the meteor. He replied he had not, which surprised me, though he had the town lights not far behind him, and he was looking away from the north-east. I had not finished asking him about the meteor, when I heard a loud but distant report, which I can only put down to the same source. It sounded like distant artillery, or more particularly like a six-pounder at six miles distance on a still evening. The interval of time between the sight and the sound I should estimate at a minute. T. HERBERT CLARK.

Wingfield, Trowbridge, April 30.

A New Mountain of the Bell.

HAVE the kindness to correct two typographical errors in my communication describing the "New Mountain of the Bell," printed in your issue of April 25. On p. 607, col. 2, line 7, an unfortunate superfluous comma after the word quartz should be expunged, so as to read quartz pebbles and veins.

Near the bottom of the same column "modern gong" should read "wooden gong." As a matter of fact the *Nagous* is far from "modern." It consists of a heavy plank nearly 2 inches thick, 14 feet long, and suspended by ropes at two points 4 feet from either end. When struck with a wooden mallet, this primitive gong emits a loud sound. At the Monastery of St. Catherine, three of these are in use, one small one to call to their noonday meal the numerous *cats* which inhabit the rambling old building. H. CARRINGTON BOLTON.

London, May 1.

KLEIN'S "IKOSAHEDRON."[1]

IT has recently been said, with great truth, that pure mathematics is at the present moment the most progressive of all the sciences. It is, we must confess with sorrow, equally true, that the means at the disposal of English pure mathematical students for making themselves familiar with the recent advances in their science are deplorably scanty. This is not the place to discuss the reasons why it has so long been the case in this island that the stars of our mathematical firmament have been

"*Étoiles qui filent, filent et disparaient!*"

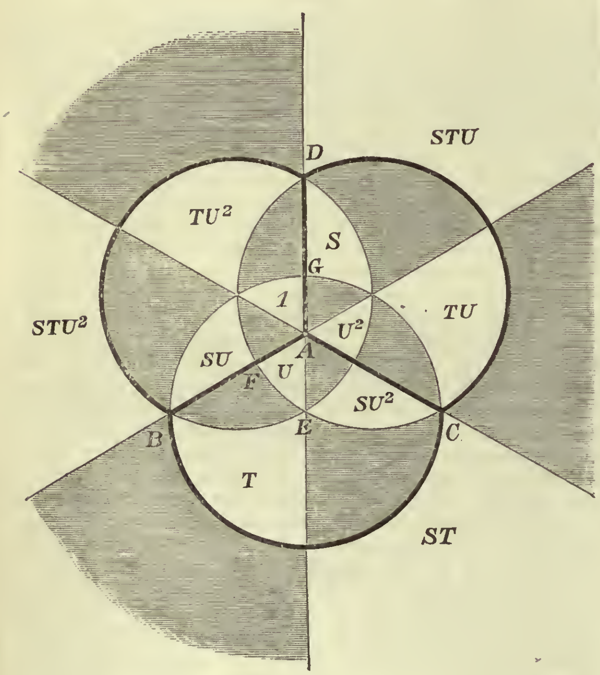
and not fixed suns, with minor but still useful bodies around them, receiving their light and completing their systems. But it is obvious that this shortcoming has been closely associated with the backward state of our text-book literature in pure mathematics. There exist in the English language so few books through whose pages the reader can so much as descry the frontier land of pure mathematics that every addition is an event of importance. Such an addition is Mr. Morrice's translation of Klein's "Ikosahedron." Klein's book is in many respects the most charming piece of modern mathematical writing that has appeared for many a day. It is a rare combination of great originality with wide and far-reaching views, Teutonic minuteness of scholarship, and a candour in dealing with the work of others which does not always accompany the other high qualities just mentioned. If we were asked to name a single book that would beyond others give the reader a comprehensive glance over the wide field of modern pure mathematics, and give him an introduction to this study which would at once both interest and instruct him, we should without hesitation name Klein's "Ikosahedron." The work interweaves, in a singularly felicitous and natural way, the most remote and apparently unconnected branches of higher pure mathematics. In the course of its perusal the reader will make acquaintance with the geometry of the regular solids, the theory of substitutions, the theory of functions of a complex variable, invariants, the theory of linear differential equations, Riemann's researches on the hypergeometric series, Galois's theory of the resolution of algebraic equations, elliptic functions, Plücker's line geometry, and the special theory of quintic equations. This enumeration will sufficiently indicate the wide sweep of the work; but let not the reader be alarmed. If he is ignorant of all these subjects, so much the more will he enjoy the pleasure of Prof. Klein's introduction to them. He will find that he is led, by easy and pleasant ways, first to see the interest and importance of these subjects, then to panoramic aspects of them, and finally to just so much detail as will make him (if he be right-minded) thirst for more. Speaking from past experience, we should say that one of the greatest disadvantages of modern specialism is the repulsive force which it establishes at every point to the entrant. Let an English student sit down, for example, to Jordan's "Théorie des Substitutions." He is at once plunged into a sea of new terms and definitions. He is baffled by a kaleidoscopic array of subtle distinctions between con-

[1] "Lectures on the Ikosahedron, and the Solution of Equations of the Fifth Degree." By Felix Klein. Translated by George Gavin Morrice, M.A., M.B. (London: Trübner and Co., 1888.)

ceptions that are unfamiliar to him. He toils through the solution of abstract problems whose formulation he imperfectly grasps, and whose interest and importance he has not been permitted to see beforehand. The very beauty and logical rigour of the work is a hindrance to him; it entangles and suffocates him at the outset. And yet M. Jordan's work could not be otherwise, could not be better for its purpose, could not be dispensed with. But let the learner first read Klein's "Ikosahedron." He will there see the substitution theory first applied in simple cases with concrete illustration, and will then be led by degrees to see its all-embracing character. Then let him return to Jordan, and he will say of the theory of substitution,

"Her loveliness I never knew,
Until she smiled on me."

Under ordinary circumstances, any detailed analysis of a mathematical work would be out of place in the pages of NATURE. The appearance of the "Ikosahedron" in English is, however, an event of such importance that it would be wrong to miss the opportunity of giving the



English mathematical world some account, however imperfect, of its contents.

The proper subject of the work may be said to be the general theory and applications of functions which are transformable into themselves (*i.e.* are unaltered) by a finite group of substitutions. By a *group* of substitutions, or indeed of any operations whatsoever, is meant a complete set of operations of such a nature that the combination of any two or more of them is equivalent to some one of the set. The number of operations in a group is called its order, and the order may in general be finite or infinite. A leading feature of Klein's work, indicated by its title, is the geometrical connection which he establishes between certain groups of substitutions, and the rotations which cause a regular solid to return into itself. It is obvious beforehand that the totality of such rotations for any given regular solid forms a group of finite order, for any two successive rotations of the kind may be replaced by a single one. The accompanying figure will make the connection plain. It represents the stereographic projection of the traces on a circumscribed sphere made by the planes of symmetry of a regular tetrahedron, A B C D, the vertex of projection being the antipodal point to A, and the plane of projection the diametral plane of which A is the pole. The spherical surface is obviously divided by the planes of symmetry into twelve (non-shaded) congruent triangles, and twelve other (shaded) congruent triangles, each of which is the image of one of the former in a plane of symmetry. These triangles lie in sets of $\nu_2 = 2$ about points such as F, which correspond to mid-edges of the tetrahedron, in sets of $\nu_2 = 3$ about points such as E, which correspond to centroids of the faces, and in sets of $\nu_3 = 3$ about the points which correspond to vertices of the tetrahedron. It is farther obvious that any one of the unshaded triangles can be transformed into each of the other twelve unshaded triangles by one of the group of N = 12 rotations which cause the tetrahedron to return into itself. If we mark one of these by inscribing 1, and if S denote a rotation of period 2 (*i.e.* of angular magnitude $2\pi/2$) about G, T a rotation of period 2 about F, and U a rotation of period 3 about A, then the rotations by which the region 1 is transformed into the other twelve are—

$$1, U, U^2, S, SU, SU^2, T, TU, TU^2, ST, STU, STU^2;$$

and these give the twelve rotations of the tetrahedral group expressed succinctly in terms of three of them.

The same holds for the shaded triangles. Hence, if we pair each non-shaded triangle with a shaded one, and thus form a *fundamental domain*, then we see that any point within such a domain (boundary and summit points excepted) is transformed by the N tetrahedral rotations into N other points, one of which lies in each of the N domains. (Here we count the transformation of the point into itself, viz. the rotation represented by the identical symbol 1.) We pass over the questions that arise regarding the composition of a group and the conception of the extended group which embraces reflections in the planes of symmetry as well as rotations, and merely mention that a similar theory is established for the dihedron, *i.e.*, the figure composed of a great circle of the sphere divided into n equal parts, the octahedron, and the ikosahedron, the characteristic numbers being given by the following table:—

	ν_1	ν_2	ν_2	N
Dihedron ...	2 ...	2 ...	n ...	$2n$
Tetrahedron ...	2 ...	3 ...	3 ...	12
Octahedron ...	2 ...	3 ...	4 ...	24
Ikosahedron ...	2 ...	3 ...	5 ...	60

The next step is to connect each point on the sphere with the value of a complex variable z, or with the ratio of two complex variables $z = z_1/z_2$. This is done, after the manner of Riemann, by representing $z = x + yi$ in an Argand-diagram on the diametral plane of the sphere, and then projecting the point (x, y) stereographically upon the sphere. The point on the sphere is then spoken of as the point (z) or (z_1, z_2).

It is next shown that every dihedral, tetrahedral, octahedral, or ikosahedral rotation is equivalent to a non-homogeneous linear substitution of the form—

$$z' = (Az + B)/(Cz + D),$$

or to one or other of two pairs of homogeneous substitutions of the form—

$$z_1' = Az_1 + Bz_2, \; z_2' = Cz_1 + Dz_2;$$

and the proper values of A, B, C, D are calculated for each case.

If we consider the values of z corresponding to a point, and the N − 1 other points into which it is transformed by the N polyhedral rotations, we see that they are the roots of an algebraical equation of the Nth degree, say $Z \equiv f(z) = c$, the characteristic Z of which must have the property of remaining unaltered by every one of the N non-homogeneous substitutions. And there must likewise exist homogeneous integral functions of $F(z_1, z_2)$ of the Nth degree in the two variables z_1, z_2, containing one arbitrary parameter, which remain unaltered, to a factor *près*, for each of the group of 2N homogeneous polyhedral substitutions. The functions of the latter kind ("ground forms") are first determined. First, a special function F_1 (of degree N/ν_1 is determined, such that $F_1 = 0$ gives one of the ν_1 summits on the sphere, and the $N/\nu_1 - 1$ other points into which it is transformed by the polyhedral rotations. Then $F_1^{\nu_1}$ is a particular function having the property sought for. By an elegant application of the theory of invariants, two other functions, F_2 and F_3, corresponding respectively to the ν_2 and ν_3 summits, are derived from F_1. We then have for the general invariant function required—

$$\lambda_1 F_1^{\nu_1} + \lambda_2 F_2^{\nu_2} + \lambda_3 F_3^{\nu_3},$$

which contains only one arbitrary parameter, since there is in each case an identity of the form—

$$\lambda_1^{(0)} F_1^{\nu_1} + \lambda_2^{(0)} F_2^{\nu_2} + \lambda_3^{(0)} F_3^{\nu_3} = 0,$$

connecting F_1, F_2, F_3. In the particular case of the ikosahedron we have—

$$F_1 \equiv z_1^{30} + z_2^{30} + 522(z_1^{25}z_2^5 - z_1^5 z_2^{25}) - 10005(z_1^{20}z_2^{10} + z_1^{10}z_2^{20});$$

$$F_2 \equiv -(z_1^{20} + z_2^{20}) + 228(z_1^{15}z_2^5 - z_1^5 z_2^{15}) - 494 z_1^{10}z_2^{10};$$

$$F_3 \equiv z_1 z_2(z_1^{10} + 11 z_1^5 z_2^5 - z_2^{10});$$

and $F_1^2 + F_2^3 - 1728 F_3^5 \equiv 0$.

The non-homogeneous function Z is next discussed. It is shown that any form of Z, whatever, is a linear rational function, $(\alpha Z' + \beta)/(\gamma Z' + \delta)$ say, of any particular form Z^1; so that it is sufficient to determine a special form Z subject to the conditions that Z assumes the values $1, 0, \infty$, for the ν_1, ν_2, ν_3 summits respectively. It is found that $Z = cF_2^{\nu_2}/F_3^{\nu_3}$, and thus the synthesis of the polyhedral functions is completed.

In Chapters III. and IV. of his first part, Klein discusses the inversion of the polyhedral functions. If, in the polyhedral equation $cF_2^{\nu_2}/F_3^{\nu_3} = Z$, we suppose Z given and z required, z appears as an N-valued function of Z, whose properties it becomes our business to discuss. Parallel to this problem we have a "form-problem." There are for each of the five polyhedra a set of three forms which are *absolutely* invariant for the 2N homogeneous polyhedral substitutions; thus, for the ikosahedron, these are the special forms F_1, F_2, F_3, themselves. We may then suppose the values of these absolutely invariant forms given, subject to the identical relation which in all cases connects them; and require the values of Z_1 and Z_2. There are in each case 2N solutions of this "form-problem," and it is shown that these can all be obtained from the N solutions of the corresponding polyhedral equation by adjoining an accessory square root. It is, of course, obvious that the N solutions of the polyhedral equation and the 2N solutions of the corresponding form-problem can all be derived from any one of them by the N non-homogeneous and the 2N homogeneous polyhedral substitutions respectively.

A brief graphical discussion is given of the functions Z, Z_1, Z_2; and it is shown that Z satisfies the differential equation—

$$\frac{Z'''}{Z'} - \frac{3}{2}\left(\frac{Z''}{Z'}\right)^2 = \frac{\nu_1^2 - 1}{2\nu_1^2(Z-1)^2} + \frac{\nu_2^2 - 1}{2\nu_2^2 Z^2} + \frac{1/\nu_1^2 + 1/\nu_2^2 - 1/\nu_3^2 - 1}{2(Z-1)Z} \quad \ldots \text{(A)}$$

the left-hand side of which is the differential invariant which Cayley has called the Schwarzian derivative of z with respect to Z (see Forsyth's "Differential Equations," § 61 and chapter vi.); and that Z_1 and Z_2 each satisfy the linear differential equation—

$$y'' + \frac{y'}{Z} + \frac{y'}{4(Z-1)^2 Z^2}\left\{-\frac{1}{\nu_2^2} + Z\left(\frac{1}{\nu_2^2} + \frac{1}{\nu_3^2} - \frac{1}{\nu_1^2} + 1\right) - \frac{Z^2}{\nu_3^2}\right\} = 0.$$

Through the latter equations z_1 and z_2 are identified as particular cases of the Riemannian P-function, and thus connected with the theory of the hypergeometric series. Here Klein's work comes in contact with the well-known researches of Schwarz—"Ueber diejenigen Fälle, in welchen die Gaussische Hypergeometrische Reihe eine Algebraische Function ihres vierten Elementes darstellt" (*Crelle*, Bd. 75).

The inversion of the polyhedral functions is next considered from the standpoint of Galois's theory of the resolution of an algebraical equation. An attractive outline of this theory is given, so far as it concerns the problem on hand. The starting-point may be said to be the famous theorem of Lagrange, which, in a generalized form, runs as follows: If R, R_1, R_2, ... be rational functions of the variables $x_1, x_2, \ldots x_n$, and if R remain unchanged by all the substitutions of the x's which leave $R_1, R_2, \ldots$ simultaneously unaltered, then R can be expressed as a rational function of $R_1, R_2, \ldots$ and of the elementary symmetric functions of the x's. In particular, if we characterize all the functions which admit (*i.e.* are unaltered by) a given group of substitutions, G, as belonging to the family G, we see that all the functions of any family are rationally expressible in terms of one another.

Suppose now that we have any algebraical equations, $f(x) = 0$, whose roots are $x_1, x_2, \ldots x_n$, and we "adjoin" thereto a group of asymmetric functions, $K_1, K_2, \ldots$, of its roots, whose values along with the coefficients of $f(x)$ are supposed to be "known," then there exists a group of substitutions, G, that, viz., for which K_1, $K_2, \ldots$ are unaltered, such that all functions of the family G and no others are rationally expressible in terms of the "known quantities." If R be a function of $x_1, x_2, \ldots x_n$, not belonging to the family, but say to the family g where g is a sub-group in G of the order $\nu = N/n^1$, then we can form an equation for R, viz.,

$$(R - R_1)(R - R_2) \ldots (R - R_{n^1}) = 0,$$

whose coefficients are rational functions of the known quantities. Such an equation is called a resolvent of $f(x) = 0$. All the resolvents constructed by means of functions R which belong to the same family g_1 are identical in the sense that they are rationally transformable into each other, and with these are also identical all resolvents arising from functions belonging to the families $g_2, g_3, \ldots$, where $g_2, g_3, \ldots$ are the sub-groups "associated with g_1" in the main group G of the original equation. There are therefore as many different kinds of resolvents, as there are different sets of associated sub-groups in G. The group Γ of every resolvent is isomorphous with the original group G; that is to say, we can order the two groups so that to every substitution S in G corresponds one S^1 in Γ, and to every combination of substitutions STU .... in G corresponds $S^1T^1U^1$ .... in Γ. If this correspondence be holohedric (one S for every S^1), then the resolvent and the original equation are equivalent in the sense that every root of the one is rationally expressible in terms of the roots of the other and of the known quantities; each is in fact a resolvent of the other. Pre-eminent among this species of resolvents stands the Galois resolvent, whose R is a perfectly asymmetric function as regards the substitutions G. The degree of this resolvent is the highest possible, viz. N. Since the sub-group g_1 belonging to any root R_1 of this equation reduces to the identical substitution, it follows that we can express each of the x's in terms of R_1. In fact, all the roots of the Galois resolvent are rational functions of any one of them; and it has the remarkable property of being transformable into itself by a group of N rational transformations, which stands in holohedric isomorphism with the group Γ. It is also established that an irreducible equation of the Nth degree which is transformable into itself by a group of N rational transformations is its own Galois resolvent; and its group is holohedrically isomorphous with the group of the N transformations. We are now enabled to perceive a very important property of the polyhedral equations, viz. each of them is its own Galois resolvent; the N rational transformations in question being simply the N linear polyhedral transformations. Every polyhedral equation therefore stands in a fundamentally simple relation to any equation of which it can be shown to be a resolvent.

If we consider the case where the isomorphism of the groups G and Γ is not holohedric—that is, where to each of the S^1's corresponds a group of the S's, we see that this necessitates the existence of a self-conjugate (*sibi*-associate) group γ in G to which belong the whole of the R's. If to the other known quantities we now adjoin the R's, the solution of the original equation $f(x) = 0$ will be simplified, because its group is now γ, which is smaller than G. Moreover, the R's themselves are calculable in terms of the known quantities by means of an equation whose group Γ is also smaller than G. In this case, therefore, an essential simplification in the formal solution of the equation $f(x) = 0$ can be effected. If the group γ be either intransitive or composite, a further simplification would ensue, in the one case by the "reduction" of $f(x) = 0$, in the other by the construction of another resolvent having a smaller group than γ.

The application of the latter part of the general theory in combination with the data regarding the groups of the polyhedral substitutions obtained in the earlier chapters, leads at once to important conclusions regarding the polyhedral equations. It is found that the octahedral equation can be solved by extracting in succession a square root, a cube root, and finally two square roots; the tetrahedral equation by the same series of operations, if we omit the first, and the dihedral equation by extracting a square root and then an nth root. All these equations are therefore soluble by means of the ordinary *elementary* algebraical irrationalities.

The ikosahedral equation stands by itself because the ikosahedral substitutions form a "simple" group; its lowest resolvents correspond to the five associate tetrahedral and the six associate dihedral sub-groups of the ikosahedral main group, and are of the fifth and sixth degrees respectively. This is, from one point of view, the main part of the theory, for it leads us to see that the solution of the ikosahedral equation involves an irrationality which exists independently of the ordinary algebraical irrationalities.

Since Abel demonstrated the impossibility of solving general equations whose degree exceeds the fourth by means of elementary algebraical irrationalities, two, or perhaps we should say three, great classes of problems in the higher theory of equations have arisen: (1) to characterize and classify all those exceptional cases of equations of a degree exceeding the fourth which can be solved by elementary irrational operations; (2) to circumscribe the domain of the higher algebraic irrationalities—that is, to characterize and exhaustively classify all the essentially distinct irrational operations which are required for the solution of any algebraical equation of finite order,—this is not to be confounded with the interesting and practically important, but perfectly distinct, question regarding the solution of such equations by means of transcendental irrationalities, such as circular and elliptic functions; (3) in connection with each distinct higher irrationality, there arises, of course, the question as to the characteristics of the various equations which can be solved by means of this irrationality and others of a lower order.

Much has been done in the working out of the first problem by Abel, Kronecker, and others; but comparatively little progress has been made with the second class of problems. In Klein's work we have an important contribution to this new branch of the theory of equations; and a sketch of a general method which seems to promise farther advance in the immediate future. The latter part of the book under review is almost entirely occupied with this subject. He there shows by two different methods that the solution of the general quintic equation can be effected by means of the ikosahedral irrationality combined with an accessory square root. A brief sketch of his first method will enable the reader to understand the general march of the investigation. If to the rational coefficients of the quintic equation we adjoin the square root of its discriminant, its Galois group becomes the 60 even permutations of its roots. Now this is isomorphous with the group of the ikosahedral equation, and therefore (since that group is simple) with the group of any of its resolvents. But it is shown that one of the ikosahedral resolvents ("the principal resolvent") is an equation of the fifth degree of the form $y^5 + 5Qy^3 + 5Ry + S$, where Q, R, S are rational functions of three arbitrary parameters m, n, Z. The question then naturally arises, Can we rationally connect the roots of this resolvent with the roots of the general quintic by properly determining the parameters m, n, Z? By means of a Tchirnhausian transformation, we can reduce the general quintic to a "principal equation" of the form $y^5 + 5\alpha y^2 + 5\beta y + \gamma = 0$; and it is shown that the necessary operations become rational after the adjunction of the square root of the discriminant of the quintic. We have thus two equations, each involving three arbitrary parameters; and it is shown that the determination of m, n, Z in terms of α, β, γ so as to satisfy the equations $Q = \alpha$, $R = \beta$, $S = \gamma$ involve no farther irrational operations. The calculations in both methods are full of beautiful details, partly geometrical and partly analytical in character.

In the last chapter of the first part a general survey of the theory of the polyhedral functions is given, wherein their relation to a variety of other functions is pointed out. In particular it is shown that the polyhedral functions virtually embrace all functions that "admit" a *finite* group of linear transformations. The proof of this depends essentially on the fact that the diophantine equation, $\Sigma(1 - 1/\nu_i) = 2 - 2/N$, where the ν_i's and N are all finite and positive, has only four solutions, viz. the values of ν_1, ν_2, ν_3, N (given in the above table), which characterize the polyhedral functions. In these four cases $1/\nu_1 + 1/\nu_2 + 1/\nu_3 > 1$. If in the differential equation (A) we give to ν_1, ν_2, ν_3 other integral values for which $1/\nu_1 + 1/\nu_2 + 1/\nu_3 =$ or < 1, we get the Schwarzian functions, which are transcendents admitting infinite groups of linear substitutions. Among these, as a limiting case corresponding to $\nu_1 = 2$, $\nu_2 = 3$, $\nu_3 = \infty$, are found the elliptic modular functions. This fact naturally leads to the attempt to solve the polyhedral equations by means of transcendentally irrational functions; and it is shown that, just as the binomial equation, $Z^n = A$, can be solved by means of logarithms, and the dihedral equation, $z^n + z^{-n} = -4Z_1 + 2$, by means of circular functions, so the tetrahedral, octahedral, and ikosahedral equations can be solved by means of elliptic modular functions.

The above imperfect sketch of Klein's "Ikosahedron" will, we trust, be held sufficient to justify us in saying that Mr. Morris's hope that his translation "may contribute towards supplying the pressing need of text-books upon the higher branches of mathematic" is not a vain hope. He could not, in our opinion, have made a better beginning. If our critical responsibility compels us to point out some defects in the execution of the work, we trust that this will be understood as indicating our desire to see the book made perfect; and not construed into depreciation of a valuable service to the cause of pure mathematics.

We strongly advise the author to have the translation read by some one who is familiar with both English and German idioms, and who possesses also some familiarity with the departments of mathematics concerned. In proof of the necessity for such a revision, we draw the author's attention to the following points, which are merely a few of those that have attracted our attention. When Klein says (Pt. I. chap. iii., § 7), "Die Lineare Differentialgleichung zweiter Ordnung, verlangt also, . . ., zu ihrer Lösung nur noch eine einzige Quadratur;" he does *not* mean, "The linear differential equation of the second order, therefore, requires, . . . , only a single *square root* besides in order to solve it." *Quadratur* means simply *quadrature* (*i.e.*, direct integration), it never means *square root*. Here a knowledge of the properties of the Schwarzian derivative might have helped the translator to divine the meaning of the German technical term. On p. 96, "But *for this* the determination of the R's themselves is more easy to carry out," is not a good, but in fact a misleading translation of the German "Dafür aber ist die Bestimmung . . ." *Dafür* here means "in compensation for this." At the foot of the same page occurs a very common confusion between *wenn eben* and *wenn gleich*, which has the effect of exactly reversing the meaning of the note. "Hierdurch kann $f(x) = 0$ (wenn eben γ, in den x geschrieben, nicht transitive ist) möglicherweise reducibel geworden sein," means, "Hereby $f(x) = 0$ may possibly have become reducible (namely if (or precisely if) γ, when expressed in terms of the x's, is intransitive)" for, of course, an equation is reducible if, and not unless, its group be intransitive. A still more important error occurs on the following page, where, in the definition of the Galois resolvent, "ihre einzelne Wurzel bei jeder in G enthaltenen Vertauschung der x umgeändert wird" is translated "its individual roots are *unaltered*, &c." First of all, this makes nonsense of the definition, as definite knowledge of the subject would have shown; and farther, supposing the translator to have read *un-* by mistake for *um-*, a knowledge of German idiom would have shown him that "ungeändert *wird*" makes nonsense of the German. The error is deliberately repeated on the following page, where "in umgeänderter Reihenfolge" is translated in "unaltered sequence," instead of "in altered sequence." These are vital errors, which should at once be corrected by means of an "errata-slip"; for they would be a serious rock of offence for a tyro in reading the passages where they occur. There are many other cases, however, where loose translation somewhat obscures the crisp and lucid exposition of Klein, which is a pity, for this quality is not all too common among Klein's countrymen. There are a considerable number of misprints, many of them copied from the original. An amusing instance of this occurs in the first footnote on p. 73, where the title of Schwarz's well-known memoir begins "Ueber *dienigen* Fälle, &c."; this is in the original, but the transcriber should have known that *dienigen* is impossible German. Nevertheless, we declare, with all the sanction of our critical stool of infallibility, that Mr. Morris's translation is a notable piece of good work; and he did well to publish it without waiting to perfect his knowledge of German idiom or of Galois's theory. The blemishes alluded to can be easily amended when another edition is called for, which will be speedily, if our good wishes avail.

G. CH.

THE NORTHFLEET SERIES ELECTRIC TRAMWAY.

On Monday, April 29, there was opened for regular passenger traffic an electric tramway at Northfleet, near Gravesend, which marks an era in the history of electric traction. This line has been run experimentally for the last month, but the seven years Board of Trade certificate having been received, this line now enters on the commercial stage of its existence. Four tramways on which electricity is the motive power have been in regular use for the last few years in Great Britain: it is not, therefore, because the Northfleet line is the first electric tramway in this country that it has attracted considerable attention; nor is it because it is the longest electric tramway, for two of the other four are of much greater length; but it is because this Northfleet line has been constructed on a totally different principle from that hitherto adopted on this side of the Atlantic that it is worthy of special consideration.

When a number of electric lamps or motors have to be supplied with power from a common centre, there are two well-known methods by which this can be done. They can either be joined "in parallel," as it is technically called, or they can be coupled up "in series." In the parallel system, the one generally adopted with electric lighting, and hitherto the only method that has been employed with the electric tramways in Europe, the electric current that passes through any lamp or motor does not pass through any other, and the dynamo produces a large current equal to the sum of all the currents passing through all the lamps or motors. In proceeding, therefore, from the dynamo end of the circuit to the distant end, there is a steady falling off in the current, but the electric pressure remains, or may remain, nearly constant. In the series system, on the other hand, the whole current produced by the dynamo passes through all the lamps or motors in succession, and therefore this current can be small. The initial electric pressure, on the other hand, must be large, since the energy imparted by the current to each lamp or motor is represented by a drop in the electric pressure. Since the energy furnished by the dynamo depends on the product of the current into the electric pressure it produces, while the waste of power in heating the conductor depends on the square of the current flowing through the conductor, it is clear that while any amount of energy can be supplied by either system, the use of high pressure and small current is by far the more economical as regards the power wasted in heating the conductor, this economy being the greater the greater the number of lamps or motors on the circuit.

Until a few years ago, however, it was not clear how it was possible to run motors electrically in series when the motors were themselves in bodily motion, as they must be when employed to propel tramcars. In 1881, Profs. Ayrton and Perry, for the purpose of diminishing the loss of power through the leakage of the current that occurs from the insulated rail of an electric railway to the earth, and which becomes serious when the line is long, proposed a plan of electrically subdividing the railway track into sections so arranged that the electric current was only supplied to that section of the track on which a train happened to be at any moment. This system was described and shown in action at a lecture given by one of the inventors at the Royal Institution in 1882, and the late Prof. Fleeming Jenkin, on reading the account of this lecture, saw that the device of employing an electrically subdivided conductor supplied the means of running electrical trains *in series*. A combination was, therefore, brought about between these three Professors to develop electric traction. This combination resulted in the formation of the Telpherage Syndicate, and lastly in the Series Electrical Traction Syndicate, to whom is due the construction of the first series line in Europe, the one that was opened for public traffic at Northfleet, on April 29.

The track itself does not at first sight appear to differ from an ordinary horse tramway track, there being no overhead wires as in the American electric tramways, nor auxiliary raised insulated rail, as at Portrush, nor central trough, as at Blackpool. A closer inspection, however, shows that one of the rails at Northfleet, instead of being simply grooved, is a double rail with a cavity or slot between the two portions. Fig. 1 shows the general cross-section of the line, the upper portion only of which is of course visible to the passer-by. In the cavity "the arrow," as it is called, glides, being drawn along by the moving car, the function of the arrow being to open the electrical

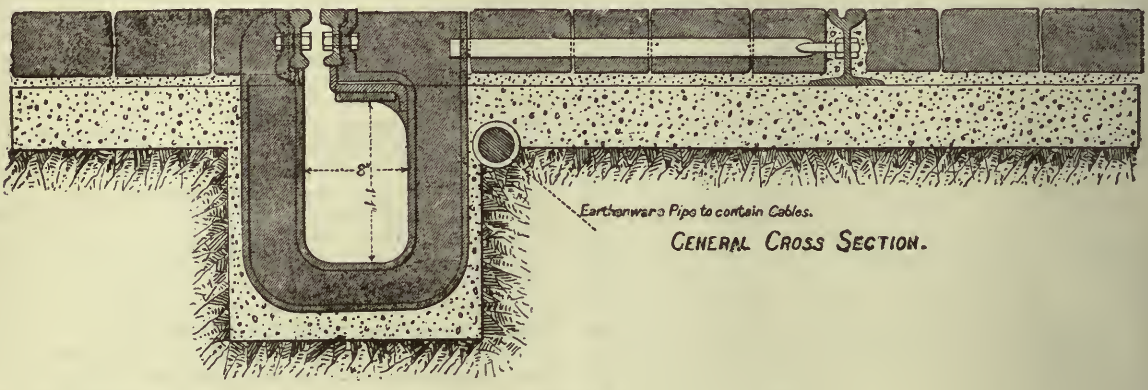


Fig. 1.

conductor at successive points, and insert the electric motor carried by the moving car in the electrical circuit. This arrow is made of flexible leather with a kind of steel spear-head at each end; it is coated with two flexible conducting strips, 1, 2 (Fig. 2), insulated from one another, and permanently connected respectively with the two terminals of the motor. As this arrow glides along, it passes, as seen in Fig. 3, between the two portions of each spring-jack, the spring-jack being shown in detail in Fig. 4. The arrow keeps open two spring-jacks at any one time, the portion of the cable joining them being either cut out of circuit or short-circuited, its place in the electric circuit being temporarily occupied by the motor on the car. This result is attained by the con-

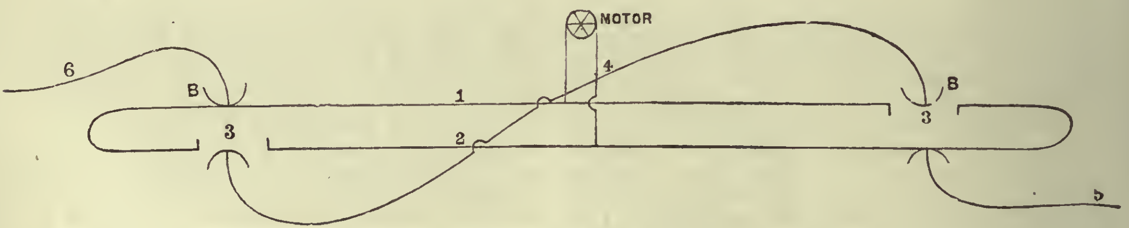

Fig. 2.—The Arrow.

ducting-strips 1, 2 (Fig. 2) on the arrow, being each wrapped round one end, and by an insulated space, 3, 3, being left on each side, slightly longer than the surface of contact B of the spring-jack. When the sceptical Englishman, who, in the past, could not realize that railways could ever succeed if the carriages were not shaped and painted like mail-coaches, reads a description of the Northfleet series tramway, he at once jumps to the conclusion that stones must necessarily get wedged in the slot; that the cavity will get filled up with mud; that the arrow must stick; and that the method is impossible in practice, though very pretty in theory. When he is told that a *series* electric tramway has been running successfully for some time in Denver, Colorado, and that

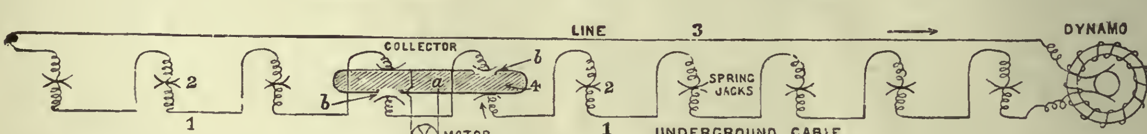

Fig. 3.—Diagrammatical Illustration of Series Line.

another *series* line, twelve miles long, with forty cars on it, is completed, or on the verge of completion, in Columbus, Ohio, he merely shrugs his shoulders and implies that such crude ideas may do for America, but that in this country we want time-honoured well-tried methods, and not new-fangled notions. The Northfleet cars, however, seem to have a marked disregard for conservative prejudices, since the arrow, with an ease and lofty contempt that makes one respect the silent power of the electric current, simply whisks out of its way any stone that has been intentionally jammed into the slot as tightly as any mischievous London urchin can fix it.

The spring-jack (Fig. 4) consists of a pair of glazed earthenware blocks, 14 × 3 × 4 inches. To each block is attached, by means of a double spiral spring, a gun-metal casting, curved at its ends to allow of the easy entrance of the arrow. The spring-jacks are arranged so that they can be taken out or replaced in the conduit in a few minutes in case of any failure. The electric resistance that they offer is much smaller than would have been anticipated, the total measured resistance of the entire line being but little higher than the calculated resistance of the insulated cable. This is probably due to the surfaces of the spring-jacks being kept bright and clean by the arrow constantly running through them.

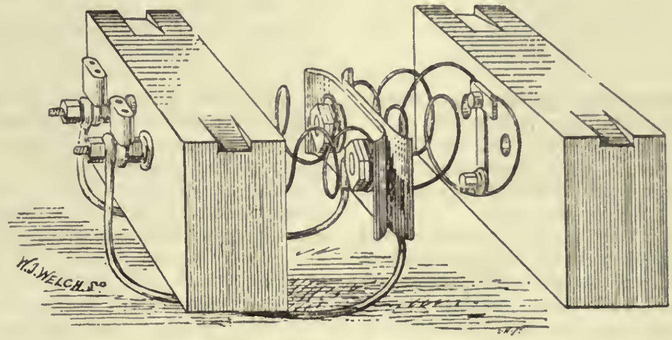

FIG. 4.—The Spring Jack.

In order that the speed of any one car shall not be affected by the starting or stopping of any other, it is necessary, with series working, that a *constant current* should be supplied to the circuit. Now while it is possible, by winding the field-magnets of a dynamo in a particular way, known as "compounding," to cause it, when running at a fixed speed, to supply perfectly constant pressure to a circuit, no matter how the resistance of the circuit may vary, no such solution has yet been practically attained when the supply conditions are *constant current*. Hence some mechanical device is necessary in the latter case, and the one employed with the Northfleet dynamo is that due to Messrs. Statter, and

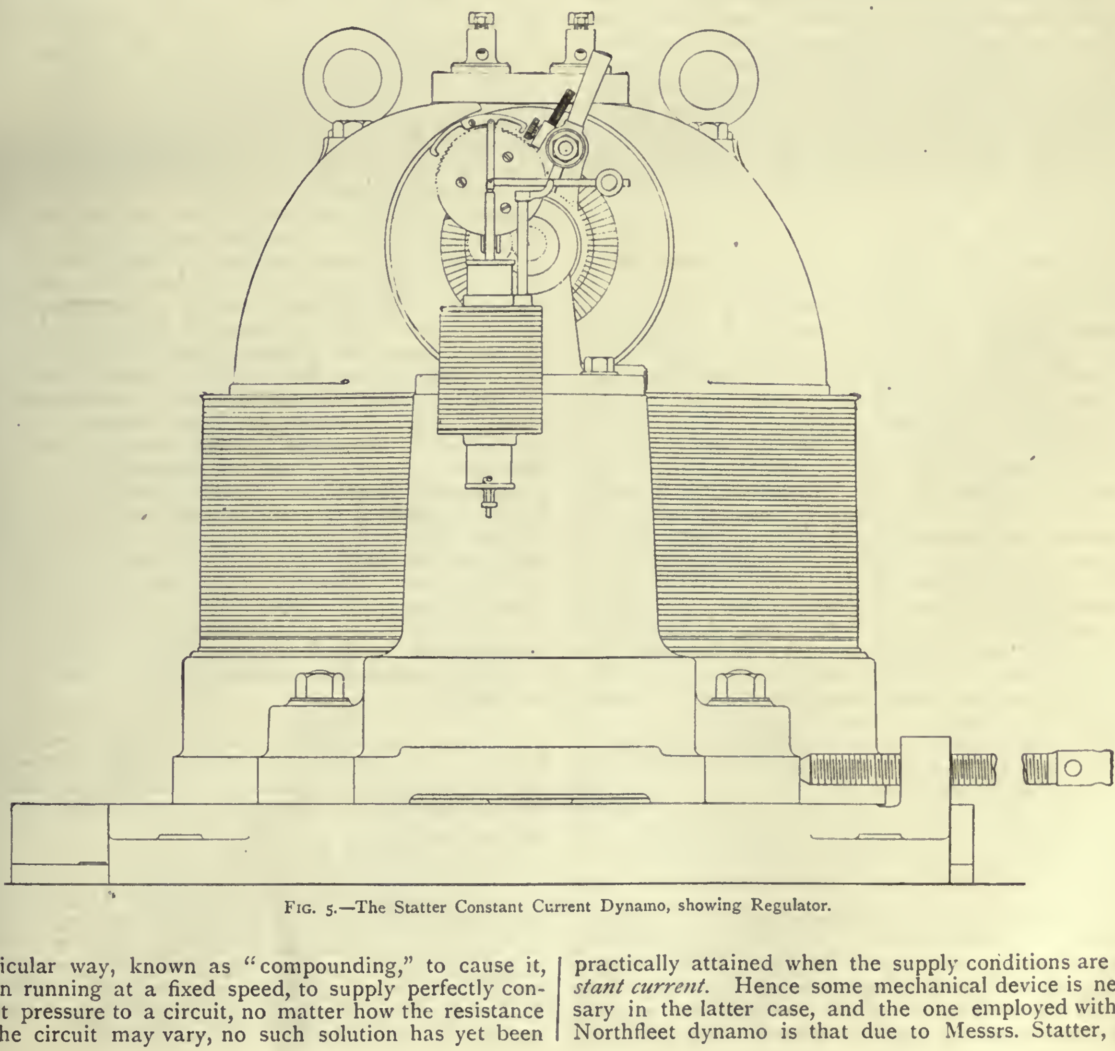

FIG. 5.—The Statter Constant Current Dynamo, showing Regulator.

seen in Fig. 5. A small pinion rotated by the dynamo shaft rocks a double ratchet by means of an eccentric. One or other of the ends of this ratchet is pulled down and made to engage with the ratchet wheel depending on whether the current is greater or less than 50 amperes, the normal current supplied to the line. The rotation of the ratchet wheel alters the positions of the brushes on the commutator, until the current is diminished or increased to 50 amperes, when the iron core attached to the ratchet, and which was previously sucked down below its normal position by the solenoid, or not sucked down so far, is now held in its normal position, and the ratchet kept free of the ratchet wheel. This mechanical constant current regulator works well, with a surprisingly small amount of sparking at the commutator.

As constant current is supplied to the line, the speed of the car could not be altered by introducing resistance into the circuit; what is done therefore is to shunt the field magnets of the motor with a less and less resistance by moving a lever on the car, as less and less power is required to be developed by the motor. When the car is at rest at the end of the journey, the motor is entirely cut out of the circuit by the handle being pushed full home. With horse tramcars a mechanical brake must be employed, and the energy of the moving car wasted in friction; indeed with the continuous vacuum brakes on the modern railway trains, not merely is the energy of the train wasted, but coal is actually burnt to stop the train. Some years ago, however, Profs. Ayrton and Perry pointed out that when an electric train was running down hill, or when it was desired to stop the train, there was no necessity to apply a mechanical brake and waste the energy of the moving train in friction, because by turning a handle the electromotor could be converted into a dynamo, and the train could be slowed or stopped by its energy being given up to all the other trains running on the same railway, so that trains going down hill could help the trains going up hill, and the stopping trains could help the starting trains. And at that time they proposed detailed methods for carrying out this economical mutual aid arrangement whether the trains were running in parallel or in series. But there is this great difference between the two systems, that whereas with motors in parallel it is only as long as a stopping train is still running fairly fast that it can help other trains; on the other hand, when one of a group of motors in series has been temporarily converted into a dynamo by the reversal of the connection of its field-magnets, this motor can return energy to the system down to the very last rotation of its armature. This difference, which is greatly to the advantage of the series system, will be easily understood if it be remembered that a motor will help other motors in series with it if it supplies a forward electromotive force, however small, whereas if the motors be in parallel it is necessary, in order that a motor should give energy to the system, that it should be able to reverse the direction of the current that was previously passing through it—in other words, produce an electromotive force actually larger than the potential difference set up between the mains by the dynamo itself.

And not only is this form of brake very economical in that it acts by saving power instead of by wasting it, but in addition its application imposes no tax on the driver's strength, as is the case with mechanical brakes where the pressure of the brake blocks is actually exerted by the driver's hand or foot—a consideration of considerable importance in these days of the natural revolt of the "tram slave."

At each end of the Northfleet cars there are two handles, one of which regulates the resistance shunting the field-magnet of the motor, and which therefore replaces the handle working the throttle valve of a steam locomotive, while the other handle reverses the terminals of the field-magnet, or short-circuits them when it is in its middle position, and therefore replaces the handle which operates the link motion in the locomotive. During the several journeys we made in the cars, we had frequent opportunity of seeing how perfectly they were under control, even when descending the steep hill near the Northfleet railway station.

One defect of the parallel system of working electric tram-lines is that it is possible for a mischievous person to cut off the power from the whole line, while at the same time the constant potential difference dynamo is made to produce far more than its normal current, by his laying an iron crowbar so as to electrically connect the going and return conductor. This result he may be able to accomplish without much difficulty, since both these conductors must be sufficiently exposed along their whole length that the passing train can maintain electrical contact with both of them. With the series system, on the other hand, such a catastrophe is impossible, since the return conductor, 3, marked "line" in Fig. 3, is completely buried out of sight.

A considerable amount of ingenuity has been displayed in the mechanical details both on the cars themselves and on the track at Northfleet. The motor, for example, is geared directly to a spur wheel on the car wheel shaft by double helical gearing, which runs without biting, and at the same time without any chance of slip, since the axle of the motor and the axle of the car wheel driven by it are always maintained at exactly the same distance apart. The result is attained by supporting one end of the motor framework from two bearings on the axle of the car wheel, and the other end by stout springs from the car itself. The tram-line is for the greater portion a single track, hence several places where the up and down cars can pass, "turn-outs" as they are technically called, have been provided. As both the up and down lines at the turn-outs are electrically in series, special electrical devices which appear to work very well have been provided for the facing points at the two ends of each turn-out. At one portion of the line the road is so narrow that it would have been very inconvenient to the ordinary horse traffic, had an up and a down tramcar gone along the same side of the road. An up car has therefore to pass the horse traffic by following the "near side," so also has a down car—in other words, the electric tramcar if it be going in one direction has to be on the opposite side of the road from that followed by an electric tramcar when going in the contrary direction. But as the road is too narrow for two sets of rails the track here consists of three rails, A B and C, A and B being used by the car when going in one direction, and C and B when it is returning; the facing points at the ends of this section being fitted with special mechanical and electrical devices, which also appear to accomplish their aims with perfect satisfaction.

A portion of the line has a long steep gradient of 1 in 32, but instead of jaded horses having to tug the cars up this hill, they ascend it at a rate of about nine miles an hour, so that the whole journey, which is a little under one mile, is accomplished when desired in three minutes and a half.

It is but a few weeks ago that the first trial trip of the Northfleet line was made; it is but now that it is opened for public use; and yet already the passers-by and the shopkeepers along the route have ceased to wonder how it is that horseless cars full of people rush up hill without smoke, quickly start in either direction, and as quickly stop when directed by the passengers to do so. After the Englishman has been spending some time conclusively proving to himself that a *series* tram-line was a practical impossibility, while the American was engaged in carrying out the trite saying that "the best way to do a thing is just to go and do it," our countrymen now accept the regular daily running of the *series* tram-line at Northfleet as a matter of course, and have forgotten that its very marked success ought to astonish them.

THE EXAMINATIONS FOR WOOLWICH AND SANDHURST.

THE revised Code for these examinations has at length been published. It is to come into force after January 1, 1891. There is to be a preliminary examination in elementary Arithmetic, Euclid, Algebra, French or German, writing English from dictation, elementary Latin, Geometrical Drawing, and Geography, for which no marks are given. We regret that as this examination has now been extended till it includes nearly all the main subjects of a modern education, an elementary knowledge of some branch of science is not also required. There is also to be a further examination for those who pass the preliminary, for which the following Code has been adopted:—

Class I.—*Obligatory.*

Mathematics (for Woolwich) ...	3000 Marks
,, (for Sandhurst) ...	2500 ,,
Latin	2000 ,,
French or German	2000 ,,

Class II.—*Any two Subjects may be taken up.*

Higher Mathematics	2000 Marks
German or French	2000 ,,
Greek	2000 ,,
English History	2000 ,,
Chemistry	2000 ,,
Physics	2000 ,,
Physical Geography and Geology	2000 ,,

Class III.—*All may be taken.*

English Composition	500 Marks
Freehand Drawing	500 ,,
Geometrical Drawing	1000 ,,

Notwithstanding the relative positions of science and Latin—which seem indefensible in regard to the Woolwich Cadets—this Code of marks is decidedly better than that which was the subject of so much adverse criticism in the early months of last year. In the first place, the allotment of marks which had such disastrous effects when adopted a few years ago in the Sandhurst competitions is at length abandoned, and candidates will no longer be at any disadvantage in this respect if they offer themselves for examination in such subjects as science, history, or Greek.

In the second place, it will now be possible for candidates to offer Greek or history, together with a branch of science, or to offer both chemistry and physics. In the case of some candidates this may prove a considerable advantage; though the fact that the obligatory and advanced mathematics can to some extent be studied concurrently may probably induce a large proportion to select the latter from Class II.

Thirdly, the better position that was claimed for experimental sciences in the Woolwich competition has now also been given to these subjects in the Sandhurst examination.

At first sight it may appear, after all that has been said and done, that the position of the experimental sciences as members of Class II. is not very splendid. It is therefore worth while to point out, lest it should be overlooked by teachers, that chemistry and physics are so important in the curriculum at the Royal Military Academy, that it will be greatly to the advantage of candidates for the scientific branches to study and offer one of these subjects, now their prospects of success will no longer be diminished by doing so. Hence, as a whole, the scheme for selecting and educating cadets for the Engineers and Artillery is now reasonably favourable for those who exhibit an aptitude for the experimental branches of science. We think this will soon be recognized by the candidates themselves, and that those who are interested in the science of our public schools will also quickly perceive the importance of the changes that have been secured in the face of very considerable difficulties by the action of Sir Henry Roscoe and the other scientific members of the House of Commons.

Altogether, therefore, it may decidedly be said that the authorities at the War Office are to be congratulated on the result of their consultations with Sir Henry Roscoe and other educational authorities. The new Code is not ideal. It does not fully recognize the importance of natural science in modern education, and it is to be feared that it will lengthen the examination to some extent. But, if it be fairly carried out, scientific candidates will not in future be placed at any great disadvantage, as compared with those who have studied other subjects, in the examinations for admission to either branch of the Army. In regard to this last point, however, it would be well if the Civil Service Commission took steps to remove the blot in their system of conducting public competitive examinations to which attention was called, some years ago, by Sir Lyon Playfair, in his Presidential Address to the British Association. We allude to the irregularity with which marks are awarded for the various subjects at more than one of these examinations. These irregularities are still unduly large. We have before us an account of the marks given in six examinations for Woolwich, taken at random during the years 1884–88, and it appears that, at these examinations, successful candidates who have offered French, German, Greek, and experimental science have been given, on an average, 38, 35, 29, and 28 per cent. of the allotted maximum marks. A successful candidate offering Greek and science would, on an average, have obtained 1154 out of the maximum of 2000; whilst one offering French and German would have been given 1491 out of the same maximum. A similar tale is told by the highest marks awarded in the respective subjects. It will scarcely be contended that, on the whole, the superior teaching of modern languages, as compared with that of Greek and science, justifies this. It is perhaps too much to hope for absolutely equal rates of marking, as between different subjects at each separate examination. But we do not think that during such considerable periods of time the variations should be so great as they have been, especially in the case of subjects taken up by fairly large proportions of the candidates. Such variations do real harm by encouraging the mark-hunter, who is ever on the alert, and by artificially stimulating the favoured subjects at the expense of others of importance.

We understand that the examiners are not to be blamed for this state of things, but rather that the Civil Service Commissioners are directly responsible. For it is stated by Mr. Oscar Browning, in the *Journal of Education* for April, that the examiners "receive a paper as a model which they are told to copy as exactly as possible. They are informed of the average of marks given at the last examination, and they are enjoined to adhere to the standard with special care." If this goes on year after year, as seems to be implied, it is difficult to see how any code of marks can secure a fair examination. If the candidates who offered any subject were hardly treated in 1888, the chances are that those who offer the same subject in 1889 will also suffer hardness. For if the candidates in that subject be better in 1889 than they were in 1888 they will be relatively still more hardly treated. If of similar calibre they will be treated equally badly. Only if they happen to be inferior will they stand at an advantage.

If the system of examining be as it is represented, it is high time that it should be revised by those who are responsible for it.

NOTES.

We regret to announce the death of Mr. Robert Damon, of Weymouth, the well-known naturalist and geologist. He died suddenly on Saturday, the 4th instant, from heart disease. Mr. Damon was the author of an excellent work on the "Geology of Weymouth and the Isle of Portland," now in its second edition. He was a most extensive traveller and an assiduous collector. He obtained a marvellous series of fossil fishes from the Cretaceous beds of the Lebanon, Syria, now in the British Natural History Museum, also the most complete skeleton of that rare and extinct Sirenian, "Steller's Sea-cow," from Behring Island. Although in his seventy-fifth year, he contemplated another trip to Siberia to procure an entire Mammoth's skeleton for the National Museum. Only a few years ago he took passage from Nijni Novgorod, down the Volga to Astrakhan, for the purpose of collecting a complete series of the fishes of the Caspian Sea, in which he was most successful. He lately purchased the celebrated zoological collections forming the "Godeffroy Museum" in Hamburg, and he had perhaps the largest collection of recent shells in this country. Mr. Damon's loss will be long felt by a wide circle of scientific friends in all parts of the world, by whom he was warmly esteemed and respected.

The Paris Exhibition was opened on Monday by the President of the French Republic. As usual on such occasions, there was a great display of empty spaces which ought to have been, and soon will be, filled with exhibits. The British Section was greatly in advance of the others. M. Carnot, in speaking of the general character of the Exhibition, referred emphatically to "the surprises reserved for our generation by the marvellous progress of science."

At the Royal Academy banquet, on Saturday last, Sir Henry Roscoe responded to the toast for "Science." He spoke of the intimate relations between science and art, and, as an illustration of the services rendered by the former to the latter, referred to the fact that this year we celebrate the jubilee of the discovery of photography. "In 1839," he said, "the power of the sun to draw in black and white was first indicated by Daguerre and Fox Talbot. In her infancy exhibiting but slight promise of artistic life, Photography, in her maturity, has developed true artistic power, so that she has now grown to be a trusted and valued helpmate to the artist, while she can produce effects and catch expressions which might defy the brush of a Turner or a Reynolds."

An International Congress of Photography will be held in Paris from August 6 to 17. If we may judge from the programme, which has been issued by the Organizing Committee, the proceedings are likely to be of great interest. Anyone may suggest subjects of discussion on condition that the suggestions are sent to the secretary (M. S. Pector, 9 rue Lincoln, Paris) at least fifteen days before the opening of the Congress. On August 20 there will be a public conference on the labours of the Congress.

The third of the series of One-Man Photographic Exhibitions at the Camera Club is now open to visitors on presentation of card. The Exhibition will continue for about two months. The object of this series of exhibitions is to bring together, in turn, representative collections of the work of the best photographic artists. The photographs shown on the present occasion are by Mr. J. Gale. They are chiefly photographs of landscape, and landscape with figure, and are printed in platinum and in silver processes.

Science gives the following as a complete list of the papers presented and read to the American National Academy of Science, at its meeting in April: on composite coronagraphy, by D. P. Todd; additional experimental proof that the relative coefficient of expansion between Baily's metal and steel is constant between the limits zero and 95° F. (read by title), by W. A. Rogers; notice on the method and results of a systematic study of the action of definitely related chemical compounds upon animals, by Wolcott Gibbs and Hobart Hare; on sensations of colour, and determinations of gravity, by C. S. Peirce; on the Pliocene Vertebrate fauna of Western North America, and on the North American *Proboscidea*, by E. D. Cope; on the mass of Saturn, by A. Hall, Jun.; on the nature and composition of double halides (read by title); on the rate of reduction of nitro-compounds, and on some connection between taste and chemical composition, by Ira Remsen; recent researches in atmospheric electricity, by T. C. Mendenhall; measurement by light-waves, by A. A. Michelson; on the feasibility of the establishment of a light-wave as the ultimate standard of length, by A. A. Michelson and E. W. Morley; on the general laws pertaining to stellar variation, by S. C. Chandler; review of the trivial names in Piazzi's Star Catalogue, by C. H. F. Peters; on Cretaceous flora of North America, by J. S. Newberry; terrestrial magnetism (read by title), Cleveland Abbe; spectrum photography in the ultra-violet, by Romyn Hitchcock; North American *Pelagidæ* (read by title), and development of Crustacea (read by title), by W. K. Brooks; the plane of demarcation between the Cambrian and pre-Cambrian rocks, by C. D. Walcott; report of the American Eclipse Expedition to Japan, 1887, by D. P. Todd.

It is reported from India that Mr. Blanford, Meteorological Reporter to the Government of India, who retires at the end of his furlough, has been recommended for the special pension of 6000 rupees per annum.

The following "resolution" of the Government of Bombay, which has just been published, tells its own story, and adds another to the already numerous examples of the well-judged munificence of the Parsee community of Bombay. The resolution is entitled "Scientific Medical Research." "(1) The sum of Rs. 75,000 having been placed at the disposal of his Excellency the Governor by Mr. Framjee Dinshaw Petit, for the purpose of erecting and fitting a laboratory for scientific medical research, on a site which has been approved by the donor, in the immediate vicinity of the Grant Medical College, the Governor in Council has much pleasure in accepting the offer, and, in doing so, desires publicly to thank Mr. Framjee Dinshaw Petit for his munificence in supplying an institution, the want of which has long been felt by those most interested in promoting the cause of higher medical education in this Presidency. (2) The Governor in Council is pleased to direct that the institution shall be called 'The Framjee Dinshaw Petit Laboratory for Scientific Research.' (3) Instructions for the preparation of the necessary plans and estimates for the proposed building have already been given."

The native population of Benares cannot be said to have very advanced ideas as to the importance of sanitary science. The other day a monster meeting was held in that city to protest against certain proposed drainage and water supply schemes, and a petition to the Government condemning the entire action of the municipality in the matter is said to bear 100,000 signatures. According to the Calcutta Correspondent of the *Times*, the petitioners emphatically decline to pay by increased taxation for any new system.

Last winter the Vienna Medical School was attended by 150 British and American medical graduates, among whom were many Edinburgh men. As many medical students, on their arrival at Vienna, do not know German, the Vienna *Weekly News* has opened a special "medical inquiry office" near the hospital, where information as to lectures, lodgings, &c., is given without charge to British and American medical men.

The same journal publishes weekly a list of forthcoming courses of lectures at the Universities of Vienna and Berlin.

THE *Times of Colombo* announces the arrival in Ceylon of two naturalists, Herr Frühstorfer and Herr Kannegieter, the former a German, the latter a native of Amsterdam. Herr Frühstorfer has already travelled over a great part of the world making natural history collections, while his companion is travelling on behalf of the collection of Herr Van de Poll. Both were about to proceed to the southern part of Ceylon, and after a few weeks' exploration they intended going, one to Malacca and Borneo, the other to Sumatra and Java, for scientific purposes.

A SEVERE earthquake lasting four seconds occurred at Agram on April 27 at 8.35 p.m.

A NEW stalactite cave has been found at Hönnethal, in Sauerland, not far from the village of Sanssouci. It is not very large, but has many beautiful stalactites.

COMPLAINTS having, on several occasions, been made to the Fishery Board for Scotland that salmon smolts are exposed for sale and sold, the Board have issued a notice to the effect that such sale, or exposing for sale, is illegal, and renders the seller or exposer liable to severe pecuniary penalties. The word "salmon" in the Salmon Fishery Acts of 1862 and 1868 means and includes "salmon, grilse, sea trout, bull trout, smolts, parr, and other migratory fish of the salmon kind." All offences under the Salmon Fishery Acts of 1862 and 1868 may be prosecuted, and all penalties incurred may be recovered, "before any sheriff or any two or more justices acting together, and having jurisdiction in the place where the offence was committed, at the instance of the clerk of any District Board, or of any other person."

WITH regard to Prof. Harker's article on a new farm pest, printed in NATURE last week, Miss Ormerod writes that, "if, by any accident, readers should think that what her valued friend Prof. Harker meant only as a courteous acknowledgment of specimens was an expression of belief in the injurious powers of this worm, she would in such case like to be able to mention that up to the present time she sees no reason for alarm."

A SERIES of experiments upon combustions in nitric acid vapour have been made by Dr. P. T. Austen, of Rutger's College, U.S. The gaseous nitric acid is most conveniently obtained in the following manner. Into a large flask, whose neck is sufficiently wide to admit a good-sized deflagrating spoon, a quantity of sulphuric acid is poured, so as to form a layer about half an inch deep. About ten to twenty grammes of potassium nitrate, in crystals averaging a quarter of an inch in size, are then added. On careful heating, the air is rapidly expelled, and the flask becomes filled with the clear vapour of nitric acid. A glowing chip of wood held in this vapour inflames and burns energetically, something after the manner of combustion in oxygen; but, as the red tetroxide of nitrogen, N_2O_4, is formed by the reduction of the nitric acid, a ruddy halo is seen to play around the flame. Charcoal, especially bark-charcoal, burns brilliantly, the scintillations in the red tetroxide gas producing an unusually fine effect. In a similar manner a steel watch-spring may be burnt as in oxygen, the combustion being started with a little sulphur; the effect, however, is quite different from that in oxygen, owing to the formation of a red halo around each melted globule of iron as it falls. A layer of sand should be placed in the bottom of the flask in this experiment, in order to prevent fracture. Phosphorus burns with great beauty, the dazzling white flame passing into a deep red at the edges. By far the most beautiful effects, however, are obtained by the combustion of readily oxidizable gases from jets suspended in the nitric acid vapour. Hydrogen burns with an intensely white flame, totally unlike that in oxygen, surrounded by a deep red envelope. Coal gas continues to burn with a white centre, enveloped as in case of hydrogen by a red halo; when first introduced the flame becomes musical, then degenerates into a series of rapid slight explosions; at length, after a certain amount of nitrogen tetroxide has formed, it burns quietly. Sulphuretted hydrogen gas burns with a bright yellow flame, and the flask becomes filled with a cloud of minute chamber-crystals, resulting from the action of the sulphur dioxide and water formed upon the tetroxide of nitrogen simultaneously produced. Ammonia gas burning in nitric acid vapour is perhaps the most beautiful case of simple combustion yet investigated. Success in this experiment appears to depend entirely upon the size of the orifice of the jet, which should not be less than an eighth of an inch in diameter. As soon as the jet, which of course should be turned upwards, from which a good stream of ammonia is issuing, is lowered to a level with the mouth of the flask, it may be readily ignited. On lowering it into the centre of the flask, the flame is seen to consist of a bright yellow nucleus surrounded by a greenish-yellow envelope; this, in turn, passes into an outer envelope of a carmine-red colour, which deepens as the amount of nitrogen tetroxide increases.

ACCORDING to the *Manchester Guardian*, a technical school has lately been added to the ancient Chetham College, "the most unique piece of antiquity" left in Manchester. It seems that a well-known employer of labour in Salford, and a strong supporter of technical education in Manchester and the neighbourhood, generously offered to fit up a workshop and supply it with all necessary tools for the use of Chetham College. The offer, which was regarded both as a very generous and a very happy one, was accepted by the authorities. The result was the erection of a building at the north-east rear of the College dormitories. The building, which is very well lighted and comfortably heated, has been fitted up with lathes (for wood and iron) driven by a steam-engine; also benches, drilling machines, grindstones, blacksmith's forge, vices, &c. The results so far are regarded as highly satisfactory. Some forty-five of the boys are now regularly engaged in the shop; fifteen working in the morning, fifteen in the afternoon, another batch of fifteen the next morning, and so on. Each boy works nine hours in the shop every week.

MR. ROWLAND WARD writes to the *Times* that on Saturday, April 27, one of the keepers on the estate of Mr. Farnal Watson, in Surrey, trapped a fine specimen of the kite (*Falco milvus*)—"a grand bird," says Mr. Ward, "at one time common on our moors before men became so many in the land, and their hospitality, even to such visitors, so scant." Mr. Ward notes that these birds are still sometimes encountered in Wales.

MR. ALLAN HUME proposes to issue a second edition of his "Nests and Eggs of Indian Birds." It will be edited by Mr. E. W. Oates, author of a "Hand-book to the Birds of British Burmah," and will incorporate all the notes which Mr. Hume's numerous correspondents in all parts of India have sent to him since 1873, as well as some notes from other sources. The work will be published in three volumes, 8vo, of 500 pages each; but for the convenience of subscribers it will be issued in six parts, one of which will be completed every three months, beginning from an early date. The publisher will be Mr. R. H. Porter, 18 Princes Street, Cavendish Square, London, W.

A COLLECTION of Prof. Weismann's essays on heredity has been translated under the care of Mr. E. B. Poulton, of Oxford, and will form the second volume of the series of translations of foreign biological memoirs which the Clarendon Press are publishing. The volume is nearly ready, and may be expected shortly.

MESSRS. CROSBY LOCKWOOD AND SON have published a second edition of M. Eissler's "Metallurgy of Gold." The work has been enlarged by about 150 pages and 40 additional illustrations.

WE have received the seventh part of Cassell's "New Popular Educator," which will be completed in forty-eight parts. This part contains a lithograph presenting the constellations visible in Britain.

MESSRS. C. GRIFFIN AND CO. have published the sixth annual issue of the "Year-book of the Scientific and Learned Societies of Great Britain and Ireland." The work, which is compiled from official sources, comprises lists of the papers read during 1888 before Societies engaged in fourteen departments of research.

THE additions to the Zoological Society's Gardens during the past week include an Indian Wolf (*Canis pallipes* ♀) from India, presented by Major C. S. Skipton, R.A.; two Stone Curlews (*Œdicnemus scolopax*), British, presented by Mr. Brunsden; a Golden Eagle (*Aquila chrysaëtus*) from Inverness-shire, presented by Mr. Thomas G. Henderson; a Cape Mole-rat (*Georychus capensis*), a Geometric Tortoise (*Testudo geometrica*), four Tuberculated Tortoises (*Homopus femoralis*), six Narrow-headed Toads (*Bufo angusticeps*), thirty-four Gray's Frogs (*Rana grayi*), a Spotted Slowworm (*Acontias meleagris*), rom Cape Colony, South Africa, presented by the Rev. G. H. R. Fisk, C.M.Z.S.; a Puff Adder (*Vipera arietans*) from the Cape of Good Hope, presented by Mr. F. Streatfield; six European Tree Frogs (*Hyla arborea*), European, presented Mr. H. Bendelack Hewetson, F.Z.S.; a Rhesus Monkey (*Macacus rhesus* ♀) rom India, deposited; two White-eyed Ducks (*Nyroca ferruginea*), European, two Black-necked Swans (*Cygnus nigricollis*) from Antarctic America, two Lineated Kaleege (*Euplocamus lineatus*) from Tenasserim, a Brazilian Tortoise (*Testudo tabulata*) from South America, a Blackish Sternothere (*Sternothœrus subniger*) from Madagascar, purchased; a Persian Gazelle (*Gazella subgutterosa*), two Chinchillas (*Chinchilla lanigera*), four Long-fronted Gerbilles (*Gerbillus longifrons*), born in the Gardens.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1889 *MAY* 12–18.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on May 12

Sun rises, 4h. 15m.; souths, 11h. 56m. 10·1s.; daily decrease of southing, 1·2s.; sets, 19h. 38m.: right asc. on meridian, 3h. 17·9m.; decl. 18° 15′ N. Sidereal Time at Sunset, 11h. 1m.

Moon (Full on May 15, 7h.) rises, 15h. 55m.; souths, 21h. 57m.; sets, 3h. 45m.*: right asc. on meridian, 13h. 20·1m.; decl. 2° 58′ S.

GEOGRAPHICAL NOTES.

DR. H. MEYER, in a paper read before the Geographical Society of Leipzig, deals with the snowfall on the summit of Kilimanjaro. Having shown that the southern and south-eastern slopes of the mountain are exposed during summer to the south-eastern trade winds, while the summit rises into the region of the anti-trades, and that local winds, sometimes of considerable force, ascend the mountain slope during the day, and descend during the night, he explains how these winds produce rain and snow. Dr. Meyer looks upon the wall of ice which stopped his further progress as the edge of a cap of *névé* which covers the summit, and which, owing to the combined influence of the wind and radiation, has melted away on its northern side. On the south, however, it seems to form a true glacier, which issues from the ancient crater-trough of Kibo.

SOME of the conclusions come to by Dr. K. W. Schmidt, in his paper on the soil and climate of German East Africa, in the current number of *Petermann's Mitteilungen*, are worth giving in detail. The wooded and mountainous region of Usambara and the western part of Bondei, in consequence of the favourable character of the soil, the copious rainfall, and extensive irrigation, may be truly described as fertile, and in the opinion of the author these countries have a great future before them. West of Usambara extend vast steppes, utterly unfit for cultivation. The mountain mass of Kilimanjaro, composed of recent volcanic, basaltic, and trachytic rocks, and clothed with a wealth of forests, should become of great importance. The physical condition of the country between the Pangani and the Wami are apparently not very favourable. Westwards the country of Nguru, in its geological formation, its magnificent forests, its numerous streams, and its meteorological conditions, resembles Usambara. Southern Useguha, as far as the Kingani and Gerengere, including the districts of Udoe and Ukewere, is nothing but a vast waterless steppe. Ukami, in its western part, abounds in lofty forest-clad mountains and rushing streams, and its soil is well adapted for cultivation; the soil of the eastern part of Ukami is, on the other hand, composed almost exclusively of quartz pebbles and gravel. Immediately to the west of Ukami stretches the vast desolate Mkata steppe, beyond which rises the mountainous country of Usagara, divided by the Mukondokwa River. The plain of Farhani, traversed by the river, is fertile and well populated. The mountainous district of Usagara itself suffers from a lack of streams, and also from the sparsely wooded character of its mountain slopes, at least in the eastern part. The country of Khutu, in its various river valleys, might furnish soil suitable for extensive cultivation. The general results of Dr. Schmidt's observations is to show that there is a great difference in the fertility and consequent value of the various countries comprised within the German protectorate in East Equatorial Africa, and that while there is a considerable extent of extremely fertile territory, the greater part does not appear to be capable of remunerative cultivation.

THE LIVERPOOL MARINE BIOLOGY COMMITTEE'S EASTER DREDGING CRUISE.

THE Liverpool Salvage Association's s.s. *Hyæna* left the Mersey on Thursday, April 18, on her fifth scientific cruise under the direction of the Liverpool Marine Biology Committee. The old gunboat had been generously placed at the disposal of the L.M.B.C. for five days, and the proposed course was to cross to Port Erin, at the south end of the Isle of Man, and then dredge southwards to Holyhead through the deepest water to be found in this district; then to work along the coast of Anglesey to Puffin Island, and from that back to Liverpool. Besides the ordinary dredging and tow-netting operations, it was hoped that two interesting new methods of collecting would be tried on this cruise: (1) the submarine electric light, which gave such good results in the *Hyæna* expedition of last summer, was to be used as an attraction in the nets let down to the bottom at considerably greater depths than was the case in last year's experiments at Ramsey and Port Erin; (2) Mr. W. E. Hoyle's new tow-net (recently described in the Proc. Biol. Soc. Liverpool, vol. iii.), which can be opened and closed at any required depth, so as to insure that the contents were captured in a particular stratum of water, was to be taken with the view of trying how it worked.

After the first day, however, the weather although fine on land became very unfavourable for marine work, and the programme had to be considerably altered. Thursday was spent in crossing to Port Erin. On Friday morning we steamed south-west towards the deep water, but a strong wind was blowing, and after a haul of the dredge in 27 fathoms, about five miles out, some bottom and surface tow-netting, a sounding in 50 fathoms, and a further run to about nine miles from land, it was found that the heavy rolling of the vessel rendered dredging operations impossible out in the open sea; so the *Hyæna* was put about and returned to Port Erin, where tow-netting and other work was carried on in the bay. The following day the wind was still stronger, so it was decided to give up the Anglesey part of the cruise and devote the remaining days to shore and shallow-water work round the south end of the Isle of Man. Accordingly the rocks at Port Erin, Port St. Mary, Poyllvaaish Bay, and Fleshwick Bay were explored on the third day, while on the fourth most of the day was spent on board the *Hyæna*, at anchor in Port Erin Bay. Tow-nets were let down, both on the surface and weighted so as to reach the bottom, and a small dredge with a long canvas net was taken out in a boat and used for obtaining samples of mud and sand to examine for small animals, such as Foraminifera, Copepoda, and Ostracoda. The strong wind blowing was utilized by Captain Young, who suggested floating tow-nets across the bay with life-buoys, and devised a sailing apparatus, consisting of an old life-buoy rigged up with a mast and sail, and having a tow-net suspended from it, which was let out carrying a long line to leeward and was then hauled in, the net keeping distended and working well during both the outward and the return journeys. Another surface-net was even rigged up attached to a large kite, but this did not work satisfactorily.

In the afternoon the *Hyæna* made two runs from Port Erin southwards to the Calf, dredging homewards with the wind, and got two excellent hauls, which contained amongst other things: *Sarcodictyon catenata*, *Stichaster roseus*, *Palmipes membranaceus*, *Porania pulvillus*, *Adamsia palliata*, and *Fagurus prideauxii*, *Ebalia* sp., *Lyonsia norvegica*, *Pectunculus glycimeris*, and *Ascidia venosa*.

After dark on two consecutive nights the electric light was used for a couple of hours in collecting bottom and surface free-swimming animals round the ship, in much the same way as during last summer's cruise. A pair of large arc lamps of 2000 candle-power each were hoisted up in such a position as to illuminate the deck and cast a bright light on the water for some distance on each side of the ship. Three submarine incandescent lamps of 50 candle-power each were then fitted in the mouths of tow-nets and were let down, two of them to the bottom at a depth of 5 fathoms, and the third to a foot or so below the surface of the sea. Each of these nets was put out twice, so that we got four bottom hauls and two surface hauls with the electric light tow-nets. Another tow-net, without any lamp, was let over the side of the *Hyæna*, and lay in the brightly illuminated surface water. All these nets were stationary, but were kept fairly distended by the tide. At the same time Mr. I. C. Thompson was rowed round and round the ship dragging an ordinary tow-net in the bright area. Consequently all the nets were, on this occasion, used in water lighted up, the surface nets being in the glare of the 4000 candle-power lamps, while the bottom nets were further from this bright light, but had each their own smaller lamps. All gave, so far as we yet know, from a cursory examination, practically similar results which are markedly different from both the bottom and surface gatherings taken at the same place during the previous day. The electric light gatherings contain chiefly Schizopoda, Cumacea, Amphipoda, and a few Copepoda. The Cumacea are the most marked feature, they are very abundant, and form a conspicuous characteristic in the gathering whenever it is transferred from the net into a glass jar. In none of the daylight tow-nettings, either bottom or surface during the cruise, was a single Cumacean obtained, while every gathering on the two nights when we had the electric light going contained Cumacea in abundance. I think there can be little doubt that those captured in the surface-nets had been attracted from the bottom by our brilliant deck-lights, which had been shining for fully half an hour before the nets were put over.

On the fifth day the *Hyæna* started in the morning from Port Erin and arrived at Liverpool at midnight. A little dredging and tow-netting was done on the way. A good haul was obtained from a stony and shelly bottom, at about 15 miles south-east of the Chicken Rock, depth 30 fathoms, which yielded large numbers of Polyzoa, chiefly incrusting forms. At this spot also, it being the deepest water on our track from Port Erin to Liverpool, we let the electric lamp down to the bottom in a tow-net twice, and got gatherings consisting mainly of Copepoda, *Sagitta*, Amphipoda, Zoëas, and other larval forms.

That free-swimming Crustaceans are attracted to a stationary net by the electric light may now be considered established beyond doubt; and that the illuminated tow-net can be used in, at least, such moderately deep water as is commonly met with in dredging round our coasts was evident to all who saw the success with which the net was worked on board the *Hyæna* in 30 fathoms.

The various tow-net gatherings and dredged collections were as usual preserved and brought home, and are now in the hands of the specialists who are working at the different groups of animals for the Liverpool Bay "Fauna."

W. A. HERDMAN.

SOCIETIES AND ACADEMIES.

LONDON.

Linnean Society, May 2.—Mr. C. B. Clarke, F.R.S., in the chair.—With reference to a recent exhibition, by Mr. D. Morris, of leaves of different species, or varieties, of plants included under *Erythroxylon Coca*, Lamarck, Mr. Thomas Christy made some remarks on the leaves of a variety from Japan. These he described as brittle and thin, with hardly any trace of cocaine, though yielding 8 per cent. of crystallizable substance. The thicker leaves of the Peruvian plant yielded more cocaine, though at first rejected on account of their more glutinous nature.—Mr. John Carruthers read a short paper on the Cystocarps, hitherto undescribed, of a well-known seaweed, *Rhodymenia palmata*, upon which remarks were made by Mr. G. Murray and Mr. A. W. Bennett.—The second part of a monograph of the *Thelephoreæ* was communicated by Mr. G. Massee.—Mr. Mitten contributed a paper on all the known species of *Musci* and *Hepaticæ* recorded from Japan. An interesting discussion followed on the character of the Japanese flora, in which Mr. J. G. Baker, Dr. Braithwaite, and Mr. G. Murray took part.

Geological Society, April 17.—W. T. Blanford, F.R.S., President, in the chair.—The following communications were read:—On the production of secondary minerals at shear-zones in the crystalline rocks of the Malvern Hills, by Charles Callaway. In a previous communication the author had contended that many of the schists of the Malvern Hills were of igneous origin. Thus, mica-gneiss had been formed from granite, hornblende-gneiss from diorite, mica-schist from felsite, and injection-schists from veined complexes which had been subjected to compression. As a further instalment towards the elucidation of the genesis of the Malvern schists, he discussed the changes which the respective minerals of the massive rocks had undergone in the process of schist-making.—The northern slopes of Cader Idris, by Grenville A. J. Cole and A. V. Jennings. From the publication of Mr. Aikin's paper in the Transactions of the Geological Society in 1829 to the second edition of the

Survey Memoir on North Wales, the relations of the geological and physical features of Cader Idris have been pointed out in some detail. The present paper dealt with the nature of the eruptions that took place in this area, and the characters of their products at successive stratigraphical horizons.—Discussions followed the reading of both of these papers.

Paris.

Academy of Sciences, April 29.—M. Hermite in the chair.—On a means of obtaining photographs of true chromatic value by the use of coloured glasses, by M. G. Lippmann. By the judicious employment of green, yellow, and red glass in the way here explained, excellent results have been obtained even with present plates, notwithstanding their greater sensitiveness to blue. The impressions are described as clear and free from brown patches, the green foliage, the red or yellow draperies, instead of yielding brown tints, being reproduced in delicately modelled design as in a well-executed engraving.—Loss and gain of nitrogen as determined by the experiments carried on at Grignon from 1875–89, by M. P. P. Dehérain. A general survey of the results of these experiments leads to the conclusion that all soils containing considerable quantities of nitrogen in combination, say two grammes to the kilogramme, lose, if cultivated without manure, far more nitrogen than is absorbed by the crops, but in proportions varying according to the nature of those crops—more with beetroot, less with maize grown for fodder, still less with potatoes and wheat. But when the ground has thus been impoverished, no longer containing more than 1·45 or 1·50 grammes to the kilogramme, the losses ceases and the ground begins, on the contrary, to recover a certain proportion of nitrogen, the gain being much greater on grass-grown than on tilled lands.—Underground growth, seed, and affinities of the Sigillaria, by M. Grand'Eury. The author, who has had a favourable opportunity of studying these fossil plants in the Carboniferous formations of the Gard, confirms the view always held by Prof. Williamson, that they are true Cryptogams of the vascular order, despite the radiated structure of the wood. But they are not directly connected with any living type, and form a family of fossil plants which entirely disappeared towards the close of the Palæozoic period.—Two eruptions observed on the sun in September 1888, by le Père Jules Fényi. These eruptions, observed on September 5 and 6, are described as of an extremely violent character, and as all the more remarkable because occurring at the epoch of minimum intensity. Both appear to have taken place about the same region of the solar disk, and the protuberance accompanying the first contained the vapours of several metals, such as sodium, barium, and iron, besides two very bright red rays of an unknown element, one between B and C, the other between B and *a*.—On the alloy of the standard international kilogramme, by M. J. Violle. The alloy of platinum and iridium in the proportion of 10 per 100, prepared with the greatest care by M. Matthey, is here found to be still somewhat defective. M. Violle's researches show that an alloy of 9 parts platinum and 1 iridium yields more uniform and accurate results both as regards density and specific heat. The density thus obtained is an absolute constant, incapable of further modification under cold-hammering, annealing, or any other severe test.—Dilatation and compression of carbonic acid, by M. Ch. Antoine. In a previous note (January 21, 1889), the author showed that the reciprocal β of the coefficient of dilatation under constant pressure is given by the relation—

$$\beta = \frac{pv_s}{\delta} - t_s,$$

δ being a constant coefficient, t_s and v_s the temperature and volume at saturation under the pressure p. Here he finds that more simple values may be obtained both for pv_s and β.—On electrolytic polarization by metals, by M. N. Piltschikoff. A general result of these researches is that one metal may be polarized by another.—On the formation of earths containing nitrogen, by MM. A. Müntz and V. Marcano. The authors describe numerous caves in Venezuela, both on the coast ranges and on the slopes of the Andes, which contain vast deposits richly charged with nitrates and interspersed with the remains of large extinct animals. The bones are so friable that they crumble to dust at contact of the finger; hence the difficulty of determining the species. They consist almost exclusively of phosphate of lime; carbonate of lime is entirely absent, and there are but slight traces of organic matter. In these caves, sheltered from the action of rain-water, the nitrogen yielded by the nitrified organic remains was gradually accumulated. In some places the beds are over 30 feet thick, containing from 4 to 30 per 100 of nitrate of calcium, and from 5 to 60 of phosphate of calcium.—On the art of utilizing statistics, by M. Delauney. With a view to the better utilization of statistical returns, especially in the sphere of meteorology, the author here proposes a solution of the problem: Given the statistics of a phenomenon, to find a certain method by means of which the laws controlling that phenomenon may be discovered.

BORNEO.

Borneo: Entdeckungsreisen und Untersuchungen; Gegenwärtiger Stand der Geologischen Kenntnisse; Verbreitung der Nutzbaren Mineralien. Von Dr. Theodor Posewitz. (Berlin: Friedlander, 1889.)

IN the work before us, Dr. Theodor Posewitz, of the Hungarian Geological Institute, gives the results of his three years' personal explorations in the Island of Borneo, with which he has incorporated the more important observations which are recorded in the literature of the subject. The larger portion of this literature being in Dutch, it is, as a whole, not very widely known; it is, accordingly, a matter of considerable importance to have it here summarized and critically examined by so competent an authority.

The three parts into which the volume is divided are: (1) Political and Historical; (2) Geological; and (3) Economic Mineralogy. Each of these parts is further subdivided into a number of clearly-defined sections, so that there is no difficulty experienced in at once mastering the range and contents of the work, which are further indicated by means of four excellent maps, showing respectively, (1) the routes of travellers, (2) the political divisions, (3) the geological structure, and (4) the distribution of useful minerals.

We are told, in Part I., that two-thirds of the island belong to the Dutch, but that the States on the north coast are more or less under British influence.

The history of exploration, as conducted by the Dutch, is treated separately from that which originated in connection with British colonial enterprise. During the last century, only one extensive journey was undertaken in Dutch Borneo, and scientific exploration was then altogether prohibited.

The genuine exploration of the country did not begin till 1820–30, when a Natural History Commission was established in Batavia, and its members undertook to investigate and describe various islands. Among others, Horner, G. Müller, Dr. Schwäner, and Von Gaffron devoted themselves to Borneo, and to the two last we owe our knowledge of South Borneo. Between the years 1850–60, systematic explorations for useful minerals were carried on by Dutch engineers in South-West Borneo, and these explorations have been recently resumed, after an interval of twenty years.

To Alexander Dalrymple, who travelled in 1769, we are indebted for our first knowledge of North Borneo; other early travellers were Burns, Hugh Low, and Spenser St. John, who visited Sarawak, Brunei, and the north-east coast, and ascended the Kina Balu Mountains. Among later travellers, Crocker and H. Everett merit special notice; as also do the courageous pioneers in the British North Borneo Company's territory—Dobrée, Peltzer, Wetti, Von Donop, Pryer, and F. Hatton.

With regard to the geological and physical structure, which are dealt with in Part II., we are told that there is no uninterrupted central mountain chain in Borneo, though such is represented on most maps. Isolated mountains occur at intervals, surmounting table-lands which extend in a north-east to south-west direction; but it is not yet decided whether a regular chain exists in any part of the interior. The Kina Balu Mountains, which have a maximum elevation of 13,698 feet, are, so far as is at present known, the highest in the island; they are situated in the territory of the British North Borneo Company.

The largest rivers—the Barito, Kapuas, Redjang, and Mahakkam—rise in the centre of the island.

The geological structure is remarkably free from complexity. The isolated mountains are of slate or schist penetrated by granite and diorite—conditions, it may be remarked, which are in many countries accompanied by the occurrence of mineral veins; this also seems to be the case in Borneo.

Succeeding these are rocks of Devonian age, in which auriferous veins occur. Till quite recently no formations had been recognized between them and the Tertiary deposits which have long been known, but Carboniferous strata (mountain limestone), which it is believed occur throughout a large area in Northern Borneo, have within the last few years been recognized, and Cretaceous rocks have been discovered in a single locality in West Borneo.

Tertiary formations belonging to several subdivisions are distributed over considerable areas; they form the plateaus through and above which the mountain chains rise. The older Tertiary strata were first studied by Verbeek and Pengaron in South Borneo. They are divisible into sandstone, marl, and limestone groups. The majority of the coral deposits occur in the sandstone, and the limestones consist mainly of wide-spreading coral reefs. These older Tertiary strata are often much disturbed and broken by intrusive masses of andesite. Oligocene strata are only known in East Borneo, where they include extensive deposits of coal.

The diluvium of our author is of considerable economic importance. It spreads over wide undulating tracts surrounding the Tertiary hills. It includes the principal sources of the gold and diamonds which, together with coal, constitute the most valuable mineral resources of the island. From the diluvium to the alluvium which is in process of formation at present, there is a gradual transition.

There are no evidences of any post-Tertiary volcanic energy in Borneo. The Kina Balu Mountains, at one time thought to be volcanic, are now known to consist of ancient eruptive masses. Earthquakes occur, but rarely, and so far as is known they originate in neighbouring islands.

In West Borneo a deposit which appears to be identical with one form of Indian laterite, is described as resulting from the weathering of the rocks. A similar laterite occurs near Singapore.

Taking a general survey of the probable geological history of Borneo, it appears that, up to the beginning of the Tertiary period, what now forms one united island consisted of an archipelago like that between Singapore and Banka. After the deposit of the Tertiary strata there followed a period when the island had the form of the Celebes. A tradition among the natives, that the sea formerly reached to the foot of the mountains, is referred to as confirming the view that the present form of the island has only been acquired recently.

The useful minerals are described in Part III., and their distribution is indicated on the map already referred to. Of most of them Dr. Posewitz has previously published separate descriptive monographs.

The rich coal-fields are first described. The seams are exposed in many river cuttings in Sarawak and Brunei. Coal also occurs on the Island of Labuan and in Sabah. There are said to be rich and extensive deposits in East Borneo also, but they have not been worked.

Gold is of the next importance to coal as a mineral product. Mining in the older formations has hitherto not proved remunerative, the best field being from the diluvial deposits, which are worked almost exclusively by Chinese. The richest gold regions are in the south-east, near Tanah Laut and Kusan, on both sides of the auriferous Meatus Mountains; and in the north-east, in the Chinese districts of West Borneo and Sarawak. Recently, what promise to be rich gold deposits have been discovered in the Upper Segamah River in Sabah.

The production of gold was much more considerable formerly than it is at present. In West Borneo it amounts annually to 120,000–150,000 kilogrammes, and in Sarawak it amounted to 28,281 kilogrammes in 1886.

Diamonds are not, comparatively speaking, so abundant as gold, but they occur in the same deposits. They are searched for by Chinese. Since the introduction of the cheaper Cape diamonds, the production has fallen. In 1884, 2727 carats were exported from West Borneo, and 1200 carats from Sarawak in 1886.

Dr. Posewitz refers to the late Prof. Lewis's speculation as to the connection between diamonds and serpentine (*Peridotite*) (NATURE, vol. xxxvi. p. 571), but states that it is not yet known how far his conclusion is correct, that diamonds and platinum are only found in Borneo in streams which traverse areas containing serpentine. Indeed, it may be added that serpentine is of rare occurrence in the principal diamond regions of India, and in some of them none whatever has been observed.

The famous "diamond" of 367 carats, known as the "Matan," from the territorial title of the Rajah to whom it belongs, has been estimated to be worth £269,378 (Crawfurd). The Dutch made very large offers of money and warlike material for it early in the present century, but these were always refused. The stone, it now appears, was examined in 1868, and proved to be only a rock crystal with a specific gravity of 2·63, thus confirming doubts perviously expressed as to its being really a diamond.

Platinum is of very local occurrence in Tanah Laut only.

Antimony and quicksilver only occur, so far as is known, in sufficient quantities to be regularly mined in Sarawak.

Iron ores are widely distributed, but are of no present economic value. The introduction of cheap European iron has put an end to the native iron industry, as is the case, too, in many parts of India.

Dr. Posewitz states that the condition of mining industries generally in Borneo is at present very poor. In the south, private coal-mines existed, but were put an end to by an insurrection. The well-known Government mines at Pengaron ceased working after thirty-six years' existence, as they were no longer remunerative. A private company has now commenced to work valuable mines on the east coast. In Sarawak, mines have been worked by the Government since 1881, and in 1886 produced 44,167 tons. In Labuan, mines were also worked for some time, but are now closed. The principal source of supply at present is from Brunei (Muara coal). It is hoped that in the British North Borneo Company's territory extensive workings of gold and coal will be established.

It is impossible to give here an adequate idea of the careful details with which each topic discussed in this work is illustrated. At the same time there is a highly meritorious conciseness of treatment which, together with the soundness of the author's views and his careful quotation of his authorities, makes the work a text-book for which it is to be hoped that a competent translator into English and an enterprising publisher will be found. It is emphatically a work which was much wanted, as our knowledge of the geology of this important island has hitherto been most fragmentary and imperfect, and we trust, therefore, that, ere long, steps may be taken to make Dr. Posewitz's labours better known to English readers. V. B.

GRAPHICS.

Graphics; or, the Art of Calculation by drawing Lines, applied especially to Mechanical Engineering. With an Atlas of Diagrams. By Robert H. Smith, Professor of Engineering, Mason College, Birmingham. Part I. (London: Longmans, Green, and Co., 1889.)

MAXWELL was the first, according to the Introduction of the present treatise, to state the principles in a very complete and general manner by which stress-diagrams are drawn, in the *Phil. Mag.*, xxvii., 1864; and also in the Trans. Roy. Soc. Edinburgh, vol. xxvi.

But Maxwell himself is careful to point out that he derived the original idea from Mr. W. P. Taylor, or at least was unaware of his previous use of the method.

The method is of much greater antiquity, and can be traced through Moseley's "Mechanical Principles of Engineering and Architecture," 1843, to Hutton's "Course of Mathematics," 1811, and probably still further back.

It is, however, only of recent years that Maxwell's treatment has been followed up and developed by Cremona, Culmann, von Ott, and others; and now the method is considered indispensable in practice for the calculation of the stresses in bridges, roofs, and engineering and architectural structures generally.

Two great advantages of the graphic method recommend it to the practical man—the first, that the diagram is itself a check upon the correctness of its construction; and the second, that the numerical results of the diagram are read off on a scale only to the really practically significant number of figures, the very roughness and imperfection of the draughtsman's work showing the margin of variation to be allowed for.

As to the relative rapidity of the graphic method compared with ordinary numerical calculation by logarithms and arithmetical processes, the author points out that, while for a single isolated calculation the graphic method may easily be distanced, it is in the long-continued series of operations of the same character required by the engineer, shipbuilder, or constructor in general, that the graphic method takes the lead once the calculator has got his mental operations thought out, and his instruments in good order; for which purpose Chapter I., on instruments, gives valuable hints and information.

Chapter II. explains succinctly the plan of the book in its applications to graph-arithmetic, Chapter III.; graph-algebra, Chapter IV.; grapho-trigonometry and mensuration, Chapter V., &c., and lastly, grapho-dynamics, experimental and mathematical tabulation.

It is in the later chapters that the full power of the graphic method is developed, but in the earlier chapters the student is exercised by well-chosen practical examples in the mental operations and manipulation required in the advanced processes. The student of ordinary mathematical processes will find here graphic solutions of geometrical loci, and the solution of quadratic, cubic, and other algebraical and trigonometrical equations, illustrated by carefully-drawn diagrams in the atlas of plates. But the author appears to underrate the value of the planimeter on p. 63, in its application to the evaluation of the irregular areas encountered in indicator diagrams, shipbuilding, and railway engineering.

In Chrystal's "Algebra," the importance of the graphic solution in integers of the loci represented by indeterminate equations of the first and second degree is pointed out; and in the present work the graphic solution of the general quadratic and cubic equations by means of a carefully-drawn curve, $y = \frac{x^2}{10}$, or $y = \frac{x^3}{100}$, and its intersections with a straight line, is also developed, and illustrated in the Atlas of Diagrams.

The logarithmic curve, $y = e^x$, or 10^x, would also be useful for the graphic solution of transcendental equations of the form—

$$Aa^x + Dx + F = 0,$$

required in the problem of the hydraulic buffer.

Again, in trigonometry, the solution of the equation—

$$a \cos \theta + b \sin \theta = c,$$

or the summations $\Sigma \cos (a + n\beta)$ or $\Sigma' \sin (a + n\beta)$ by a graphical method, or drawing Lissajous's figures graphically, would tend to impart freshness to a subject at present running in a narrow dry rut. Paper ruled into small squares of centimetres and millimetres, suitable for graphic methods, can be obtained in Germany, of Carl Schleicher and Schüll in Düren, for instance.

It is curious to notice that the fresh and original ideas and treatment of elementary mathemathical subjects due to Maxwell and Clifford are to be found embodied and adopted only in practical and technical treatises, such as the present work. Elementary mathematical treatises are in danger of becoming as dry and orthodox as a religious creed: examiners, on the one hand, are forbidden to set ideas out of the groove of a few antiquated text-books; and examinees, on the other hand, dare not allow themselves to learn new ideas and methods, for fear of finding themselves at a disadvantage with old-fashioned examiners.

Some reflections on p. 181 of the present work on the radiant-energy-carrying ether show, however, that the author allows himself occasionally to indulge in the purely abstract speculations dear to Sir W. Thomson and Mr. Macfarlane Gray.

Chapter IX., on the "Kinematics of Mechanisms," covers much the same ground as Kennedy's "Mechanics of Machinery," and follows Reauleaux's treatment in his "Kinematik." Chapter X., on "Static Structures, Frames, or Linkages," and Chapter XI., on "Flat Static Structures, containing Beam-Links," contain the applications of the graphic method to problems most commonly encountered by the practical designer.

The consideration of "Solid Static Structures" in Chapter XII. follows very usefully as a check upon the *in plano* treatment of the subject in the two preceding chapters. The failure of many very scientifically-designed bridges in America has shown that it is not sufficient to treat the beam in elevation only, as if it was a vertical plane structure; but that the torsional rigidity is of importance whenever the load is applied in the least degree eccentrically.

A glossary of special terms and symbols is inserted at the beginning, containing without redundancy the new terminology useful in this subject; and an index completes the work, in which we should like to have seen a complete list of books in English bearing on this and kindred subjects, such as Cotterill's "Applied Mechanics,' Eagles's "Constructive Geometry," Clarke's "Graphic Statics," Wormell's "Plotting, or Graphic Arithmetic"; also McLay's articles on "Geometrical Drawing," now appearing in the *Practical Engineer.*

The author promises a second part dealing with "The Distribution of Stress and Strain," "The Strength, Stiffness, and Design of Beams and Struts," "Economy of Weight in Structures," "Stresses in Redundant Structures," "Statics and Dynamics of Machines," "Frictional Efficiency," "Governors and Fly-wheels," "Valve Gears," "Practical Thermodynamics of Furnaces, Boilers, and Engines," "Hydrostatics and Hydrokinetics of Ships and Hydraulic Machines"—all subjects of great practical and theoretical interest, to which we shall look forward with much pleasure. A. G. GREENHILL.

THE CHEMICAL ANALYSIS OF IRON.

The Chemical Analysis of Iron. By Andrew Alexander Blair. (London: Whittaker and Co. Philadelphia: J. B. Lippincott, 1888.)

OF all the branches of quantitative analysis practised for the control of industrial processes, none is of greater importance than that which concerns iron. The precise relationship of chemical composition to mechanical properties is by no means fully ascertained; but a great deal of excellent work has been done in this direction, and we know in several cases the kind of variation in physical properties which is, *cæteris paribus*, to be expected to accompany a variation in the quantity of one constituent. We know, moreover, how extraordinarily great this physical change may be, compared with the change in composition. When we reflect that a quantity, which in most other technical analyses is within the error of experiment, may become the criterion by which an iron is appraised, we must recognize the necessity of accurate methods of analysis for this particular commodity.

The present work is stated to be a "complete account of all the best known methods for the analysis of iron, steel, pig-iron, iron-ore, limestone, slag, clay, sand, coal, coke, and furnace and producer gases," and we may say at once that the book realizes its title in a very admirable way.

The author brings high credentials to his task, having—as chief chemist to the United States Board, appointed to test iron, steel, and other metals in 1875, and as chief chemist to the United States Geological Survey and tenth census 1880—devoted many years to the subject. He records, he says, the results of his own experience, and there is a personal flavour about the work such as is too seldom found in modern hand-books. One feels in reading the descriptions of apparatus, processes, and precautions, that they are not merely what the author has collated, but what he has seen and done and learned. There are many novel arrangements of apparatus described, many improvements of detail in various analytical processes, and altogether the subject is handled in a thoroughly authoritative and practical manner.

The most striking thing, however, is the elaborateness and refinement insisted upon in the performance of the more important operations. There is no attempt to compromise unwisely between accuracy and rapidity—these two *desiderata* are treated separately. Thus there is a method described for determining silicon with elaborate precautions by volatilization in a current of chlorine, and another in which the amount of silicon in a pig-iron can be determined in twelve minutes from the time the ladle is put into the molten iron.

The book begins with a description of apparatus and manipulation required for sampling, and subsequent analytical operations. This portion of the work will no doubt be found useful—but we regard it as sufficient rather than exhaustive. We can scarcely say as much of the following 20 pages, devoted to reagents. There seems to be some uncertainty as to the chemical knowledge expected from the operator. The information about chlorine that it is a yellowish gas, about two and a half times heavier than air, sparingly soluble in water, and the somewhat obvious truth which completes this description, that "when required it must be made," will probably fall flat upon a person who a few lines further on is expected to know that chromic acid should not be dried by filter-paper. And again, if one is to be told the equations which represent the preparation of ammonium sulphide, why should not one be told *why* it "becomes yellow by age, or on exposure to air"? We think this portion needs revision; superfluous information should be removed, and the descriptions should be made more complete. We think also that it would be much to the benefit of the very large number of half-informed persons engaged in the routine analysis of iron, if the theory of the analytical process were described always at the beginning of a chapter instead of being interspersed (and then often imperfectly) with the details of operations. In these respects Mr. Blair's work might be improved, but in the main features there is no fault either of omission or commission. The book is beautifully printed, is supplied with full marginal notes and luxurious woodcuts, and is altogether a much more presentable volume than the British analyst is accustomed to have about him. We have no doubt it will be very cordially welcomed in the numerous iron and steel works laboratories of this country.

OUR BOOK SHELF.

Agricultural Canada: a Record of Progress. By W. Fream, B.Sc., LL.D., &c. (1889.)

LAST year, Dr. Fream, as Commissioner of the Canadian Government, visited Canada, for the purpose of reporting upon the position and prospects of agriculture in the Dominion, and his Report has now been published under the direction of the Government of Canada. The author, who was well fitted for the task by his previous knowledge of Canada, appears to have visited every province in the Dominion, from Nova Scotia on the Atlantic seaboard to British Columbia on the Pacific. Numerous details concerning the climate, and the geological, botanical, and other natural features of the northern half of the North American continent, are interwoven with the more prosaic facts bearing upon the agricultural development of an area as large as that of Europe. Some parts of the Dominion, little known even in Canada, are dealt with in special detail. The fine rolling prairie occupying North-Western Manitoba, and stretching away through Assiniboia to the banks of the North Saskatchewan River, is selected for favourable notice, but this region has at present to be explored on horseback or on a "buckboard." Far away to the west, in Alberta, there appears to be another fertile and beautiful region awaiting development, in the Rosebud country, which includes the Red Deer Valley. The attempt to unravel the complicated surface features between the Rocky Mountains and the Pacific deserves notice, and some reference is made to the little-known Kootenay district. The Commissioner extended his travels across an arm of the Pacific to Vancouver Island, the southern point of which is capable of considerable agricultural development. To the production of cattle, horses, grain, cheese, and fruit, the agricultural energies of the Dominion are chiefly directed, and the Report strongly urges the Government not to moderate one iota the stringency of the quarantine regulations, whereby alone Canadian cattle are kept free from contagious disease. The Report, as a whole, might advantageously take the place of nine-tenths of the school-books which profess to deal with Canada.

Longmans' School Arithmetic. By F. E. Marshall, M.A., and J. W. Welsford, M.A. (London: Longmans, 1889.)

THIS work owes much of its value to its being drawn up on the lines laid down by De Morgan. This is shown by the importance attached by the authors to computation in the early part of the work, and by the copious use of diagrams in the chapters devoted to vulgar fractions. A moving cause to such a casting of the book is the importance which has been attached to De Morgan's methods in the recently issued report of the Arithmetic Committee of the Association for the Improvement of Geometrical Teaching. With such an admirer of the Professor as the late President of the Association is, on the said Committee, we should expect such a result. Much space is devoted to oral exercises; this being so will account, in a measure, for the written explanations not being quite so full as we have seen them in other text-books. The treatment of recurring decimal fractions is thorough, the unitary method is employed in the solution of examples, and considerable care has been expended upon the commercial arithmetic. A large body of exercises is furnished in the text for solution, and very many specimens of examination papers as well as papers of miscellaneous exercises come at the end. There are a few small matters, in an appendix and elsewhere, which call for more careful and precise statement, but on the whole the work is calculated to be useful, and we can recommend it for school use.

Glimpses of Feverland: or, A Cruise in West African Waters. By Archer P. Crouch, B.A. Oxon. (London: Sampson Low, 1889.)

IN this volume Mr. Crouch presents a record of the impressions made upon him by the land and people of certain portions of West Africa, which he visited in connection with the laying of a cable to put various places, principally French and Portuguese, in telegraphic communication with Europe. A large part of the book is devoted to an account of what he saw during his passage from Accra, on the Gold Coast, to the Portuguese island of St. Thomé. Afterwards we have a full description of St. Thomé and St. Paul de Loanda, and in several concluding chapters the author sums up the incidents of his voyage homewards. Mr. Crouch is so good an observer, and has so frank and lively a style, that his narrative, taken as a whole, is fresh and interesting, although his subject is often, apart from his treatment of it, dreary enough. He is particularly successful in those passages in which he seeks to give his readers glimpses of native customs and superstitions. It is worthy of note that he has formed a very unfavourable judgment as to the intellectual and moral qualities of the Negro race; but on this question, with regard to which he differs widely from Mr. Stanley, he perhaps speaks rather more positively than the extent of his experience warrants.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Meteoritic Theory.

I HAVE during the past six months been led from the study of our own atmosphere to consider certain phenomena relating on the one hand to the solar *atmo-physics*, and on the other hand to the evolution of our own globe and its atmosphere. There has thus arisen in my mind a system of cosmogony which has led me, quite independent of Mr. Norman Lockyer's published course of reasoning, back to a meteoric theory that will, I hope, be acceptable to yourself and others. Awaiting the preparation of these views for publication, I have had occasion to look over the report on the total eclipse of the sun, July 1878 (Professional Papers of the Signal Service, No. 1, Washington, 1881). I quote from pp. 49 and 50 some paragraphs to show the connection between views then held and those at which I have recently arrived.

Washington, April 29. CLEVELAND ABBE.

"Under these circumstances, I could but regard the suggestion that occurred to me on July 29 as a slight but important extension and modification of the views previously held. . . . It amounted to saying that a large part of the phenomena of the outer corona is essentially non-solar, having to do with cold meteoric matter that is beyond the solar gaseous atmosphere and is shining by reflected light, . . . rushing on its way to plunge into the sun's atmosphere, where, within a few hours, it would be dissipated. . . . That these beams were due to wholly new meteor streams . . . now for the first time approaching the sun. . . . I am now inclined to extend this view to very many of the radiating dark and bright lines observed during eclipses, and would explain most of them as due to brightly illuminated groups and streams of meteors and to large meteors followed by trains. . . . Those meteors that enter the solar atmosphere and become incandescent will of course shine with a greatly increased splendour, and thus constitute a portion of the inner corona; these thus show us the limit of the gaseous atmosphere of the sun. . . . The extreme limit may be located at a distance of five minutes (of arc) above the sun's surface, and is very likely to be less than this. . . . Meteors glow as shooting-stars when they strike our atmosphere with a relative velocity of from twenty to forty miles per second, and at an altitude of about one hundred miles, where the density of the atmosphere may be about 3×10^{-9} times that which prevails at the surface. Now these same meteors will, when they have approached to within 130,000 miles of the sun's surface, have a momentum at least a hundred times greater than that with which they enter the outer limit of the earth's atmosphere; therefore we are allowed to assume the density of the outer limit of the supposed solar atmosphere to be but the hundredth part of that of the earth, or 3×10^{-11}; this gives us for the base of the solar atmosphere a density and a pressure quite within plausible bounds."

The Structure and Distribution of Coral Reefs.

THOSE who have read the additional appendix in the edition just published of Mr. Darwin's work on coral reefs will doubtless have observed that whilst the recent evidence there produced against the theory of subsidence lies chiefly in observations on living reefs in the Florida seas, in the Western Pacific, and in the Indian Ocean, the new testimony advanced on behalf of the theory is in the main indirect in bearing, and is based on assumptions that have yet to be proved.

Referring to the latter evidence in the order of mention, I come first to the 90-fathom reef off Socotra, a reef that is assumed to have been lowered by a movement of subsidence into its present position. So defective is our knowledge of the depths at which coral reefs may grow, and so incomplete is our acquaintance with the complex agencies that combine to produce a coral reef or to limit and prevent its growth, that the inference respecting the depth of the Socotra reef may be truly characterized as based on an unproved assumption. At present our acquaintance with the fauna of the submarine slopes of tropical islands in the Indian and Pacific Oceans, between the depths of 20 and 100 fathoms, is of the scantiest description; and we are not in a position to hazard even a guess on the subject, much less to assume that an island like Socotra has experienced a movement of subsidence because it possesses a reef "submerged in some places to a depth of over 90 fathoms." It is owing to our ignorance of the fauna in these depths that it has not been possible to identify the great numbers of minute molluscan shells, which occurred in the upraised post-Tertiary muds discovered by me in the Solomon Islands; and it is of the lack of such knowledge that Prof. K. Martin in his recent great work on the Tertiary formations of Java naturally complains. Surely, when the biologist is fain to acknowledge his want of acquaintance with the matter, and when as a consequence the palæontologist and the geologist have to bring their labours to a standstill from the lack of comparative material, it seems rather dangerous for the coral reef speculator to assume what has never been properly examined.

If, therefore, we have yet to determine the limit of depth of the growth of coral reefs, we are scarcely in a position to advance as evidence in behalf of subsidence the thickness of certain upraised beds of coral limestone in the West Indies and in the Sandwich Islands. Even if such evidence should be ascertained to be valid in itself, it must be remembered that Mr. Murray in his theory places no limit to the possible thickness of coral reefs, and that in the outward growth of a reef a considerable thickness may be produced. There was, in truth, no circumstance more impressed on my mind in the Cocos-Keeling Islands than the seaward extension of coral reefs.

Once more, however, I would impress on future investigators the extent of our ignorance of the depths in which coral reefs may form. In one of my papers (Proc. Roy. Soc. Edin., 1885-86, p. 887) I have pointed out that the estimates of observers in different regions vary between 5 and 40 fathoms. It is also singular how different observers may vary in the conclusions they draw from the same lines of soundings. The soundings off Keeling Atoll were made by Captain Fitzroy himself, and he places the limit of depth at 7 fathoms ("Voy. *Adventure* and *Beagle*," ii. 634); whilst his companion, Mr. Darwin, judging from the same soundings, concluded that it lay between 12 and 20 fathoms. In truth, as long since pointed out by Prof. Semper, the whole question of the depth of the reef-coral zone has never been methodically investigated. It never occurred to Mr. Darwin or Prof. Dana that coral reefs might grow in depths *beyond the belt of sand that apparently limited their growth.* Yet such I found to be actually the case on the slopes of Keeling Atoll, where Captain Fitzroy's soundings were taken. Few, in fact, who have read the work of the young naturalist of the *Beagle*, can sufficiently realize how scanty were the data on which the fundamental inference of the theory of subsidence was based; and I may safely add that few must be the scientific questions that have been settled on a scantier basis of observation than that relating to the depths at which reef-corals grow.

With regard to the sections exhibiting the submarine profile of the reef of Masámarhu Island, I was first at a loss to understand why their character should be advanced as favouring the idea of a movement of subsidence, since, when they first appeared in NATURE (vol. xxxvi. p. 413), I regarded them as favouring Mr. Murray's views. However, it soon appeared that this opinion was based on our inextensive acquaintance with the habits of corals, especially with the limiting causes of their extension in depth. The "ditches" shown in these sections I look upon as indicating the formation of barrier-reefs at considerable depths, and as giving remarkable support to my views on the origin of these reefs. In the paper above quoted I have been led by the observations of Agassiz in the Florida seas, and by my own in the Solomon Islands, to the conclusion that the main determining condition of the depth in which reef-corals thrive is to be found in the injurious effect on coral growth of the sand and sediment produced by the breakers, and that the distribution of these materials is dependent on the angle of the seaward submarine slope and on other less important circumstances.

It follows from this that in those localities where the submarine slope is moderate, a barrier-reef will form beyond the belt of detritus derived from the shore-reef inside it. But when the slope is fairly steep, as in the case of Keeling Atoll, the reef *débris* will cover an area of much less horizontal extent, and, as at these islands, an off-lying line of coral shoals will spring up at a distance only of 150 or 200 yards from the inner reef. Should, however, the slope be precipitous, as at Masámarhu Island, the reef *débris* will extend to considerable depths; and beyond the area thus covered with sand and gravel, a line of reef will in the course of time grow upwards, giving rise to the so-called "ditches" of the sections.

Reefs of all classes, as I hold, have a two-fold mode of growth seawards. There is first the advancement of the outer edge of a reef on its own talus, as dwelt upon by Mr. Murray. In the second place, they grow seaward by a reclaiming process, whether they be fringing, barrier, or circular reefs. The distribution of the sand and *débris*, guided by the angle of the submarine slope, determines, as above shown, this second mode of growth, which may result, as at Keeling Atoll, in a line of adjacent coral banks that ultimately reclaim a new strip and add it to the width of the reef, or a more distant barrier reef may appear at the surface, the lagoon of which silts up and is choked with coral in the course of ages, or, as at Masámarhu Island, there may occur a deeply-submerged barrier-reef that can be discovered only by methodical soundings.

Let us take the instance of Keeling Atoll to illustrate the present condition of this controversy. In a series of papers on this celebrated atoll, that I am preparing for the Royal Scottish Geographical Society, I have shown that the direct evidence of subsidence adduced in its case by Mr. Darwin is, according to Mr. G. C. Ross, its present proprietor, founded in error. In truth, Mr. H. O. Forbes, during his visit in 1878, observed evidence leading in his opinion towards a movement of upheaval. In default, then, of direct evidence, we have to look for the indirect proofs to certain *a priori* considerations, based on a few soundings that appeared to demonstrate once and for all the limit of depth of the reef-coral zone, a subject concerning which we still have very incomplete data. Then we are transported across the Indian Ocean to the 90-fathom reef of Socotra, the origin of which, for the reason just stated, is hidden in mystery. Afterwards, appeal is made to the thickness of reef limestones in Cuba and in the Sandwich Islands, limestones which, it is alleged, could only have been formed during subsidence, notwithstanding that their exact nature has not yet been determined, and in spite of the circumstance that reefs can attain a considerable thickness, as Mr. Murray rightly holds, solely by their outward growth.

If a visitor from another planet, having thus far followed the discussion, were to inquire in an apologetic manner whether, instead of going to the other hemisphere for evidence we had methodically endeavoured to investigate the problem on the spot, by patiently studying the complex agencies at work on this atoll, by carefully inquiring into the changes of the past, and by interpreting through their aid the processes of the present, we should be obliged to answer: "Scarcely at all. A theory advanced on the very threshold of such an investigation explained so well our limited knowledge by a movement of subsidence, that it is only of late years that doubts have arisen and that a new theory has been advanced opening up the lines of research to which you refer."

H. B. GUPPY.

"Bambangala."

I SHALL be glad if you will allow me to call the attention of those who visit the Congo Free State to the curious antelope called "*Bambangala*," which is spoken of by Captain Bateman in his "The First Ascent of the Kasai," lately published by Messrs. George Philip and Son. Captain Bateman describes it as being "in size as large as a mule; of a bright chestnut colour, striped with creamy white, much in the manner of a zebra, on the back and sides, and dappled on the neck and flanks."

From the form of the horns shown in the figure (which, by the kind permission of Messrs. George Philip and Son, is here reproduced from Captain Bateman's book), it would appear that this antelope must belong to the genus *Tragelaphus*, but probably to a new species.

I should be very glad to examine specimens of the head and horns of this antelope, in case any of your correspondents in the Congo should meet with it, or to have some further information on the subject from those who have visited that region.

Inclusion of the Foot in the Abdominal Cavity of a Duckling.

A DUCKLING, four days old, sent from Eastry in Kent, hatched on April 25, 1889, presented the above curious abnormality. The right lower extremity was normal in every respect; the left appeared on superficial examination to be absent. An incision made through the skin over the left flank at once disclosed the left limb, the joints being flexed to their utmost extent, and the thigh adducted, so that it lay in contact with the abdominal muscles of the left side; at the tibio-tarsal joint the limb passed through the wall of the abdomen, a few millimetres above the symphysis pubis. A portion of the yolk-sac protruded at the aperture by which the foot penetrated the abdominal wall. Opening the abdomen showed the remainder of the yolk-sac, its connection with the ileum, and the left foot lying upon the surface of the intestines. This included foot was fully developed, having a complete web, and being covered with scales. An adhesion existed between the outer surface of the yolk-sac and the left leg in the region of its tibio-tarsal joint, and there were also adhesions of the sac to the skin of the abdomen, covering the lower part of the tibial muscles. This adhesion of the yolk-sac to the leg had apparently taken place after the full development of the limb; and the yolk-sac, in the course of its withdrawal into the cavity of the abdomen, had apparently drawn the foot in with it. The withdrawal of the yolk-sac is generally held to be brought about by the absorption of its contents; if the above explanation of the existing condition be correct, a considerable force must be exerted by this act of absorption if it is capable of dragging the foot, from its normal position, into the cavity of the abdomen.

Atmospheric Electricity.

I SEND you the following account of a curious, and, I believe, rare electrical phenomenon witnessed last week by a friend of mine and myself.

We had, in the course of a long mountain ramble, reached the summit of Elidyr Fawr (3033 feet), a mountain lying to the north-east of Llanberis, and about four miles north of Snowdon. Being a short distance in front of my friend, I sat down and rested with my back to the cairn, sheltering myself from a cold south wind which was blowing with considerable velocity. In about two minutes I heard a curious buzzing sound commence, apparently proceeding from the top of the post set up not long ago by the Ordnance surveyors. I had heard the same noise about three years ago while descending the *arête* of the Weisshorn, and on that occasion, as on this, there was a south wind blowing, accompanied by snow—on the Weisshorn in large flakes, on Elidyr Fawr in fine powdery flakes. On the Weisshorn, for above an hour every rock seemed to emit the peculiar buzzing noise, and our ice-axes did the same. We were in too great a hurry, however, to pay much attention to the phenomenon. A day or two after, I related my experience to a gentleman, Mr. Powell—who, I trust, will forgive me for mentioning his name—and learned from him that he had had a similar experience on the Unter-Gabelhorn, near Zermatt. The day was on that occasion, if I remember right, clear, when the noise was heard, followed in a short time by a flash, and a shout from two of the party that they were struck. No harm was done by the shock, but the sensation was described as being like that which would be felt if every hair of the head were caught hold of and violently twisted. Having heard the sound before, I readily recognized it on Elidyr Fawr, and resolved if possible to study the phenomenon more closely. I first climbed on to the cairn, and found that the sound proceeded from the whole surface of the wood for about two feet from the top of the post. I then raised my stick, which had an iron point, and found that the sound began to proceed from it directly a height of about six feet from the ground was reached. I then put my hand on the part emitting the sound, but could feel nothing. On putting my stick down, and keeping my hand up, the sound proceeded from my hand—from more or less of it according as I raised it higher or lower—and I imagined that on the back of my hand the sensation of being very slightly pricked in many places was perceptible. My friend was much impressed by the peculiarity and intensity of the sound, and agreed with me that it would not be wise to stay long. As we proceeded along the ridge, after a slight drop, we rose again, and while standing on some rocks, the noise began in our caps, accompanied by such an agitation of the hair that it quite seemed as if we had literally a "bee in the bonnet." There was no sound of thunder, and in the course of about half an hour the snow-storm passed away, not however before we had descended far below the enchanted summit.

Halo of the Moon and Formation of Peculiarly Shaped Clouds at Oxford.

I NOTICED the following very beautiful phenomenon on the night following May 8, and it seems to me worth recording. At 9.45 p.m. the moon was surrounded by a very large halo, the sky being quite clear in the immediate vicinity of the same, with the exception of a small accumulation of clouds at the lower part of the halo (to the left of the spectator).

At 10.45 the halo had completely disappeared, and a large cloud was obscuring it and the moon. The margin of the cloud was split up into tongue-like protuberances. At 11.20 the halo had again appeared, but it was not so bright; the moon was hidden from the spectator by some clouds.

At 11.30 the clouds had disappeared, and the moon was shining out brightly, but the halo was only very slightly visible, and that only at its highest point. Just before it began to disappear gradually, some of the clouds with the peculiar tongue-like protuberances already mentioned were formed, but they disappeared again after a few minutes. As was to be expected, we had rain on the following day, and some already during the same night.

I need only just mention that the halo is supposed to be produced by the refraction of light by crystals of ice. Brewster proved this by viewing the sun through some plate-glass on which he had allowed some alum to crystallize out in a thin sheet, when he saw a number of rings closely resembling halos.

Spherical Eggs.

THE problem of packing the greatest number of equal spheres into a given space, to which Prof. Aldis has drawn attention in your columns, is the simplest case of a more general problem which I have employed in my theory of crystallization (Cam. Phil. Trans., vol. xiv. part 3)—that is, the packing of the greatest number of equal and similar ellipsoids into a given space. The solution is that the ellipsoids should be arranged in a manner similar to that described for spheres by Profs. Aldis and Greenhill, so that every ellipsoid be touched by twelve others, and, further, that all the ellipsoids be similarly situated. The curious result comes out that so long as the ellipsoids are all similarly situated the orientation of the axes makes no difference in the number of them per unit volume. They may be turned about, provided they are all similarly turned, without affecting the ratio between the space filled by them and the unfilled space between them.

In the case of spheres, if tangent planes be drawn through all the points where the spheres touch one another, they will cut up space into regular rhombic dodecahedrons, every sphere being circumscribed by such a dodecahedron. Now, of plane-faced figures which can be described about a sphere and which will exactly fill space, the smallest in volume is the rhombic dodecahedron; hence the spheres arranged in the way described occupy the minimum volume. In like manner if tangent planes be drawn through all the points where the ellipsoids touch one another, they will divide space into dodecahedrons with quadrilateral faces, which will be unsymmetrical, but will be all similar and equal. If the ellipsoids be all turned in a similar manner the dodecahedrons will alter in form but not in volume. These dodecahedrons are the smallest which can be described about the ellipsoids consistently with the condition that they shall exactly fill space. The condition of similarity in the situation of the ellipsoids involves the consequence that, if we consider one ellipsoid and the twelve others which touch it, four planes can be drawn each passing through the centres of seven ellipsoids. The points of contact of the ellipsoids will lie in those planes, and the tangent planes through these points will be parallel to the diameters conjugate to those planes. Other geometrical properties follow which do not concern the present problem.

Cambridge, May 10. G. D. LIVEING.

Columnar Structure in Ice.

THERE are several notices in existence on the subject of the columnar structure of ice, to which attention has been called by Mr. La Touche (NATURE, May 9, p. 35). For instance, a letter by myself in the first volume of NATURE (p. 481), which contains references to sundry cases of the occurrence of the structure in Britain and in other parts of Europe, and offers a suggestion as to the cause. The structure may often be seen, if looked for, and is be t exhibited when a very gradual thaw follows a hard frost.

T. G. BONNEY.

SCARLET FEVER AND COW DISEASE.

FEW questions have within recent years more engrossed the attention of the veterinary and medical professions of this country, and have been the subject of greater or more acute controversy, than the relation of human scarlet fever to cow disease. As is well known, the Medical Department of the Local Government Board, through the Reports of Mr. Power, Dr. Cameron, and Dr. Klein (1886), have brought forward a formidable array of facts, by which it was established that, in an epidemic of scarlet fever prevailing towards the end of 1885 in the north of London, the contagium was distributed through a milk supply derived from particular milch cows at a dairy farm at Hendon, which cows were affected with a specific eruptive and visceral disease—the Hendon disease. It was further shown (Report of the Medical Officer of the Local Government Board, 1887) that this cow disease is to be considered as cow scarlatina, and that both human and cow scarlatina are associated with and caused by a microbe, the *Streptococcus scarlatinæ*.

The veterinary profession, headed by the Agricultural Department of the Privy Council, have been foremost in the opposition to these statements. In the Report "On Eruptive Diseases of the Teats and Udders of Cows," issued towards the end of 1888 by Prof. Brown, the chief of the Agricultural Department, a superabundance of opinions were forthcoming, and, as often happens under the circumstances, fact has appeared for a while in danger of being smothered in the confusion engendered. But, happily, facts are stubborn things, and not easily stifled. However much trampled on, facts are ever prone to reassert themselves and to multiply, and one result of the cow controversy has been that the recently issued Report of the Medical Officer of the Local Government Board gives promise of a new and abundant crop of them. The first subject bearing on this controversy and dealt with in the recent volume is the significance of the *Streptococcus scarlatinæ*. Many and various have been the assertions as to this microbe being an unessential concomitant of the disease. The experiments now made by Dr. Klein (Appendix B, No. 1, Section A.), with artificial cultures of the *Streptococcus scarlatinæ* on recently-calved milch cows, show that an eruptive and visceral disease is produced in these cows which closely resembles the Hendon disease, and consequently lend firm support to the view previously enunciated by the Medical Department that the *Streptococcus scarlatinæ* is the real microbe of scarlet fever.

Amongst a further array of facts therein marshalled, some that are historical obtain, in view of the cow controversy, fresh interest and importance. It is pointed out (Section B.) that, before the time of Jenner, "cow-pox" was the familiar name given to every sort of sore on cows' teats; that, with recognition by Jenner of a form of sore denominated by him *variolæ vaccinæ*, one particular cow-pox obtained the distinctive name of "true," while all others became designated as "spurious"; and that, except for Ceely's notable endeavours to obtain better knowledge, "spurious cow-pox," blister-pock, and the like vague terms continued to be used indifferently for all sores on the teats and udders that were not "true cow-pox." So the matter stood for eighty years, until at the Hendon farm a second definite member of this group was recognized by Mr. Power, when the old division into true and spurious cow-pox became manifestly insufficient. It was now seen that the name "spurious cow-pox" had in all probability been used to cover a variety of sores having essential differences in nature, just as, until the time of Jenner, the name "cow-pock" had covered along with various other things the disease which we know as vaccinia. But it is one thing to have learnt the essential nature of those sores of the cow that are concerned with vaccinia or scarlatina in the human subject, and quite another thing to affirm the distinguishing characters by which these may be recognized from other sores that once on a time laid claim to being equally with them "cow-pox" or "spurious cow-pox." It is very obvious, too, that our new discontent with the name "spurious cow-pox" does not at once give us knowledge of those sores which remain on the list, while it is equally clear that there are many kinds of such sores.

In these circumstances there was nothing to be done but to begin over again the study of cow-poxes with a view to learning of each one its complete natural history. And this has been the procedure of the Medical Department, with the result that a considerable instalment of positive knowledge respecting certain cow eruptions is afforded in the Report already referred to. When it is said that there was no alternative procedure to that adopted by the Medical Department, no more is meant than that from the scientific stand-point no alternative was possible. Other ways there were, of course, of dealing with the subject, as, for instance, in its "practical" or trade aspects, or from the sentimental point of view. That adopted by the Veterinary Department of the Privy Council is not easy of definition, but it may be described as a method of composite character by which uncertain science and excess of sentiment are oddly interjumbled.

It has consisted in flat denial of the possibility of cow scarlatina, along with reversion in the matter of cow-poxes to the attitude of the cow-man of pre-Jennerian days. Thus Prof. Brown, in the earlier pages of his Report in denial of cow scarlatina, speaks indifferently of "eruptive disease among cows," "udder disease among cows," "outbreaks of udder disease common as usual," "a very common eruptive affection which is usually called cow-pox by dairymen," and the like. And throughout his Report Prof. Brown studiously avoids giving a name to any udder disease or diseases with which he is dealing. Only once does his reader, when referred to Plate 4, at the end of Prof. Brown's volume, obtain hope of some definite nomenclature; but he turns to the plate in question only to be confronted with such terms as "blister-pock" and "blue-pock"—terms of the pre-Jennerian prototype. Having thus smoothed the way for discovery of a cow-pox (or "Hendon disease") not associated with scarlatina among consumers of the milk of the affected animals, Prof. Brown would seem to exercise almost superfluous caution in his phrasing of the following passage at p. vii. of his Report:—"Leaving for the present the subject of the original Hendon cow disease in 1885–86, it is necessary to refer to outbreaks of the same *or similar*[1] cow disease which occurred at Hendon and elsewhere in 1887–88." Be this as it may, he had of course no difficulty whatever in finding instances of one or another cow malady, which it pleased him to call "Hendon disease," not associated with scarlatina among persons consuming the implicated milk. This sufficed for Prof. Brown, and for a while, perhaps, he was altogether content.

But Prof. Brown's confidence in his own opinion, fortified as it had been by his failure in the early stage of his investigation to find any udder affection associated with illness of scarlatinal sort among consumers of the milk of the affected cows, was destined later on to receive somewhat rude shocks. Prof. McFadyean, a coadjutor of Prof. Brown's, having made discovery at Edinburgh of an udder malady associated with sore throat among persons consuming the milk of the cows affected by it, Prof. Brown, on personal examination of the Edinburgh cows, was constrained to admit for this disease clinical characters distinguishing it from any that he himself had been investigating, and pathological features very similar to those of the original Hendon disease.

Of this Edinburgh disease (the pathology and ætiology of which are described by Dr. Klein in Appendix B., No. 2) Prof. McFadyean notes that it "differed in every important respect from true cow-pox," and that (like the Hendon disease) "it did not cause sores on the hands of the milkers." Here, then, on the evidence of the Veterinary Department, was a cow malady that was not cow-pox,

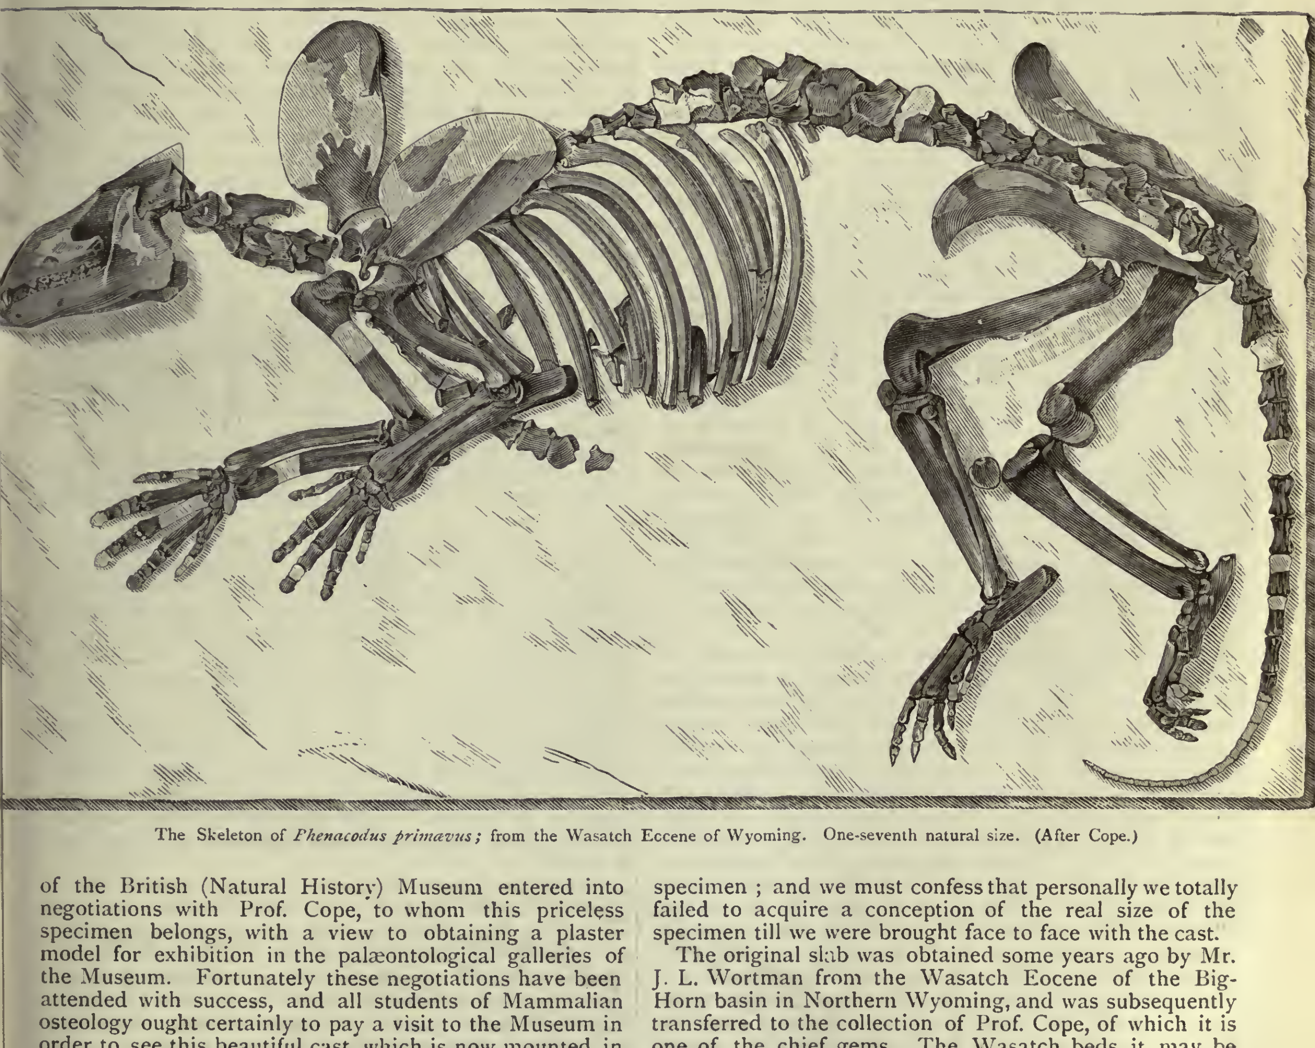
[1] The italics are ours.

that was not the "Hendon disease" of Prof. Brown, but which was associated with throat illness among consumers of the milk of the affected cows—just such a cow malady, in fact, as the Medical Department stated could have, and had, existed without recognition by veterinary surgeons.

SKELETON OF PHENACODUS.

ALL readers of the *American Naturalist* must be familiar with a striking woodcut of the entire skeleton of a peculiar fossil Ungulate, which occurs throughout a long series of numbers among the advertisements, and bears the following somewhat startling subscription, viz. "The five-toed horse—the ancestor of lemurs and man." This figure we are enabled, through the courtesy of Prof. Cope, to reproduce in the accompanying woodcut. The name given by its describer, Prof. E. D. Cope, of Philadelphia, to the animal of which the skeleton is so marvellously preserved, is *Phenacodus primævus;* the genus forming one of the best-known representatives of that very curious extinct group of generalized Ungulates for which the Professor has proposed the name Condylarthra.

Till quite recently those zoologists who have not enjoyed the good fortune of visiting the United States have been acquainted with this remarkable and unique fossil only by description and figures; the largest figure being the fine plate in Prof. Cope's magnificent quarto work on the "Tertiary Vertebrata of the West," published a few years ago by the United States Government among the Reports of the Geological Survey of the States. Some months ago, however, the Keeper of the Geological Department of the British (Natural History) Museum entered into negotiations with Prof. Cope, to whom this priceless specimen belongs, with a view to obtaining a plaster model for exhibition in the palæontological galleries of the Museum. Fortunately these negotiations have been attended with success, and all students of Mammalian osteology ought certainly to pay a visit to the Museum in order to see this beautiful cast, which is now mounted in its place, and is, we will venture to say, of far more value to the student than many of the real but fragmentary fossil specimens for which large prices have been paid. We may indeed congratulate the popular Keeper of the Geological Department in not hesitating to pay what we believe was a somewhat heavy price for the acquisition of this cast.



The Skeleton of *Phenacodus primævus;* from the Wasatch Eocene of Wyoming. One-seventh natural size. (After Cope.)

No figures could, indeed, possibly give an adequate idea of the marvellous state of preservation of the original specimen; and we must confess that personally we totally failed to acquire a conception of the real size of the specimen till we were brought face to face with the cast.

The original slab was obtained some years ago by Mr. J. L. Wortman from the Wasatch Eocene of the Big-Horn basin in Northern Wyoming, and was subsequently transferred to the collection of Prof. Cope, of which it is one of the chief gems. The Wasatch beds, it may be observed, are low down in the Eocene, and when we consider that so many of even the Upper Eocene Mammals of Europe are known only by isolated and often imperfect skulls, teeth, or limb-bones, we are struck with the marvellous preservation of the American form. The dimensions of the slab are about 49 by 28 inches; and Prof. Cope describes the animal as intermediate in point of size between a sheep and a tapir. The animal lies on its right side, with the tail bent suddenly down behind the posterior limbs, and the shoulder-blades thrown up from their proper position some distance above the line of the vertebral column. The skull is almost entire, and although the scapulæ are imperfect, and the right pectoral limb has sustained some losses, all the bones of the skeleton are in their original juxtaposition, so that we may note the arrangement of the bones of the carpus or tarsus almost as well as in the skeleton of a recent type. It strikes us, indeed, that it would have been quite easy to have extracted the skull and many of the bones of the limbs from the matrix, and made entire casts from them, which could have been placed in cavities in the cast from the original slab.

The chief importance of this and other American specimens of fossil Mammals belonging to totally extinct types is their completeness, whereby we are enabled at once to gain a very fair idea of the affinities of the animals to which they belonged. In Europe, with the exception of the well-known Mammals of the Upper Eocene (or Lower Oligocene) of the Paris basin, our efforts are nearly always hampered by the imperfect nature of our specimens—as witness the question whether the limb-bones from Hordwell described by Kowalewsky are or are not referable to the *Dichodon* of Owen, which was founded upon the evidence of the skull—so that we can very rarely speak confidently and fully as to the affinities of any particular form. It may, indeed, be stated, without any fear of contradiction, that we could never have hoped to have attained anything like our present knowledge as to the mutual affinities of the various sub-orders (or orders) of Ungulate Mammals and their relations to other groups, had it not been for the fortunate discoveries of such a host of well-preserved specimens in the Tertiaries of the United States. And we may here express the obligations which all European students are under to those palæontologists who, like Messrs. Cope, Leidy, Marsh, Osborn, Scott, and others, have laboured so indefatigably to collect and describe the Vertebrate faunas of past epochs in the so-called New World. In expressing thus briefly our obligations to these eminent exponents of the life-history of a former world, we must, however, not omit also to mention the enlightened liberality of the Government and of various learned Societies in the States, which have furnished the funds necessary to render these treasures available to the world, through the means of the magnificent publications in which they are described.

In concluding this brief notice of the new treasure recently aquired by our National Museum, we may say a few words regarding some of the chief characters of the Condylarthrous Ungulates. One of their most essential features is the comparatively simple arrangement of the bones of the wrist and ankle joints (carpus and tarsus); the various rows preserving their original distinction, and having only very slight mutual interlocking. In this respect, this group agrees with the existing Hyracoidea so closely that Prof. Cope has considered himself justified in brigading the two groups together under the common title of Taxeopoda. Usually the dentition comprises the full number of teeth found in those higher, or placental, Mammals in which the teeth are differentiated into groups; and very generally the cheek-teeth have their crowns formed on what is known as the bunodont type. That is to say, their crowns are low, and carry three or more low and blunt tubercles, as exemplified in the pig and in man. Further, the eye or canine teeth are well developed, and recall those of the Carnivora. Again, the humerus, or bone of the upper arm, has a foramen at its lower extremity, which is totally unknown in all other Ungulates, and likewise recalls the Carnivora and some of the lower orders. The digits are nearly always five in number, and their terminal joints are so pointed as frequently to render it difficult to say whether their coverings should be termed nails or hoofs. The femur, or leg-bone, has a third trochanter, like that of existing Perissodactylate Ungulates; and the ankle-bone, or astragalus, has its lower articular surface uniformly convex, instead of flattened or facetted as in all modern Ungulates. The astragalus and the wrist joint are, indeed, very similar to the same parts in the generalized Carnivora of the Eocene. The tail was larger and heavier than in any existing Ungulate, and was thus more like that of many Carnivora, such as the wolf. In walking, it appears that the three middle toes of each foot touched the ground, whilst the first and fifth toes stuck out on the sides and behind, after the fashion obtaining with the second and fifth toes of the pigs.

The curious approximation made in the osteology of this remarkable type of Mammal to the generalized Carnivora of the Eocene, to which Prof. Cope has applied the name of Creodonta, is so marked that Dr. Max Schlosser, of Munich, considers that we are now justified in regarding the Ungulates and the Carnivores as divergent branches of a single primitive stock. *Phenacodus* is regarded, moreover, by Prof. Cope, as the ancestral type from which a number of the more specialized Ungulates have been derived; and there appears every probability that this genus should be placed as one of the earlier links in the chain which culminates in the modern horse.

Recently, however, the American Professor has proposed to include in the Taxeopoda not only the Hyracoidea and Condylarthra (which it was originally formed to receive), but also the Primates of English zoologists, which it is proposed to divide into the Daubentoidea, represented by the existing aye-aye (*Chiromys*) and the extinct *Mixodectes*; the Quadrumana, embracing the other lemurs and monkeys; and the Anthropomorpha, which is taken to include the man-like apes and man. A complex genealogical tree is given, in which the *Phenacodontidæ* are represented as not only the progenitors of the other Ungulates, but also as giving origin on the one hand to the so-called Daubentoidea, and on the other to the Quadrumana, from which the Anthropomorpha are derived as a secondary branch from the Eocene Lemuroid *Anaptomorphidæ*, which group is itself derived from the *Adapidæ*, as represented by the well-known *Adapis* of the Upper Eocene of Europe.

Now, with all due respect to Prof. Cope, we venture to say that no English zoologist will be inclined to accept a classification which includes in a single "order" such widely different forms as man and the hyrax, while the other Ungulates are apparently regarded as constituting a totally distinct order. Again, in regard to the genealogical tree it appears to us to be incomprehensible how an order like the Primates, all the members of which are furnished with fully-developed clavicles, can have taken origin from an Ungulate type like *Phenacodus*, in which it appears that those bones are totally wanting. While, therefore, fully recognizing the great interest of *Phenacodus* as an ancestral type, we totally fail to see how it can also be regarded as the "ancestor of lemurs and of man."

R. L.

THE IRON AND STEEL INSTITUTE.

THE twentieth session of the Iron and Steel Institute was opened on Wednesday, May 8, when the President, Sir James Kitson, gave his inaugural address, which was of a technical character, and was devoted mainly to the consideration of the best Yorkshire iron as an industrial product; but the subject of iron alloys, to which we shall refer again, the extending application of iron and steel for railways and ships, and other matters of interest, such as technical education and the revival of trade, were also referred to.

The first paper read was one on the alloys of nickel and steel, by Mr. James Riley. This led to a very lengthy and interesting discussion, from which it appeared, as has often occurred in similar instances, that another metallurgist had been working in the same direction for a considerable time. The results obtained by Mr. F. J. Hall, of Messrs. Jessop's, of Sheffield, and Mr. Riley are very similar in character, but whilst the former appears to have made what may be called industrial experiments, those of the latter have been mainly confined to the laboratory. Nickel can be made to form an alloy with steel, in quantities varying from a hardly appreciable amount up to as much as 50 per cent.; the alloy does not require an excessively high temperature to melt it, special attention is not necessary in its production, the resulting metal is definite in character, and is easily worked both under the hammer and in the rolls. A very remarkable increase in the tensile strength and elasticity of steel is produced by alloying it with nickel. Among many tests given by Mr. Riley, the following specially referred to by him may be cited:—"In No. 6, the carbon present (0·22) is low enough to enable us to make comparison with ordinary mild steel, which would give (when annealed) results about as follows: elastic limit, 16 tons, breaking strain, 30 tons, extension 23 per cent. on 8 inches, and contraction of area 48 per cent. Therefore, in this case the addition of 4·7 per cent. of nickel has raised the elastic limit from 16 up to 28 tons, and the breaking strain from 30 up to 40·6 tons, without impairing the elongation, or contraction of area to any noticeable extent." In his remarks Mr. Hall referred to his applications of nickel steel to gun barrels, propeller blades, and other purposes during recent years, and concluded by observing that in an experiment he had made about twelve months ago, he had obtained with nickel steel a tensile strength of 97 tons per square inch, with an elongation of 7 per cent. Another important point with regard to nickel steel referred to by Mr. Riley is its non-corrosibility when the alloy contains 25 per cent. of nickel, for, with low proportions of nickel, ordinary mild steel and nickel steel appear to corrode in about the same proportion. In the discussion Mr. White (the Chief Constructor of the Navy) drew attention to the question of cost, as affecting the application of materials in practice, and with nickel at £224 a ton, or £56 as the cost of the nickel in a ton of 25 per cent. nickel steel, it is a consideration.

The next paper, on the manufacture of basic open-hearth steel, by Mr. J. H. Darby, also gave rise to an important discussion. From the paper and discussion it may be inferred that the basic steel industry has not made so much progress in this country as it has done in Germany. This may be due to the circumstance that German ores are mainly phosphoric in character (Mr. Thielen, who spoke as to his experience in Germany, stating that of the steel now produced in the Siemens furnace in Germany 70 or 80 per cent. was produced in the Siemens basic furnace), or to the "Batho type" of furnace used in this country being inapplicable to steel-making, an opinion expressed as well by the author of the paper as by speakers who followed him. Mr. Windsor Richards could not understand why they had gone away from the rectangular furnace of Sir William Siemens, and was pleased to say that since he had returned to it his difficulties had come to an end; whilst Mr. John Head, Mr. Frederick Siemens's representative, spoke of a new form of regenerative gas furnace, recently built and tried, which consumed about 50 per cent. less coal than the original regenerative gas furnace, and promised a paper on the subject for the autumn Paris meeting of the Institute.

A statistical paper on the progress made in the German iron industry since 1880 was read by Mr. R Schroedter.

One on the influence of copper on the tensile strength of steel was read by Messrs. E. J. Ball and A. Wingham, in which the authors state that from a general consideration of the results of their experiments it would seem that within certain limits copper does not prejudicially affect the mechanical properties of steel. In this they agree with a theory brought by Prof. Roberts-Austen before the Royal Society last year to the effect that small quantities of a metallic impurity exert a deleterious effect on a large mass of another metal only if the atomic volume of the impurity is greater than that of the metal in which it is hidden. Mr. Bauerman, in discussion, expressed the opinion that it was not the copper, but the sulphur which generally came with the copper, that was injurious to iron.

The papers on universal rolling-mills for the rolling of girders and cruciform sections, by Mr. H. Slack, and on the Thomasset testing-machine, by M. Gautier, were mainly of mechanical interest. M. A. Pourcel read a paper on the application of thermal chemistry to metallurgical reactions.

ROBERT STIRLING NEWALL, F.R.S.

OBSERVANT travellers by the Great Northern Scotch express may see, as it nears Newcastle, the low dome of an astronomical observatory on the eastern side of the line. It is a spot which will be memorable in the history of astronomy, and it marks the home of a man who combined the practical sagacity and inventive skill which have made England the first industrial nation in the world, with the love of science which must be added to these if it is to hold its place.

Mr. Newall, whose death we chronicled a fortnight ago, was a successful manufacturer. When he was still a young man, a friend who was studying mining in Saxony informed him that cables made of iron wires were largely used there, but that the process of making them was "unmechanical," and suggested that he should invent a machine for the purpose. This he did, and wire ropes of his construction are now used all over the world. From time to time he improved on the original design, and so lately as 1885 he devised a new machine by which the rope is made at one operation, the double process of first making the strands and then combining them being avoided.

His interest in his business was not, however, confined to the gradual development of his earlier patents. He was quick to see that wire rope might help in solving the difficulties which had to be overcome before submarine telegraphy was an accomplished fact.

Sir Charles Wheatstone had clearly conceived the possibility of electric communication between England and the Continent as early as 1837. In 1840 he gave evidence on the subject before a Committee of the House of Commons, and references were made to his suggestion in the public Press. His drawings and notes show, however, how difficult the problems of insulating and preserving the cables seemed to these early pioneers.

The insulation was attained by the use of gutta-percha—of which Mr. Newall received a portion of the first sample transmitted to this country—but the cumbrous devices at first suggested for protecting the outer covering of the cable were forgotten when Mr. Newall proposed that the "gutta-percha lines containing insulated wire should be surrounded with a strong wire rope" (pamphlet by Mr. R. McCalmont, dated September 19, 1850).

The first cable, laid between Dover and Cape Grisnez, in which this plan was not employed, broke after one day. The first successful cable, which was laid on September 25, 1851, by Mr. Crampton, was manufactured by Mr. Newall, and protected by wire.

The submergence of cables in seas deeper than the English Channel presented greater difficulties, and the Newall drum-brake, which was introduced in 1853, and afterwards for a time abandoned, has since been again employed, so that, as Mr. F. C. Webb stated at the Institute of Telegraph Engineers in 1876, "we have come back to the old drum-brake of Newall."

Mr. Newall took an active part in superintending the actual laying of many cables, and on these occasions he showed the qualities of a leader of men—cool in an emergency, confident in his own resources, and undismayed in disaster. "Gentlemen, it's over now; ye may go to bed," was his only remark when a cable broke involving a loss of many thousands of pounds.

During the Crimean War he laid a wire insulated in gutta-percha without sheathing of any kind from Varna to the Crimea. It was run out over the stern through hand leathers held by the cable men in turn. He formed one of the boat's crew that left to seek help for the passengers of the P. and O. steamship *Alma*, wrecked in 1859 in the Red Sea.

But, during this busy life, Mr. Newall never allowed his love of pure science to be crushed by the weight of the practical affairs in which he was engaged. The success of submarine telegraphy was due to no one individual only, but to Mr. Newall belongs the credit of inaugurating a new era in the construction of refracting telescopes. He had long wished to possess a refractor of large dimensions, and in the Exhibition of 1862 he discovered two large disks of crown and flint glass, manufactured by Mr. Chance, of Birmingham. He at once saw that his opportunity was come, secured the glass, and placed it in the hands of Mr. Cooke, of York.

As the result of his boldness in risking a very large sum on an experiment the success of which was most uncertain, Mr. Newall carried, at one bound, the diameter of the largest object-glass from 15 to 25 inches. His observatory was a spot to which the most distinguished astronomers journeyed, and to which Profs. Newcomb, Holden, and Alvan Clark came as a deputation from the other side of the Atlantic.

Mr. Newall's original idea was to mount the telescope in the Mauritius, and spend as much time as possible there himself. This plan has never been carried out, and the great Newall refractor has never yet had a fair chance under the adverse skies of Newcastle. Almost his last act was to offer it as a gift to the University of Cambridge, and it is to be hoped that it may there add to the high scientific reputation that University has won.

To have established a new industry, to have taken an active part in securing a triumph of applied science which will modify the history of the world, and to have led the way in the development of the refracting telescope, is a record of achievement to which few attain, but which does bare justice to the life-work of Robert Stirling Newall.

NOTES.

THE Report of the Royal Commission appointed to consider the expediency of establishing a Teaching University for London, has been laid on the table of the House of Commons, and the Blue-book may be expected in the course of the next week. The Commissioners are agreed—first, that the petition of the Royal Colleges of Physicians and Surgeons to be authorized to grant degrees in medicine should not be entertained; secondly, that it is desirable that London should have a Teaching University. On the third point—whether a charter shall be granted to the associated Colleges of King's and University, constituting these Colleges the Teaching University of London—the Commission are divided. The three Commissioners connected with the teaching profession (Sir William Thomson, Prof. Stokes, and Mr. Welldon), are in favour of it; the three lawyers (Lord Selborne, Sir James Hannen, and Dr. Ball), are opposed to it. The Report ends with a request that this question be referred back to the Commission for their further consideration, in order that they may determine whether it is not possible to devise a scheme of common action between the two Colleges and the existing University of London.

PROF. STOKES will deliver the Rede Lecture on Wednesday, June 12, at 2 p.m., in the Senate House, Cambridge, the subject being, "Some Effects of the Action of Light on Ponderable Matter."

THE Museums and Lecture Rooms Syndicate, Cambridge, have been authorized to have quantities taken out and tenders invited for the proposed Anatomical and Physiological Buildings, in three distinct blocks.

MRS. DE LA RUE has presented to the Royal Institution the philosophical apparatus of the late Dr. Warren de la Rue. A fine portrait of Sir Humphry Davy has been presented to the same Institution by Mr. James Young, grandson of the late Dr. James Young, F.R.S., of Kelly, the former owner of the portrait.

THE Swedish Government has decided to send a man-of-war to New York to bring home the body of Captain Ericsson, who expressed a strong desire to be buried at Långbanshyttan, in Vermeland, the place of his birth. In his will no directions are given as to the disposal of his valuable collection of models, but Swedish journals state that the executors will present them to the Smithsonian Institution.

THE last mail from Bombay brings news of the formal opening, by Lord Reay, of the Jubilee Technical Institute in that city. The *Times of India*, commenting on this event, says it forms a notable landmark in the educational history of Bombay. That the Institute meets a public want is shown by the circumstance that it already numbers two hundred and forty students, while nearly half as many are awaiting nomination. The origin of the Institute is this. When Lord Ripon was about to leave India, a movement was set on foot to signalize his Viceroyalty by a memorial of some kind, and subscriptions were collected for the purpose. Soon after Lord Reay's arrival in Bombay there arose suggestions for the formation of a technical school. The Government in January 1887 promised a grant of 25,000 rupees annually, and recommended to the Municipal Corporation of Bombay that 80,000 rupees which they proposed to devote to commemorating the Jubilee of the Queen's reign should be devoted to the founding of a technical institute. The other funds were amalgamated with this, and a Board of management was formed; but still the funds were found insufficient, until at last the munificence of Sir Dinshaw Petit came to the rescue. He presented the Board with a noble building, and work began at once, and the formal official opening took place recently, although, in fact, the Institute has been open for several months. The immediate and signal success of the Institute Lord Reay attributes in no small measure to the fact that in starting the movement its originators did not allow themselves to yield to the demand for a programme.

THE Upsala University and the Swedish Geographical Society have sent Dr. Carl Forsstrand to study the marine fauna of the West Indian Islands during the present summer.

THE Indian papers report the death from cholera, at Rangoon, of Dr. Robert Romanes, Professor of Science in the Rangoon College, and Chemical Examiner to the Burmah Government.

IN the horticultural part of the Paris Exhibition there are some splendid beds of Darwin tulips in full bloom. The flowers are magnificent, and a *sergent de ville* keeps watch over them—an unusual proceeding in France, where flowers are never in ordinary circumstances stolen from public gardens. Unfortunately the presence of an unusual number of foreigners makes this precaution necessary. In the same part there is a very curious exhibit of Japanese horticulture. It consists of a number of specimens of dwarfed trees—trees which are usually tall, but in the present case hardly attain the height of 2 or 3 feet. This exhibit excites much interest among gardeners.

ZOOLOGISTS will be interested in the exhibit of the Principality of Monaco at the Paris Exhibition, as all the implements used by the Prince in his dredging experiments are to be shown, with numerous specimens of deep-sea fauna. The exhibit of the results of the *Talisman* researches will unfortunately be scanty.

LAST week, Mr. Ralph Moore, Inspector of Mines for the Eastern District of Scotland, on his retirement from that post, which he has held for twenty-seven years, received a farewell present from a number of gentlemen connected with the Scottish coal and iron trades. In thanking the donors, Mr. Moore gave some interesting details of the improvement in mining appliances since he first was a colliery manager, forty-eight years ago. At that date, he said, there were cages at two or three collieries in the county of Edinburgh, but there was none in Lanarkshire. The coals were all drawn in corbes. A few years after, there was not a single colliery without them. Pug engines were first introduced about 1845. Ventilating furnaces were of the most primitive description. Fans were unknown. The first fan in Scotland was put up in 1868; now there were hundreds, and scarcely anyone thought of doing without a fan. The amount of ventilation in a colliery was from 8000 or 10,000 down to as low as 1000 cubic feet per minute, and now there were some collieries in the district with 250,000 cubic feet per minute. Last year he made the calculation that eight tons of air were sent into the mines for every ton of coals extracted. Wire ropes were not in use at the time of which he spoke; now there was nothing else. Underground mechanical haulage was practically unknown; now it was universal. Many large collieries had only one shaft, now all had two. A coal-owner putting out 100,000 tons a year was a large coal-owner. There were coal-owners now putting out over 600,000 annually. As a consequence of all these improvements, the output of minerals in the district, which in 1856 was 4,500,000 tons, was now 17,000,000 tons, and the death-rate, which in 1853 was one for every 250 persons employed, is now about one in 800.

IN connection with the Congress of German Anthropological Societies, which is to meet this year at Vienna, a large exhibition of prehistoric objects is being formed. All the smaller public collections and the most important private ones of Austria will be represented.

SIR W. BRANDFORD GRIFFITH, Governor of the Gold Coast, has reported to Lord Knutsford the occurrence of a smart shock of earthquake at Accra on April 5, at 12.2 noon. The seismic wave seemed to run from south to north, and was felt at Aburi, twenty-six miles to the northward of Accra. Sir W. B. Griffith had not heard of any serious damage being caused in the colony, nor, so far as he could hear, was the earthquake felt at sea or at Addah. Christiansborg Castle, the Government House at Accra, was once laid in ruins by an earthquake.

EARTHQUAKES still continue in the neighbourhood of Vyernyi in Turkestan. On February 19, at 3 p.m., an earth-tremor was felt after a fortnight of absolute rest. The shock was quite isolated, and lasted but a few seconds. Another slight shock was felt during the night, at 2 a.m. On February 25, at 11 a.m., a noise like that of a discharge of a battery of guns was heard, and the soil was set in motion for about three seconds. Many houses cracked, but there was no loss of life.

La Nature of April 27 contains a representation, by photolithography, of an interesting synoptic table of weather prediction, by MM. Plumandon and Colomès, whereby anyone may find mechanically the probable weather, by observing the direction of the wind, as based upon fourteen years' observations at the Puy-de-Dôme Observatory. The table from which the representation is reduced, is printed in six colours, and is divided into eight sectors corresponding to the principal directions of the wind, and comprising 216 weather conditions. A movable indicator, with three arms, works upon a pivot; one arm being moved to represent the wind direction as shown by the clouds or a good wind-vane, the others then point to the region of lowest barometer, and to the probable weather, indicated by one of the cases referred to. These conditions are contained in a few words, and differ for each season of the year, and for different states of the barometer, *e.g.* high, low, &c. The principle involved is merely an application of the rule known as Buys Ballot's law: "Stand with your back to the wind, and the barometer will be lower on your left hand than on your right," combined with the experience gained in weather prediction during the last thirty years. A card somewhat similar in principle was published some years ago by the late F. Pastorelli. Persons unable to consult daily weather charts may find the diagram very useful.

IN a private letter recently received from Dr. Macgregor, the Governor of British Guinea, an interesting account of his trip in the *Hygeia* through the Louisiade Archipelago and the adjacent groups of islands is given. He found them, he says, all thickly inhabited, the natives being in thousands, and in many cases very wild—so wild, in fact, that he thinks it probable they had never seen a white man before. On some of the islands he found hot mud-springs, some of them being strongly impregnated with sulphur. Gold was found on many of the islands, but in no instance was it in payable quantities.

ACCORDING to *Allen's Indian Mail*, the Madras Museum now possesses the skeleton of the largest elephant ever killed in India. This elephant was the source of great terror to the inhabitants of South Arcot, by whom it was killed and buried. The Museum authorities despatched a taxidermist to the spot to exhume the bones and transfer them to Madras. The skeleton is exactly 10 feet 6 inches in height, being 8 inches higher than the highest hitherto measured in the flesh by Mr. Sanderson.

MR. LESTER WARD has recently claimed an American origin for the entire genus Platanus, of which the plane and the sycamore are the best-known species. It occurs abundantly, however, in these isles, in the Lower Eocenes of Mull, Reading, and the Middle Eocene of Lough Neagh, the former being probably at least as old as the beds in which it makes its earliest appearance in America. It probably came into existence in the Old World in late Cretaceous times.

DR. MARION describes, in the *Annales des Sciences Géologiques*, a new conifer, having the foliage of Araucaria with the cones of Dammara, and therefore an essentially Australasian type, which only became extinct in France in the Miocene. The material is so perfect and ample that very little more would remain to be learnt about it, were it still living. The same, or a nearly allied, species abounded in the Isle of Wight in the Oligocene. In outward form the tree must have resembled Cryptomeria.

THE May number of the *Kew Bulletin* opens with an interesting account (with plate) of the Persian dye plant *Zalil*, prepared by Sir Joseph Hooker for the April number of the *Botanical Magazine*. This is followed by an account of Tasmanian woods, some curious details as to lily flowers and bulbs used as food, a paper on Pu-êrh tea, an account (with plate) of the short-podded yam-beam, and a list of the staffs of the Royal

Gardens, Kew, and of botanical departments and establishments at home, in India, and in the Colonies, in correspondence with Kew.

IN his Report for 1888, just issued, the librarian of the Mitchell Library, Glasgow, notes, for the third year in succession, a decrease in the number of volumes issued to readers. This is believed to be mainly due to the fact that the rooms are not nearly large enough to provide accommodation for those who wish to use the library. Even now, notwithstanding the decrease of attendance, the rooms are often inconveniently crowded. It seems strange that in a wealthy and intelligent city like Glasgow there should be the slightest difficulty about the provision of a proper building for so good a collection of books—a collection which, according to the librarian, "is becoming year by year richer in all departments of literature, better fitted to supply the wants of every student and every reader."

THE Burton-on-Trent Natural History and Archæological Society have begun to issue "Transactions"; and if we may judge from the first volume, which we have just received, succeeding volumes are likely to contain a good deal of interesting work. The most important paper in the present volume is a Report, by Mr. John Heron, on certain explorations carried on at Staplehill in 1881, under the auspices of the Society. In the course of these explorations the remains of upwards of thirty-six human bodies were found, accompanied in some cases by personal ornaments, small iron knives, or weapons of a kind which showed that the ground had been a burial-place of the English in pagan times. The various "finds" are clearly described by Mr. Heron, whose paper is admirably illustrated by a frontispiece and ten plates.

THE third chapter of the revised edition of Dr. Elias Loomis's "Contributions to Meteorology" has been issued. In this chapter the author deals with the mean annual rainfall for different countries of the globe; describes the conditions favourable, and the conditions unfavourable, to rainfall; examines individual cases of rainfall in the United States, in Europe, and over the Atlantic Ocean; and defines the areas of low pressure without rain. Many valuable plates accompany the text.

THE May number of *Himmel und Erde* (Berlin) opens with an interesting description of the Lick Observatory, and an account of its foundation by the Director, Prof. Holden. The article is illustrated by a view of the giant refractor and the interior of the Observatory, the presence of three of the observers serving to give an idea of the immense size of the instrument. Dr. Mohn continues his account of the Norwegian North Sea Expedition, and Dr. Wagner concludes his article on the Krakatão eruption. Other articles and astronomical data for the month are also given.

THE new number of the *Folk-lore Journal* (vol. vii. part 2) contains an interesting paper, by Mr. John Abercromby, on the beliefs and religious ceremonies of the Mordvins, a people of Finnish descent inhabiting parts of Central Russia, who were pagans up to the beginning of the present century. The paper gives their conception of the Deity, a list of the various objects of worship, their account of the creation and the fall of man, and descriptions of their feasts and sacrifices. The paper is one of considerable length. Mr. Edward Clodd follows up his recent paper on "The Philosophy of Punchkin" by a similar one called "The Philosophy of Rumpelstiltskin," the latter being a generic title derived from the character in Grimm's well-known *Märchen*. An interesting bibliography of variants of the tale is appended. Students of folk-lore anxious to aid the Society by practical work will be glad to have their attention attracted to the appeal of the Council for volunteers to tabulate certain works which are mentioned, the method of tabulation being shown at the end.

MESSRS. SMITH, ELDER, AND CO. have issued a new edition of "Wild Life in a Southern County," one of the finest of the late Mr. Richard Jefferies's writings.

AT a recent meeting of the Linnean Society of New York City, Dr. G. B. Grinnell read an instructive paper upon the Rocky Mountain goat (*Mazama montana*). The limits of the range of this animal have never been fully defined by any one writer. It is a mammal belonging to the Arctic fauna, and only found among the high and rugged mountains of the Rockies and Coast Range, where the snow lies all the year. The centre of its abundance seems to be in Western Montana, Idaho and Washington Territories, and British Columbia, and it has been found from about latitude 44° to about latitude 65°; its southernmost records being on the highest peaks of the Sierra Nevada, near Mount Whitney. This goat is in no immediate danger of extermination, as it inhabits the most inaccessible localities, and has few natural enemies.

URIC ACID has been synthesized by Drs. Behrend and Roosen, of Leipzig, in a manner which completely settles the question of its constitution. A few months ago a synthesis of this important natural compound was effected by Horbaczewski, by fusing together glycocine, $CH_2.NH_2.COOH$, and urea, $CO\langle{}^{NH_2}_{NH_2}$. High temperature reactions, however, are never satisfactory as indicating the constitution of organic compounds, inasmuch as there is always a possibility of inter-molecular change. Hence a new mode of synthesis at lower temperatures has been devised by the Leipzig chemists, and carried out in an admirable manner, every stage being most critically investigated so as to be absolutely certain of the constitution of the intermediate compounds. The process consists of seven stages:—(1) The substances started with are aceto-acetic ether, $CH_3.CO.CH_2.COOC_2H_5$, and urea, $CO\langle{}^{NH_2}_{NH_2}$. These two compounds combine together with elimination of water, forming an ether of crotonic acid in which one of the hydrogen atoms is replaced by the radical of urea,

$$\begin{array}{l} \qquad\qquad\quad CH_3 \\ \qquad\qquad\quad | \\ NH_2.CO.NH—C=CH—COOC_2H_5 \end{array}$$

(2) This substance on saponification with caustic potash yields the potassium salt of the corresponding acid. The free acid itself readily splits off water, forming the anhydride,

$$\begin{array}{lll} NH & — C & — CH_3 \\ | & \| & \\ CO & CH & \\ | & | & \\ NH & — CO & \end{array}$$

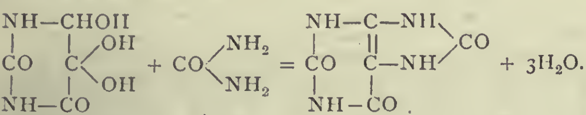
, methyl uracil, as it is termed. (3) On treatment with fuming nitric acid, the CH_3 of methyl uracil becomes oxidized to the acid radical, COOH, a nitro-group, NO_2, being simultaneously introduced,

$$\begin{array}{lll} NH & — C & — COOH \\ | & \| & \\ CO & C & — NO_2 \\ | & | & \\ NH & — CO & \end{array}$$

. (4) On boiling this nitro acid with water, a molecule of carbonic anhydride is eliminated, leaving a substance termed nitro-uracil,

$$\begin{array}{lll} NH & — CH & \\ | & \| & \\ CO & C & — NO_2 \\ | & | & \\ NH & — CO & \end{array}$$

. (5) On reduction with zinc and hydrochloric acid, nitro-uracil yields iso-barbituric acid—a compound which has been shown in a previous paper of Dr. Behrend's to possess the constitution  (6) By oxidation of iso-barbituric acid with bromine water another acid is obtained, which is found to be isomeric with dialuric acid, but differs entirely from that acid in properties; it is therefore termed iso-dialuric acid. From its reactions it is shown to correspond to the constitution  It crystallizes in long rhombic prisms containing a molecule of water of crystallization, which it loses at 100° C. The yield is very good, 80 per cent. or more of the theoretical. (7) It now only remains to mix this iso-dialuric acid with one equivalent of urea and six equivalents of sulphuric acid, the latter to take up three molecules of water which are eliminated in the reaction between the two former substances. The reaction is complete in the cold in twenty-four hours, or in five minutes if the mixture is gently warmed upon a water-bath. On cooling and adding water, uric acid is precipitated in small crystals, which, on purification, exactly resemble those of natural uric acid. The equation is very readily understood, there being a simple combination of iso-dialuric acid and urea with formation of uric acid and elimination of three molecules of water—



Iso-dialuric acid. Urea. Uric acid.

Hence the formula of Medicus and Fischer for uric acid may now be considered as finally proved.

THE additions to the Zoological Society's Gardens during the past week include a Purple-faced Monkey (*Semnopithecus leucoprymnus*) from Ceylon, presented by Mr. J. H. Taylor; a Vervet Monkey (*Cercopithecus lalandii* ♂) from South Africa, presented by Dr. W. K. Sibley; an Otter (*Lutra vulgaris*) from Cornwall, presented by Mr. Basset; a Long-eared Owl (*Asio otus*), British, presented by the Hon. Eric Thesiger; a Herring Gull (*Larus argentatus*), British, presented by Mrs. Gainsford; a Yellow-billed Amazon (*Chrysotis panamensis*) from Panama, presented by Lord William Cecil; two Common Kestrels (*Tinnunculus alaudarius*), captured at sea, presented by Captain Janes; two Common Rheas (*Rhea americana*, juv.) from Uruguay, presented by Mr. J. D. Kennedy; a Black Swan (*Cygnus atratus* ♂) from Australia, presented by Mrs. Siemens; a Long-eared Owl (*Asio otus*), British, presented by the Rev. F. Hopkins; two Natterjack Toads (*Bufo calamita*), British, presented by Master H. Millward; two Natterjack Toads (*Bufo calamita*), British, presented by Master A. Smith; a Bonte-bok (*Alcelaphus pygargus* ♂) from South Africa, deposited; a Squacco Heron (*Ardea railoides*) from South Europe, three Japanese Teal (*Querquedula formosa* ♂ ♀ ♀), from North-East Asia, an Amherst Pheasant (*Thaumalea amherstiæ* ♂), from Szechuen, China, purchased; two Moor Harriers (*Circus maurus*) from South Africa, received in exchange.

OUR ASTRONOMICAL COLUMN.

THE RESIDUALS OF MERCURY.—In a recent discussion of the perturbations of Mercury (*Astronomical Journal*, No. 191, April 15, 1889), Mr. O. T. Sherman has arrived at some important and highly suggestive results relating to the residuals. His method of determining these appeared in No. 173 of the *Astronomical Journal*, and this process has been employed in obtaining the data given in the article referred to. The values arrived at show a remarkable relation to the heliocentric latitude of the planet, the maximum effect being nearer the solar equator, and the effect decreasing as the latitude increases. Since the lower latitudes correspond to maximum and the higher ones to minimum solar activity, the apparent connection of the disturbances of the planet with solar phenomena should also bear some relation to the sun-spot period, and Mr. Sherman gives figures to show that this is the case. The chief disturbances occur in the years when the sun-spots are increasing in frequency, and it is pointed out that this result is in strict accordance with the retardations of Encke's Comet during perihelion passage.

It is further stated that "the forces deflecting the planet are sunward when the planet is in that part of space towards which the sun is travelling, and away from the sun when the planet follows in his path." This, taken in conjunction with the disturbances of Encke's Comet, seems to Mr. Sherman "to indicate a considerable amount of matter coming to the sun from space. If so, its place of meeting with the matter coming from the sun should abound in collisions, and display local spectra showing bright lines. Our knowledge of the zodiacal light is fully in accord with such a supposition."

If the more detailed investigations of the residuals, which it is intended to make when more observations have been collected, confirm the results already obtained, we may look for a considerable advance of our knowledge, especially of the nature of the solar surroundings. Already the residuals clearly admit of explanation by supposing that the sun, with its meteoritic surroundings, in the form of the corona and the zodiacal light, is moving with considerable velocity through a meteoritic plenum. In that case the planet would encounter most meteorites when on the advancing side of the sun, and it would obviously be more retarded there than elsewhere.

The apparent relation to the sun-spot period is of great interest in connection with the meteoritic theory of the formation of sun-spots. According to this theory, there should be most meteorites in the solar surroundings at maximum spot period, and greater disturbances of the planet at that period would therefore be expected. The collisions between the two sets of meteorites would further produce the spectroscopic phenomena associated with the zodiacal light—namely, the appearance of a line near wave-length 558, which has been ascribed to manganese. It seems probable that the variability of this spectrum which has been suspected by Mr. Sherman (letter to Mr. Lockyer, quoted in Roy. Soc. Proc., vol. xlv. p. 248) may also subsequently be shown to be connected with the sun-spot period.

RIGHT ASCENSIONS OF NORTH CIRCUMPOLAR STARS.—Prof. T. H. Safford, Field Memorial Professor of Astronomy at Williams College, Mass., has just published a very useful piece of work in the shape of a Catalogue of North Polar Stars. This Catalogue, which is a first instalment of a more extensive one, the observations for which are now in progress, has been constructed by Prof. Safford in order to strengthen what he felt to be the weak point of all the standard Catalogues, viz. the right ascensions of Polar stars. It was also a consideration with him that it would be easier to take account of instrumental corrections if a more extended list of Polars were generally used than has been the custom. These stars are also of importance in the study of proper motions, since their early observations are accurate.

The observations for this Catalogue were made at the Field Memorial Observatory, and not at the Hopkins Observatory of Williams College, and the meridian circle with which they were made was a fine one of $4\frac{1}{2}$ inches (French) aperture, by Repsold. The observations were made at first by eye and ear, but a fillet chronograph was used in 1887 and 1888. Prof. Safford's intention throughout was to make his Catalogue a differential one; the stars he has relied upon for his instrumental corrections, being those of Publication 14 of the Astronomische Gesellschaft, which lie within 10° of the Pole. Besides the catalogue itself, which contains 261 stars, of which just 200 are within 10° of the Pole, a very important part of the work is the discussion of the right ascensions, with a view to clearing up certain points as to mode of observation, as well as to find the weights and systematic corrections necessary for combining this series with others. The result of this discussion is to show that it tends to greater accuracy to base a catalogue of Polar R.A.'s on standard places in all hours of right ascension rather than on double transits alone; that the eye-and-ear method should be used as the standard only near the Pole; and that a thorough comparison of it with the chronographic method through a wide range of magnitude and declination is desirable; that modern meridian instruments are subject to irregular small changes of position which are not direct functions of temperature; and that, therefore, it is well not to trust the instrumental zero points for more than two hours without re-determining the most essential.

Prof. Safford is at work on a paper, now well advanced, on the proper motions of the stars within 10° of the Pole, and he hopes shortly to complete the comparison of the chronographic and eye-and-ear methods which the present discussion had shown him to be needed.

TWO REMARKABLE SOLAR ERUPTIONS.—Father Jules Fényi, of the Kalocsa Observatory, records, in a note to the Paris Academy of Sciences, his observation of two remarkable solar eruptions which he observed on September 5 and September 6, 1888. Both eruptions would have been remarkable had they occurred at a time of maximum activity; but, coming as they did nearly at dead minimum, they stand out as most unusual. The first prominence was seen to rise from a height of 25″, as seen at 6h. 6m. (Kalocsa M.T.), to 151″·4 at 6h. 19m., its speed of movement attaining at one time 171 kilometres per second. A number of brilliant metallic lines were seen, some so bright that, with a wide slit, they showed as a small prominence, reaching 19″ in height on 1474 K and 15″ on the D lines. The second eruption was seen eighteen hours later, on September 6, at 11h. 45m., and was even more violent. In 6½ minutes it mounted from 37″ to 158″, with a speed at one time of 296·8 kilometres per second. It was of dazzling brilliance whilst it lasted, but passed away in about 14 minutes. The two eruptions were nearly but not quite in the same heliographic latitude. The first was on the east limb in S. lat. 18°; the other was distant some 4½°, and, as the base of each was about 3° in length, they could not have overlapped, and if connected in origin, must have sprung from a deep-seated source.

COMET 1889 *b* (BARNARD, MARCH 31).—This object is now too near the sun for observation, but accepting the elements of its orbit as hitherto determined, it will not travel far from its present position for some time to come. Dr. Krueger gives its position for Berlin midnight (*Astr. Nach.*, No. 2893) for the end of May and beginning of July as under, but with reserve from the uncertainty of the elements:—

GEOGRAPHICAL NOTES.

IN the new number of *Petermann's Mitteilungen*, Dr. Rink describes the recent Danish researches in Greenland, especially those carried out in East Greenland under the leadership of Captain Holm. The aim of the expedition was mainly antiquarian and ethnological; at the same time the report of its work contains valuable observations on the geology, geography, and especially the glacial conditions of the region visited. In the first volume of the Report, the first chapter, by Prof. Steenstrup, is devoted to a discussion of the situation of Osterbygd. The second chapter contains the report of Captain Holm and Lieutenant Garde on the results of the expedition of 1883–85. The principal results may be thus summarized:—Graah's map of the east coast of Greenland has been corrected and completed; a map has been prepared of a part not previously surveyed, and now named Christian IX. Land; and, after sketches and information from the natives, the outline of the coast has been continued from 66° to 68½° N. lat. It was found that the country called after Christian IX. was inhabited by a branch of the Eskimo which, before the arrival of the expedition, had not been in contact with Europeans. Detailed observations have been made on their mode of life, their customs, language, legends, &c., and a large collection made of articles of ethnological interest. During the various journeys of the expedition, and especially in their winter quarters, systematic researches were made in the physical geography of the country. Geological and botanical observations were made and specimens collected along the east coast. It was found that the east coast of Greenland is not so inaccessible as has hitherto been supposed. The expedition explored the east coast as far to the north as it was at all likely Osterbygd could have been located, without discovering the least trace of buildings which were not of Eskimo origin, and without finding anything in the physiognomy, the customs, mode of life, or legends of the natives that could furnish the slightest ground for inferring former relations with Europeans. From this it is concluded that Osterbygd could not have been situated on the east coast of Greenland. The third chapter deals with the geography of Danish East Greenland, *i.e.* as far as 66° N. This part of the east coast is divided into five natural zones—(1) the most southerly part as far as Anarket; (2) from Anarket to Ikermiut; (3) from Ikermiut to Igdlolnarsuk; (4) from Igdlolnarsuk to Inigsalik; (5) the section which extends to the east of the last-named place. Zones 1, 3, and 5 have strong resemblances with each other, as also zones 2 and 4. The three first-mentioned zones are cut by deep fjords, crowned with lofty serrated mountains, never covered by the continental ice. Some places are characterized by a vegetation comparatively rich. Beneath the mountains there are, in general, numerous glaciers, which often descend to the fjords, and towards the interior is found a mountainous region filled with large local glaciers. Zones 2 and 4 have a different aspect. The country is very barren, and the continental ice descends almost directly to the sea, or to the edge of the fjords, only a few mountains or rounded groups of mountains emerging from the ice. Another characteristic of the east coast is the parallelism of most of the fjords in an E. ¾ S. direction, as compared with the south-west direction of the fjords on the west coast.

THE new number of the *Mitteilungen* also contains a map of the flora of Schleswig-Holstein, with accompanying text by Dr. Ernest Krause, and an account of a journey to the sources of the Tigris by Prof. Wimsch.

THE paper read at Monday's meeting of the Royal Geographical Society was by Mr. J. R. Werner, on his journeys up the Ngala and Aruwimi tributaries of the Congo. The Ngala enters the Congo a little south of 2° N. lat., coming from a generally north-east direction. A little above its junction with the Congo is a channel through which the waters of the latter flow into the Ngala. For a considerable distance the banks of the river are low, swampy, and forest-clad. Gradually hills appear, and latterly bluffs, between which the channel narrows considerably. In May of last year, Mr. Werner accompanied the steamer to the Aruwimi, which was taking the men to Major Barttelot's camp at Yambuya. He was surprised at the number of sand-banks on the lower river, and the difficulties of navigation. After passing the town of Mokulu, the whole character of the country seemed to change, the islands stood higher out of the water and were covered with forest, which was crowded with palms, the crowns of which looked very pretty above the trees. The high banks on either side were lined with villages, or rather the sites of former villages, for the Arabs had been raiding here, and the natives were now living under roughly put-up sheds of leaves and sticks; the conical huts described by Stanley had almost entirely disappeared, and during the time Mr. Werner was on this river he only saw six, four of which were inside Major Barttelot's camp at Yambuya, and the other two in the village of Irungu. On the high bluff on which Stanley had found the large town of Yambumba, there was not a single hut on the vast clearing where the town had been, while on the opposite bank of the river such of the natives as had not been killed or carried into slavery were living under sheds and awnings of sticks and palm-leaves. On this side of the river the bank was quite low, and offered a strange contrast to the precipitous bluff on which the town had formerly stood. Above Yambumba the Aruwimi runs between two ridges of low hills, which are covered with magnificent timber. There are no more villages on its banks until Yambuya is reached.

AFTER the reading of Mr. Werner's paper at the Geographical Society, there was a discussion on the letter from Mr. Stanley which was read at the previous meeting. In this discussion Sir F. De Winton, Sir Samuel Baker, Colonel Grant, Rev. Horace Waller, and others took part. Sir Samuel Baker's statement was of considerable geographical interest. Against Mr. Stanley's doubts, Sir Samuel maintained the accuracy of his original observations as to the southward extension of Lake Albert Nyanza. He pointed out that Mr. Stanley himself refers to the very marked decrease in the size of the lake in the last few years, a decrease quite analogous to that which has taken place in Lakes Tanganyika and Nyassa. This decrease has no doubt tended to diminish the southern extension of the lake, and bring to light the vast extent of Ambatch or Sud which Gessi and others refer to. Sir Samuel maintains, moreover, that it will most probably be found that the two lakes (Albert Nyanza and Muta Nzigé) are really one, and are known among the natives by one name. The region which lies between them on our maps has never been visited by any European explorer. Sir Samuel pointed out the vast importance to Egypt of a precise knowledge of the laws which govern the increase or decrease of water in the Albert Nyanza, which is really one of the great sources of supply for the regions on the lower river.

IN the May number of the *Scottish Geographical Magazine* will be found a very complete account of Samoa and its people by Dr. G. A. Turner, who has lived many years on the islands.

THE town Kara-kol, on Lake Issyk-kul, has received the official name of "Prjevalsk" in commemoration of the explorer of Central Asia.

A GEOGRAPHICAL expedition, under the two brothers Grum-Grzimailo, has lately started for the exploration of the Eastern Tian-Shan. On April 19 it had reached Tchardjui, on the Trans-Caspian Railway. Its aim is to connect the explorations of M. Potanin in North-Western Mongolia with those of Prjevalsky. One of the two brothers is already well known for his explorations of the Pamir.

THE Russian Geographical Society is sending out the following expeditions:—M. Vilkitzki, who has made pendulum-observations on Novaya Zemlya, will continue the same measurements in Central and South-Eastern Russia. M. Faussek is sent out to the shores of the White Sea in order to make zoogeographical explorations in the Kandalak Bay, as well as for observations upon the secular rising of the coasts of the White Sea. M. Andrusoff, whose interesting researches into the geological history of the Caspian Sea have attracted a good deal of attention, will continue the geological exploration of Daghestan and Kuban; and M. Kuznetsoff will continue in the Caucasus his work upon the geography of plants. M. Antonoff is sent out to the Transcaspian region for the study of the conditions of animal and vegetable life in the desert; and MM. A. P. Semenoff and Yaschenko will visit the same region for zoological and botanical researches. Of ethnographical expeditions that of M. Katanoff to North-Western Mongolia is worth noting. The investigation of the folk-lore of the White Russians (Byelorusses) will be continued by MM. Romanoff and Dobrovolsky.

THE expedition to Tibet, the departure of which was delayed by the death of Prjevalsky, is now at the town Prjevalsk (formerly Kara-kol), and it will start in a few days, *viâ* the Bedel Pass, to Kashgar. The original plan of reaching Lhassa has been abandoned, and the expedition will limit its explorations to Eastern Turkestan and North-Western Tibet. It is under the leadership of Colonel Pyevtsoff, who accompanied Prjevalsky in all his memorable journeys. It includes also two other travelling companions of Prjevalsky—MM. Roborovsky and Kozloff—and a geologist, M. Bogdanovitch, who is commissioned by the Russian Geographical Society.

THE ROYAL SOCIETY CONVERSAZIONE.

THE annual *conversazione*, held by the Royal Society on May 8, was in every way brilliantly successful. There was a numerous attendance, and the programme had been arranged with the greatest skill and care. We refer to some of the most novel and important objects exhibited. In addition to these, the results set forth in many recent papers to the Royal Society were illustrated by experiments.

Mr. C. V. Boys, F.R.S., exhibited:—(1) Portable Cavendish apparatus for demonstrating the attraction of gravitation. This apparatus differs only from the well-known apparatus of Cavendish in matters of detail. First, instead of the beam 6 feet long, carrying heavy weights, used by Cavendish, or half a metre long, used by Cornu, the beam consists of a piece of lead only 1 centimetre long, and this is inclosed in a round tube of metal, outside which the attracting weights are placed. This reduction of size has been rendered possible by the use of quartz threads, the production of which was shown two years ago. The advantages gained by the reduced dimensions are increased sensibility, and almost perfect elimination of temperature disturbances. The particular apparatus exhibited is designed to show the effect, and that it is the same from time to time, rather than to determine the constant of gravitation absolutely. By arranging the two attracting weights and the two ends of the attracted body at different levels, the deflection is nearly doubled.—(2) Experiment showing the insulation of quartz. A pair of gold leaves are supported by a short rod of quartz which has been melted and drawn out about three-quarters of an inch. The atmosphere is kept moist by a dish of water. Under these circumstances a glass insulating stem allows all the charge to escape in a second or two. With the quartz but little change is observed in four or five hours. The quartz may be dipped in water and put back in its place with the water upon it. It insulates apparently as well as before.—(3) Apparatus for testing the elasticity of fibres. One of these pieces of apparatus consists of a microscope cathetometer arranged vertically, and a gravity bob which is deflected by the vertical pull of the fibre on a side arm. The lower end of the fibre is made fast to a beam carried by the microscope. A scale, to which the upper end of the fibre is fixed, is viewed by the microscope, which thus shows the stretch of the thread; the pulling force is found by subtracting the stretch from the vertical movement of the microscope and multiplying by a constant previously found. The second piece of apparatus is used to measure the fatigue of fibres after torsion.

Results of experiments with working model of the tidal Seine, exhibited by Mr. L. F. Vernon Harcourt. These experiments were undertaken with the object of obtaining an indication of the effects which the various schemes proposed for the improvement of the estuary of the Seine, by the prolongation of the training walls below Berville, would have upon the estuary if carried out. After ascertaining, by experiments, that the former and present conditions of the Seine estuary could be reproduced in miniature in the model, the various schemes proposed were successively introduced in the model, with the results shown upon the diagrams exhibited. The method of working this model has since been applied to the model of another estuary, which may be seen in operation at 6 Queen Anne's Gate, Westminster.

Profs. A. W. Rücker, F.R.S., and T. E. Thorpe, F.R.S., exhibited maps to illustrate the direction and magnitude of the regional magnetic disturbing forces in the British Isles. The British Isles can be divided into a comparatively small number of districts, in each of which the horizontal disturbing forces tend towards centres or loci of attraction, which are also regions of large vertical force. The shaded portions of the maps are districts of high vertical force, and it will be seen that the arrows which represent the horizontal forces on the whole point towards them. In Scotland the forces indicated by the dotted arrows were deduced from data collected in 1857–58 by Mr. Welsh. The five principal lines towards which the magnetic disturbing forces in Great Britain converge are in the immediate neighbourhood of (1) the Caledonian Canal; (2) the basalt of the Western Isles; (3) the centre of the Scotch coal-field, in which basaltic crystalline rocks occur; (4) the line in South-East Yorkshire, in which the Jurassic and Liassic strata thin out, and passing thence to the Lakes; (5) the Palæozoic ridge between London and the South Wales coal-field. There are well-marked centres of attraction, (1) between Reading and Windsor, (2) near the Wash, which have been specially studied. The disturbance which culminates in the first extends from Kenilworth to the Channel, and from Salisbury to the North Sea. The well-known anomaly in the difference of the declinations at Greenwich and Kew is thus accounted for. The maps also afford indications of other subsidiary centres.

Captain H. Capel L. Holden, R.A., showed:—(1) Chronograph for measuring the velocity of projectiles and small periods of time. This chronograph, of which the latest form with Captain Holden's most recent improvements is exhibited, is of the gravity type, originally invented by M. Le Boulengé; since its first introduction it has been improved by Captain Bréger, of the French Marine Artillery. Broadly speaking, it consists of a heavy pillar, to which are affixed two electro-magnets (the circuits of which are arranged to be interrupted by the action of the body whose velocity it is required to measure) which can support two rods, the shorter one of which, in falling, strikes a trigger table and releases a knife, which marks the other as it falls. The time elapsing from the commencement of the fall of the short rod until the knife strikes the other rod is obtained mechanically by means of the instrument called the disjunctor, which breaks both of the separate circuits simultaneously: a commutator in connection with this disjunctor enables errors due to the circuits not being broken simultaneously to be detected and corrected for. When an interval of time occurs between the two circuits being broken, the mark made on the rod by the knife will be more or less above that made when the disjunctor is used, and the space between the two marks gives the means of ascertaining the time, since the rod falls under the influence of gravity. In ordinary use, the screens, where the interruption of the circuit takes place, are made of a continuous wire in circuit, each with its electro-magnet and battery, and these screens are broken by the passage of the projectile through them. The disjunctor reading is arranged so as to be adjustable by altering the height of the magnet, so that, the screens being a fixed distance apart, a scale can be engraved on the micrometer bar of velocities in feet per second, thus saving time and avoiding frequent calculation.—(2) Holden hydrometer. This is intended more especially for use in connection with secondary batteries, for observing the density of the acid during charge and discharge. It consists of two parts—the hydrometer-float and the scale. In use, the scale is clipped to the battery plates or to the side of the containing vessel, the point being pushed down until it just touches the liquid, and the reading is then taken from the top of the hydrometer stem on the ebonite scale. The range of density and the size of the divisions can be varied according to the requirements. The advantages claimed for this form over the ordinary type of hydrometer are: greater sensitiveness, more open scale, and increased legibility owing to the reading being above the level of the liquid and side of the cell, freedom from adherence to the plates or side of the vessel, and the ready correction for temperature by means of a sliding scale.

A model illustrating the formation of ocean currents, exhibited by Mr. A. W. Clayden. This is practically a map of the Atlantic in which the land surfaces are raised about half an inch above the portions occupied by the sea. The continents and larger islands are made of wood cut into the required shape, while the smaller islands are represented by pins or small pieces of sheet metal driven into the board which forms the basis of the whole. This raised map forms the bottom of a shallow tray which can be filled with water up to the level of the land surfaces, thereby obtaining a map (on Mercator's projection) in which the seas are represented by the surface of water. Underneath the tray a wind chest is fixed, and a number of tubes are brought up from it through the continents, and bent over so that the jets of air delivered from them may impinge upon the water. These jets are so arranged as to approximately reproduce on a small scale the actual circulation of the atmosphere as laid down on a chart of the prevalent winds for the year. Care is taken to have as few tubes as possible, and they are so placed as to hide the least possible amount of the sea. The strong and persistent trades are simulated by bringing the openings of the tubes near to the surface of the water, while the fitful and uncertain winds of northern latitudes are imitated by allowing the jet to be considerably dispersed before coming into contact with the water. A foot-blower is attached to supply the wind, and any movement of the water is rendered visible by scattering over it some Lycopodium powder. A few moments after the blast is turned on, the whole surface of the model sea is in motion. All the principal currents of the North Atlantic are shown, including the return current between the great equatorial currents, and the northward stream along the west coast of Greenland. If a narrow opening is made in the Isthmus of Panama all that happens is that some of the return stream round the Mosquito Bay and Gulf of Darien flows into the Pacific, leaving the North Atlantic practically unaffected. But if a large part of Central America is removed, almost the whole of the tropical water passes through the opening, and the currents from Baffin's Bay and the Arctic Ocean are drawn down to the Azores and the Canary Isles. There is an absence of evident connection between the slack water close to the New England coasts and the Labrador current, but the apparatus does not attempt to imitate differences of temperature or differences of rotational velocity, hence any effect due to either of those causes must necessarily be absent. All that is attempted is to demonstrate the connection between the prevalent winds and general oceanic circulation, by showing that nearly all the movements of the water are determined by the direction of the winds and the contours of the coasts.

Mr. James Pitkin exhibited:—(1) Pitkin and Niblett's fire-damp meter. By means of these instruments it is possible to detect and estimate the percentage of oxygen or hydrogen in mixtures of these gases. In its simplest form it consists of two ordinary cylindrical bulbed mercurial thermometers. These are mounted on a suitable base, and are then graduated off in the ordinary way to Fahrenheit or Centigrade scale. One tube registers the temperature of the mixed gases. The other, which is the gas indicator, has its bulb coated with one of those metals which when in a very finely divided state have the peculiar property of occluding and facilitating the chemical combination of certain gases. When placed in a gaseous mixture and during the combination of the gases due to the above property of the metal, a considerable amount of heat is developed. The heat generated thus produces a corresponding rise in the mercurial column. To read the instrument the difference between the two scale readings is taken, and then, by comparison with a table supplied with each instrument, the percentage of gas may be read off. In the case of fire-damp and air or coal-gas and air, the amount of heat developed appears to correspond approximately to the explosive activity of the mixed gases. A sliding scale may be fixed on the instrument, which can be graduated in terms of percentages of any particular gas.—(2) Pocket electric lamp. This lamp is constructed for astronomical and other scientific purposes where a steady and a safe light is occasionally required. Its total weight is 1 lb. 13 oz., and it gives a light of 1 candle-power for a period of six hours. Its charging current is 1 ampere at a potential of 5 volts for four hours.

A series of ancient wreaths and plant remains from the cemetery of Hawara, Egypt, exhibited by Mr. Percy E. Newberry, by permission of the Director of the Royal Gardens, Kew. These wreaths and plant remains were discovered last year by Mr. Flinders Petrie, in coffins of the Ptolemaic period, and date from about the first century before Christ. They are fully described by Mr. Percy E. Newberry, in Mr. W. M. Flinders Petrie's "Hawara, Biahmu, and Arsinoë," and were presented to Kew some few months since.

Gramme ring, rotating under the influence of the magnetism of the earth, exhibited by Mr. J. Wilson Swan. It is a motor of the type of the ordinary dynamo-electric machine, but without field magnets other than the north and south magnetic poles of the earth. The current passing in the ring is about half an ampere.

Preparations of the new element gnomium, recently discovered by Gerhard Krüss and F. W. Schmidt, of Munich, exhibited by Dr. Hugo Müller, F.R.S. Gnomium oxide; gnomium chloride (in aqueous solution); nickel from which the gnomium, which up to the present always accompanied it, has been separated; nickel oxide free from gnomium. Gnomium is a metallic element which, according to the discovery of Krüss and Schmidt, is always associated with cobalt and nickel, and consequently neither of these metals have up to the present been known in the pure state.

Illustrations of the new and the old astronomy, exhibited by Mr. Isaac Roberts. Among these was the photograph of the nebula 51 M. Canum Venaticorum; the original negative being shown under the microscope.

Mr. H. J. Chaney showed a hollow cylinder and sphere, used in the re-determination of the weight of a cubic inch of distilled water, 1889. $t = 62°$, B = 30 inches. One cubic inch = 252·286 grains.

Voltaic balance, exhibited by Dr. G. Gore, F.R.S. Used for measuring voltaic energy in chemical analysis; strength of aqueous solutions; effect of light and heat on aqueous solutions; detecting chemical changes in liquids and measuring their rates: detecting chemical compounds and their combining proportions; measuring losses of voltaic energy during chemical combination; measuring chemical energy. By means of it the influence of 1 part by weight of chlorine in 500,000 million parts by weight of water has been detected.

Films of metals and metallic oxides deposited by electric sparks, exhibited by Prof. W. N. Hartley, F.R.S.

Hair from the Yenisei Mammoth, obtained by F. Schmidt, of the Academy of Sciences, St. Petersburg, exhibited by Prof. G. H. Seeley, F.R.S.

Drawings illustrating the feeding of Scrobiculariæ, exhibited by Dr. H. C. Sorby, F.R.S. The feeding of Scrobiculariæ, as also of Tellinæ, is by actively taking in mud by the indraught syphon and afterwards discharging it by the same, unlike the quiet habit of most other Conchifera.

Mr. J. Young showed—(1) a cluster of nests of a species of Swift (Collocalia) taken in one of the Society Islands; (2) a specimen of *Pluvianellus sociabilis*, a plover obtained in South America, of which only two specimens (obtained fifty years ago) were previously known in Europe; (3) the tail of a Japanese barndoor cock, 11 feet long.

Mr. W. H. Preece, F.R.S., exhibited—(1) calcedonified tree-trunk, from Arizona, U.S.A.; (2) transverse, tangential, and radial microscopical sections of the wood, to illustrate the original vegetable structures and the mineralogical changes which have taken place during and subsequently to the silicification of the woody tissues.

Egyptian blue ("Vesterien") artificially prepared by Prof. F. Fouqué, of the Collège de France, Paris, exhibited by Prof. J. W. Judd, F.R.S. This substance is shown to have the formula CaO, CuO, 4SiO. It has been obtained, not only in a glassy form, but in crystals, which are remarkable for their intense pleochroism (dark blue to rose pink), as was shown in specimen under microscope. For comparison specimens of ancient objects (Scarabei and ornaments used in mosaic work) were exhibited by Mr. R. H. Soden Smith, to illustrate the method in which this blue enamel was employed by the Egyptians. Other specimens of antique ornaments glazed with the Egyptian blue, exhibited by Mr. John Evans, Treasurer of the Royal Society.

A revolving stage for the microscope, exhibited by Prof. R. J. Anderson.

Prof. H. Marshall Ward, F.R.S., exhibited various parasitic fungi, and specimens of diseased timber showing characteristic symptoms of injury caused by them. The chief of these are:—(1) piece of larch stem, affected with the "larch disease," and exhibiting the cups of *Peziza* (*Helotium*) *willkommii* on the cancerous cortex; (2) specimen of fructification of *Polyporus sulphureus*; (3) piece of larch timber attacked by *Polyporus sulphureus*, showing the characteristic symptoms of the injury; (4) piece of oak timber, exhibiting the characteristic symptoms of disease due to the ravages of *Stereum hirsutum*; (5) piece of oak attacked by *Thelephora perdix*, showing the very different mode of injury due to this fungus; (6) piece of spruce fir, attacked by the mycelium of *Trametes radiciperda*, and exhibiting the very characteristic dark spots which serve to diagnose the disease; (7) piece of pine injured by *Agaricus melleus*, and showing the very different symptoms which betray the presence of this fungus; (8) piece of deal with grey mycelium of *Merulius lacrymans*, causing the common "dry rot" of timber; and a similar piece of timber attacked by the white mycelium of *Polyporus vaporarius*, another and quite different fungus, which produces a form of "dry-rot"; (9) portion of pine stem infected with *Peridermium pini*, the Æcidium form of *Coleosporium senecionis*,—the other form of this parasite is found on various species of groundsel (it does much damage to the pines in some forests, producing so-called "cankers" as disastrous as those of the "larch disease"); (10) specimen of wheat infested by *Ustilago carbo* (*U. segetum*), showing the destruction of the ears by the fungus, the black spores of which completely occupy the interior of the grain; (11) specimen of grass attacked by *Epichloe typhina*, a destructive ascomycetous fungus which infests the flowering shoots of pasture grasses: (12) culture specimens of *Sclerotia* developed from species of *Botrytis*, which destroy certain garden plants. Microscopic preparations of these are also exhibited.

Models illustrating a cause of contortions of strata, exhibited by Dr. Charles Ricketts. To induce these flexures, dry and powdered clay of different colours is spread in consecutive layers in a trough, when by the access of water, the clay becomes plastic, sand is poured on some special part, its weight in the experiment being supplemented by extra pressure; this causes the heavier substance to subside into the plastic mass; at the same time the clay-beds are squeezed outwards, the layers underneath being formed into films still continuous with those at the sides, which are rendered considerably thicker than in their original state, and are curved into folds, representing on a small scale such as frequently occur in stratified rocks. The experiment so exactly coincides with natural phenomena that it is reasonable to expect it will afford a true explanation of a frequent cause of contortion, and also of cleavage of strata (see "On some Physical Changes in the Earth's Crust, Part 3," *Geological Magazine*, April 1889, p. 165).

Amorphophallus campanulatus, exhibited by the Director of the Royal Gardens, Kew.

New optical apparatus for lecture demonstration, invented and exhibited by Mr. Eric Stuart Bruce:—(1) Apparatus for projecting Crookes's radiometer in action on the screen, so as to render its effects visible to large audiences.—(2) "The electro-graphoscope." A striking method of showing the illusions produced by persistence of vision to large audiences. In this apparatus a narrow lathe of wood, about an inch wide, is made to revolve rapidly by means of an electric motor, the effect being an almost invisible haze, but when the revolving lathe is placed in the path of the rays of light proceeding from an oxyhydrogen lantern, in which there is a transparent picture or photograph, the image is apparently cast upon the air, in the case of a statue giving the effect of bold relief. In reality minute portions only of the image are cast upon the revolving plane, in such rapid succession that they are united into the perfect whole by the retentive action of the retina of the human eye.

Mr. Eadweard Muybridge exhibited projections by the electric lantern of automatic electro-photographs, exposed at regulated intervals of time, illustrating the consecutive phases of bipedal locomotion, as synchronously viewed from two or more points of sight.

SCIENTIFIC SERIALS.

American Journal of Science, May.—The electrical resistance of stressed glass, by Carl Barus. Following up Warburg's experiments, which have thrown so much new light on the thermal relations of the resistance of glass, the author here deals specially with the effects of stress on electrolyzing glass kept as nearly as possible at different constant temperatures between 100° and 360°. He finds generally that a solid electrolyte like glass is a better conductor of electricity when in a state of strain or torsion than when free from strain. The influence of temperature in changing the value of the electrolytic effect of stress is not marked; the same pull per unit section does not apparently increase the conductivity of glass more at 350° than at 100°, if indeed it increases it as much.—On the formation of siliceous sinter by the vegetation of thermal springs, by Walter Harvey Weed. These researches on the origin of the deposits of siliceous sinter found in the basins of the Yellowstone National Park make it evident that such deposits are largely formed by the vegetation of the hot spring waters. Waters too poor in silica to form sinter deposits by any other cause may be accompanied by beds of siliceous sinter formed by plant life; the extent and thickness of these deposits establish the importance of this form of life as a geological agent.—Marine shells and fragments of shells in the Till near Boston, by Warren Upham. These fossils, occurring in drift deposits near Boston, are usually regarded as evidence of a marine submergence within the Pleistocene or Quaternary period. But Mr. Upham's observations made last year show that they were transported from the bed of the sea on the north by the ice-sheet in the same manner as the materials of the drift have been carried southwards and often deposited at higher elevations than the localities from which they were brought. Hence these shells afford no proof of the former presence of the sea at the level where they are now found.—A platiniferous nickel ore from Canada, by F. W. Clarke and Charles Catlett. The careful analysis here made of these ores from the mines at Sudbury, Ontario, places beyond all doubt the presence of platinum in appreciable quantities. It probably exists in the ore as sperrylite, though this point has not yet been determined.—Stratigraphic position of the Olenellus fauna in North America and Europe, by Chas. D. Walcott. The general result of these researches is to remove the Olenellus fauna both in the Old and New World from the Middle Cambrian to the base of the whole Cambrian system. The paper, which is not concluded, gives full tables of this fauna, with its areas of geographical distribution east and west of the North Atlantic.—Earthquakes in California, by Edward S. Holden. The statistics of seismic disturbances in this region with incidental remarks are brought down to the end of the year 1888.—Chemical action between solids, by William Hallock. In his recent note on a new method of forming alloys, the author undertook to carry out some additional experiments, the results of which are here given. He infers generally that chemical action may take place wherever the products are liquid or gaseous, even though the reagents are solid, with perhaps the added condition that one or both reagents be soluble in the liquid produced.

Revue d'Anthropologie, troisième série, tome iv., deux^{e}. fasc. (Paris, 1889).—On the colour of the eyes and hair of the Aïnos, by M. Lefèvre. These notes were drawn up at the suggestion of Dr. Colignon, while the author was acting as Professor at the Military College of Japan. The principal point commended to his notice was to determine whether there was any foundation for the statement, made by various travellers, that many of the Aïnos present the anomalous condition, that while the hair of the head is red, the beard, and the hair with which various parts of their bodies are profusely covered, are deep black, the skin being sallow, and the eyes light. This coloration is completely at variance with all known physiological relations, and it is obvious from the author's observations that the statement must have arisen from a misconception, due, perhaps, in part to the practice pursued by the Aïnos of colouring their heads a bright red, and tattooing the lips in circular rings of black and blue. The interest of racial coloration is considerable when judged from an ethnological point of view, and special importance attaches to the subject in regard to the Aïnos, who, although undoubtedly a white race, have undergone various modifications in accordance with the different parts of the empire in which they were settled. Thus, while in some districts the people have been forced to adopt the dress and habits of the Japanese, in the neighbourhood of Sapporo, the capital of the Island of Yesso, they have hitherto been enabled to retain their old customs, and keep themselves far more free than elsewhere from intermixture with the Japanese. It is, therefore, the more worthy of notice that in this district no blonde or blue-eyed Aïnos are to be met with, while the people generally have absolutely black hair. It would, in fact, appear that the hair of the normal Aïnos is of a jay-like blackness, coarse and stiff, but bright and lustrous, although in the case of a few of those who have long occupied the sea-coast, the hair is of a dark brown, presenting almost the same softness as that of Europeans. In no section of the people is there the slightest evidence of any anomalous colouring of the hair, eyes, and complexion. M. Lefèvre considers that the stature of the Aïnos is somewhat higher than that of the normal Japanese, while their cranial index, which is found to range from the extremes of dolichocephalism to that of brachycephalism, would seem to give very strong weight to the assumption that these people are not a pure race, and that they differ in accordance with the extent to which Mongolian or other ethnic elements have modified their primitive character.—On the writings and opinions of Samuel Zarza, by M. Salomon Reinach. Considerable interest was excited by a statement made in 1877 by Dr. Topinard, in one of his lectures, afterwards published in the *Gazette Médicale*, according to which a Jew, named Samuel Zarza, was burnt alive in 1450, for having maintained the antiquity of man. This statement excited much attention, and M. Cartailhac, who doubted its accuracy, appealed to his *confrères* for information in regard to the documents from which M. Topinard had quoted. This appeal remained unanswered until the question was lately taken up by M. Reinach, who associated with himself in the necessary investigations a learned Russian Jew, M. Salomon Fuchs. To the latter we are indebted for a commentary on the numerous works of Zarza, surnamed Ben S'né, which, according to his own report, were undertaken in the hope of reviving among his co-religionists in Spain their interest in philosophical and theological inquiries, which had nearly died out amid the miseries they had endured during the civil wars between Peter the Cruel and his brother, Henry II. M. Fuchs has failed to find in these works any opinion expressed concerning the antiquity of man, although the writer appears to have adhered to the belief of the eternity of the world. It is, moreover, obvious from his reference to his age when he completed his second work, entitled "Mikhalal-Yophi," *i.e.* "Perfection of Beauty," in 1369, that he could not have survived until 1450, which is given by the commentators of the seventeenth century, from whom Dr. Topinard borrowed his references, as the date of his presumed martyrdom. While M. Fuchs thus supplies another proof of the inaccuracy of many of the earlier commentators, he at the same time shows by his summary of Zarza's writings that Hebraists might throw interesting light on the early dawn of scientific inquiry by a careful study of the numerous still unprinted remains of Zarza, and of his Spanish co-religionists, who undoubtedly exercised an active influence on the progress of learning in the Middle Ages.—On the belief in familiar household spirits and other forms of superstition, by Dr. Berenger-Feraud. The interest of this paper to the student of folk-lore depends upon the writer's detailed narratives of the local superstitions still prevailing, or only recently exploded, in the rural districts of France; his elaborate exposition of the superstitions of other countries has little value for the English reader.—On questions regarding the Aryans, by M. de Lapouge. The author believes that, at the present stage of our knowledge, we are justified in assuming that in the ancient Aryans we have a blonde dolichocephalic race, whose cradle was in the north-west of Europe as it existed in the second half of the Quaternary age.—On the steatopygia of the Hottentots in the Garden of Acclimatization by M. Topinard.

SOCIETIES AND ACADEMIES.

London.

Royal Society, March 7.—"On the Wave-Length of the Principal Line in the Spectrum of the Aurora." By William Huggins, D.C.L., LL.D., F.R.S.

I think it is very desirable that I should put on record some observations of the spectrum of the aurora which I made in the year 1874, but which, up to the present time, have remained unpublished. These observations were made with a powerful spectroscope, and under conditions which enabled me to determine the wave-length of the principal line within narrow limits of error. The spectroscope was made by Sir Howard Grubb, on the automatic principle of his father, Mr. Thomas Grubb. It is furnished with two "Grubb" compound prisms; each has 5 square inches of base, and gives nearly twice the dispersion of a single prism of 60°—namely, about 9° 6′ from A to H.

The observations were made on February 4, 1874. There was a brilliant aurora, showing a whitish light; a direct-vision spectroscope resolved this light into a brilliant line in the yellow and a faint continuous spectrum.

The "Grubb" spectroscope was directed from the window of the Observatory upon the brightest part of the aurora. In the first instance, an estimation by eye was made of the position of the bright line by comparing it in the instrument with the spectrum of a spirit-lamp. The bright line was seen to fall on the more refrangible side of the line for which Watts gives the wave-length 5582 (*Phil. Mag.*, vol. xli., 1871, p. 14), Ångström and Thalén 5583 ("Spectres des Métalloïdes," *Nov. Act. Soc. Sci. Upsal.*, vol. ix., 1875, p. 29), by from one-fifth to one-fourth of the distance of this line from the beginning of the band. If we take one-fourth, we have λ 5569·6; one-fifth gives λ 5572·3. The mean of these values gives for the

Aurora line λ 5570·9 . . . . (1)

The cross-wires of the spectroscope were then brought upon the line, and the reading 3476 showed the line to fall about midway between two strong lines in the spectrum of tin, λ 5564 and λ 5587 respectively, according to my measures ("Spectra of the Chemical Elements," Phil. Trans., 1864, p. 139). The position of the cross was then compared directly with those lines in the spectrum of an induction spark taken between electrodes of tin. The further details of this comparison are not given in my note-book, but the result only, which placed the

Aurora line at λ 5571 . . . . (2)

Consulting my map of the chemical elements, I found that there was a line of tellurium very near this place—namely, at λ 5575; I therefore brought the spark from tellurium before the slit, when the cross appeared on the more refrangible side of the tellurium line. The measure of the distance of the cross from this line came out equal to λ 0003. The place given in my paper for this line of tellurium is 5575. Thalén gives for the same line 5574·1 (Brit. Assoc. Rep., 1885, p. 292). If we take the mean of these values and deduct 0003, we get for

The line of the aurora λ 5571·5 . . . . . (3)

There are strong lines of iron very near this position in the spectrum, and I made use of these also for a further determination of the place of the aurora line. The cross, after having been placed upon the line of the aurora, was confronted with these lines in the spectrum of iron.

The condensed account in my note-book does not give further particulars of this comparison, but states only that the place of the

Aurora line came out λ 5571·5 . . . . . (4)

Summing up these determinations we have—

(1) Eye-estimation	λ 5570·9
(2) From tin	5571·0
(3) From tellurium	5571·5
(4) From iron	5571·5

From these values I think that we are justified in taking for the aurora line, as a position very near the truth,

λ 5571 ± 0·5 . . . . (5)

Among the numerous determinations of other observers, those of Prof. H. C. Vogel in 1872 (*Lepzig Math. Phys. Berichte*, vol. xxii. p. 285) seem to me to have great weight. A direct-vision spectroscope with a set of five prisms was used. The reduction of the readings of the micrometer into wave-lengths was based upon the repeated measures of 100 lines of the solar spectrum.

The screw had been thoroughly examined. After each observation of the aurora line, readings were taken of the lines of sodium or of hydrogen. The observations extended over four nights. On three nights four separate readings were obtained; on the fourth night two only. Vogel gives as the mean result of the fourteen observations—

Aurora line λ 5571·3 ± 0·92 . . . . . (6)

The recent observations on the spectrum of the aurora by Gyllenskiöld, at Cap Thordsen, in 1882, deserve special mention.[1] With a Hoffmann spectroscope, furnished with a scale, he obtained at Cap Thordsen in 1882 a mean result of λ 5568 ± 1·6; later, in 1884, at Upsala, with a Wrede spectroscope furnished with a micrometer screw, a mean value for the aurora line, λ 5569 ± 6·2.[2] Gyllenskiöld discusses in detail nearly all the recorded observations of the spectrum of the aurora from 1867 to 1882, and then brings them together in a table, with such probable errors as the original statements of the observers enabled him to assign to them.

Gyllenskiöld then calculates by the method of least squares the mean value of all the determinations, and finds the following result:—[3]

Mean value of the 23 observations, λ 5570·0 ± 0·88 . . (7)

The recent measures by C. C. Krafft,[4] depart largely from Gyllenskiöld's mean value. Krafft found on

1882 November 2	λ 5595
,, ,, 11	5586

and measures with the same instrument made by Schroeter, on November 17, gave λ 5587.

Now, though Ångström's original value, λ 5567, may not be quite accurate, his observation fixed a limit towards the red beyond which the aurora line cannot lie. Angström says: "Sa lumière était presque monochromatique, et consistait d'une seule raie brillante située à gauche" (on the more refrangible side) "du groupe connu des raies du calcium" ("Spectre Solaire," Upsal, 1868, p. 42). The position of the most refrangible line of this calcium group is accurately known; according to (Brit. Assoc. Rep. 1884, p. 372)

Kirchhoff	λ 5580·9
Thalén	5580·9
Huggins	5581·0

It is certain therefore, from Ångström's first observation in 1867, alone that the aurora line lies well on the more refrangible side of wave-length 5580. This limit towards the red was confirmed afterwards by Ångström himself; he says later that the yellow line falls almost midway between the second and third line of the shaded carbon group (NATURE, vol. x. p. 211). The positions of these lines of comparison are, according to Ångström and Thalén, λ 5538 and λ 5583 (*Acta Upsal.*, vol. ix. 1875, p. 29).

It follows that Krafft's values, λ 5586, λ 5587, and λ 5595, must be from some cause inaccurate. A possible explanation may be found in the small number of solar lines employed by Krafft for the reduction of the measures into wave-lengths. The curve was drawn through the six Fraunhofer lines, B, C, *a*, D, E, and *b*. There was no control for the curve between D and E, and a very small deviation of the curve from its true position here would be sufficient to account for the position of less refrangibility of from λ 0016 to λ 0024, which his measures give for the aurora line.

It should be stated that Krafft expresses regret that more attention could not be given to the spectroscopic observations. He says:—"Leider gestatteten die obligatorischen Beobachtungen nicht, den spectroscopischen Untersuchungen die gehörige Aufmerksamkeit angedeihen zu lassen. . . . Ich glaubte ausserdem diese Messungen um so mehr auslassen zu können, als der Platz der gewöhnlichen Nordlichtlinie oft und sehr genau bestimmt ist."

To sum up, we have the following values for the principal line of the aurora:—

(6) 1872, Vogel	λ 5571·3 ± 0·92
(5) 1874, Huggins	5571·0 ± 0·5
(7) Gyllenskiöld's mean of twenty-three observers from 1867 to 1884 . . .	5570·0 ± 0·88

These values agree closely, and fix within very narrow limits, the position in the spectrum where we have to seek the chemical origin of the line.

Gyllenskiöld, from his observations of the changes which occur in the spectrum of the aurora, comes to the conclusion

[1] "Observations faites au Cap Thordsen, Spitzberg, par l'Expédition Suédoise," vol. ii. part 1, "Aurores Boréales," par Carlheim-Gyllenskiöld (Stockholm, 1886).

[2] *Ibid.* p. 166.

[3] *Ibid.* p. 169.

[4] "Beobachtungs-Ergebnisse der Norwegischen Polarstation," &c. A. S. Steen (Christiania, 1888).

that "le spectre de l'aurore boréale résulte de la superposition de plusieurs spectres différents," and that "la raie principale forme un de ces spectres élémentaires ; elle apparait très souvent seule." A similar view was taken many years ago by Ångström (NATURE, vol. x. p. 210) and by Vogel (*Leipzig Math. Phys. Berichte*, vol. xxiii. p. 298).

[After consideration, I think that I ought to point out that Mr. Lockyer's recent statement (Roy. Soc. Proc., vol. xlv., 1889, p. 234), that "the characteristic line of the aurora is the remnant of the brightest manganese fluting at 558," is clearly inadmissible, considering the evidence we have of the position of this line.

In support of this statement Mr. Lockyer says :—"Ångström gave the wave-length of the line as 5567, and since then many observers have given the same wave-length for it, but probably without making independent determinations. Piazzi Smyth, however, gives it as 558, which agrees exactly with the bright edge of the manganese fluting. R. H. Proctor also gives the line as a little less refrangible than Ångström's determination. He says: 'My own measures give me a wave-length very slightly greater than those of Winlock and Ångström' (NATURE, vol. iii. p. 468)."

By reference to Gyllenskiöld's table it will be seen that the probable errors of the determinations by Piazzi Smyth and Proctor, 5579 ± 9·5 and 5595 ± 25·0 respectively,[1] are too large to entitle these measures to special weight.

Mr. Lockyer says, further :—"Gyllenskiöld's measures with the Wrede spectroscope also give 5580 as the wave-length of the characteristic line. I feel justified, therefore, in disregarding the difference between the wave-length of the edge of the manganese fluting and the generally accepted wave-length of the aurora line."

Gyllenskiöld's single measure of 5580, on which Mr. Lockyer relies, differs widely from the values which Gyllenskiöld himself assigns to this line—namely, from observations at Cape Thordsen in 1882, λ 5568 ± 1·6, and from observations at Upsala in 1884, with the Wrede spectroscope, λ 5569 ± 6·2.

Speaking of Krafft's observations, Mr. Lockyer says (Roy. Soc. Proc., vol. xlv., 1889, p. 241) :—"The wave-lengths obtained for the aurora line were 5595, 5586, and 5587. Unlike most observations, these place the aurora line on the less refrangible side of the manganese fluting. Hence, we have an additional reason for neglecting the difference between the wave-length of the brightest edge of the manganese fluting, and the commonly accepted wave-length of the aurora line, as given by Ångström. . . . These observations are the latest which have been published, and were obviously made with a full knowledge of all previous work, so that their importance must be strongly insisted upon."

I have already pointed out that Krafft's measures were not made under circumstances which assured to them a high degree of accuracy ; and Krafft's own words, which I have quoted, disclaim expressly any special attempt on his part to redetermine the position of the principal line with a higher degree of accuracy than the observers who preceded him.—March 4.]

May 2.—"The Accurate Determination of Carbonic Acid and Moisture in Air." By J. S. Haldane, M.A., M.B., and M. S. Pembrey (Physiological Laboratory, Oxford). Communicated by Prof. J. Burdon Sanderson, F.R.S.

The authors show that, in spite of the efforts which have been made in recent years to improve the method of Pettenkofer for determining CO_2 in free air, the results obtained by different observers still seriously disagree. They also point out the serious defect in the ordinary "chemical" method of determining moisture in air, that in spite of its superior accuracy it only gives accurate results over a long period, while the proportion of moisture in the air is constantly changing.

A method is then described for determining simultaneously the CO_2 and moisture in air. The method is gravimetric. The CO_2 is estimated by the increase in weight of an apparatus of simple construction containing soda lime, through which a known volume of the air has been passed. The moisture is similarly estimated by means of an apparatus containing pumice soaked in sulphuric acid. The increased accuracy and convenience of the method depend on the facts: (1) that a very rapid current of air may be passed through the apparatus without fear of non-absorption of either CO_2 or moisture ; (2) that by the method of counterpoising with a dummy apparatus during weighing the "errors of weighing" are reduced to about a tenth of what they would otherwise be. It is shown that with these two improvements the method for moisture gives in a period of experiment of one minute a result equal in accuracy to that obtained with the ordinary method in a period of two hours.

Using their own method for CO_2 as a standard, the authors have also tested the Pettenkofer method. They find that the latter method usually gives results for free air about a fifth too high, but that the error is less in proportion with air containing larger amounts of CO_2.

As a number of sets of absorption apparatus can easily be carried about, the new method is well suited for experiments in hygiene, and especially for cases in which a series of experiments require to be made in rapid succession. Both kinds of absorption apparatus last over a large number of experiments without refilling.

Physical Society, April 13.—Prof. Reinold, President, in the chair.—Mr. Shelford Bidwell, F.R.S., showed a lecture experiment illustrating the effect of heat on the magnetic susceptibility of nickel, and an experiment showing an effect of light on magnetism. In the first experiment a piece of nickel was attached to one side of a copper pendulum bob, which was held out of the vertical by bringing the nickel in contact with a fixed magnet. On placing a spirit-lamp flame below the nickel, the bob was, after a short time, released, and oscillated until the nickel had cooled, when it was again attracted and the operation repeated itself. The second experiment had been recently shown before the Royal Society. One end of an iron bar, which had been magnetized and then demagnetized, was placed near a magnetometer needle. On directing a beam of light on the bar an immediate deflection of the needle resulted, and on cutting off the light the needle promptly returned to near its initial position. The direction of magnetization induced by the light is the same as the previous magnetization, and the bar seems to be in an unstable magnetic state. That the effect is due to light and not heat, the author thinks is rendered probable by the suddenness of the action. The President said he had tried the experiment himself and failed to get any effect, but after seeing the arrangement of apparatus used, he believed his non-success due to the comparatively great distance between his bar and needle. Mr. C. Richardson asked if the results were different for different coloured rays, and Prof. S. P. Thompson inquired whether the magnitude of the effect varied with the intensity of illumination as in selenium, and also if any change was produced by altering the direction of vibration of the incident light. Mr. G. M. Whipple wished to know whether any difference was produced by blackening the bars, and as bearing somewhat on the same subject mentioned an induction magnetometer in which an iron bar used was demagnetized by plunging in hot water. The results obtained were very irregular after the first magnetization, and this may have been due to the instability shown to exist by Mr. Bidwell's experiment. In reply, Mr. Bidwell said red light produces most effect, and blackening the bar makes the action much slower. As regards selenium, the character of the effect is similar, but he believes the causes to be different. Polarized light produces no change. In answer to Prof. Herschel, he said that any part of the bar is sensitive to light, and showed that illuminating both sides of the bar increased the effect.—Mr. G. M. Whipple read a note on the dark flash seen in some lightning photographs. After expressing his dissent from the explanations offered in the report of the Lightning Flash Committee of the Meteorological Society and Prof. Stokes respecting ribbon lightning and dark flashes, the author described some experiments he had made on the subject. Ribbon lightning he conceived to be an effect produced by taking the photographs through windows, and to test this, lines on a blackboard were photographed, (1) direct ; (2) through good plate-glass placed obliquely ; and (3) through window-glass, the result being that the double, triple, and ribbon flashes were closely imitated. As regards "dark flashes," the author believes the appearance due to the prints being taken in oblique light, and to be produced by successive reflection from the reduced silver forming the dark line on the negative and the upper surface of the glass of the negative. Prof. Perry suggested that this might be easily proved by examining a negative, the prints from which show the dark flash. Mr. Baily pointed out that, if the explanation given were correct, the dark line should be parallel to the bright one, and this he understood was not always the case. Mr. Boys remarked that one dark flash exhibited minute wriggles not seen in the bright one, and Mr. C. V. Burton thought these might be due

[1] Gyllenskiöld's statement of Proctor's value is based on NATURE, vol. iii. p. 347 and p. 68.

to irregularities in the upper surface of the negative. Dr. Gladstone said he was not satisfied with Prof. Stokes's nitrous oxide explanation, but thought the phenomenon may be due to some kind of reversion. He also mentioned that a negative might probably be obtained from Mr. Shephard, of Westbourne Grove. As regards multiple flashes, Mr. Boys said he had often seen seven or eight flashes traverse the same path in rapid succession. On the motion of the President, the discussion was adjourned until the next meeting, when Mr. Whipple hopes to exhibit the negative referred to, together with photographs of his experimental dark flashes.—On quartz as an insulator, by Mr. C. V. Boys, F.R.S. In making quartz fibres the author observed that the ends of fibres broken during the shooting process coiled up into screws, and projected themselves against anything brought in their vicinity. After a short time they released themselves and sprang back to their original position. This could be repeated indefinitely, and the only explanation he could think of was that the fibre was electrified. If so, then to exhibit such phenomena the insulating qualities of quartz must be very great, and experiments were shown to demonstrate this deduction. A small pair of charged gold leaves were suspended from a short quartz rod in a moistened atmosphere, and the deflection fell one-quarter the original amount in about five hours. A clean glass rod under the same conditions would discharge the leaves in a few seconds. Dipping the quartz into water did not seem to diminish its insulating properties, and ordinary chemicals produced no permanent prejudicial effect. The author considers that quartz will be very useful in electrostatic apparatus, for the troublesome sulphuric acid may be dispensed with.—On a refraction goniometer, by Mr. A. P. Trotter. The goniometer, which was designed when determining the figure of a refracting surface to effect a special distribution of light, is practically a movable four-bar linkwork, representing the figure given in Deschanel (p. 924); two of the bars are parallel to the incident and emergent rays, and the other two normals to the faces of the prism. By its means the angle of a prism to produce a given deviation, when the index of refraction and angle of incidence are known, can be readily found. A series of curves expressing the relation between incidence and deviation for prisms of various angles were shown, and the same curves show the minimum deviation and limiting angle for prisms of all angles represented. The author thinks the instrument will be useful in physical laboratories for adjusting optical apparatus and for the calculation of lighthouse and other polarized lenses, Fresnel prisms, &c. Prof. Herschel said he found a wooden model illustrating the relations between the angles of incidence and refraction very useful in teaching; and Mr. Blakesley sketched an arrangement of links and cords devised for the same purpose. Mr. Boys considered that all such relations were best seen on a slide rule.—A note on apparatus to illustrate crystal forms, by Prof. R. J. Anderson, was read by Prof. Perry. The apparatus is constructed of cords, pulleys, and weights arranged to produce the required figure when in equilibrium. By increasing or decreasing some of the weights the corresponding axes of the crystal forms can be lengthened or shortened, and the passage from one system to another effected. In one arrangement the forces may be divided or united, and the pulleys are carried by rings capable of rotating on different axes. By this apparatus the various conditions are said to be beautifully illustrated, and methods of deriving the oblique from the rectangular systems are shown in photographs which accompany the paper.

Entomological Society, May 1.—Mr. Frederick Du Cane-Godman, F.R.S., Vice-President, in the chair.—Mr. W. L. Distant announced the death of Dr. Signoret, of Paris, one of the Honorary Fellows of the Society.—Dr. Sharp exhibited male and female specimens of *Rhomborhina japonica*, in which the thorax was abnormal; also, a specimen of *Batocera roylei*, which he had kept in a relaxed condition in order to be able to demonstrate the power of stridulation possessed by this species.—Dr. N. Manders exhibited a small collection of Coleoptera, including several remarkable and very interesting species, recently made by him in the Shand States, Burmah.—Mr. C. O. Waterhouse exhibited, for Mr. Frohawk, a series of wings of British butterflies, prepared in accordance with a process (described by Mr. Waterhouse in the Proc. Ent. Soc., 1887, p. xxiii.), by which they were denuded of their scales so as to expose the neuration.—Dr. P. B. Mason exhibited cocoons of a species of spider—*Theridion pallens*, Black.,—from Cannock Chase, distinguished by the presence of large blunt processes on their surface.—Mr. H. Goss exhibited, for Mr. N. F. Dobrée, a number of scales of *Coccidæ*, picked off trees of *Acacia melanoxylon* and *Grevillea robusta*, growing in the Market Square, Natal. These scales had been referred to Mr. J. W. Douglas, who expressed an opinion that they belonged to the family *Brachyscelidæ*, and probably to the genus *Brachyscelis*, Schrader. He said that most of the species lived on *Eucalyptus*.—Captain H. J. Elwes exhibited a long and varied series of specimens of *Terias hecabe*. He remarked that all the specimens which had strongly defined markings were taken in the cold and dry season, and that those which were without, or almost without, markings, were taken in the hot and wet season; further, that he believed that many specimens which had been described as distinct were merely seasonal forms of this variable species. Mr. W. L. Distant, Mr. F. D. Godman, F.R.S., Prof. Meldola, F.R.S., Mr. H. T. Stainton, F.R.S., and Mr. G. Lewis took part in the discussion which ensued.—Mr. H. Burns exhibited, and made remarks on, a number of nests of living ants of the following species, viz. *Formica fusca*, *Lasius alienus*, *L. flavus* *L. niger*, *Myrmica ruginodis*, *M. scabrinodis*, &c. One of the nests contained a queen of *L. flavus*, which had been in the exhibitor's possession since September 1882.—Mr. W. Dannatt exhibited specimens of *Thaumantis howqua*, West., from Shanghai.—Mr. G. C. Bignell communicated a paper entitled "Description of a New Species of British *Ichneumonidæ*."—Mr. A. G. Butler communicated a paper entitled "A Few Words in reply to Mr. Elwes's statements respecting the incorporation of the Zeller Collection with the General Collection of Lepidoptera in the Natural History Museum." Captain Elwes, Mr. Stainton, Mr. Godman, and others, took part in the discussion which ensued.

PARIS.

Academy of Sciences, May 7.—M. Des Cloizeaux, President, in the chair.—On elliptical polarization by vitreous and metallic reflection; extension of the methods of observation to the ultra-violet radiations, by M. A. Cornu. The principles on which Cauchy has established the theory of these two orders of phenomena and the form of the laws controlling them differ so greatly that most physicists regard them as essentially distinct. But these experiments show that this is not the case, and that the same substance may present a continuous transition from one to the other according to the nature of the reflected radiation. It follows that the phenomena presented by transparent substances with metallic sheen (fuchsine, platinocyanides, &c.), far from being exceptional, merely constitute particular forms of the general phenomenon of reflection.—On the origin of bronze, by M. Berthelot. The author has analyzed specimens from a statuette from Tello in Mesopotamia, and from the sceptre of the Egyptian king Pepi I. (sixth dynasty), both dating back to about 4000 B.C., and both consisting of pure copper. From this he argues that, as in the New World, the Stone Age was followed by a Copper Age in the eastern hemisphere, and that the bronze period cannot be more than some fifty or sixty centuries old.—On the thionic series; action of the alkalies, by M. Berthelot. Having already determined the heats of formation of the thionic compounds (*Comptes rendus*, cviii. p. 773), the author here deals with the reciprocal transformations of these compounds under the influence of the alkalies. The pentathionates, tetrathionates, and trithionates are treated in detail, and it is concluded that these as well as other compound substances, such as metaphosphoric and pyrophosphoric acids, hitherto regarded as isolated and exceptional, all come within the same general theories as the organic acids.—Note on an iron meteorite discovered buried in the ground at Haniet-el-Beguel in Algeria, by M. Daubrée. This meteorite, found at a depth of 5 metres, while sinking a well in the Wed Mzab district, appears to be of great age, having fallen probably during the Quaternary epoch. It shows the Widmanstätten figures quite distinctly, and its other characteristics place its extra-terrestrial origin beyond all doubt.—Remarks accompanying the presentation of the third part of the *Bulletin international de la Carte du Ciel*, by M. Mouchez. In these remarks special attention is called to Mr. Isaac Roberts's *pantograveur stellaire*, an ingenious and valuable process, by means of which the photographic impressions of the stars can easily be transferred to metallic plates, and thus preserved from all danger of perishing. The method is simple and economical, and allows of an unlimited number of copies being taken for general use. By this invention all risk is removed of the labours of the International Association for photographing the Heavens being lost to future generations.—Researches on the application of the measurement of rotatory power to the study of the compounds formed by the action of the magnesium and lithium molybdates on the solutions of tartaric acid, by M. D. Gernez. The present series of experiments are analogous to those already described in previous communications, demonstrating the great increase experienced by the rotatory force of certain active compounds when their solutions are placed in contact with various substances without proper action on polarized light. Here M. Gernez studies more particularly the action of the neutral magnesium molybdate on solutions of tartaric acid, and the action of the neutral lithium molybdate on the same solutions. Combining these with the results already obtained, he is now able to formulate the following general conclusion: The simplest combinations which are produced in aqueous solution between tartaric acid and the neutral molybdates and tungstates hitherto studied, and which correspond to a maximum rotatory power, are formed by the union of the acid with the salt molecule for molecule.—On the atomic weight of ruthenium, by M. A. Joly. In a previous communication (*Comptes rendus*, cvii. p. 994) the author announced that the analysis of compounds of nitric oxide with rutheno-chlorides led to a reduction of about two units in the atomic weight of ruthenium (104–103·5) as determined by the latest researches of Claus. He now finds this view confirmed by his own studies, and provisionally fixes the atomic weight of this element at 101·4. In its preliminary transformation into compounds containing nitric oxide the ruthenium was completely freed from osmium, the atomic weight of which, according to Seubert's last determinations, is nearly double (191), and this would explain the considerable reduction in the atomic weight of the ruthenium itself.—On α-oxycinchonine, by MM. E. Jungfleisch and E. Léger. A detailed description is given of the preparation, properties, salts, and various derivatives of this substance, the formula of which is $C_{38}H_{22}N_2O_4$.—On the alcoholic fermentation of the juice of the sugar-cane, by M. V. Marcano. The object of these studies has been to determine the agent of the alcoholic fermentation, as well as the nature of the products accompanying the alcohol yielded by the juice of the sugar-cane.—Action of zinc chloride on isobutylic alcohol in the presence of hydrochloric acid, by MM. H. Malbot and L. Gentil. The points here chiefly studied are the part played by the isobutyl chloride, and the properties of the polybutylenes.—On an artificial silk, by M. de Chardonnet. The author has prepared from a pure cellulose octonitrate a silk-like fabric of great elasticity and softness, more lustrous than the silk of cocoons, and capable of being dyed by the ordinary processes. Specimens will be shown at the Universal Exhibition.—M. Daubrée paid a tribute to the memory of the late M. Lory, Corresponding Member of the Section for Mineralogy, who died at Grenoble on May 3.

BERLIN.

Physical Society, April 5.—Prof. von Helmholtz, President, in the chair.—Prof. Rosenthal, of Erlangen, described his calorimeter and the experiments he had made with it on the heat-production of the animal body. (See report of the Physiological Society in NATURE of April 25, p. 624.) He then showed a small experiment on making flames non-luminous. This result can be obtained either by means of a strong current of air or by considerable cooling. The speaker, however, produced the same effect in the following way. A small gas-flame is made to burn brightly inside a cylindrical chimney; it becomes non-luminous as soon as a platinum crucible is placed on the chimney so as to incompletely close the upper end of the cylinder. Prof. Rosenthal believes that in this case the current of air through the chimney is very considerably slowed, hence the gas issuing from the burner becomes disseminated throughout the whole mass of air, and as a result of this, the temperature being low, it burns without giving any light. Several other explanations of the phenomenon were suggested by the members present at the meeting.—Dr. Fröhlich made a further communication in connection with his older, resultless experiments on the objective demonstration of the vibrations of a telephone-disk, in order to describe his new method by which positive results had been obtained. In his earlier experiments he employed manometric flames, and endeavoured to photograph their movements with the help of a rotating mirror; now, however, he attaches a small mirror to the iron plate of the telephone, and from this the light of an electric lamp is reflected on to a polygonal rotating mirror, from which it falls upon a screen. The vibrations of the plate were thus made visible on the screen, and since each side of the polygonal mirror cast its own image, when the mirror was rotated the curves were seen moving over the screen. The more rapidly the mirror was rotated the slower did the curves move over the screen, and when the rotation was as rapid as the vibration of the plate, the curves became stationary and could thus be exactly observed and drawn. These luminous curves could also be photographed. The speaker had employed this method in a series of researches on certain electrical phenomena which might influence the efficiency of the telephone. Thus the action of alternating currents, of self-induction, of the rise and fall of the current on making and breaking, of the introduction of electro-magnets, and of other conditions, were studied by means of the altered mode of vibration of the telephone plate. The speaker had further obtained a graphic record of the vibrations of the telephone plate when vowels and consonants are sung and spoken into it. Many other problems may, by the above method, be brought nearer to their solution.—Dr. Reichel showed a lecture-experiment with a water-hammer. When the bulb in which the fluid is contained is grasped in the warm hand, the fluid is driven over to the other side by means of the vapour which is then formed. When all the fluid has thus passed over, bubbles of vapour finally make their way through the fluid, and at this moment the hand which is grasping the bulb experiences a distinct sensation of cold.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

THURSDAY, MAY 23, 1889.

THE NEW TECHNICAL EDUCATION BILL.

AFTER the storms which have wrecked so many previous attempts to deal with the question of technical education, it is no less surprising than gratifying to find that on Wednesday, May 8, Sir Henry Roscoe's Bill, representing the views of the National Association for the Promotion of Technical Education, slipped through the second reading stage in less than a minute, with no opposition and amid general cheers. If would be too much to expect that the same easy course lies before the Bill in Committee, but at least it may be said that we are much nearer the settlement of this vexed question than we seemed to be a month ago.

The Bill itself, which we reprint elsewhere, does not differ materially from its predecessor of last year —we mean the Bill introduced last year by Sir Henry Roscoe, not the hapless measure drafted by the Government. There is, indeed, an alteration in the definition of technical education, which now includes, besides instruction in the branches of science and art named in the Science and Art Directory, the working of wood, clay, metal, &c., commercial subjects, and "any other subject applicable to the purposes of agriculture, trade, or commercial life and practice, which may be sanctioned by a minute of the Department of Science and Art made on the representation of a School Board or local authority that such a form of instruction is suited to the needs of its district." This is an improvement on last year's definition, which gave the initiative in this matter to the central Department instead of the local authorities. The more freedom that is given to localities to adapt their scheme of technical instruction to the diverse needs of their own industries the better.

But the Bill is essentially unaltered, and it ought to meet with the same approbation from friends of education as greeted its predecessor. It is, like all the measures that have been drafted, an enabling Bill; that is to say, it gives powers to localities to provide technical instruction if they think fit. The Bill deals with the case both of elementary and secondary schools. Technical instruction given in the former will be provided by the School Board, and a school will not cease to be a public elementary school by reason of technical instruction given therein. If, however, a School Board fails to do its duty in the matter, the local authority (*i.e.* the County, District, or Borough Council, or the Urban Sanitary Authority, as the case may be) may step in and make the requisite provision themselves. In the case of higher technical instruction, provision may be made either by the School Board or, except in the case of London, by the local authority. Provision is made for the payment of fees of deserving students, the establishment of scholarships, grants for laboratories, apparatus, museums, libraries, &c. Grants may be made to the higher technical schools by the Science and Art Department, and to elementary schools giving technical instruction by the Science and Art Department, or the Education Department, or both.

The Bill was allowed to pass the second reading unchallenged only on the understanding that certain alterations should be made in Committee. Until the Government amendments are put on paper, it is hard to give an opinion as to the future chances of the measure. It would of course be out of the question to try to revive the clause of the last Government Bill compelling School Boards either to abstain from providing technical instruction altogether, or to make the same provision for voluntary schools as for schools under their own management. It ought not, however, to be difficult to arrange a satisfactory compromise, and so remove what is undoubtedly a defect in the present measure as it stands, viz. the absence of any provision for the large majority of children who are educated in denominational schools.

It would, indeed, be pitiable if the settlement of the question were again postponed owing to the endless difficulty of the relation between Board and voluntary schools. After all, it should be remembered that by far the most important part of technical instruction necessarily falls within the realm of secondary, not of elementary education. The ground may be prepared in the primary school, but that is nearly all. In our opinion, therefore, the most important clauses of the Bill are those dealing with non-elementary schools, and at all costs these must be preserved, and, if possible, extended; for, as we read the Bill, it is doubtful whether they give the local authority the requisite powers to build new technical schools. This, however, is a matter which can easily be set straight in Committee.

We do not wish to undervalue the part of the Bill dealing with elementary schools. It is most undesirable that a School Board that wishes to build a workshop, or provide tools for manual training, should continue to run the risk of surcharge by the auditors, and it is right that the work of the so-called higher elementary schools should be formally recognized, and established on a satisfactory basis. But if there are any who expect, as a result of the measure, that a system of distinctively technical instruction will be introduced wholesale into our elementary schools, they are destined, in our opinion, to be disappointed.

We note with pleasure that the present Bill is not hedged round by the cumbrous and harassing restrictions which disfigured the Government Bill of last year. There is no requirement of a poll, no restriction in the amount of the rate; and, above all, no clause restricting technical instruction in elementary schools to children in the sixth and seventh standards. Of all alterations that may be proposed, an amendment embodying the last-named restriction would, in our opinion, be the most disastrous. It would at once cripple the work of the higher elementary school, and destroy science as a class subject and (in the fifth standard) as a specific subject throughout our elementary school system. The representatives of the Technical Education Association will doubtless be on the watch to see that no sinister alteration of this kind is introduced, for it would virtually convert the Bill into a measure for prohibiting the provision of technical instruction throughout the greater part of the elementary school course.

There are one or two criticisms which we may offer on the measure as it stands. In the first place, it does nothing for girls—for instruction bearing on domestic economy can hardly be brought under any of the heads enumerated in Clause 11. This objection might be met by slightly extending that clause so as to include cookery, laundry work, &c. Another flaw is the omission to provide expressly for Imperial grants other than payments on results of individual examination. It is true that the Bill leaves the mode in which such grants shall be made to the discretion of the Science and Art Department, but something more definite than this is required. It would be a great mistake if payments for technical instruction were made on results, like the present Science and Art grants; they ought rather to bear a certain proportion to local contributions, and a clause to this effect should, if possible, be embodied in the Bill. Lastly, why should School Boards and local authorities be required to confine any entrance examination which they may institute, to reading, writing, and arithmetic?

In spite of these minor defects in matters of detail, the Bill as a whole ought to meet with the hearty approval of the public, and we trust no stone wi l be left unturned to secure that it shall be passed into law this session. Another year's delay would be most disastrous, as it would have the effect of paralyzing local activity, especially in those centres which have already prepared schemes and collected funds for technical schools, but are waiting year after year to see what form legislation on this subject will take.

A TEXT-BOOK OF HUMAN PHYSIOLOGY.

A Text-book of Human Physiology. By Dr. Austin Flint. Fourth Edition. (London: Lewis, 1888.)

THE present edition of Dr. Flint's "Human Physiology" is a capital manual of the subject. The book has been re-written from the third edition, which was published nine years ago. As might have been expected from the author of the previous work, the style of the text is always clear and eminently readable. Upon the whole the selection of the matter is good, and the illustrations are almost without exception excellent. Detailed description of apparatus and of methods of experiment has been excluded as unsuited to the character of the book. In the same way digression into the laws of physical and chemical science has been avoided as far as possible, on the ground that such knowledge is already within the possession of the student of physiology, or that to obtain it he can turn with advantage to special treatises.

Amid much that is praiseworthy in the work, one may single out some points for especial commendation. The brief historical introductions to certain chapters are of marked excellence, and notably the sketch relating the progress in our knowledge concerning the functions of the heart and blood-vessels. The discussions of the terms hunger and thirst, and of the value of the various constituents of the urine as indices of the general metabolism of the body, are exceedingly full and satisfactory. Very interestingly given, too, is the account of the uses of water and inorganic chemical substances which pass through the organism; and the probability of the formation of a considerable amount of water within the organism during severe muscular exercise is related with striking vigour and force of argument. As its title implies, the volume is devoted particularly to the physiology of man, and the portion dealing with the special mechanisms for voice and speech is exhaustive. The chapters upon the cranial nerves, upon sight, and upon hearing, are perhaps, upon the whole, the best in the entire volume. The illustrations to these chapters are particularly deserving of praise.

In a science developing with such rapidity as of late years physiology has done, peculiar difficulties stand in the way of furnishing a text-book that shall pretend to some degree of completeness, and shall at the same time avoid statement of all that is not absolutely worthy of credence. Dr. Flint has to a great degree succeeded in accomplishing this difficult task. But he has done so somewhat at the expense of matter that might, we think, have been introduced into his text-book with advantage. One finds no definite mention in his work of rhythmic contractility as a function of the fibres of the cardiac muscle *per se*, apart from nervous connections they possess. There is no adequate discussion in this manual, consisting of nearly 900 pages, of the phenomenon of inhibition as an exhibition of temporary diversion of cell-activity into channels of anabolism. When treating of uric acid the writer is silent as to the synthesis from urea and glycocoll, although that fact throws a flood of light upon the origin of the acid in the animal body. A long paragraph is devoted to the pineal gland, and finally the remark is made that in structure it resembles the ductless glands; surely such a suggestion is worse than worthless, in view of the discovery of its relation to the dorsal median eye of Sphenodon.

On the other hand, when writing of the superficial and deep reflexes, no hint is given of any doubt as to the truly reflex nature of the latter. The balance of evidence is decidedly in favour of the patellar jerk being really of the nature of a reflex, yet an unqualified statement on so important a subject is scarcely fair to the student.

In so excellent a chapter as that on sight, it is disappointing to find hardly one word of mention of the phenomena of colour-sensations. The Young-Helmholtz theory is not alluded to, much less any rival hypothesis such as that of Hering. One hears nothing of three primary sensations of colour, or that colour-blindness is most frequently a defect for the rays of the longer wave-lengths. In a physiological work treating especially of man, this ought not to be the case. We are not so poverty-stricken in our knowledge of the functions of the semicircular canals as Dr. Flint would let his reader imagine. No adequate description is given of the symptoms which appear when they are separately injured. No adequate representation is made of the views of the long series of more recent workers on the subject. In the statement of the motor-paths by which nervous impulses arrive at the urinary bladder, no reference is made to the sacral spinal nerves, although the contraction brought about through sympathetic channels is incomparably weaker than that effected along the former route. One must add here, however, that the diagram, from Küss, exhibiting the various forms and positions assumed by the organ in question when distended in various degree, is remarkably useful and well-chosen.

Dr. Flint alludes to, rather than describes, the way in which, by partial superposition and fusion of simple contractions, the tetanic contraction of muscle is obtained. He is far too brief upon the matter, especially as he gives it no pictorial illustration in aid of his text. The student whose grains of knowledge on this head had been gleaned only in the five-lines field that Dr. Flint here allows him, would, one must think, find his garner too empty to satisfy the pillaging of the College examiner. And one sincerely hopes he would. On the other hand, upon the very next page, the significance of the so-called vibration of voluntary muscular contraction is treated in a thoroughly satisfactory way, and in view of extremely recent experiments

One might have expected, in a text-book of human physiology, to find some description of experiments in hypnotism, or at least some mention of the matter. It is a subject that more and more demands attention from the physiologist and from the physician, and a subject to which the student of medicine can have no better introduction than from the objective, non-metaphysical side from which the physiologist makes his inquiries. One has failed to discover any reference to the subject in this work.

A few instances of curious, and one may say unjust, omission of certain authorities demand mention in a notice of the book. On p. 53 it is related that following ligature of the coronary arteries the heart ceased to beat after a mean interval of twenty-three and a half minutes in six experiments by Erichsen. One would have thought the laborious and all-important research on this subject by Cohnheim and his pupil, Von Schulthen-Rechberg, not to speak of previous work by Panum, and by Samuelson, and Von Bezold, was at least worthy of some comment in the connection, and the more so that the results obtained were so infinitely more significant and valuable than those of the experiments here quoted by Dr. Flint. In describing the endings of nerve-fibres in the fibres of striated muscle, Doyère and Rouget are mentioned, and very properly so; but the name of Kühne does not appear, and nothing is said of the nucleated "sole." The description, too, is illustrated by two figures from Rouget, more than a quarter of a century old. On p. 262 occurs the following:—"It is possible, however, that future researches may show that micro-organisms play an important part in actual digestion, as is foreshadowed in a recent article by Pasteur (August 1887). Pasteur has isolated seventeen different micro-organisms of the mouth. Some of these dissolved albumen, gluten, and caseine, and some transformed starch into glucose." "These observations are very suggestive, and they seem to open a new field of inquiry as regards certain of the processes of digestion." To most readers, these lines would certainly infer that observations of this kind had first been recognized in their full bearing by Pasteur, or that, indeed, the observations of Pasteur were the earliest or the most important of the kind. To do this is to do signal injustice to a large number of investigators, who, possessed of the idea, have obtained experimental evidence of its truth, much more complete than, and several years in advance of, that published by Pasteur. One need only mention the names of Duclaux, Marcano, Hueppe, Miller, Wortmann, Escherich, Bourquelot, Brieger, Wolff; and there are many others.

A minor point on which one is inclined to join issue with Dr. Flint is the terminology he employs. He does not employ the word metabolism, but the notion is expressed by employment of "assimilation," and "dis-assimilation." The latter has a peculiarly uncouth ring. The words "anabolism" and "katabolism" one does not find. To speak of serum albumin as serine; of paraglobulin as metalbumen, and of this last as "dissolved fibrin" is likely to render more confused subjects that are sufficiently so already. It is not usual to spell the name lecithin indiscriminately lecithene and lecethine. Gustation and olfaction are not pretty words.

In the matter of illustrations the volume is thoroughly and artistically equipped. Fig. 64 and one or two more of the same kind are, however, severe blemishes. How, one asks, can the drawing of a dog with a fistulous wound in the body benefit the student? What good purpose can it subserve? The figure is a useless, gratuitous exhibition of what must to every mind be the unfortunate and repulsive accompaniment of physiological research. Intellectual and material boons conferred upon society justify to the full a pursuit of the science in despite of every difficulty of this kind, because those boons can be obtained for it by no other course of action. They do not, however, justify for such a book as Dr. Flint's one single picture such as those referred to.

As was to be expected, the question of the elimination of nitrogen from the body is treated with that pleasant decision and competence that can be assumed only by an author who has himself carried on research in the field of which he is writing. The observations of Dr. Flint upon Weston the pedestrian are seemingly at variance, as he remarks, with those of Parkes, and of Fick and Wislicenus, made upon other persons. The suggestion is valuable that the difference may be explained by the much more strenuous character of the exertion undergone by Weston than by Parkes's soldiers, or by the physiologists who walked up the Faulhorn. Dr. Flint found that the excretion of urea was increased by a walk of 100 kilometres a day for five consecutive days, the walker being upon the same generous diet during as well as before and after the exertion. Fick and Wislicenus during their ascent and for a short time beforehand abstained from all nitrogenous food. They found an actual decrease in the amount of urea excreted in the period of exertion. But in the main result the researches are in accord. They all alike fail to yield evidence of increased degradation of proteids sufficient to account for the increased quantity of energy set free.

In conclusion one has to add one word in praise of the form and typography of the book. It is evident that, as the author says in his preface, "the publishers have spared nothing in the mechanical execution of the work." C. S. S.

GEOGRAPHY IN GERMANY.

Beiträge zur Geophysik: Abhandlungen aus dem geographischen Seminar der Universität Strassburg. Herausgegeben von Prof. Dr. Georg Gerland. I. Band. (Stuttgart: Koch, 1887.)

Bericht über die Entwickelung der Methodik und des Studiums der Erdkunde. Von Prof. Dr. Hermann Wagner. Im *Geographisches Jahrbuch*, 1888. (Gotha: Perthes.)

IN 1886–87 there was much discussion among English geographers about the limits and methods of their subject. The whole matter had been gone into by the Germans a few years before. It is curious to note that just when we had relapsed into something like silence on the point, and had agreed to put our views to the test of practice, the debate was vigorously revived in the Fatherland. In part this was the effect of the sympathy and of the supply of material for criticism which came across the water, but in the main it was due to Dr. Gerland's striking introduction to the first volume of the Strassburg "Contributions to Geophysics." In the last *Geographisches Jahrbuch* Dr. Wagner sums up both the English and the German discussions, and, though he differs radically from Dr. Gerland's fundamental positions, he gives to his essay the place of honour. The clearness and richness of its style, the closeness of its argument, the extreme and unhesitating views it enunciates, and its author's great experience command attention, and must be the excuse for once more bringing an almost threadbare subject before English readers.

The three propositions which Dr. Gerland aims chiefly at establishing are that geography has to deal not merely with the earth's surface, or even the earth's crust, but with the earth as a whole; that the human element should be shut out entirely from the view of the geographer, and that geography must be a single science characterized by a single method of investigation, the "mathematical-physical" to the exclusion of the "biological-historical." He defines the task of geography as the study of the "interaction between the earth's interior and the earth's surface," of the "interaction of the forces connected with the earth's matter, and the arranging and rearranging—the development—of the earth's matter as a result of these forces;" in a word of "the earth as a whole," the surface being but the expression of the interior. He enumerates five "geographical disciplines"—mathematical geography, geophysics, *Länderkunde*, geography of organisms, history of geography—and of these geophysics is the most important. He regards mathematics, physics, and geology, as the sciences auxiliary to geography, but mathematics as the least dispensable. He agrees with the views expressed in England in 1887, in laying down the difference between geology and geography as consisting not in the objects studied, which are to a certain extent the same, but in the point of view from which they are studied. After comparing the definitions and programmes of geology according to Naumann, Lapparent, Lyell, and Credner, he terms geography the science of the forces of the earth as a whole (*Kräfte der Gesammterde*); geology, that of the structure of the earth's crust (*Structur der Erdrinde*). It should be noted that his *Länderkunde* is purely physical, the "special part of geophysics"; and that his geography of organisms refuses to touch the organism man. He excludes the human element, or, to use Ratzel's term, *Anthropogeographie*, from geography, on the grounds that, while geography is a science auxiliary to history, the converse is not true; that geography would have two methods—the "mathematical-physical-exact" and the "biological-historical-conclusive"; that mastery of the two methods exceeds the power of one man, and that, as an educational discipline, geography loses force and logical cohesion owing to the mixture of the two methods. He assigns anthropogeography to the historian, whose point of view is that of the microcosm, man.

Dr. Gerland claims for geography, as defined by him, that it is a single science, dealing with a homogeneous mass of facts, with one method and a logical unity, making it a true field for the investigator, and of value to the teacher. His essay of fifty-four pages contains a wealth of examples and of neat formulæ which compel admiration; but it is questionable whether he does much good with his chief positions. With Dr. Wagner, we are disposed to think that he exaggerates the importance of his point that the earth *as a whole* is the subject of geography. He keenly combats the view that the surface of the earth, the topographical, is the specific characteristic of geography. Yet surely the burden of what has been recently said, on the part even of those who hold this view, has been that you must not stop short at the defining of relative position, but inquire into causes, and those causes lie largely within the earth. But Dr. Gerland's second position, his uncompromising exclusion of the human element, has more substance. Bold though he is, he has not dared to exclude the geography of (non-human) organisms. Does not his inconsistency here invalidate his programme? All through his essay one fancies there is a certain undertone of contempt for the merely probable results of anthropogeography. But are the results of the investigation of the distribution of animals at best more than highly probable? Are they not attained by the biological-historical-conclusive method? Are they capable of mathematical expression or certainty? Again, is it fatal to geography that it is too much for one man? Is any man equally master of all the methods of any science? Dr. Gerland is hardly fair to anthropogeography. He says, "river and town are heterogeneous conceptions which geography can never bind logically together." Surely a river may be viewed under two aspects—physical and human. It is part of a great circulation beginning and ending in the ocean, and it is an obstacle or an advantage, according to circumstances, to human communication. Lines of human communication and points of human settlement are not heterogeneous conceptions.

But the real seriousness of Dr. Gerland's contention lies in its results in education; indeed here only is it important. You cannot hedge in the original investigator; you cannot forbid him to cultivate the march-lands which sever the different fields of knowledge. You are only entitled to define what you expect of a geographical teacher and text-book. To exclude the human element would be fatal to the early or general learning of geography. None but mathematical specialists have the preliminary knowledge needed for Dr. Gerland's geography. It would be equally bad to have two geographies, one for the schoolmaster, another for the professor, for it is just because the Universities have neglected this subject that the school teaching has been so ineffectual. Logically, mathematical geography should no doubt come first, but a teacher rarely does well to begin his teaching with the first principles of his subject. H. J. MACKINDER.

OUR BOOK SHELF.

Gleanings from Japan. By W. G. Dickson. (Edinburgh and London: W. Blackwood and Sons, 1889.)

AFTER an interval of twenty years, Mr. Dickson revisited Japan in 1883-84, and in the present volume he gives an account of what he saw. The book contains no very novel information; so many travellers have lately recorded their impressions of Japan that it would now be hard for a writer to present any part of the subject from a wholly new point of view. Nevertheless, Mr. Dickson's book is one of exceptional interest, for, having already been in Japan, and having carefully studied its history, he knew exactly, on his return, the kind of phenomena which it would be best for him to study. Accordingly, we find in his narrative that he fastens attention chiefly on what is really characteristic of Japanese life, and that he understands how to connect particular facts with the general tendencies of Japanese society. Mr. Dickson was, of course, greatly struck by the enormous changes which had taken place from the time when he had formerly visited Japan, and he adds largely to the value of his observations by steadily comparing and contrasting the conditions which came under his notice four or five years ago with those he had noted twenty years before. About Japanese customs and institutions, so far as they are of native origin, he writes in a kindly and appreciative spirit; and he also finds something to admire in the effort of the educated classes "to advance in Western learning and the acquisition of scientific information." He declines, however, to commit himself to any very decided opinion as to the future of Japan. That she may have serious troubles in store for her he does not dispute; but, if they come, they will, he thinks, spring altogether from internal causes, and he has sufficient respect for her rulers to suggest that they "may have wisdom to avert a crash."

Statics for Beginners. By John Greaves, M.A. (London: Macmillan and Co., 1889.)

To simplify the subject of statics, and to make it attractive at the same time, is by no means an easy task, but the author of this little book has gone far towards succeeding in doing this. With the approval of several experienced teachers, the principle of the transmissibility of force has been discarded in favour of the ordinary method. The parallelogram of forces is deduced from the laws of motion, Duchayla's proof being given as an alternative. The definitions are admirable, and the various proofs are as simple as they well can be.

The examples are progressive and very numerous, typical ones being fully worked out.

The book is admirably adapted to serve as a stepping-stone to the larger treatises.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Structure and Distribution of Coral Reefs.

As I have had no personal experience of coral-reefs, I do not wish to touch more than the literary side of the controversy, but, in regard to this, Mr. Guppy's letter in the last number of NATURE (p. 53) obliges me to call attention to the fact that the "90-fathom reef" which he mentions is not at Socotra, but at Rodriguez. Also that, apart from Mr. Guppy, I found little evidence of "ignorance of the depths in which coral-reefs may form." On the contrary, there appeared to be a remarkable concurrence of testimony on the part of observers that, though occasionally a reef-building species may be found alive at depths greater than about 25 fathoms, this bathymetric limit for the growth of reefs, assigned by the earlier observers, is sufficiently accurate for all practical purposes.

It seems, then, to me that, with the evidence before us, the *onus probandi* of the supposition that a reef may commence at any depth which the exigencies of a particular case require, rests on Mr. Guppy (this done, no theory of coral-reef formation is needed—they may grow anywhere). But, till he can establish this hypothetical but fundamental proposition, Masámarhu Island is a fact for Darwin. T. G. BONNEY.

The Turtle-headed Rock Cod.

A RARE specimen of the turtle-headed rock cod (*Glyptauchen panduratus*) has just come into the hands of Mr. J. Douglas Ogilby, of the Ichthyological Department of the Australian Museum at Sydney. This extraordinary fish belongs to the family of the red rock cods. Not many years ago these fishes (the red rock cod and its allies) formed a part of a most miscellaneous collection of species, which, under the general title of *Triglidæ*, included the true gurnards (*Trigla* and *Lepidotrigla*), the flying gurnards (*Dactylopterus*), and the flat-heads (*Platycephalus*). In 1860, however, Dr. Günther wisely separated these fishes from the *Triglidæ*, which family he broke up into four distinct groups. The first of these, named by him *Scorpænidæ*, is that to which the specimen just captured at Sydney belongs. All the *Scorpænidæ* are carnivorous marine fishes, most of which live at the bottom of the sea, and are generally provided with a powerful armature of the head and fin spines; while many possess skinny appendages on the head and body variously developed, which, owing to their resemblance to the fronds of seaweeds, serve the double purpose of enabling them the more easily to obtain their food, and the more effectually to conceal themselves from their enemies. As they are mostly of a small size, this latter point is evidently of no slight value, because, being slow, lazy fishes, they would, without some such means of protection, be unable to cope with their swifter antagonists. Nature has additionally protected this family by enabling it to vary its coloration according to any change of locality which it may be necessary to make, so as, chameleon-like, to fit itself for adaptation to the various phases of life under which it may be called on to exist. The genus *Glyptauchen*, of which the species just received by Mr. Ogilby is the sole representative, was separated in 1860 by Dr. A. Günther from the Cuvierian genus *Apistus*, for the reception of a fish from King George's Sound, Western Australia, described many years ago by Sir John Richardson under the name of *A. panduratus*. It has since been recorded from Port Jackson (Sydney), and the present specimen comes from Manly Beach, a few miles to the north of Port Jackson.

Atmospheric Electricity.

YOUR correspondent, Mr. C. A. C. Bowlker, will, probably, be interested to learn that an electrical discharge, exactly similar to that which he recently experienced on the Glydyr Fawr (? "Elidyr") was described by the late Dr. Mann, and by Mr. F. G. Smith, in the Quarterly Journal of the Meteorological Society for October 1875.

Mr. Smith was engaged in August 1865 in ascending the Linguard Mountain from Pontresina, when his party was overtaken by bad weather. They reached the summit, however, and found, at one end of the ridge of which it consists, a flag-staff tipped with an iron point, and, at the other, a flat metal disk, serving to indicate bearings. Snow was falling, and nothing was visible except mist, but the "otherwise death-like stillness of the spot was broken by a strange, intermittent noise, resembling the rattling of hailstones against the panes of a window. A careful investigation of the cause of this noise soon made it apparent that it proceeded from the flag staff, and was due to the passage of a continuous electrical discharge from the cloud in which the summit was wrapped."

After a time, the party, although, by Mr. Smith's own admission, "alarmed," held their alpenstocks, points upward, in the air, and, at once, each became conscious of an "electrical discharge passing through him, and causing a throbbing in the temples and a tingling in the finger-ends. The noise was still vigorously proceeding when, after three-quarters of an hour's stay, Mr. Smith and his party left the summit."

I called attention to a somewhat similar phenomenon ("An Engineer's Holiday," vol. i. p. 204), which I experienced on crossing the divide separating Central City from Idaho Springs, Colorado, the height of the ridge being 10,000 feet above sea-level.

There was thunder, and "it was raining, but without lightning, as we neared the divide, when I felt a tickling sensation on the backs of my hands. Presuming that a discharge was taking place between our bodies and the cloud, I tried to increase its intensity by holding my wet umbrella, point upwards, above the waggon. This, at once, produced distinct sensations in the hand and arm, the driver remarking, 'Oh! that's common enough here, though many don't know what it is, and others don't notice it.' This man was very nervous about crossing the divide at all while it was thundering, and plainly said if there was lightning he must wait for fair weather."

Possibly, sound might have accompanied this discharge, but the noise of our wheels would have drowned it.

Holmwood, Putney Hill, May 19. DAN. PIDGEON.

Rain-Clouds.

THE rain-cloud which Mr. Abercromby sketches in NATURE of May 2 (p. 12) is often seen in Upper Austria in summer. I have given a rough sketch of these thunder-clouds in the Austrian *Meteorological Journal*, vol. viii., 1873, p. 104.

Vienna, Hohe Warte 38. JULIUS HANN.

THE MUYBRIDGE PHOTOGRAPHS.[1]

MR. MUYBRIDGE is of English birth, a citizen of the Great Republic, and a professional photographer. Long before he applied his knowledge and skill to the subject of instantaneous photography of moving animals and human beings, he had obtained recognition by his work in producing valuable views of Californian scenery, of Panama and the West Indies. In 1872 he made the first lateral photograph of a horse trotting at full speed, for the purpose of settling a controversy among horsemen as to "whether all the feet of a horse while trotting were entirely clear of the ground" at at any one instant of time. It was not until 1877, however, that he conceived the idea that animal locomotion, which was then attracting considerable attention through the experiments of Prof. Marey, of the Collège de France, might be investigated by means of instantaneous photography, with results of value both to the artist and to the naturalist.

Marey's investigations were made by means of elastic cushions, or *tambours*, which were placed on the feet of the moving animal, and connected by flexible tubes to pencils writing on a chronograph. A record of the impact of each foot on the ground was thus obtained, and important information was deduced from these records as to the succession of footfalls and the time-intervals separating them in the various "gaits" of the horse.

Mr. Muybridge proposed to settle this and similar problems once for all by a complete and demonstrative graphic method. He arranged a number of cameras side by side, parallel to the track along which a horse was to be ridden. Each camera was provided with a specially contrived "exposer" (the word suggested by Mr. Muybridge in place of "shutter"), which could be let go by the pulling of a string. The strings connected with the "exposers" were placed across the path of the horse, so that they must be broken by him successively in his passage. At the instant of the breaking of the string, the exposer was brought into play in the corresponding camera, and thus the horse was photographed in a succession of intervals of about 14 inches, representing, according to the rate of progression of the horse, a time-interval of more or less than one-twentieth of a second.

In this way, in 1878, with the wet plates then in use a few sets of horses moving with various gaits were taken by Mr. Muybridge. The results were astonishing and conclusive. They were published at the expense of Mr. Leland Standford, under the title of "The Horse in Motion," and were exhibited in Europe in 1882 by Mr. Muybridge, together with other photographs taken in 1879. The reception which Mr. Muybridge met with on his visit to Paris and London was a great encouragement to him to proceed with his work. Meissonier, the great French painter, was enthusiastic in his admission of the value of the photographs as a guide to the observation required for all true artistic work, and the story goes that a particular attitude of the horse presented by him in one of his best known pictures which had been objected to by the critics as unnatural, was demonstrated by the Muybridge photographs to be perfectly correct. The series of little black *silhouettes*, which were at that time the form in which Mr. Muybridge obtained his pictures, were so contradictory of all preconceived notions as to what were the actual phases of attitude passed through by a trotting or a galloping horse, and so difficult to reconcile with the conventional representations of what is of course a totally different thing, viz. what we see when a trotting or galloping horse crosses our field of vision, that Mr. Muybridge determined on his return to America in 1883 to pursue the subject, and to apply improved methods of photography to the study of the rapid movements of a variety of animals and of man. The new dry plates now made it possible to obtain in exposures of 1/5000 of a second and less an amount of detail which was previously impossible. New automatic methods of registration and exposure were to be employed, larger pictures obtained, and the selected series printed without re-touching by a permanent photogravure process. The funds necessary to carry out this scheme were beyond Mr. Muybridge's own resources, and he for some time failed to obtain the necessary aid from any publisher or scientific institution. A Committee of the University of Pennsylvania thereupon came forward and placed £6000 at Mr. Muybridge's disposal, solely on condition that the first proceeds of the sale of the photographs when ready for publication should be assigned to the reimbursement of this sum. The words of Dr. William Pepper, the Provost of the University, in recording this most worthy action, are remarkable, and ably state that conception of the part of the University in the life of the State which we have so often advocated in these pages. "The function of a University," says Dr. Pepper, "is not limited to the mere instruction of students. Researches and original investigations, conducted by the mature scholars composing its Faculties, are an important part of its work; and in a larger conception of its duty should be included the aid which it can extend to investigators engaged in researches too costly or elaborate to be accomplished by private means. When ample provision is made in these several directions, we shall have the University adequately equipped and prepared to exert fully her great function as a discoverer and teacher of truth."

As a result of the action of the University of Pennsylvania in providing Mr. Muybridge with the means to carry out his experiments, we have a really marvellous set of plates—781 in number—each containing a series of from twelve to thirty pictures representing successive instantaneous phases of movement. About 500 of the plates represent men, women, and children, nude and semi-nude, in successive phases of walking, running, jumping, dancing, bathing, fencing, wrestling, boxing, and other such exercises. The rest of the plates give similar studies of the various gaits of horses, asses, mules, oxen, deer, elephants, camels, raccoons, apes, sloths, and other quadrupeds, as well as of the flight of birds. Many of these photographs have been, this spring, exhibited in London by Mr. Muybridge, projected on the screen by electric light—at the Royal Society, the Royal Institution, the Royal Academy, and the South Kensington Art School. The whole series can now be obtained by those who desire to possess them, and to assist the University of of Pennsylvania by bearing a portion of the expense of their production. Series of not less than one hundred plates are also to be disposed of, and may be seen on application to Mr. Muybridge, who is at present in London.

The interest which these photographs present from the scientific point of view is threefold:—

(A) They, first of all, are important as examples of a very nearly perfect method of investigation by photographic and electrical appliances.

[1] "Animal Locomotion: an Electro-photographic Investigation of Consecutive Phases of Animal Movements." By Eadweard Muybridge. (Published under the auspices of the University of Pennsylvania, 1888.)

(B) They have also a great value on account of the actual facts of natural history and physiology which they record.

(C) They have, thirdly, a quite distinct and perhaps their most definite interest in their relation to psychology.

It seems, indeed, that the most interesting problems which are brought before us in the Muybridge photographs of the galloping horse are not so much those of animal locomotion itself as these, viz. how is it that this (which is demonstrated by the photograph to be the actual series of attitudes assumed by the galloping horse) has given rise through the human eye and brain to the conventional representation with outstretched fore and hind legs? Can the conventional representation be justified? If it cannot, what do we really *see* as opposed to what really *is*? What is the objective fact—the brain-picture—as opposed to the objective fact—the sun-picture? for it is the former which the painter struggles to reproduce. Here, in fact, science and art are absolutely united in one common search after truth.[1] On this subject I hope to say more in a subsequent article.

With regard to the method and apparatus employed by Mr. Muybridge in the present series of photographs, it is to be noted that they are different from those employed in 1878–79. As in his earlier photographs, so in the later series, Mr. Muybridge's object was to obtain successive clear and separate pictures. In this respect his method differs altogether from the simpler and much cheaper one used by Marey since the publication of Muybridge's first results. Marey's method is, no doubt, efficient, and in a certain sense sufficient, for the purpose of determining some of the main facts as to the phases of the limbs in locomotion. The object to be studied moves in sunlight before a dark background. A photographic camera faces it. A large disk with one or more openings in it is rapidly revolved in front of the lens. Whilst the opening is passing the lens, the moving object is photographed; then there is darkness in the camera until an opening again passes the lens. The moving object has now a new position, and is photographed anew on the same plate; and so on, again and again, as often as required, or until the object has moved beyond the range of the plate. Thus on the same plate are developed a series of images, readily compared and faithfully depicting phases of the movement studied at definite intervals of time. The advantage of this method consists in the simplicity of the apparatus required; its defect is that with rapidly moving objects the amount of light necessary is not easily obtained together with a sufficiently dark background.

Mr. Muybridge's perfected apparatus consists of three batteries, each of twelve (or more) cameras. One battery is parallel to the track, a second looks up it from behind the moving object, a third faces the moving object. Each camera is provided with a specially contrived "exposer" or shutter (so called) which is "let off" by means of an electric current. The exposure thus given is as small as the 1/5000 of a second. The electric connection is such that in each of the batteries A, B, C, a camera, A1, is exposed absolutely synchronously with cameras B1 and C1. So, too, with regard to cameras A2 B2, and C2, and with the rest up to A12, B12, and C12. Each exposure thus gives a group of three synchronous pictures recording lateral, fore, and hind views of the moving object. The intervals between the exposures of the successive trios of cameras, ABC1, ABC2, ABC3, &c., is determined by the rotation of a wheel carrying a metallic brush in front of a circular plate, on the circumference of which are placed equidistant metal studs, one connected with the wires going to each trio. The circuit is completed by the contact of the metal studs with the moving metallic brush. The wheel can, by a special mechanism, be rotated so that a revolution is effected in one second or in any fraction of a second. During one revolution the twelve studs make contact at equal intervals of time, and twelve groups of three photographs each, exposed for the 1/5000 of a second and separated from one another by one-twelfth of the time occupied by a revolution, are taken. Usually, Mr. Muybridge found it convenient to set the wheel so that it should rotate at such a rate as to give 1/30 of a second between the contact of the twelve studs, but longer intervals were also employed. Behind the track along which the object was made to move was a black screen divided by white threads into squares of about 2 inches to the side. The bright sunlight of the open space was the illuminating agent, no artificial light being sufficiently powerful. A full account of the apparatus will be found by those specially interested in the subject in a book published by Lippincott Company of Philadelphia in 1888, entitled "The Muybridge Work at the University of Pennsylvania—the Method and the Result." Enough has been said here to give an idea of the perfection attained in the apparatus.

With regard to the results, in the form of facts recorded of interest to the naturalist and physiologist, it is not easy to speak in the brief space at my disposal. The branch of inquiry opened out by this method of instantaneous photography is in its infancy, and generalizations of any consequence can hardly be looked for at present. The questions to be answered—the hypotheses which it will be necessary to test—have not yet been formulated. What we have in Mr. Muybridge's published plates is a number of individual studies. By far the most complete investigation is that of the various gaits of the horse, which may be considered as very nearly exhaustive. An interesting generalization which perhaps might have been arrived at without the aid of the camera—but could not have been clearly demonstrated without it—is that the walking gait of all Mammalia is the same, including the quadrupedal crawl of the infant man, and the progression of the sloth as it hangs from a horizontal pole. An apparent exception to this rule is found in the baboon, which instead of extending one pair of "diagonals"[1] simultaneously and then bringing them together beneath the body whilst the other pair is extended, exhibits the simultaneous extension of a lateral pair followed by their approximation whilst the opposite lateral pair are extended. The analysis of various gaits involves many points besides the mere swing of the limbs, the most obvious and important of which are the succession of the footfalls, the weight of impact, and its exact period (which need not coincide with visible contact of foot and ground), the exact mechanical value of the complex stroke given by the limb, and the exact period at which it is applied (which need not altogether coincide with that part of it given by the foot as it leaves the ground). Another factor to be studied is the rotation of the various segments of the limb.

Information and suggestion on these points are furnished by the photographs, but it is by no means to be supposed that it is possible that once for all these problems can be settled by any set of photographs, however elaborate. The turning of the quill-feathers of the bird's wing during the upward movement or recovery of the wing, so that they cut the air instead of pressing it with a broad surface, is one of the prettiest demonstrations which Mr. Muybridge has obtained. That such a movement takes place seems to have been observed by the ordinary man in the remote past, for the word "feathering," applied to the similar movement of an oar in rowing, implies a knowledge of the setting of the feathers in the upward movement of the bird's wing.

[1] Mr. Francis Galton, in NATURE, vol. xxvi. p. 228, has made a valuable suggestion on this subject—which is repeated by Mr. George Snell in the *Century* in 1883—to the effect that the brain-picture consists of a blending of the extreme positions of extension of the hind limbs and the fore limbs, which, although not actually coincident in time, are longest in duration of all the phases passed through.

[1] The "diagonals" are the right fore limb and the left hind limb, and the left fore limb and the right hind limb; the "laterals" are the right fore and hind limbs and the left fore and hind limbs.

Whilst the photographs furnish abundant material for the further study and consideration of the normal movements of a variety of animals and of man, there are some in the series which are especially suggestive of new lines of research. Amongst these are the series illustrating locomotion in man in diseased conditions, such as locomotor ataxia, and lateral sclerosis. A distinct line of scientific inquiry is suggested by those photographs which represent men, women, or children, in the course of movement which is associated with emotion. A new chapter in Mr. Darwin's "Expression of the Emotions" could be written by the aid of some of these series, and a most interesting line of investigation, to be followed up by new photographic analysis, is indicated. Not only is the play of facial muscles connected with the series of emotions of the base-ball player recorded in half a dozen pictures taken between the moment of raising the bat and striking the ball, but in other photographs we have unconscious expression of mental condition exhibited by rapidly transient movements of the whole body. These are especially noticeable in the series of a naked child approaching a stranger in order to offer to her a bunch of flowers, and in the three or four phases of movement of the young woman springing from her bath after she has been unexpectedly "douched" from head to foot with a bucket of ice-cold water.

It is clear enough that the correlation of movements of facial and limb muscles in the expression of emotion can be best studied by such instantaneous photographic series as the Muybridge publication contains; and, as Darwin, with his marvellous insight, showed, such study of emotional states furnishes some of the most important evidence with regard to the relationship of man and animals.

It is no doubt true that the immediate result of Mr. Muybridge's work, from the scientific point of view, is the desire which they evoke to apply this method systematically and experimentally to a variety of subjects of investigation. The present pictures have great value, and many of them great—indeed astonishing—beauty (*e.g.* the wrestling boys). They should be purchased by those who can afford them for the purpose of bearing a share in the expense of so important an experiment as that set agoing by the University of Philadelphia. But we should like to see the batteries turned on again, and a number of new subjects investigated. Terrestrial locomotion has been gradually developed through an amphibious transition from aquatic locomotion. The movements of fishes, of tadpoles, salamanders, turtles, and crocodiles should be included in the scope of any study of vertebrate limb-play. But even more necessary is it that in future the scientific method, of theory, test hypothesis, and experiment, should be followed in the application of the photographic batteries, so that each set of photographs may definitely prove some particular point or points in the orderly development of a general doctrine.

For my own part, I should greatly like to apply Mr. Muybridge's cameras, or a similar set of batteries, to the investigation of a phenomenon more puzzling even than that of "the galloping horse." I allude to the problem of "the running centipede." I have a series of drawings made from large West Indian specimens which I kept alive for some time in my laboratory at University College. At the same time I made drawings and recorded as well as I could the movements of the legs of *Peripatus capensis*, which was also (through Mr. Sedgwick's kindness) living in my laboratory. I am anxious to compare with these movements the rapid rhythmical actions of the parapodia of such Chætopods as Phyllodoce and Nephthys on the one hand, and the curious "gait" of the Hexapod insects, of which Prof. Lloyd Morgan has already written a few words in NATURE. Passing on to scorpions and spiders, and then to shrimps, lobsters, and crabs, we should eventually possess the outlines of an investigation of Arthropod locomotion. There is no doubt that the Muybridge battery would be the one effective means of study in the case of the centipede and marine worms, although in some cases a good deal may be done by intent observation and hand-drawn records. The difficulty of this investigation, and the disastrous results in the way of perplexity which follow from too close an application to it *without* the aid of Mr. Muybridge, is set forth in certain lines, the authorship of which is unknown to me or to the friend who kindly sent them to me on hearing that I was studying the limb-play of centipedes. May I be pardoned for quoting them, and associating in this way fancy with fact, whilst expressing the hope that Mr. Muybridge will take steps to prevent any such catastrophe in the future as these lines record!

> A centipede was happy—quite!
> Until a toad in fun
> Said, "Pray which leg moves after which?"
> This raised her doubts to such a pitch,
> She fell exhausted in the ditch,
> Not knowing how to run.

E. RAY LANKESTER.

ON THE DETERMINATION OF MASSES IN ASTRONOMY.

IN the *Annuaire du Bureau des Longitudes* for 1889 occurs an interesting article by M. Tisserand on the methods employed in the measurement of the masses of the heavenly bodies. The writer begins with an explanation of the elementary principles leading to the law of Newton that *all bodies attract one another with a force which is proportional to their masses and inversely as the square of the distance between them.* He proves, in a popular manner, that this force is equal to the product of mass into acceleration; and therefore, speaking theoretically, to compare the masses of two bodies it is only necessary to apply directly to each of them the same force and to measure the acceleration produced; or, if a body be placed in succession at the same distance from the sun and the earth it will be attracted towards each with a force which is proportional to their masses. Hence, since the space traversed by a body is directly proportional to the acceleration, if during the first second the body fell 330 metres towards the sun, and 1 millimetre towards the earth, it would be obvious that the sun had a mass 330,000 times greater than the earth. Similarly, by applying the law of inverse squares, the relative masses of the sun and earth might be found when the distance of the body from each was not the same. We find that the earth falls towards the sun 10·60 metres in a minute, and that our moon falls towards the earth 4·90 metres in the same time. But the earth is 386 times nearer the moon than it is to the sun, so correcting for difference of distance we get $\frac{4 \cdot 9}{(386)^2} =$ 0·0000328 metre as the fall of the moon towards the earth in a minute. Therefore the sun's mass is to the earth's mass as 10·6 is to 0·0000328—that is, 1/323,000. This method is, however, dependent on our knowledge of the distance of the sun and moon. The same calculation may be employed, without modification, to find the mass of a planet having a satellite. Kepler's third law is used for expressing the mass m of a planet in terms of the sun's mass M. The formula being:—

$$\frac{m}{M} = \left(\frac{a'}{a}\right)^3 \left(\frac{T}{T'}\right)^2,$$

where a is the semi-major axis of the planet's orbit and T the time of revolution round the sun; a' and T′ representing similar terms for the satellite.

In the case of Jupiter, observations of the four satellites may be made and the mean result taken. A recent determination by M. Schur gives the value 1/1047·232 as compared with the sun.

Saturn's mass has been obtained from observations of its two largest satellites, Titan and Japetus. Bessel's researches made it 1/3502, whilst Struve found a value 1/3498. This gives roughly the fraction 1/3500 as the planet's mass.

Newcomb deduced, from observations of the four satellites of Uranus, a mass 1/22,600, and by observations of Neptune's one satellite found a value 1/19,380 as the planet's mass.

Before the discovery of the Martian satellites by Hall, the mass of the planet was a matter of great uncertainty. The discoverer's observations of the satellites led him to assign 1/3,100,000 as the mass of Mars, a result probably not far from the truth.

The Masses of Planets without Satellites.

For the determination of the masses of Mercury and Venus a different and much less exact method of procedure is used. If the masses of Venus and the earth were known, the perturbations they would give to the motion of Mercury could be easily calculated. Let the orbit be calculated which Mercury would have if it existed alone with the sun, and then let its true path be found. By comparing the two paths the disturbing effect of Venus and the earth may be also found. In a similar manner the calculated and true paths of Venus may be compared; the disturbing masses being Mercury and the earth. In this way a series of equations is obtained from which the masses of Mercury and Venus may be isolated. The result in the case of Mercury is 1/5,000,000.

The Mass of Jupiter.

M. Tisserand gives a full discussion of the methods of determining Jupiter's mass, which, being so considerable, shows itself in its effects upon many bodies of our system.

Beginning with comets, he quotes the comet of Lexell as a typical case. In 1769 this comet approached very near to Jupiter, and by the planet's action was brought within our range of vision and given a period of $5\frac{3}{5}$ years. Its return in 1776 could not be observed, and before another revolution could be completed, viz. in 1779, the comet was shown by Lexell to have again approached very near to Jupiter, nearer than the fourth satellite. The probable result was that the elliptic orbit was transformed into a parabolic one by the predominance of the planet's attraction over that of the sun, and the comet left our system, never to return.

From observations of the perturbations of Winnecke's comet, M. de Haertl found Jupiter's mass to be 1/1047·175, whilst Faye's comet gave the value 1/1047·788.

Some of the asteroids approach very near to Jupiter, amongst these are (24) Themis, (49) Pales, and (153) Hilda, and from observations of the motion of Themis the planet's mass has been found 1/1047·538. Estimations have also been made by observations of the perturbations of Saturn, but, since the necessary series should cover a cycle of 900 years, and only 120 years are available, the method is not yet very exact. This accounts for the anomalous result 1/1070·5 found by Bouvard in 1821.

It is also mentioned that Airy, from 1832 to 1836, observed the motion of the fourth satellite and found for Jupiter a mass 1/1047·64, whilst Bessel in 1841 found 1/1047·905.

The following are the masses of the planets given by M. Tisserand, with the earth as unit:—

Mercury	$\frac{1}{16}$	Jupiter	310
Venus	$\frac{4}{5}$	Saturn	93
The Earth ...	1	Uranus	14
Mars	$\frac{1}{10}$	Neptune	17

Cavendish's method for determining the mean density of the earth is next explained, and it is shown that, knowing the relative masses of the planets as given in the above table, we may express their weights in pounds.

Determination of the Masses of Asteroids.

Some pages are devoted to a discussion of these small bodies. It has been found that the effect of each asteroid is to give a motion to the line of apsides of Mars's orbit. The sum of these effects is the same as would be produced by taking a mean orbit of all the asteroids and distributing them uniformly in it. Leverrier made a calculation on the assumption that the total mass of the asteroids was equal to that of the earth, and he found that, if they had a mass only equal to one-fourth that of the earth, Mars would be disturbed by an amount clearly perceptible to us. M. Swedstrup has found the assumption too high, and has calculated that the sum of all the asteroids known up to August 1880 is only about 1/4000 of the earth's mass, or about 1/50 that of the moon. Three comparatively large asteroids have had their diameters measured. Sir W. Herschel found the apparent diameter of Ceres and Pallas to be 0″·35 and 0″·24 respectively; the equivalent in kilometres being 250 and 170. For Vesta, Mädler found an apparent diameter 0″·65, or 470 kilometres. If these bodies be supposed to have the same density as the earth, their proportional masses will be found—Ceres, 1/130,000; Pallas, 1/420,000; Vesta, 1/20,000. By photometric means, the diameters of these asteroids have been determined by Prof. Pickering, and also of some much smaller, such as Eve, with a diameter of 23 kilometres, and Menippe, whose diameter is only 20 kilometres, being no larger than the meteorites met by the earth daily.

Determination of the Masses of Satellites.

The method of determining the mass of our satellite based upon the fact that it is the common centre of gravity of the earth and moon, and not the earth itself, which moves in an elliptic orbit round the sun, is fully explained by the writer. By means of it, the mass of the moon has been found 1/81 that of the earth. Observations of the proportion of lunar to solar precession, as well as lunar and solar tides, also furnish a means of determining the moon's mass.

Masses of Jupiter's Satellites.

These bodies, so proportionally small, the greatest being only 1/10,000 of the planet's mass, cannot have their masses accurately determined by the measurement of the angle subtended by the line joining the planet to the common centre of gravity; for, since the line joining the planet to its satellite is divided into parts inversely proportional to their masses in order to find this point, the line in question is very small. Hence the best method of determining the measures of the satellites in this case is, according to M. Tisserand, by measurement of the disturbances upon each other. This method was propounded and worked out by Laplace with the following results, in terms of Jupiter's mass:—

1st satellite ...	1/59,000	3rd satellite ...	1/11,000
2nd ,, ...	1/43,000	4th ,, ...	1/23,000

This proportion would give the third satellite a mass about double that of our moon.

The Satellites of Saturn.

Titan, as its name suggests, is the largest of the family, and consequently exercises a considerable influence over the others. Prof. Hall found that under its action the major axis of Hyperion's orbit made a complete revolution in about eighteen years. Newcomb, Tisserand, Stone, and Hill have each investigated the matter, but it is mainly due to the two latter observers that Titan's mass has been found 1/4700 that of Saturn. Prof Pickering has compared the diameters of the other satellites with that of Titan by photometric means, and, if they all have the same density, the following numbers represent their masses, Saturn's mass being unity :—

Mimas ...	... 1/500,000	Rhea ...	... 1/32,000
Enceladus	... 1/270,000	Hyperion	... 1/1,800,000
Tethys ...	... 1/75,000	Japetus	... 1/110,000
Dione ...	... 1/85,000		

The mass of Saturn's rings has been found 1/620 that of the planet by observations of the rotational movement which it imparts to the major axes or line of apsides of the satellites.

The masses of the satellites of Uranus and Neptune are not known to any degree of accuracy. The two satellites of Mars have had their masses deduced from photometric measures, but they are so small—about 10 kilometres in diameter, being no larger than the smallest known asteroids—that the numbers found cannot be very exact.

Masses of some Stars.

M. Tisserand rightly gives a dissertation, full and clear withal, of this subject. Sir William Herschel was the discoverer of the relative motions of binary stars in 1802. The obvious conclusion from such a discovery was that the laws of gravitation were universal. Truly, it was not logical to make such an assumption, and some objections have been raised, but the *onus probandi* rests with those who doubt it. In considering the motions of the components of a binary star system, it must be remembered that they revolve round a common centre of gravity. It is usual, however, to consider the principal stars as fixed, but augmented by the mass of its satellite, the latter having an orbit which is the mean of the two. Knowing the fall of the satellite to its primary in one second, we may calculate what it would be if at the same distance from it that the earth is from the sun. But we know by how much the satellite would fall towards the sun, since it would fall as the earth. Hence the consideration of the two falls will give the sum of the masses of the stars in terms of the sun's mass.

The following is the formula employed :—

$$\frac{m + m'}{M} = \left(\frac{a}{p}\right)^3 : T^2 ;$$

m and m' are the masses of the two stars ; M that of the sun ; a is the angle, expressed in seconds, which is subtended at the earth by the semi-major axis of the satellites orbit ; p is the "annual parallax" of the binary group expressed in seconds ; whilst T is the time in years of one revolution of the satellite. These are the numbers that have been obtained for four groups, the distances of which from the earth are known :—

Star.	Parallax.	Magnitude.	Sum of Masses.
α Centauri	0″·80	1	1·8
η Cassiopeiæ	0″·15	4	8·3
70 ρ Ophiuchi	0″·17	4·5	2·5
o^2 Eradini	0″·22	4·5	1·0

Sirius and its Companion.

The article concludes with a complete history of the work which suggested the existence of a companion to Sirius. Bessel had determined the proper motion of thirty-six stars by observations of their right ascensions and comparing with Bradley's, but he found that in the case of Sirius the hypothesis of a uniform variation was irreconcilable with them, and suggested that the irregularities might be produced by the action of some obscure body. As a proof that obscure bodies exist in the heavens, the case of Tycho Brahé's Nova is quoted, this being a star which suddenly appeared in Cassiopeia in 1572, and then gradually disappeared without change of place. After Bessel's death Peters found that it was possible to account for the irregularities by the supposition that Sirius described an orbit in fifty years whose eccentricity was about 0·8. Safford, in 1861, from a discussion of the declinations of Sirius, came to the same conclusion as Peters ; whilst Auwers, in 1862, after investigating about 7000 right ascensions and 4000 declinations, found the time of revolution to be forty-nine years, and the eccentricity 0·601. At the same time as Auwers was engaged with his calculations, Alvan Clark discovered a small star only about 10″ from Sirius, which appeared to be the companion. Future considerations supported the surmise, and proved that this body was precisely what was required to account for the orbit of Sirius round the common centre of gravity.

If Gill's measure of the parallax of Sirius be taken as correct, viz. 0″·38, the sum of the masses of the two stars is equal to 4·4 that of the sun. Sirius has about twice the mass of its companion, and they are separated by a distance a little more than twice the distance of Uranus from the sun.

From a discussion of similar little irregularities in the proper motion of η Cassiopeiæ, Struve found its mass to be 6·6 compared with the sun, whilst its companion was 1·7 times as great.

A reflection on the inability of astronomers before Copernicus to make such measurements as those preceding, concludes this retrospect.

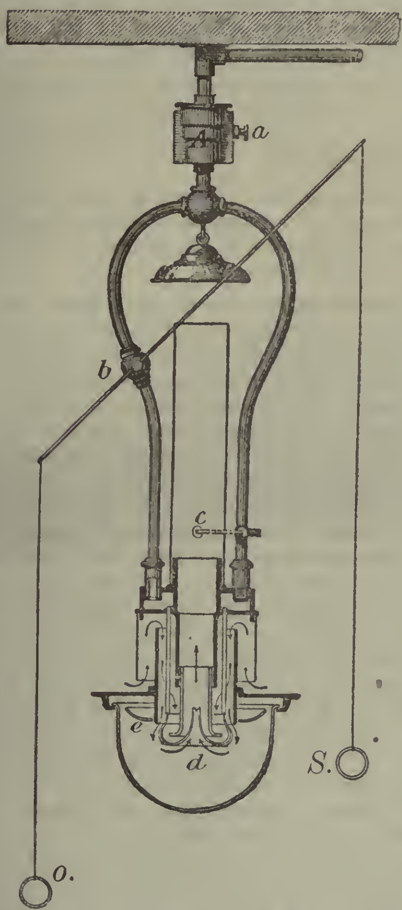
R. A. GREGORY.

A NEW FORM OF REGENERATIVE GAS-LAMP.

FROM the time when Mr. Frederick Siemens first introduced regenerative gas-burners, now ten years ago, down to the present day, this method of burning gas for illuminating purposes has been adopted all over the world, and has come to the assistance of the gas companies by illustrating the fact that, with proper appliances, gas can produce the same brilliant effects as are ordinarily produced by means of electricity, at much less expense both as regards first cost and working. We would explain that in regenerative lamps the heat which is usually wasted in ordinary burners is to a great extent returned to the flame. The manner in which this result is brought about is by intercepting, by means of a regenerator, the heat passing away with the products of combustion, and applying the heat thus saved to raise the temperature of the air which feeds the flame, thus increasing the temperature of the latter, and its illuminating power ; for it may be admitted that the higher the temperature of a body rendered incandescent by heat, the greater is the proportion of light rays emitted out of the total amount of energy radiated. This being the case, the amount of heat carried from such a source of illumination to the surrounding atmosphere by conduction and convection must be less than in the case of a burner consuming the same quantity of gas burning at a lower temperature, which circumstance, combined with the well-known economy resulting from the use of these burners, accounts to a great extent for the popularity which regenerative lamps have attained.

Mr. Frederick Siemens has lately introduced a new form of regenerative gas-lamp, which we understand is highly efficient, and is in consequence being largely adopted ; its construction is shown in the accompanying diagram. It is known as the Siemens inverted type, and is produced in various ornamental designs, which have been much admired. After passing through the governor A, and the tap b, the gas enters an annular casing ; in the lower portion of this, a number of small tubes are fixed, forming the burner, from which tubes the gas passes out in separate streams. By this means, combustion of a very perfect character takes place, as the air is directed round each separate stream of gas, and thus enabled to combine most intimately with it. Within the circle of small tubes is a trumpet-shaped porcelain tube, d, and around the outside and inside of this the gas burns downwards and slightly upwards, as indicated by arrows, thus producing a steady powerful flame of beautiful appearance. This porcelain tube forms the lower portion of the chimney, around which is placed the regenerator. The products of combustion, in passing away, heat the regenerator by conduction, through the metal of the same; and the air, passing upwards and downwards between its metallic surfaces, as also indicated by arrows in the diagram, carries the heat back to the flame. The lamp is closed below by a glass globe, which, however, need not be removed for lighting, as a flash-light is provided for that purpose.

These lamps are made of different sizes, with a consumption varying from 10 to 40 cubic feet of gas per



hour; with London gas they give a light of from ten to twelve candles per cubic foot consumed per hour, which is from four to five times as much as is obtained with ordinary burners. It would have been easy to arrange the lamp we have just described so as to produce a much higher result than that given above; but, to produce this effect, the air supplying the burner would have to be passed through small channels, which would be liable to be partly closed up by oxidation, and thus, by reducing the air-supply, cause the lamp to smoke, whereas the Siemens lamp has been specially designed to provide against this unpleasantness, to which regenerative gas-lamps are more or less liable.

HEINRICH GUSTAV REICHENBACH.

ON the 6th inst., there died at Hamburg, in the sixty-seventh year of his age, a botanist long and familiarly known to his English colleagues, and one whose name will be preserved in the annals of botany.

Heinrich Gustav Reichenbach had been Professor of Botany and Director of the Botanic Garden at Hamburg since 1862. He was born in Leipzig, his father having been also a well-known botanist and Professor in Dresden from 1820 till his death in 1879. Much of the younger Reichenbach's work was done in association with his father, with whom he co-operated in the production of the later volumes of the carefully elaborated *Icones Floræ Germanicæ et Helveticæ*. But work of this character, carefully and critically executed though it was, was cast into the shade by the magnitude of his labours among the Orchidaceæ. Reichenbach the younger devoted more than forty years of his life, almost (though, as we have seen, not quite) exclusively to the study of orchids.

At the commencement of his career, Lindley was still in the plenitude of his powers, but when, some quarter of a century since, the great English botanist failed in health, and subsequently died, there was no one to question the supremacy of Reichenbach so far as orchids were concerned.

From that time to the present the Hamburg Professor has reigned with undisputed sway. His reign corresponds in its progress with the development of that passion for the cultivation of orchids which has attained such large proportions in this country. This is a fashion which at present shows no sign of waning here, whilst it is spreading widely in other countries. It has proved of signal service to orchidology in its systematic aspect, and to a less degree to morphology and biology, as witnesses, to cite only one illustration, the work of Darwin on the "Fertilization of Orchids." A hundred years ago about three hundred species were catalogued in the later editions of Linnæus's "Species Plantarum," and those three hundred were very imperfectly known or illustrated. About sixty years have elapsed since Lindley began his first systematic enumeration of the genera and species, a work in which he was at first greatly aided by the previous labours of Brown and by the splendid drawings of Bauer. In 1840, at the conclusion of the "Genera and Species," Lindley mentions that the total number of species included in that work amounted to 1980, of which the author himself had analyzed three-fourths. Later estimates in the "Vegetable Kingdom" bring the numbers up to 394 genera and 3000 species. Bentham, in 1883, calculated the known species as between 4500 and 5000; while Pfitzer, the most recent census-maker, gives the extreme number of species as 10,000. Granting that this latter figure is excessive, it at least suffices to illustrate the enormous increase in our knowledge of orchids. This advance has been, as we have said, chiefly due to the orchidomania which originated as a consequence of the exhibition of a few remarkable forms at the early meetings of the Horticultural Society, and which has been growing ever since. We never heard of any material good arising from the tulipomania; but the passion for orchids, involving, as it has done, the exploration of the countries where they grow, and the collection and transmission of countless thousands of specimens, live and dead, not only of orchids but of plants of other orders also, has most undoubtedly been of great service to botany, and it has served also to illustrate the great, but often unappreciated, value of gardens as instruments of scientific research. Dried specimens of orchids afford a sorry spectacle at best, and the characters upon which the distinction of genera and species depend are readily obliterated or lost in the drying process. But in gardens the material is often ample, and in the best condition for examination.

Reichenbach, as we have seen, was able to avail himself to a much larger extent than any of his predecessors of the facilities offered by gardens. He became the acknowledged referee on all questions of nomenclature, and to him were constantly submitted fresh specimens for examination. Of late years, also, hybridization has been practised to a large extent among orchids, and the resultant hybrids found their way to Hamburg, there to be compared with the parental forms from which they had emanated. The result of this correspondence with orchid-growers of all classes in all countries, as well as with collectors and botanists, was that the Hamburg Professor became the depositary of the greatest amount of orchid-lore yet accumulated, and the possessor of the largest stores of materials relating to the order. Unhappily his synthetic faculty was by no means so strong as his acquisitive tendencies were great and as his analytical powers were developed; so that much is left for his successors to accomplish in collating and expounding his work. In no place in the world can this be done so readily as at Kew, so that on all accounts it is earnestly to be hoped that the late Professor's herbarium and notes may find their way to that establishment, where Lindley's collections are already enshrined.

Reichenbach was almost exclusively a systematist. He had little to say on morphological questions, and less on the biological points which lend such great interest to the study of the order. Speculations were made the subject of sarcasm by him, and to the last it may be doubted whether he had any great amount of sympathy with those researches which have furnished the clue to the explanation of the extraordinary and highly diversified structure of orchid-flowers, and illustrated alike its genetic and its physiological significance. Nevertheless, as in his lifetime he was constantly and disinterestedly at the service alike of his brother naturalists and of the orchid-growing community, shrinking from no labour or trouble where an orchid was concerned, so in that future reconstruction of the order on morphological and physiological principles which is inevitable, the botanist, be he who he may, will find himself as much indebted to the labours of Reichenbach, as unable to proceed without constant reference to them, as are the students of the present day. His title to our gratitude is indefeasible; it will be even more so to our successors.

NOTES.

The Croonian Lecture, "Les Inoculations Préventives," will be delivered at the Royal Society to-day, by Dr. Roux, of the Pasteur Institute, Paris.

The ship *Hvidjörnen* arrived at Copenhagen on May 21 from Greenland, having on board Dr. Fridtjof Nansen and his companions, who succeeded in crossing Greenland from east to west on snow shoes. The members of the expedition received an enthusiastic welcome from a large crowd.

The anniversary meeting of the Royal Geographical Society, for the election of President, Council, &c., will be held in the hall of the University of London, Burlington Gardens, on Monday, May 27, at 2.30 p.m., General R. Strachey, F.R.S., C.S.I., President, in the chair. After the presentation of the Royal medals for the encouragement of geographical science and discovery, the annual address on the progress of geography during the year will be delivered by the President.

An International Congress of Chronometry will be opened at the National Observatory, Paris, on September 7. An influential organizing Committee has been formed, of which Vice-Admiral de Fauque de Jonquières has accepted the presidency. Those who wish to become members should communicate with the secretary, M. E. Caspari.

Congregation has approved of the nomination of Dr. William Huggins, F.R.S., as a visitor of the Oxford University Observatory, in place of the late Dr. Warren de la Rue.

According to the Rome Correspondent of the *Daily News*, the Pope has decreed, owing to the wishes expressed by Padre Denza more than a year ago, that the works for the Astronomical Observatory, to be erected in the Vatican, are to be begun at once. The site selected is the tower over the rooms occupied by the Master of the Sacred College, it being the most elevated building of the Vatican Palace. The cost is estimated at a million of francs.

Mr. W. P. Johnston, Government Electrician, Calcutta, died on April 23, at Darjeeling. According to *Allen's Indian Mail*, Mr. Johnston had served for over twenty years in the Indian Telegraphs, and had specially distinguished himself in the scientific branch of the Department, his researches in connection with duplex telegraphy, the working of river cables and long stretches of land lines, having been unusually productive of good results. He was also one of the first to improve the telephone after its introduction into India.

It is reported in the Chinese Press that the Marquis Tsêng, so well known in Europe as the Ambassador of China to this country, has been appointed to the control of the Foreign Science College in Pekin.

Prof. Milne, of the University of Tokio, whose work in connection with the investigation of earthquake phenomena is well known to all readers of this journal, is in England for a short time on leave of absence.

Dr. John Gibson, who has for some time been engaged in superintending the physical work of the Fishery Board for Scotland, has recently completed a series of investigations which are likely to throw considerable light on the problems connected with ocean currents. The detailed results will appear in the next Annual Report of the Fishery Board; but from a preliminary note communicated to the Royal Society of Edinburgh it appears that two chemically distinct kinds of sea water are present in the North Sea. The difference between these two waters is rendered perfectly distinct by sufficiently accurate determinations of the relation between chlorine and density, and is not due to river water flowing into the North Sea. Water in which the relative proportion of chlorine is high reaches the North Sea from the surface of the Atlantic, round the north of Scotland and also through the English Channel, while water in which the relative proportion of chlorine is low flows into the North Sea from the north, and has been found on the surface as far north as 79° N. lat. The determinations of chlorine and density in the samples of ocean water collected during the *Challenger* Expedition, as published in the *Challenger* Reports, seem to show that similar differences of composition exist in ocean waters. To judge from these determinations, the mass of ocean water, especially in southern latitudes, approximates in chemical composition to that flowing as above mentioned into the North Sea from the surface of the Atlantic. The water in which the relative proportion of chlorine is less appears to have been met with chiefly to the north of the equator and to the south-west of the principal outlets from the Arctic Ocean. This, as well as its chemical composition, seems to point to an Arctic origin.

A severe earthquake occurred at Plevlje, in Bosnia, at 3.43 a.m., on May 8. It lasted three seconds, the direction of the shocks being from west to east.

Several shocks of earthquake occurred on April 26 in Schwyz, and at Schaffhausen and Wilchingen.

On May 20 a waterspout burst over the district of Crimmitzschau, in Saxony. Two persons were drowned at the town of that name, and a third at the neighbouring village of Lauterbach.

The British Consul at San José, in Costa Rica, in his latest report says that a Meteorological Institute has been established at San José, and several useful observations have been taken, especially of recent earthquakes. He adds that the year 1888 did not have a very propitious closing, for just two days before the end of the year, the capital and surrounding districts were visited with several severe shocks of earthquake. The first shock took place on December 29 at 8 p.m. This was followed by another at 11 p.m., and on Sunday, December 30, at 4.21 a.m., by the most severe of all, lasting 25 seconds, and of such force as to cause considerable damage to the principal buildings in San José, and to nearly all the churches, besides private houses, few of which escaped damage. The morning was pitch dark, and hundreds of people, in all kinds of costumes, hurried into the Central Park looking for their friends, not knowing what might happen or whether any portion of their houses would be left to them. Several houses have been condemned by the authorities, and have had to be pulled down, whilst energetic measures are being taken to repair the damage done to the principal buildings, and the Government have erected temporary shelters for the poor who have been rendered homeless. The total damage is estimated at half a million sterling.

THE half-yearly meeting of the Council of the Italian Meteorological Society was held on April 28. Padre Denza referred to the activity of the Society during the previous six months, during which time several observing stations had been added in Italy and at Malta and Punta Arenas (South America); and to the working of the hygienic stations established at Florence and several other important cities. He also referred to the various Conferences which are being held in accordance with the decisions of the general meeting at Venice last year, for the purpose of popularizing meteorological science in Italy. Special investigations are being carried out with the view of determining the amount of carbonic acid gas in the air, and with regard to the system of the winds in the South Atlantic. The questions of sunshine and phenological observations were also discussed, and the importance of issuing general instructions for these subjects, and for the regular geodynamical observations at the Society's stations.

AT the meeting of the Scientific Committee of the Royal Horticultural Society on May 14, Mr. Wilson made some remarks on the question of the protection of fruit-trees against winter moths. He observed that the plan recommended in the *Agricultural Gazette* of October 15, 1888, of making a ring of cart grease and Stockholm tar round the bases of fruit-trees, though very effectual in catching large quantities of wingless females, had not prevented them from attacking the trees altogether, as the leaves on certain trees thus treated (as described at the Scientific Committee on January 15, 1889) were all going at the present date. At the same meeting Dr. Masters exhibited several photographs of plants from Madeira, including one of *Phytolacca dioica* as a large tree with a massive base of confluent roots, the usual form of this plant in Europe being a herb.

AT the last meeting of the Chemical Society of Göttingen, Dr. Buchka announced the results of his investigations upon the composition of bromide of sulphur. Balard long ago showed that sulphur readily dissolves in bromine with formation of a ruby-red liquid; this liquid, as more recently shown by Mr. Pattison Muir, may be freed from excess of bromine by means of a current of dry carbon dioxide. On attempting, however, to subject it to distillation, it is found to boil at about 200° C., but with decomposition. Indeed it is possible, by repeated distillation, to completely dissociate it into sulphur and bromine. Hence it has never hitherto been possible to analyze a sample of the redistilled liquid, and so there has been a certain amount of doubt as to its composition. Most of the analyses hitherto published have pointed to the formula S_2Br_2, but Guyot ascribes to it the formula SBr_2. Hence Dr. Buchka has attempted the distillation of the crude product under diminished pressure, and finds that the experiment entirely succeeds at the low pressure of 20 mm. of mercury, the red liquid passing over without the least sign of decomposition at a temperature of 111°–113°. Analyses of this redistilled liquid confirm the formula S_2Br_2. Hence bromide of sulphur resembles the monochloride, S_2Cl_2, the most stable of all the chlorides of sulphur: it differs from the chloride, however, in being more unstable, and only volatilizable without decomposition at a pressure not much exceeding 20 mm. of mercury.

FORMALDEHYDE, CH_2O or $H.COH$, the first member of the important series of aldehydes, has been synthesized by Prof. Jahn, of Cronstadt, Hungary, in a most instructive manner. During the course of Dr. Jahn's well-known researches upon the volumetric estimation of hydrogen by means of palladium, it was noticed that the presence of carbon monoxide always considerably disturbed the occlusion of the hydrogen by the palladium. As there was a possibility that some of the hydrogen had bodily united with the carbonic oxide with formation of formaldehyde, it was determined to repeat the experiment upon a larger scale and in a more suitable form of apparatus. A mixture of carbon monoxide and hydrogen was therefore led over a layer of spongy palladium, and the products passed through a series of bulbs containing water. On detaching the bulbs the odour of aldehyde was readily perceived, and the contents at once reduced an ammoniacal silver nitrate solution with formation of the silver mirror characteristic of aldehydes. Hence it was quite evident that the carbon monoxide and hydrogen had partially united in the pores of the palladium with production of formaldehyde. Two litres of the mixed gases were found quite sufficient to give a good silver mirror. This reaction is all the more interesting in view of Dr. Loew's recent synthesis of formose, $C_6H_{12}O_6$, an artificial member of the glucoses, by condensation of formaldehyde with calcium hydroxide; for as carbon monoxide is readily prepared by passing oxygen over excess of heated carbon, it may be said that glucose has been built up directly from its elements—carbon, hydrogen, and oxygen.

THE officials of the Australian Museum, Sydney, are now engaged in working at the Percoid Fishes, and the trustees announce that they will be glad to make exchanges in this group with the authorities of other museums.

THE Paris Correspondent of the *Daily News* says the Zoological Society of France has warned the French Government that a great ornithological calamity is impending. The Department of the Bouches du Rhône has hitherto been one of the chief landing-places for swallows coming from Africa. Engines for killing them, formed of wires connected with electrical batteries, have been laid in hundreds along the coast. When fatigued by their over-sea flight, the birds perch on the wires and are struck dead. The bodies are then prepared for the milliner, and crates containing thousands of them are sent on to Paris. This has been going on for some years, and it has been noticed this spring that swallows have not landed on the low-lying coast, but have gone farther west or east, and that they go in larger numbers than formerly to other parts of Europe. There are places, says the Zoological Society in its petition, where they used to be very numerous, but which they have now deserted, although there has been no falling-off in the gnats and other flying insects on which they live.

MISS E. C. JELLY, F.R.M.S., proposes to issue shortly a catalogue of the published species of recent Polyzoa, with a full synonymy. The main lines followed are those of Hincks and Waters. Only a limited number of copies will be printed, and application for them must be made to the authoress.

THE State University of Iowa has begun to issue what promises to be an excellent series of Bulletins from its laboratories of natural history. No systematic biological survey of the State has yet been attempted, and the editors of the new

Bulletin do not suppose that it will be in their power to provide such a survey. They propose, however, to bring before their readers some idea of the natural history of Iowa, and of the manner in which it may be studied; hoping in this way to stimulate an interest in such things sufficient to lead to greater results in the future.

AN interesting note, by Mr. Arthur A. Rambaut, on some Japanese clocks lately purchased for the Dublin Science and Art Museum, has been reprinted from the Proceedings of the Royal Dublin Society. These clocks, though differing in other respects, agree in this particular, that the time is recorded, not by a hand rotating about an axis, but by a pointer attached to the weight, which projects through a slit in the front of the clock-case. This pointer travels down a scale attached to the front of the clock, and thus points out the hour. Mr. Rambaut has consulted several persons who have been resident for some time in Japan, but none of them has ever seen clocks of like construction in actual use. A young Japanese gentleman to whom the specimens have been shown, says that he has heard of such clocks being used in rural parts of Japan about twenty or thirty years ago, but that they have been almost completely superseded by clocks made on the European plan.

THE fact of intermittence in the intensity of some sensations is known to physiologists. Thus, the tick of a watch withdrawn gradually from the ear begins to be heard, by turns, distinctly and indistinctly, then times of silence alternate with the sound. M. Couetoux, in the *Revue Scientifique*, calls attention to an analogous experience he has had in the case of vision. Looking at a distant windmill, with four vanes, he could not make up his mind whether it was in slow motion (like a nearer one); for, of the three vanes projected against the sky, he saw now one, now another; but the intermittent degradation of the sensorial impression prevented his observing two successive positions. These sensorial fluctuations seem to deserve careful study.

AT a recent meeting of the Manchester Section of Chemical Industry, Mr. William Thompson read a paper on the heat-producing powers of twelve samples of coal, determined by burning in oxygen (in the apparatus devised by him), compared with their theoretical values as calculated from their chemical composition. The coal which he found to give the highest results as regards heat-producing was anthracite, which gave 8340 Centigrade units of heat. Next came Pendleton coal, with 7736 units; then Wigan coal, 7552; and the lowest of the twelve came from near Atherton, with 6448 units. The results obtained by experiment were higher in two coals than the calculated results obtained by determining by heat units given by the combustion of the carbon, hydrogen, and sulphur found by analysis, but deducting the hydrogen, which appears always to be in combination with the oxygen present, so that its hydrogen does not produce heat on burning. In two coals the heat found by calculation and that found by experiment were the same, and in seven coals the heat found by calculation was greater than that found by experiment. A short discussion followed the reading of the paper.

THE additions to the Zoological Society's Gardens during the past week include a Rough Fox (*Canis rudis* ♂) from Demerara, presented by Mr. James Coombe; a Derbian Wallaby (*Halmaturus derbianus* ♂) from Australia, presented by Mr. Buckland, s.s. *Britannia*; two Great Eagle Owls (*Bubo maximus*), European, presented by the Executors of the late Mr. W. J. Cookson; two Red-legged Partridges (*Caccabis rufa*) from the Canary Islands, presented by Captain Augustus Kent, s.s. *Fez*; six Barbary Turtle Doves (*Turtur risorius*) from North Africa, presented by Major T. Erskine Baylis, F.Z.S.; a Black-bellied Sand Grouse (*Pterocles arenarius* ♂) from India, presented by Mrs. Ayrton Pullan; a —— Falcon (*Falco* sp. inc.) from Australia, presented by Baron F. von Mueller, C.M.Z.S.; a Tuberculated Iguana (*Iguana tuberculata*) from Spanish Honduras, presented by Mr. J. B. Johnson, s.s. *Antilles*; a Grey-breasted Parrakeet (*Bolborhynchus monachus*) from Monte Video, presented by Mrs. Macnab; ten Common Vipers (*Vipera berus*) from Surrey, presented by Mr. C. F. McNiven; two Common Vipers (*Vipera berus*) from Gloucestershire, presented by Mr. Barry Burge; a Chimpanzee (*Anthropopithecus troglodytes* ♂) from West Africa, two Cormorants (*Phalacrocorax carbo*), British, deposited; a Mountain Ka-ka (*Nestor notabilis*) from New Zealand, a Green-headed Tanager (*Calliste tricolor*) from South-East Brazil, purchased; five North African Jackals (*Canis anthus*), a Japanese Deer (*Cervus sika* ♀) a Collared Fruit Bat (*Cynonycteris collaris*), a Great Kangaroo (*Macropus giganteus* ♂), born in the Gardens.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1889 MAY 26—JUNE 1.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on May 26

Sun rises, 3h. 56m.; souths, 11h. 56m. 48·8s.; daily increase of southing, 6·5s.; sets, 19h. 58m.: right asc. on meridian, 4h. 13·8m.; decl. 21° 13′ N. Sidereal Time at Sunset, 12h. 16m.

Moon (New on May 29, 17h.) rises, 3h. 2m.; souths, 9h. 36m.; sets, 16h. 24m.: right asc. on meridian, 1h. 52·8m.; decl. 6° 16′ N.

BEACON LIGHTS AND FOG SIGNALS.[1]

I.

IT is stated by Samuel Smiles in his "Lives of Engineers" that, "with Winstanley's structure on the Eddystone in 1696, may be said to have commenced the modern engineering efforts in directing the great sources of power in Nature for the use and convenience of man," efforts which, followed up by Rudyerd, Smeaton, and others, have been so successful in converting hidden dangers into sources of safety, and insuring the beneficent guidance of the mariner in his trackless path.

The famous structure of Smeaton, which had withstood the storms of more than half a century with incalculable advantage to mankind, became in course of time a matter of anxiety and watchful care to the Corporation of Trinity House, owing to the great tremor of the building with each wave stroke, during heavy westerly storms. The joints of the masonry frequently yielded to the heavy strains, and the sea-water was driven through them to the interior of the building. The upper part of the structure was strengthened with internal ironwork in 1839, and again in 1865. On the last occasion it was found that the chief mischief was caused by the upward stroke of the heavy seas against the projecting cornice of the lantern gallery, thus lifting this portion of the masonry, together with the lantern above it. Unfortunately, the portion of the gneiss rock on which the lighthouse was founded had become seriously shaken by the heavy sea strokes on the tower, and the rock had thus been seriously undermined at its base. The waves rose during storms considerably above the summit of the lantern, thus frequently eclipsing the light, and altering its distinctive character from a fixed light to an occulting. This matter of distinctive character in a beacon light was one of little importance at the date of the erection of Smeaton's lighthouse, when coal fires were the only illuminating agents along the coasts; but with the rapid development of our commerce, and the great increase in the number of coast lights, it has become an absolute necessity that each light maintain a clearly distinctive character. It was therefore determined by the Trinity House, in 1877, to erect a new lighthouse at a distance of 120 feet from Smeaton's tower, where a safe and permanent foundation was found, but at a much lower level, which necessitated the laying of a large portion of the foundation masonry below low water. The foundation-stone of this work was laid on August 19, 1879, by H.R.H. the Duke of Edinburgh, Master of the Trinity House; assisted by H.R.H. the Prince of Wales, an honorary Elder Brother of the Corporation.

On June 1, 1881, H.R.H. the Master, when passing up the Channel in H.M.S. *Lively*, landed at the rock and laid the last stone of the tower; and on May 18 of the following year H.R.H. lighted the lamps, and formally opened the lighthouse. The edifice was thus completed within four years from its commencement, at a cost of £59,255. The work was executed under the immediate direction of the Trinity House and their Engineer, and with a saving of £24,000 on the lowest sum at which it had been found that it could be executed by contract. Every block of granite in the structure is dovetailed together both vertically and horizontally, on a system devised by my father, and first adopted at the Hanois Rock Lighthouse off the west coast of Guernsey. The illuminating apparatus consists of two superposed oil lamps, each of six concentric wicks, and of two drums of lenses of 920 millimetres focal distance, twelve lenses in each drum. The optical apparatus is specially designed on the system of Dr. John Hopkinson, F.R.S., for a double flashing light, and shows two flashes in quick succession, at intervals of half a minute. Attention has of late been directed to the subject of superposed lights in lighthouses, which became a necessity when several small luminaries had to be substituted for the large coal or wood fire of our early lighthouses. The credit of first superposing lighthouse luminaries is doubtless due to Smeaton, who lighted his lantern, in 1759, with twenty-four large tallow candles in two tiers. The idea was followed in 1790 with the first revolving light, established at the St. Agnes Lighthouse, Scilly Islands, which consisted of fifteen oil lamps and reflectors, arranged in three groups, and in three tiers. The number of the lamps and reflectors at this and other first class lights was afterwards extended to thirty, and in four tiers. In 1859, Mr. J. W. D. Brown, of Lewisham, proposed superposed lenses for signal and lighthouse lanterns, with a separate light for each tier of lenses. In 1872, Mr. John Wigham, of Dublin, proposed superposed lenses for lighthouses, in conjunction with his large gas flames, and the first application of these was made in 1877 at the Galley Head Lighthouse, County Cork. In 1876 Messrs. Lepaute and Sons, the eminent lighthouse optical engineers of Paris, made successful experiments with superposed lenses and mineral oil flames, and one of their apparatus was exhibited at the Paris International Exhibition of 1878. The results of these experiments were given by M. Henry Lepaute, in a paper contributed to the Congress at Havre in 1877, of the French Association for the Advancement of Science. The Eddystone represents the first practical application of superposed lenses of the first order, with oil as the illuminant.

The apparatus at the Eddystone is provided with two six-wick burners of the Trinity House improved type, and has a minimum intensity for clear weather of about 38,000 candle units, and a maximum intensity of about 160,000 candle units for atmosphere impaired for the transmission of light. The chandelier light in Smeaton's lantern was unaided by optical apparatus. I have found by experiment that the aggregate intensity of the beam from the twenty-four candles was 67 candle units nearly. The maximum intensity of the flashes now sent to the mariner is about 2380 times that of the candle beam, while the annual cost for the mineral oil illuminant is about 82 per cent. less.

The sound signal for foggy weather consists of two bells of 40 cwt. each, mounted on the lantern gallery, and rung by machinery. If any wind occurs with the fog, the windward bell is sounded. The distinctive character of the signal is two sounds of the bell in quick succession every half-minute, thus corresponding with the character of the light signal.

The tendency of the curvilinear outline near the base of Smeaton's and of other similar sea towers that have followed it, to elevate the centre of force of heavy waves on the structure, induced me to adopt a cylindrical base for the new lighthouse, which is found to retard the rise of waves on the structure, while it affords a convenient platform for the lightkeepers, and adds very considerably to their opportunities for landing and relief. The Town Council and inhabitants of Plymouth having expressed a desire that Smeaton's lighthouse should be re-erected on Plymouth Hoe, in lieu of the Trinity House sea mark thereat, the Trinity House, who, as custodians of public money, had no funds available for such a purpose, undertook to deliver to the authorities at Plymouth, at actual cost for labour, the lantern, and the four rooms of the tower. These have been re-erected by public subscription on a frustrum of granite, corresponding nearly with the lower portion of Smeaton's tower, and it is to be hoped that it will be preserved by the town of Plymouth as a monument to the genius of Smeaton, and in commemoration of one of the most successful and beneficent works in civil engineering.

It is extremely difficult to estimate, with a fair degree of accuracy, the maximum force of the waves with which some of the most exposed of these sea structures may occasionally have to contend. The late eminent lighthouse engineer, Mr. Thomas Stevenson, F.R.S.E., carried out a long series of experiments with a self-registering instrument he devised for determining the force of sea-waves on exposed structures. He found at the Skerryvore Rock Lighthouse the Atlantic waves there gave an average force for five of the summer months in 1843-44 of 611 pounds per square foot. The average result for the six winter months of the same year was 2086 pounds per square foot, or three times as great as in the summer months. The greatest force registered was on March 29, 1845, during a westerly gale, when a pressure of 6083 pounds, or $2\frac{3}{4}$ tons nearly, per square foot was recorded. After Smeaton had carefully considered the great defect of the building of Rudyerd at the Eddystone, viz. want of weight, he replied that, "if the lighthouse was to be so contrived as not to give way to the sea, it must be made so strong as that the sea must be compelled to give way to the building." Smeaton also had regard to durability as an important element in the structure, for he adds: "In contemplating the use and benefit of such a structure as this, my ideas of what its duration and continued existence ought to be were not confined within the boundary of one age or two, but extended themselves to look towards a possible perpetuity." Thus Smeaton soon arrived at the firm conviction that his lighthouse must be built of granite, and of this material nearly all lighthouses on exposed tidal rocks have since been constructed, while those on submerged sandbanks are open structures of iron, erected on screw piles or iron cylinders. The screw pile was the invention of the late Mr. Alexander Mitchell, of Belfast.

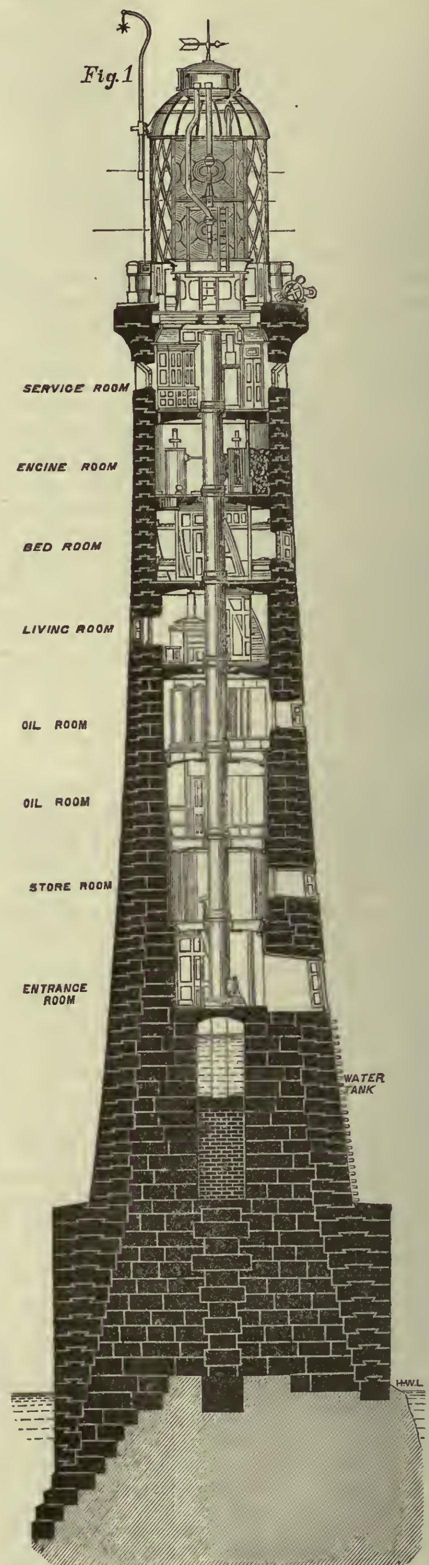
We have here a model of the first lighthouse, erected in 1838,

[1] Friday evening discourse delivered at the Royal Institution by Sir James N. Douglass, F.R.S., on March 15. We are indebted to the Editor of the *Engineer* for the use of the woodcuts illustrating this discourse.

on these screw piles, at the Maplin Sand, on the north side of the estuary of the Thames, under the direction of the late James Walker, F.R.S., then Engineer-in-Chief to the Trinity House. A lighthouse on the principle of minimum surface exposed to the force of the waves, of which we have here a model, was erected on the chief rock of the dangerous group of the Smalls, situated about 18½ miles off Milford Haven, by Mr. John Phillips, a merchant and shipowner of Liverpool. The work was designed, and erected under great difficulties, by Mr. Henry Whiteside, a native of Liverpool, and a man of great mechanical skill and undaunted courage. Added to his mechanical ability, Whiteside possessed a great love and knowledge of music, and had, previous to the erection of his lighthouse, excelled in the construction of violins, spinnettes, and upright harpsicords. The lighthouse, commenced in 1772, was intended to be erected on eight cast-iron pillars, sunk deep into the rock; this material was, however, soon abandoned for English oak, as being more elastic and trustworthy. The work was completed and lighted in 1776 with eight lamps and glass faceted reflectors, similar to the one before us. In 1817 sixteen improved lamps and silvered paraboloidal reflectors were substituted for these; and the lighthouse, although sorely tried by winter storms, was (with the aid of yearly repairs and strengthening) enabled to send forth its beneficent beam until the year 1856, when the Trinity House commenced the erection of a lighthouse of granite, as shown by this model. The vibrations of the old wooden structure must have been very considerable with heavy storms, for the lightkeepers occasionally found it sufficient to cause a bucket of water, placed in the living-room, to spill just half its contents. It was in this lighthouse that the painful circumstance occurred in the year 1802 of the death of one of the lightkeepers. In those days only two men inhabited the lighthouse at a time; one of them was taken ill, and the means employed by his companion for obtaining relief proved ineffectual; he hoisted a signal of distress, but owing to stormy weather no landing could be effected, and after many days of extreme suffering, the poor fellow, named Thomas Griffiths, breathed his last, when the survivor, Thomas Howell, fully realized the awful responsibilities of his position; decomposition would quickly follow, and the atmosphere of the small apartment would be vitiated. The body could not be committed to the sea, as suspicion of murder would probably follow. Howell was a cooper by trade, and he was thus enabled to make a coffin for his dead companion out of boards obtained from a partition in the apartment. After very great exertion the body was carried to the outer gallery, and there securely lashed to the railing. For three long weeks it occupied this position before the weather moderated, yet night after night Howell faithfully kept his lights brightly burning. When a landing was at last effected, his attenuated form demonstrated the sufferings, both mental and physical, he had undergone; indeed, several of his friends failed to recognize him on his return to his home. Since this sad occurrence the Trinity House have always maintained three lightkeepers at their isolated rock stations. The present lighthouse was designed by the late Engineer-in-Chief of the Trinity House, Mr. James Walker, F.R.S., and I had the honour of executing the work as resident engineer. The foundation-stone was laid on June 26, 1857, and the light was exhibited on August 7, 1861. The work was completed by the Trinity House, at a cost of £50,125, being about 24 per cent. under the lowest amount at which it had been ascertained that it could have been executed by contract.

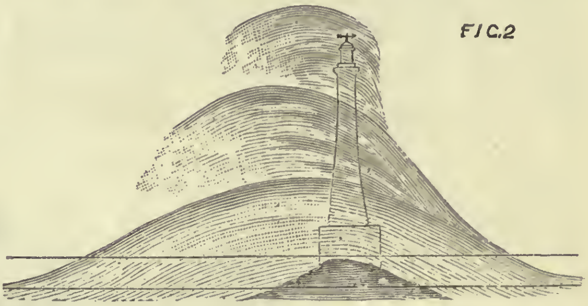
Probably the most exposed rock lighthouse is that on the Bishop (the westernmost of the rocks of Scilly), shown in Fig. 1. Its position is doubtless one of the most important to mariners, warning them, as it does, of the terrible dangers where, on October 22, 1707, Sir Cloudesley Shovel, with the *Association*, *Eagle*, and *Romney*, were lost, with about 2000 men. The Bishop is also the guiding light for the entrances to the English and Bristol Channels. The rock, composed of a very hard, pink-coloured granite, is about 153 feet long by 52 feet wide at the level of low water of spring tides. It stands in over 20 fathoms water, is steep to, all round, and is exposed to the full fury of the Atlantic. It was at first feared that the width of the rock was not sufficient for the base of a stone tower of adequate dimensions to withstand the heavy wave-shocks it would have to resist, and an open structure of wrought and cast iron [shown on the diagram] was determined on. The work was jointly designed by the late Engineer-in-Chief to the Trinity House and my father, the superintending engineer, who afterwards erected the structure, at which I had the honour of acting as assistant engineer.

Fig. 1



The work was commenced in 1847, and at the end of the working season of 1850 the lighthouse was so far completed as to be in readiness for receiving the lantern and the illuminating apparatus, and it was left with confidence to resist the storms of the approaching winter. But during a very violent storm, between 11 p.m. of the 5th and 3 a.m. on the 6th of the following February, the lighthouse was completely destroyed, and swept from the rock. On further consideration of the matter, the Trinity House determined, on the recommendation of their engineers, to proceed with a stone structure, and my father was appointed to build the lighthouse, I acting as before as assistant engineer. The work was proceeded with in the spring of 1851. In order to obtain the greatest possible diameter of base for the tower that the rock would admit of, it was found necessary to lay a portion of the foundation on the most exposed side of the rock, at the level of 1 foot below low water of spring tides; and, although every possible human effort was made by the leader and his devoted band of workers, the foundations were not completed until the end of the season of 1852. Soon after this, my brother, Mr. William Douglass, now Engineer-in-Chief to the Commissioners of Irish Lights, succeeded me as assistant engineer at the work. The lighthouse was completed in 1858, and its dioptric fixed oil light of the first order was first exhibited on September 1 of that year. Soon afterwards, its exposure to heavy seas during storms was fully realized. On one occasion the fog bell was torn from its bracket at the lantern gallery at 100 feet above high water, and the flag-staff, with a ladder, which were lashed outside the lantern, were washed away. The tremor of the tower on these occasions was such as to throw articles off shelves, and several of the large glass prisms of the dioptric apparatus were fractured. After some time it was found that several of the external blocks of granite situated a few feet above high water were fractured by the excessive strains on the building. In 1874 the tower was strengthened from top to bottom by heavy iron ties, bolted to the internal surface of the walls; but, after a violent storm in the winter of 1881, there was evidence of further excessive straining at the face of the lower external blocks of masonry, when the Trinity House, on the advice of their engineer, determined on the re-erection of the lighthouse. This was accomplished (as shown in Fig. 1) by incasing the existing tower with carefully dovetailed granite masonry, each alternate block of the new granite being dovetailed to the old. The work was one of considerable difficulty, owing to the necessity for maintaining the light throughout the progress; and the risk to the workmen was great, especially at the upper part of the old tower, owing to the narrow ledge on which the work had to be executed. I am, however, thankful to state that the new lighthouse has been successfully completed by my son, Mr. W. T. Douglass, who was also my assistant engineer at the Eddystone; and with the same complete immunity from loss of life or limb to any person employed, as with the two previous structures on this rock. The optical apparatus consists of two superposed tiers of lenses of the type adopted at the Eddystone, but of larger dimensions, as suggested by the late Mr. Thomas Stevenson, for obtaining greater efficiency with the larger-flame luminaries recently adopted. The apparatus is provided with two Trinity House improved mineral oil burners, and has a minimum intensity for clear weather of about 80,000 candle units, and a maximum intensity for thick weather of about 513,000 candle units. The character of the light is double-flashing, showing two flashes, each of four seconds' duration, in quick succession, at periods of one minute. The flashes of this light, and those of a light lately completed at about 8 nautical miles from it, on Round Island, are the most intense yet attained with oil flames for beacon lights; and it may be stated that, with no other illuminant at present known to science could these results be carried out within the space available at the Bishop Rock, and under the circumstances attending that work. The fog signal recently adopted at this station, in lieu of the bell, is by the electrical explosion of 4-ounce charges of gun-cotton, at intervals of 5 minutes. The apparatus provided for this form of fog signal is shown in Fig. 1. It consists of a wrought-iron crane (attached to the lantern) which is raised and lowered by a worm-wheel and pinion. When the crane is lowered, its end reaches near the gallery, where the lightkeeper suspends the charge of gun-cotton, with its detonator attached, to the electric cable, which is carried along the crane and through the roof of the lantern to a dynamo-electric firing machine. After suspending the charge, the jib of the crane is raised to its upper position, when the charge is fired nearly vertically over the glazing of the lantern, and thus without causing damage to it. The large and heavy optical apparatus is rotated automatically by compressed air, which is stored in two vertical steel reservoirs, fixed at the centre of the tower. The air is compressed by a small Davey safety motor. A winch, worked by the compressed air, is fixed on the lantern gallery for landing the lightkeepers, stores, &c. Fig. 2 is a sketch, from actual obser-

FIG. 2



vation, of the height and form of waves on the tower during a storm.

The numerous outlying shoals surrounding the shores of this country, particularly off the east coast, were an early cause of anxiety to those responsible for the guidance of mariners. And in addition to buoys as sea-marks by day, floating lights, as guides by night, were found to be a necessity. The first light-vessel was moored at the Nore Sand in 1732, and another near the Dudgeon Shoal in 1736. We have here a model of the latter vessel, from which we may judge of the pluck and hardihood of the crews who manned them, especially when we remember that there were no chain cables in those days, the

Fig. 3

vessel having to be moored with a cable of hemp, which, owing to the constant chafing, occasionally parted during winter storms, when, to save their lives, the crew had to put out another anchor if possible, or set such storm canvas as they could to keep her off a lee-shore, and endeavour to reach a place of safety. The illuminating apparatus of these vessels consisted of a small lantern and flat-wick oil lamps, fixed at a yardarm, and here appears to have occurred the first application of a distinctive character to beacon lights, for the *Dudgeon* was fitted with two lights, one being placed at each arm of the yard (Fig. 3). The next light-vessel was placed at the Newarp Shoal in 1790, and in 1795 one was placed at the north end of the Goodwin Sands.

The two latter vessels were provided with three fixed lights, and the lanterns were larger, and surrounded each mast-head, as shown by the model before us. An improvement was also effected in these lights by providing each lamp with a silvered reflector.

In 1807 the late Mr. Robert Stevenson, the engineer of the Bell Rock Lighthouse, to whom and his successors are due much valuable engineering and optical work connected with coast-lighting, designed a larger lantern to surround the mast, and capable of being lowered to the deck for properly trimming the lamps (Fig. 4). Soon after the adoption of the system of catoptric illumination in lighthouses, it was extended to floating lights; each lamp and reflector was hung in gimbals, to insure horizontal direction of the beams of light during the pitching and rolling of the vessel. We have here one of these apparatus. The intensity of the beam sent from it was 500 candle units, nearly.

On January 1, 1837, the Trinity House installed the first revolving floating light, at the Swin Middle, and later in the same year another, on board the *Gull* light-vessel. The lamps and reflectors were carried on a roller frame surrounding the mast, and rotated through light shaftings by clockwork placed between decks. There were nine lamps and reflectors arranged in three groups, of three each, and thus the collective intensity of each flash was equal to that of three fixed lights, or 1500 candle units, nearly. In 1872 the Trinity House further increased the dimensions of the lanterns and reflectors of their floating lights—the lanterns from 6 to 8 feet in diameter, with cylindrical instead of polygonal glazing, and the reflectors from 12 inches to 21 inches diameter at the aperture. These improvements, together with the adoption of improved burners, have effected a considerable increase in the intensity of these lights; and during the last two years a further improvement has been obtained by the adoption of concentric wick burners with more condensed flames, and of higher illuminating power, by which the intensity of the beam from each reflector has been raised to 5000 candle units, being just ten times the intensity of the smaller apparatus; while, by the adoption of mineral oil in lieu of colza, the annual cost for the illuminant has been reduced 50 per cent.

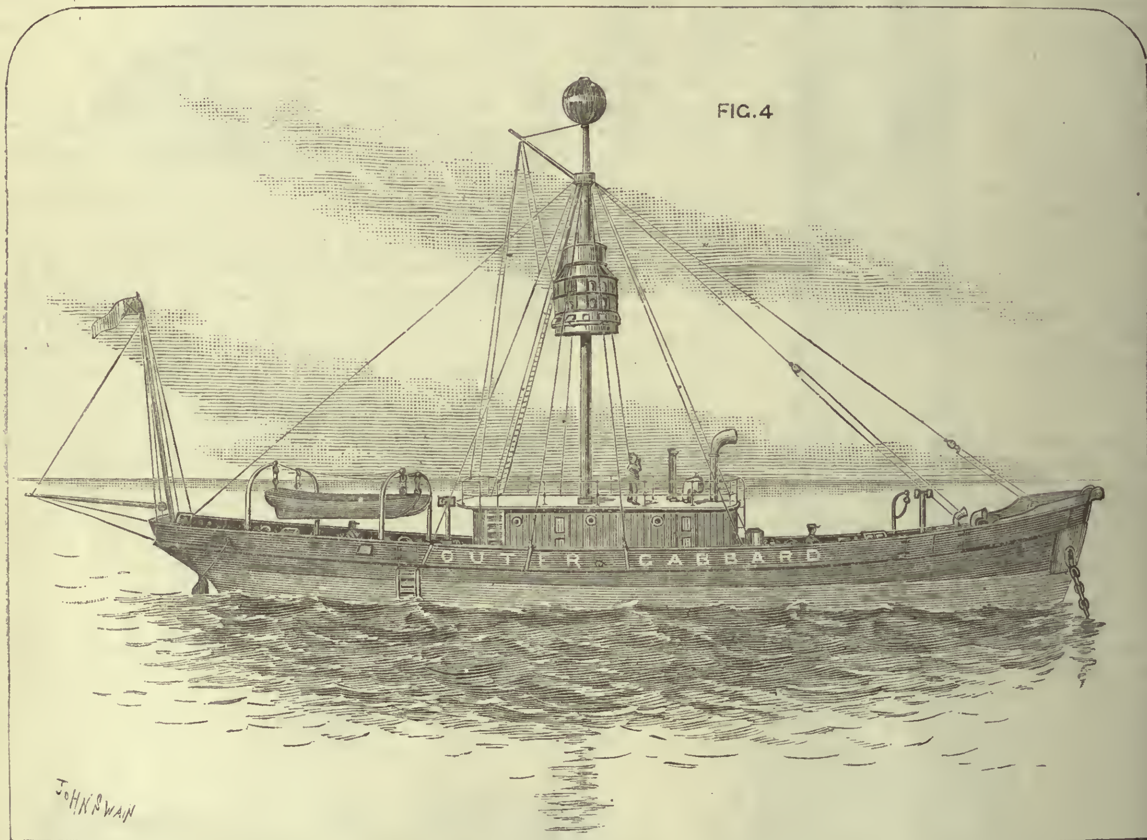


FIG. 4

Dioptric apparatus was proposed for light-vessels by M. Letourneau in 1851, several small fixed-light apparatus being intended to be employed in each lantern, and arranged nearly in the same way as the reflectors. This arrangement has been adopted in some instances by Messrs. D. and T. Stevenson, Engineers to the Commissioners of Northern Lighthouses, and by the engineers of the French Lighthouse Service; but, for efficiency and adaptability to meet the rough duty to which floating lights are occasionally subjected in stormy weather and collisions, this system has been found to be inferior for this service to the catoptric.

An interesting experiment was recently made by the Mersey Docks and Harbour Board with the electric arc light, on board one of their light-vessels, at the entrance of the Mersey; but unfortunately it did not prove successful. The present difficulties experienced afloat with this powerful illuminant will doubtless be overcome, and it will be found to be, as in lighthouses, by far the most efficient illuminant for some special stations, where a higher intensity than can be obtained with flame luminaries is demanded. Experiments have been in progress during the past two years at the *Sunk* light-vessel, off the coast of Essex, for maintaining electrical telegraphic communication with the shore for reporting wrecks and casualties in the locality. This vessel is connected with the post office at Walton-on-Naze, through nine miles of cable. The instruments adopted are the Wheatstone ABC Morse, and the Gower Bell telephone, the telephone for the first time for this purpose on board a vessel at sea, and its efficiency has been found to be so perfect that it is preferred by the operators to the telegraphic instruments. Many difficulties have been experienced in maintaining trustworthy communication during stormy weather, owing to consequent wear and tear of the connections with the vessel, but the system, which was designed and carried out by the Telegraph Construction and Maintenance Company, is now working satisfactorily. Unfortunately, however, it is found to be too costly for adoption except in very special cases.

(*To be continued.*)

A BILL TO PROVIDE TECHNICAL EDUCATION IN ENGLAND AND WALES.

THE following Bill, introduced into the House of Commons by Sir Henry Roscoe on behalf of the National Association for the Promotion of Technical Education, was read a second time without opposition on Wednesday, May 8:—

Whereas it is expedient that due provision should be made for technical education in public elementary schools and elsewhere:

Be it therefore enacted by the Queen's most Excellent Majesty, by and with the advice and consent of the Lords Spiritual and Temporal, and Commons, in this present Parliament assembled, and by the authority of the same, as follows:

1. This Act may be cited as the Technical Education Act, 1889.

2. (1) After the *passing of this Act* any school board may make provision for giving technical education in any school under their management, and either by day or evening classes, or both, as may seem fit, having regard to the daily occupations of the persons to be benefited thereby.

(2) If no such provision is made, or if it is insufficient, and if the local authority by special resolution determine that provision or further provision ought to be made, they may themselves make such provision.

3. Where technical education is given in any school, not being a public elementary school (including for the purposes of this section any college), which is not under the management of a school board or local authority, and is either within their district or accessible to the inhabitants thereof, the school board or local authority may contribute or they may join together with other school boards or local authorities in contributing from their respective funds towards—

(*a*) the maintenance or improvement of that school or of its provisions for technical education; or

(*b*) the payment of the fees at that school of deserving students who before proceeding to such school have been resident in the district of the contributing board or authority;

(*c*) the establishment of scholarships for deserving students.

The mode in which and the terms upon which contributory school boards and local authorities shall be represented upon the governing bodies of schools receiving such contributions, so far as technical instruction is concerned, shall be such as may be agreed upon between the school boards, local authorities, and governing bodies respectively in each case.

Every such contribution shall be deemed to be expenses of such school board or local authority incurred for the purposes of this Act.

4. (1) *Where any school in which technical education is given in pursuance of this Act is also a public elementary school, a parliamentary grant may be made to such school by the Education Department and by the Science and Art Department, or by either of such Departments.*

(2) *The conditions required to be fulfilled by such school in order to obtain an annual parliamentary grant shall be those contained in minutes issued by the Committee of Council on Education.*

(3) Any minute made in pursuance of this section shall not come into force until it has lain on the table of both Houses of Parliament for one month.

5. (1) *Where any school in which technical education is given in pursuance of this Act is not a public elementary school, a parliamentary grant may be made to such school by the Science and Art Department, subject to such conditions as that Department may prescribe.*

(2) Any minute made by the Science and Art Department in pursuance of this section shall not come into force until it has lain on the table of both Houses of Parliament for one month.

6. (1) All the provisions of the Elementary Education Acts relating to the powers of school boards with respect to sufficient accommodation, fees, the combination of school boards, and the acquisition of land, shall apply to school boards in whose schools technical education is given, or to be given, under this Act; and a school shall not cease to be a public elementary school within the meaning of the Elementary Education Acts by reason of technical education being given therein.

(2) A school which is under the management of a school board, and in which technical education is given under this Act, shall be conducted in accordance with the same regulations as an elementary public school under the Elementary Education Acts: Provided, however, that every such school shall be open to the inspection of any inspector appointed by the Department of Science and Art, as well as of Her Majesty's inspectors as defined in the Elementary Education Acts.

7. The expenses incurred by any school board in carrying this Act into effect, including any contributions made by the school board in aid of technical education in schools not under their management, shall be deemed to be expenses of the said school board within the meaning of the Elementary Education Acts, and payable accordingly.

A school board shall have the same powers of borrowing for the like purposes, but subject to the same consent and other conditions, as they have under the Elementary Education Acts.

8. The expenses incurred by a local authority in giving effect to this Act, including any such contributions as are abovementioned, shall be payable out of the local rate. The local authority shall have the like powers of borrowing for the purposes of this Act, but subject to the same conditions, as for other purposes.

9. The provisions of this Act with respect to a local authority shall not apply to the Metropolis.

10. It shall be competent for any school board or local authority, should they think fit, to institute an entrance examination in reading, writing, and arithmetic for persons desirous of attending technical schools or classes under their management, or to which they contribute.

11. For the purposes of this Act the expression "technical education" means instruction in—

(i.) Any of the branches of Science and Art with respect to which grants are for the time being made by the Department of Science and Art.

(ii.) The working of wood, clay, metal, or other material for the purposes of art or handicraft.

(iii.) Commercial arithmetic; commercial geography; modern languages; book-keeping, and shorthand.

(iv.) Any other subject applicable to the purposes of agriculture, trade, or commercial life and practice, which may be sanctioned by a minute of the Department of Science and Art made on the representation of a school board or local authority that such a form of instruction is suited to the needs of its district.

12. The provision to be made for technical education under this Act may include the providing of school laboratories, apparatus for teaching and experiment, museums and their contents, libraries, books, workrooms, schools or schoolrooms, or the improvement of existing provisions of any of these kinds, and the maintaining of the same in such manner as may be necessary to give effect to this Act.

13. (1) Save as otherwise provided by this Act the expressions "school board," "public elementary school," "managers," "parliamentary grant," and "Education Department," respectively, have the same meaning in this Act as in the Elementary Education Acts.

(2) The expression "local authority" means in any borough the council of that borough, and elsewhere the district council if district councils are established under any Act of the present session of Parliament, but if not then the urban sanitary authority or where there is no urban sanitary authority the county council.

The expression "local rate" means in a borough the school fund or borough fund or borough rate, and elsewhere the general district rate or other rate corresponding thereto.

14. This Act shall not apply to Scotland or Ireland.

SCIENTIFIC SERIALS.

Bulletins de la Société d'Anthropologie, tome onzième, série iii., fasc. 4 (Paris, 1888).—Conclusion of M. Variot's paper on the removal of marks of tattooing; and on an instrument for tattooing, by the same writer.—On the sacrum of a chimpanzee, by M. Chudzinski. In this case the sacrum was composed of seven vertebræ, the normal number in the Anthropoids being only five, or at most six.—A process for mounting histological specimens treated under paraffin, by M. Mahoudeau.—A description of the cranium and brain in two assassins, by MM. Fallot and Alezais. This communication gives a minute analysis of the convolutions and other parts of the hemispheres, while it supplies numerous and special measurements of the various parts of the skull together with the respective cerebral and cranial indices.—On the cranial alterations observable in rachitic conditions, by M. Regnault.—On the first temporal convolution in the right and left hemispheres, in the case of a person who was known to have suffered from deafness of the left ear, by M. Manouvrier.—A communication regarding the truth of the reports made by various travellers that cannibalism exists among the Fuegians, by M. Hyades. According to this writer there is absolutely no ground for this charge.—On a Peruvian bell, by M. Verneau.—On the antiquity of Egypt, and the evidences of its condition in prehistoric times, by M. Beauregard. In this very exhaustive article the author passes in review the material evidence remaining of the ages of cut and polished stone and of bronze. He believes that Egypt at the time of the Pharaohs exhibited the mixed condition of combining the use of flint implements with the simultaneous acquaintance with the means of extracting copper, and blending it with other metals, including tin, although no distinct hieroglyphic for the latter has been recognized in the older language of Egypt. It remains undetermined where and when first the ancient Egyptians obtained the tin which enters into the bronze fabricated in the valley of the Nile as far back as the seventeenth century before our era.—On the birth-rate in France, by M. Chervin. This paper contributes the most elaborate and detailed series of statistical tables, for the separate departments, of the births, marriages, and deaths registered, as well as of the numbers of children born in a definite number of households. The means obtained from these lists show that 8 per cent. of all the marriages in France are sterile, and that while 25 per cent. yield only one child, 100 families supply a mean of only 259 children. Many curious points of interest are suggested by this complex report, but it does not do much to explain the causes of the want of increase in the population of France, as compared with that of other countries.—On the hinged and cantoned cross in Cyprian decorative art, by M. Max Richter. The remains of ancient art in Cyprus strongly resemble those of Hissarlik, excepting that there is no trace of the *swastika*, or hinged cross on the decorated red jars of the Bronze Age, while its later appearance and disappearance in Cyprian art appears to coincide with the predominance and decline of Phœnician influence.—On the survival in Brittany of some of the usages and privileges of clanship, by M. Sébillot.—On a semi-pagan procession on St. John's day, in the Basses Alpes, by M. Arnaud. From time immemorial the peasants of Lauzet have proceeded after the benediction of the neighbouring lake to throw stones into its waters amid loud and angry cries of vengeance against the evil spirits who bring rain and hail storms. In this strange ceremony the local *curé* is constrained by popular will to take part.—On phallotomy among the Egyptians, by M. Letourneau.—On the centre of creation, and the first appearance of the human race, by M. Lombard. The writer supports Signor Saporta's view that vegetable forms, which now cover our continents, have spread slowly and continuously from north to south, recent species forcing back or obliterating those of more ancient origin. The laws which Signor Saporta endeavours to establish for the diffusion of vegetable forms, M. Lombard thinks may be extended to the animal kingdom, including man, whose cradle he would seek in circumpolar regions.—Report of sixth Conference on Transformism, under the presidency of M. Duval, by M. Bordier.—Report of fifth Broca-Conference, by M. Topinard, a member of the commission for awarding the prize instituted by Madame Broca in memory of her husband. The memoirs presented between 1885 and 1888 are not numerous, but great value attaches to two among these works, viz. the general ethnography of Tunis, by Dr. René Collignon, to whom the Broca Prize for 1888 has been unanimously awarded; and ethnological researches in regard to the human remains discovered at Spy, by M. Fraipont, who received a silver medal in recognition of the great merit of his work.—On the longevity of the Berber races, by M. Letourneau.—On a Palæolithic station on Mont Roty, and on a novel flint implement, by the Abbé Blanquet.—On an ancient cemetery at Biskra, Algeria, by M. de Mortillet.—On a sepulchral dolmen, discovered at Nanteuil-le-Houdouin (Oise), by MM. Collin and Lair.—A prehistoric station at Frileuse (Seine-et-Oise), by M. Vauvillé.

THE numbers of the *Botanical Gazette* (Crawfordsville, Indiana) for March and April contain a careful study of the histology of the leaves of *Taxodium* by Mr. Stanley Coulter, and a description of a number of new North American mosses, with illustrations, by Messrs. Renauld and Cardot. It is an evidence of the attention paid in the United States to microscopical technique, that this magazine frequently contains (as do both the numbers now before us) valuable hints as to the preparation of sections of tissues for the microscope, the use of staining reagents, or objects specially well calculated to demonstrate difficult points of structure.

IN the *Journal of Botany* for April and May, Messrs. Murray and Boodle complete their account of the genus *Avrainvillea* of Siphonocladaceæ.—Students of conifers will read with very great interest Dr. M. T. Masters's attempt to distinguish the North American pines, *Abies lasiocarpa*, *A. bifolia*, and *A. subalpina*, with their varieties or subspecies. The paper is illustrated by a series of excellent woodcuts.—Most of the other papers in these numbers are of special interest to students of British plants.

THE *Nuovo Giornale Botanico Italiano* for April, a large portion of which is devoted to a report of the proceedings of the Italian Botanical Society, contains several articles of general interest besides those devoted to the Phanerogamic and Cryptogamic botany of Italy.—Dr. H. Ross has an interesting article on the assimilating tissue and development of the periderm in the branches of plants with few or no leaves.—In pursuance of his careful examination of the Nymphæaceæ, Prof. G. Arcangeli now contributes a paper on the seeds of *Victoria regia*.—Signor U. Martelli adds a species to the few hitherto known of the genus *Riccia*—*R. atromarginata* from Sicily.—Signor C. Lumia gives the result of an examination of the composition of the gas found within the inflorescence of the common fig in an unripe condition, which contains more than 5 per cent. of carbon dioxide, showing that an active process of respiration must go on within the receptacle.—Signor G. Cuboni gives an account of experiments carried on with a view to check the plague of grasshoppers by infecting them with a parasitic fungus, *Entomophthora Grylli*, which had, however, only negative results.

Rendiconti del Reale Istituto Lombardo, April.—Palæontological notes on the Lower Lias of the Lombard fore-Alps, by Dr. C. F. Parona. These notes are communicated pending the publication of the author's exhaustive treatise on the fauna of Saltrio. They deal especially with the palæontological features of the Bergamo and Como districts in connection with the various faunas that flourished in the Lombard Sea during the Lower Lias epoch. The results of this summary survey agree generally with the conclusions arrived at by Prof. De Stefani in his comparative study of the various Lower Lias formations throughout Italy.—New measurement of the curvature of surfaces, by Prof. Felice Casorati. A new solution is presented of this problem, that of Gauss being shown to be defective and inadequate, although he laid the first solid foundation for the study of the subject in his classical work, "Disquisitiones generales circa superficies Curvas."—Prof. Giovanni Zoja contributes some historical notes on the cabinet of human anatomy in the University of Pavia, dealing more particularly with the period from 1815 to 1864 under the able administration of Bartolomeo Panizza.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 9.—"Zirconium and its Atomic Weight." By G. H. Bailey, D.Sc., Ph.D., the Owens College, Manchester.

Before proceeding with any final estimation, those salts of zirconium which were at all likely to be of service in the determination were exhaustively examined with special regard to their stability in presence of reagents and under the action of heat.

It was found that in consequence of their instability and tendency to form numerous oxychlorides, neither the chloride nor the oxychloride could be relied upon, and that the sulphate was the most suitable salt to work with. Even this salt when heated above 400° C. undergoes gradual decomposition with the production of basic salts, though it is quite stable up to this temperature A special method (applicable in a number of other atomic weights) was devised by which the normal salt could be obtained free from acid on the one hand, and from basic salt on the other. In order to have a sufficient check on the results, the carefully purified zirconia was further treated by four perfectly independent methods.

(*a*) The sulphate was prepared and its solution precipitated by means of hydrogen peroxide.

(*b*) The tetrachloride was prepared and its solution precipitated by ammonia.

(*c*) The sulphate was recrystallized several times from concentrated sulphuric acid and precipitated by ammonia.

(*d*) The oxychloride was prepared and recrystallized and precipitated by ammonia.

The average values obtained from the sulphate prepared from the specimens of zirconia so treated by determining the relation $Zr(SO_4)_2 : ZrO_2$, were :—

(*a*) 90·402
(*b*) 90·390
(*c*) 90·471
(*d*) 90·30
} mean 90·401.

In addition to the investigation of the salts which have been used in the estimation of the atomic weight, observations on the peroxides of zirconium discovered by Clève and the author are embodied, as well as an examination of the so-called metallic zirconium.

"Determining the Strength of Liquids by means of the Voltaic Balance." By Dr. G. Gore, F.R.S.

This method is based upon the circumstance that the greater the degree of concentration of a solution the larger is the amount of dilution required to reduce its voltaic energy to a given magnitude. The method of measuring the energy is described in Royal Society Proceedings, vol. xlv. p. 268.

In the present research a known volume of solution was taken, and the proportion of dissolved substance in it was found by ordinary chemical analysis. A second portion was taken, its specific gravity ascertained, and its degree of strength found by aid of the ordinary published tables of specific gravities. A third portion of known volume was then taken, its average amount of voltaic energy measured, and its degree of concentration ascertained by the amount of dilution required to reduce its voltaic energy to the same magnitude; the less dilute it was at starting the greater the amount of dilution required. The following are the results :—

By	HCl.	H_2SO_4.	HNO_3.	NaCl.	Na_2CO_3.	H_3N.
Chemical analysis	1·85	5·60	2·97	9·13	7·21	1·05
Specific gravity	1·70	5·44	2·80	8·74	7·63	1·03
Voltaic balance	1·65	5·70	2·90	8·71	7·57	1·06

A much less quantity of the substance is usually required by the voltaic balance method than by either of the other ones, and the operation is very quickly performed.

Physical Society, May 11.—Prof. Reinold, President, in the chair.—The following communications were read :—On an electrostatic field produced by varying magnetic induction, by Dr. O. J. Lodge, F.R.S. This paper describes a research made with the object of finding some connection between static electricity and magnetism. Several methods of attacking the problem, such as rotating or varying the strength of magnets in the neighbourhood of delicately suspended charged bodies, are indicated, and the one selected was based on an idea of Mr. A. P. Chattock, who conceived that a charged body in the vicinity of a closed magnetic circuit would be affected by varying the magnetic induction. From the theory of the effect it is shown that the magnitude of the quantity sought is exceedingly small, for the expression involves the inverse square of the velocity of light. The E.M.F. induced in any closed curve round the magnetic circuit or solenoid by varying the induction, I, is given by—

$$e = \frac{dI}{dt} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

If an E.M.F., e, act on a charge, Q, at distance r from the axis of the solenoid, the work done in one revolution will be eQ, and

$$eQ = F \cdot 2\pi r \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

where F is the mechanical force. Now if the E.M.F. in (1) is the same as that in (2), the impulse given to the charged body by destroying the induction will be—

$$\phi = \int_0^\infty F dt = \frac{IQ}{2\pi r} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

Since $I = \frac{4\pi n C A \mu}{l} = \mu C$ times a length, and $Q = sV = KV$ times a length,

$$\therefore \phi = \frac{K\mu CVA}{2\pi r} (\text{length})^2, \text{ and } K\mu = \frac{1}{\text{“}v\text{”}^2}; \quad \therefore \phi \propto \frac{1}{\text{“}v\text{”}^2}.$$

The magnetic circuit actually used was a wire Gramme ring of trapezoidal section, wound with copper over only a part of its periphery. The indicating apparatus was a suspended needle, consisting of two oppositely charged bodies carried on a small shellac arm, to which a mirror or pointer was attached, and was suspended vertically in the plane of the ring. Great difficulty was experienced from Foucault's currents when metallic films were used for the needle, and the magnetic properties and other semi-conductors tried further complicated the matter. Eventually, the charged bodies were made of paper, in the form of cylinders one-eighth of an inch diameter and three-eighths of an inch long. Considerable trouble was caused by the electrostatic action between the needle and exciting coils, and various methods of screening were tried and abandoned, and subsequently the wire was replaced by a single spiral of copper ribbon, the outer turn of which was put to earth. Observation was rendered difficult, owing to the wandering of the zero when the needle was charged, but this was minimized by suitably shaping the contour of the needle's surroundings. Heat also created considerable disturbance, and the convection currents were cut off by a series of concentric cylinders of tin plate. The method of observation was to charge the two insulated parts of the needle, and then reverse the magnetizing current in synchronism with the period of the needle, noting whether the amplitude of any residual swing could be increased or diminished according as the impulse assisted or opposed the motion. In this way, slight indications have been observed, and the effects reverse when the charges of the cylinders are reversed. In explaining the theory of the experiment, the author made use of a simple transformer, consisting of an ordinary hank of iron wire wound over with insulated copper and provided with several secondary coils; and by it he demonstrated that the primary current increases on closing the secondary, due, as was shown, to the decrease of self-induction of the primary caused thereby. Prof. Fitzgerald, in answer to a question from Dr. Lodge as to the influence of screens, said he had not fully considered the matter in this particular case, and, as the general effect of screens depended on the square of "v," the subject required careful treatment. As a means of checking the results obtained by Dr. Lodge, he suggested calculating the impulse, and seeing whether its magnitude approximately corresponds with that observed. Commenting on an idea for carrying out a similar experiment attributed to him in the paper, in which a charged gold leaf is placed between the poles of a magnet, Prof. Fitzgerald said he had been misunderstood, for he had conceived a disk parallel to the faces of the magnets, which, when excited, should cause the disk to turn in its own plane. Referring to the equations for mechanical force given in Maxwell, §619, he pointed out that the coefficient of e in the equation—

$$X = cv - bw - e\frac{d\psi}{dx} - m\frac{d\Omega}{dx}$$

ought to be P, where—

$$P = c\dot{y} - b\dot{z} - \frac{dF}{dt} - \frac{d\psi}{dx},$$

and considered it very important that the existence of the term $e\frac{dF}{dt}$ should be tested experimentally. Prof. S. P. Thompson mentioned some experiments on which he was engaged by which he hoped to show electric displacement in continuous dielectric circuits, such as a link of gutta-percha. Up to the present the experiments had not been successful, owing to his inability to place the two Gramme ring coils used into such relative positions as to give silence in the telephone connected with the coil used as secondary, when currents were sent through the primary. Prof. Ayrton suggested that Dr. Thompson's difficulty may arise from the fact that such rings do produce considerable external field, even when carefully wound.

Prof. Fitzgerald requested Dr. Thompson to investigate the effects of displacement-currents and of changing vector potential, and pointed out that in a single medium the former can produce no magnetic effect. As regards fields containing different media, he said the calculations would be complicated by the spurious charges on the separating surfaces. Dr. Lodge, in reply, said he had calculated the momentum to be expected in one arrangement of his experiment in which a suspended aluminium cylinder surrounds one limb of a rectangular magnetic circuit which formed the core of an induction coil; one end of the secondary was put to the core and the other to the cylinder, thus forming a condenser. The result came out about 10^{-6} dyne second, but he could not say whether such a small quantity was observable.—On the concentration of electric radiation by lenses, by Prof. O. J. Lodge, F.R.S., and Dr. James L. Howard. The authors' first attempts at concentration were made with mirrors on a comparatively small scale, and, owing to the difficulties experienced, it was considered advisable to try lenses. Two large cylindrical ones of plano-hyperbolic section were cast of mineral pitch in zinc moulds, the plane faces being nearly a metre square, the thickness at vertex 21 centimetres, and each lens weighed about 3 cwt. The eccentricity of the hyperbola was made 1·7, to approximate to the index of refraction of the substance. The lenses were mounted about 6 feet apart, with their plane faces parallel, and towards each other on a table in the College corridor, and an oscillator was placed about the principal focal line of one of them at a distance of 51 centimetres from the vertex. The field was explored by a linear receiver made out of two pieces of copper wire mounted in line on a piece of wood, and the air-gap between their inner ends was adjustable by a screw. When the oscillator worked satisfactorily, the receiver would respond at about 120 centimetres, and with the lenses the distance was 450. The receiver responded anywhere between the lenses, and within the wedge between the second lens and its focal line, the boundaries being clearly defined, but no special concentration was noticed about the focus. Interference experiments were carried out by placing a sheet of metal against the flat face of the second lens, and determining the positions of minimum intensity between the lenses. The distance between these points was 50·5 centimetres, corresponding with a wave-length of 101 centimetres, whereas the calculated wave-length of the oscillator was 100 centimetres. Prof. Fitzgerald congratulated the authors on their success, and also pointed out that although large oscillators give good results at distances within a few wave-lengths, yet at greater distances small ones were decidedly superior, owing to the energy of radiation varying as the fourth power of the rapidity. He had recently made experiments on electric radiations analogous to Newton's rings, and had successfully observed the central dark spot and the first dark band. Referring to Dr. Lodge's experiments, he inquired whether any traces of diffraction were observed near the boundary of the bundle of rays between the lenses. Speaking of polarization experiments, Prof. Fitzgerald said waves reflected from films of water exhibited no polarization, whereas those reflected from non-conductors were completely polarized. In reply, Dr. Lodge said no diffraction-effects had been observed, but in the interference-experiments to determine wave-length, the positions of minimum effect were very decided.—The President, in proposing that the thanks of the meeting be given to the authors of the papers, congratulated the Society on the presence of both Dr. Lodge and Prof. Fitzgerald on the present occasion, when subjects with which they were so well acquainted were brought before the meeting.

Chemical Society, May 2.—Dr. W. J. Russell, F.R.S., President, in the chair.—The following papers were read:—Thiophosphoryl fluoride, by Prof. T. E. Thorpe, F.R.S., and Mr. W. J. Rodger. Thiophosphoryl fluoride, PSF_3, may be prepared by the action of arsenic trifluoride on thiophosphoryl chloride, or by heating a mixture of bismuth trifluoride or lead fluoride with phosphorus pentasulphide in a leaden vessel at a temperature not exceeding 250°. It is a transparent colourless gas, which under a pressure of ten to eleven atmospheres at ordinary temperatures condenses to a colourless, mobile liquid. It is slowly decomposed by water into sulphuretted hydrogen, phosphoric acid, and hydrogen fluoride, but does not attack mercury, and can be stored in a glass gas-holder. In air it is spontaneously inflammable, burning with a greyish-green flame forming phosphorus pentafluoride, phosphorus pentoxide, and sulphur dioxide, and it spontaneously explodes with oxygen. When heated, or subjected to electric sparks, it is decomposed with separation of sulphur and phosphorus, and formation of phosphorus trifluoride, and eventually phosphorus pentafluoride, whilst if the heating be effected in a glass tube at a sufficiently high temperature the gas is ultimately converted into silicon tetrafluoride. Thiophosphoryl fluoride combines with ammonia forming a solid product $P(NH_2)_2SF$, and when shaken with a moderately strong solution of alkali it is absorbed with the formation of a thiophosphate and a fluoride.—The boiling-point of sodium and potassium, by Mr. E. P. Perman. Sodium and potassium were boiled in a hollow iron ball which was heated by means of a blowpipe; the temperature was found in each case by means of an air thermometer consisting of a glass bulb with a capillary stem which was lowered into the vapour, sealed and broken open under water. The mean result for sodium was 742°, and for potassium 667°.—Note on the heat of neutralization of sulphuric acid, by Mr. S. U. Pickering. Calculating the value of the heat of neutralization of sulphuric acid in infinity of water from the results of a series of experiments on the dilution of the acid, the author finds that it becomes reduced to 28,197 cal., a value within experimental error, the same as that of two molecules of hydrogen chloride.—α-ω-diacetylpentane and α ω-dibenzoylpentane, by Dr. F. S. Kipping and Prof. W. H. Perkin.—Acetopropyl- and acetobutyl-alcohol, by Dr. H. G. Colman and Prof. W. H. Perkin.

Royal Meteorological Society, May 15.—Dr. W. Marcet, F.R.S., President, in the chair.—The following papers were read:—Account of some experiments made to investigate the connection between the pressure and velocity of the wind, by Mr. W. H. Dines. These experiments were made for the purpose of determining the relation between the velocity of the wind and the pressure it exerts upon obstacles of various kinds exposed to it. The pressure-plates were placed at the end of the long arm of a whirling machine which was rotated by steam power. The author gives the results of experiments with about twenty-five different kinds of pressure-plates. The pressure upon a plane area of fairly compact form is about 1½ pounds per square foot, at a velocity of twenty-one miles per hour; or, in other words, a pressure of 1 pound per square foot is caused by a wind of a little more than seventeen miles per hour. The pressure upon the same area is increased by increasing the perimeter. The pressure upon a ½-foot plate is proportionally less than that upon a plate either half or double its size. The pressure upon any surface is but slightly altered by a cone or rim projecting at the back, a cone seeming to cause a slight increase, but a rim having apparently no effect.—On an improved method of preparing ozone paper, and other forms of the test, with starch and potassium iodide, by Dr. C. H. Blackley. Some years ago the author made some experiments with the ordinary ozone test-papers, but found that the papers did not always give the same result when two or more were exposed under precisely the same conditions. He subsequently tried what reaction would take place between unboiled starch and potassium iodide when exposed to the influence of ozone; but the difficulty of getting this spread evenly upon paper by hand so as to insure a perfectly even tint after being acted upon by ozone led him to devise a new method of accomplishing this. Briefly described, it may be said to be a method by which the starch is deposited on the surface of the paper by precipitation, and for delicacy and precision in regulating the quantity on any given surface leaves very little to be desired.—Notes on the climate of Akassa, Niger Territory, by Mr. F. Russell. This paper gives the results of observations made from February 1887 to October 1888 at Akassa, which is the seaport and principal depot of the Royal Niger Company, and is situated at the mouth of the River Nun in the Niger Delta.—Wind storm at Sydney, New South Wales, on January 27, 1889, by Mr. H. C. Russell, F.R.S.

Geological Society, May 8.—W. T. Blanford, F.R.S., President, in the chair.—The following communications were read:—The rocks of Alderney and the Casquets, by the Rev. Edwin Hill. The author in this paper described Alderney, Burhou, with its surrounding reefs, and the remoter cluster of the Casquets, all included within an area about ten miles long. The reading of the paper was followed by a discussion, in which the President, Prof. Bonney, Dr. Woodward, Dr. Hicks, and others took part.—On the Ashprington volcanic series of South Devon, by the late Arthur Champernowne. Communicated by Dr. A. Geikie, F.R.S. The author described the general characters of the volcanic rocks that occupy a considerable area of the country around Ashprington, near Totnes. They comprise tuffs and lavas, the latter being sometimes amygdaloidal and sometimes flaggy and aphanitic. The aphanitic rocks approach in character the porphyritic "schalsteins" of Nassau. Some of the rocks are much altered; the felspars are blurred, as if changing to saussurite, like the felspars in the Lizard gabbros. In other cases greenish aphanitic rocks have, by the decomposition of magnetite or ilmenite, become raddled and earthy in appearance, so as to resemble tuffs. The beds are clearly intercalated in the Devonian group of rocks, and the term Ashprington Series is applied to them by the author. Alrhough this series probably contains some detrital beds, there are no true grits in it. Stratigraphically the series appears to come between the Great Devon Limestone and the Cockington Beds, the evidence being discussed by the author, however, not so fully as he had intended, as the paper was not completed. The President said that the thanks of the Society were especially due to Dr. Geikie for having rescued this paper from oblivion. Dr. Geikie, after alluding to the melancholy interest attaching to the paper, said that he had himself urged the author to formulate his ideas upon the structure of the country. The present communication, however, was all that was found among his papers in a condition for publication. But it is imperfect, and no materials remained from which it could be completed; still it was too valuable a piece of work to leave unpublished. There were two principal points in this last work of Mr. Champernowne: (1) the non-intrusive character of the beds in question; (2) their geological horizon, regarding which, though, owing to the faulted nature of the country, it is rather obscure, Mr. Champernowne's surmises may turn out to be correct. There was no allusion in the paper to the compression and shearing the rocks had undergone, to which he (Dr. Geikie) attributed much of the schistose structure both of the sedimentary and igneous rocks of the region. The flaky beds of which the author speaks can be traced into the more massive rocks. The flattening out of the amygdaloids was a striking proof of this mechanical deformation. Some remarks on the paper were also offered by Mr. Rutley, Dr. Hatch, Mr. Worth, and Mr. W. W. Beaumont.

Zoological Society, May 7.—Prof. Flower, F.R.S., President, in the chair.—The Secretary read a report on the additions that had been made to the Society's Menagerie during the month of April 1889, and called attention to a young male Sinaitic Ibex (*Capra sinaitica*), from Mount Sinai, presented by Sir James Anderson; and to a young male of the Lesser Koodoo (*Strepsiceros imberbis*), from East Africa, presented by George S. Mackenzie.—Mr. Sclater exhibited and made remarks on a living specimen of an albino variety of the Cape Mole (*Georychus capensis*), lately presented to the Menagerie by the Rev. George H. R. Fisk, C.M.Z.S.—The Secretary read a letter addressed to him by Dr. E. C. Stirling, of Adelaide, containing a copy of his description of a new Australian burrowing Mammal, lately published in the Transactions of the Royal Society of South Australia, and promising to send to the Zoological Society a more complete account of the same animal.—Mr. Seebohm exhibited and made remarks on the skin of a male example of *Phasianus chrysomelas*, which had been transmitted in a frozen state from the Trans-Caspian Provinces of Russia.—A communication was read from Colonel C. Swinhoe, containing descriptions of seventy-five new species of Indian Lepidoptera, chiefly Heterocera.—A communication was read from Rev. O. P. Cambridge, containing the description of a new Tree Trap-door Spider from Brazil, proposed to be called *Dendricon rostratrum*.—Mr. F. E. Beddard read some notes on the anatomy of an American Tapir (*Tapirus terrestris*), based on a specimen lately living in the Society's Collection.—A communication was read from Prof. Bardeleben, of Jena, on the præpollex and præhallux of the Mammalian skeleton. The author recorded the presence of a two-segmented nail-clad præpollex in *Pedetes*, and that of a two-segmented pisiform (post-minimus) in *Bathyergus*. He also stated that he had discovered vestiges of the præhallux and præpollex in certain Reptilia. He then passed to the consideration of the Mesozoic *Theriodesmus* of Seeley, and denied the existence of the *scapho-lunare* of that author, while he produced good reason for believing the same observer's second *centrale* to consist of two elements, and his præaxial *centrale* to be the basal element of a præhallux.—Mr. Oldfield Thomas read the description of a new genus and species of Muridæ from Queensland, allied to *Hydromys*, which he proposed to call *Xeromys myoides*.

Mathematical Society, May 9.—J. J. Walker, F.R.S., President, in the chair.—The following communications were made:—On the solution in integers of equations of the form $x^3 + y^3 + Az^3 = 0$, by S. Roberts, F.R.S.—On the concomitants of K-ary quantics, by W. J. C. Sharp.—Note on the G function in an elliptic transformation annihilator, by J. Griffiths.—On the complete elliptic integrals K, E, G, I, by Dr. J. Kleiber, *Privat-docent* of the University of St. Petersburg.—On the motion of an elastic solid strained by extraneous forces, by Signor Betti ("by *symmetrical algebraic analysis*, the author obtains an expression, in terms of the rotations of the element, for the unbalanced couples acting on each element of a solid when strained by given forces; and he points out that the result is in accordance with a form of the elastic equations given by Sir W. Thomson").—On cyclotomic functions, § iii. the cyclotomics belonging to the f-nomial periods of the pth roots of unity, where p is a prime number, by Prof. Lloyd Tanner.

EDINBURGH.

Royal Society, April 1.—Sir W. Thomson, President, in the chair.—Prof. Tait communicated some of the results obtained from a series of experiments on impact of various bodies.—Sir W. Thomson exhibited and described new forms of magnetostatic current- and volt-meters, and an electro-static voltmeter with a multiple voltaic pile to facilitate graduation.—Mr. A. Crichton Mitchell gave an account of the properties of manganese steel.—Dr. W. Peddie described an improved method of measuring small rotations of the plane of polarization by ordinary apparatus.—Prof. Tait read a paper on the relations between line-, surface-, and volume-integrals. He showed that the well-known relation between line- and surface-integrals can be deduced directly from a particular case of the equally well-known relation between surface- and volume-integrals.

April 15.—Prof. Sir Douglas Maclagan, Vice-President, in the chair.—The Keith Prize for 1885–87 was awarded to Mr. J. Y. Buchanan for a series of communications on subjects connected with ocean circulation, compressibility of glass, &c.—The Makdougall-Brisbane Prize for 1884–86 was awarded to Dr. John Murray for his papers on the drainage areas of continents, and ocean deposits, the rainfall of the globe, and discharge of rivers, the height of the land and depth of the ocean, and the distribution of temperature in the Scottish lochs as affected by the wind.—The Makdougall-Brisbane Prize for 1886–88 was awarded to Dr. Archibald Geikie for numerous communications, especially that on the history of volcanic action during the Tertiary period in the British Isles.—Prof. Swan read an obituary notice of the late Mr. R. M. Smith.—Dr. E. Sang read a paper on the resistance of the air to the motion of an oscillating body with special reference to its effect on time-keepers.—Mr. A. Johnstone communicated a paper on a new and easy method for the rapid and sure detection of mercury.

PARIS.

Academy of Sciences, May 13.—M. Des Cloizeaux, President, in the chair.—The thionic series, by M. Berthelot. In this paper the author studies the action of the acids on the thiosulphates, which throws quite a new light on the constitution of the salts of the thionic series, by determining the limits of the heat of neutralization of thiosulphuric acid. The liberated sulphur reacts with the thiosulphuric acid before it decomposes, forming complex thionic acids.—On mesocamphoric acid, by M. C. Friedel.—The author has prepared this substance by a process different from that of Wreden, by whom it was first described, and some of whose statements are here rectified. Instead of being an inactive, non-decomposable acid, it is found to be decomposable by simple crystallization.—On the photographic spectrum of the great nebula of Orion, by Dr. W. Huggins. In 1882 the author obtained a photograph of the spectrum of this nebula, revealing a new luminous ray with wave-length about λ3730. Two recent photographs taken in 1888 and 1889 enable him to determine more accurately this wave-length, as well as to describe a certain number of other luminous rays which occur in the ultra-violet region of the spectrum of the same nebula. These photographs are figured in a drawing which accompanies the present note. The wave-length of the bright ray discovered in 1882 is here determined at λ3724. Dr. Huggins considers it probable that nebulæ yielding a spectrum of luminous rays, with a very faint continuous spectrum, which is probably formed in part by luminous rays in close proximity, are at or near the beginning of the cycle of their celestial evolution, while those resembling the large nebula in Andromeda have already reached a more advanced phase of their development. The photograph of this nebula taken by Mr. Roberts reveals a planetary system, in which some planets are already formed, and their central mass condensed.—On the surgical treatment of the foot in cases of suppurated osteo-arthritis, by M. Ollier. Hitherto amputation has generally been considered the only remedy; but the author's experiments show that, by removal of the ankle with abrasion or resection of the limiting articulations, the foot may be preserved almost in its normal state and with little detriment to its locomotive functions.—On the linear expansion of solid bodies at high temperatures, by M. Pionchon. These researches show that by means of the simple process here described M. Fizeau's well-known experiments may be repeated with the greatest ease. M. Pionchon now proposes to apply the process to the study of the linear expansion of amorphous and crystallized solid bodies at high temperatures.—On the direct measurement of the retardation produced by the reflection of luminous waves, by M. A. Potier. These experiments, which are applicable to a large number of substances, constitute a method by means of which the retardation may be directly measured, which is caused by the reflection of the luminous waves on their surface.—On the influence of terrestrial magnetism on atmospheric polarization, by M. Henri Becquerel. In a previous memoir (*Annales de Chimie et de Physique*, xix., 1880) the author showed that in a cloudless sky the plane of polarization is not generally coincident with the theoretic plane (plane of the sun), and further that the two should coincide when the latter is vertical, but that, in a region near the horizon and the magnetic meridian, the plane of polarization then deviates by a small angle in the direction corresponding to the rotation of the plane of polarization of a luminous ray traversing a column of air, subject to the magnetic influence of the earth. In the present paper he determines both the direction and the extent of the rotation, and also shows how this display of terrestrial magnetism is associated with some of the most interesting questions connected with the physics of the globe.—A study of the electric conductivity of saline solutions, as applied to chemical mechanics—the acid salts, by M. P. Chroustchoff. The author has applied M. Bouty's extremely sensitive electrometric method of measuring the electric conductivity of liquids to the study of several problems in chemical statics. In the present paper he tabulates the chief measurements of the electric conductivity of aqueous solutions containing one salt only. — Action of the atmosphere on manganese carbonate, by M. A. Gorgeu. In this paper the author discusses the question whether this action can give rise to any of the natural dioxides, as assumed by MM. Boussingault and Dieulafait.—Papers were contributed by M. L. Pigeon, on platinic chloride; by M. Aug. Lambert, on the action of borax on the polyhydric phenols and alcohols; and by M. H. Prouho, on the structure and metamorphosis of *Flustrella hispida*.—A copy of M. Seligmann-Lui's translation of Clerk Maxwell's classical treatise on "Electricity and Magnetism" was presented to the Academy by M. Sarrau.

BERLIN.

Physical Society, April 26.—Prof. Kundt, President, in the chair.—Prof. Kundt gave a short account of recent researches on electro-magnetic rotatory polarization, and developed the more general point of view from which they had been respectively undertaken. Since the time when Faraday discovered the fundamental phenomena and later physicists had accumulated a mass of material on which observations could be made, two facts had chiefly presented difficulties in connection with the established theory: of these one was the varying direction of rotation produced by different substances, some producing a positive rotation (in the direction of the Ampèrian current), others a negative rotation; the other fact was the absence of magnetic rotation in doubly-refractive crystals. Starting from some theoretical considerations, the speaker was led to surmise that rotation is not wanting in these crystals, but is only obscured by some opposing phenomenon, a view which has been fully confirmed by experiments carried out at his suggestion by Drs. Wedding, Wiener, and du Bois. When a piece of glass was made doubly refractive by pressure, its magnetic rotatory polarization diminished, becoming *nil* when the difference in path of the two rays was $\frac{1}{2}\lambda$; when the difference was $\frac{3}{4}\lambda$, then the rotation took place in the opposite direction. When the difference was λ, the rotation was again *nil*, and it varied thus in a wave-like manner, with increasingly small amplitudes until it ceased entirely. Prof. Kundt concluded from this that the power of electro-magnetic rotatory polarization is common to *all* substances, whether crystalline or isotropous. As regards the varying direction of rotation, his own experiments had shown that simple substances produce a positive rotation, and compound bodies a negative rotation; this last result may be explained by the fact that the Ampèrian currents inside compound bodies run in a direction different from that in the magnetic field. The proportionality of rotation to the strength of magnetization is also a property common to all substances; its relationship to refraction is being made the subject of further researches. Dr. Koenig (from Leipzig) pointed out many analogies which exist between the electrical rays discovered by Prof. Hertz and rays of light, more particularly the polarization of the electrical rays by means of the wire grating and the phenomena which may be observed in the immediate neighbourhood of the rays as they are advancing in straight lines, phenomena which are in exact accord with those described by Stokes in the case of light.

STOCKHOLM.

Royal Academy of Sciences, April 9.—Researches on the deviations of the plumb line in Sweden, by Prof. Rosén.—Résumé préliminaire d'une recherche expérimentale sur l'absorption de la chaleur rayonnante par les gaz atmosphériques, by Dr. Ångström.—Newly found specimens of *Anser brachyrhynchus*, Baill., in Sweden, by Dr. A. Stuxberg.—On a singular Tetrarhynchid larva, by Herr E. Lönnberg.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Eclectic Physical Geography: R. Hinman (Low).—A Treatise on the Principles of Chemistry, 2nd edition: M. M. P. Muir (Cambridge University Press).—Teutonic Mythology: V. Rydberg, translated by R. B. Anderson (Sonnenschein).—Die Entstehung der Arten durch Räumliche Sonderung: M. Wagner (Basel, B. Schwabe).—Examination of Water for Sanitary and Technical Purposes: H. Leffmann and W. Beam (Philadelphia, Blakiston).—Hourly Readings, 1886, Part 3. July to September (Eyre and Spottiswoode).—The Uses of Plants: G. S. Boulger (Roper and Drowley).—Journal of the Institution of Electrical Engineers, No. 79, vol. xviii. (Spon).—Quarterly Journal of the Geological Society, No. 178 (Longmans).—Ergebnisse der Meteorologischen Beobachtungen, Jahrg. x. (Hamburg).

THURSDAY, MAY 30, 1889.

INTERMEDIATE EDUCATION IN WALES.

IT does not often happen, in these days of slow Parliamentary progress, that two educational measures, having an important bearing on the industrial and the intellectual welfare of the country, are read a second time within a week of each other. In our last issue we gave some account of Sir Henry Roscoe's Bill for the provision of technical education, and expressed our strong hope that it would pass through the remaining stages this session. No less heartily do we wish success to Mr. Stuart Rendel's Bill for providing intermediate and technical education in Wales, which was read a second time on May 15, after a debate which practically resolved itself into a chorus of approbation. It is, indeed, high time that something should be done. Secondary education, both in England and Wales, stands sadly in need of organization, but the claims of the Principality (to which the present measure is confined) are far stronger than those of England, so far as the necessity of immediate action is concerned.

The main grounds on which the special treatment of Wales in this matter is based are to be found stated in the Report of Lord Aberdare's Committee on Intermediate and Higher Education in Wales, which was published in 1881. It is there pointed out that the aggregate income of the educational endowments of Wales and Monmouth amounted to little over £14,000, against a total of more than £600,000 for England (excluding Monmouth). Nearly a third of these scanty endowments were to be found in Monmouth. In the matter of these endowments Wales is no better off now than it was then. Since 1881, it is true, the educational resources of Wales have been increased by the grant of £12,000 a year to the three University Colleges of Aberystwith, Bangor, and Cardiff. But even including this sum, which is really intended for higher education, the educational income of Wales is not nearly so great in proportion to the population as in the case of England, and what there is is so unequally distributed as not to be available where the need is greatest.

The result is that in many counties of Wales intermediate education can hardly be said to exist. The Schools Inquiry Commission estimated that about sixteen boys in every thousand ought to be receiving intermediate or higher education. The following quotation from the Report to which we have referred will show the destitution which existed in Wales in 1881, and which unfortunately still exists to a great extent to-day :—"Taking the population of Wales and Monmouthshire to be about 1,570,000, and reducing the estimate in consideration of the exceptional conditions of Wales from sixteen to ten per 1000, intermediate school accommodation should be provided for 15,700 boys, and that number ought to be in attendance. In contrast to this, our returns show *accommodation* in the public schools for less than 3000, and that accommodation to a great extent unsatisfactory. They also show an *attendance* of less than 1600."

This estimate only applies to *boys*, and the state of the case as regards girls' education is still worse. Only from two to three hundred girls were in 1881 in schools under any kind of public supervision, and the Committee naturally found great difficulty in devising recommendations which should adequately meet a case where, as they say, "the unsatisfied requirements are so great and the available resources apparently so meagre." Probably, on the whole, intermediate school accommodation ought to be provided for at least fifteen children per 1000 of the population, making a total of 23,500 school places. Less than a fifth of this number were provided in 1881 in schools under any kind of public supervision or control.

So much for the state of the case. Lord Aberdare's Committee reported in favour of aid being given to Welsh intermediate education both from rates and Imperial grants. Progress, however, in these matters is so slow in England that nothing has hitherto been done to carry out these recommendations except the drafting of a Bill by Mr. Gladstone's Government in 1885. This measure was essentially the same as Mr. Stuart Rendel's Bill which is now before the public.

The Bill embodies most of the recommendations of Lord Aberdare's Committee. It proposes to create a Board of Education for Wales, consisting of representatives of County Councils. To this Board schemes are to be submitted by the Council of each county, to meet the educational needs of that district. The plans may include the establishment of new schools, the reorganization of endowments, and the provision of scholarships. The Board may approve or alter the plans, and the funds required to carry them into effect are to be raised by a rate not exceeding one halfpenny in the pound—a sum, by the way, which will produce about £14,000 a year for the whole of Wales. This sum may be met by a Parliamentary grant not greater than the amount raised from the rates, subject to favourable reports upon inspection. Powers are given to reorganize and utilize existing endowments, and there may no doubt be some difference of opinion as to the extent and nature of the powers in relation to this matter which the Bill proposes to give to the new Board of Education.

There are a few criticisms which may be made on points of detail. The Board of Education ought undoubtedly to include not only representatives of the County Councils, but a certain number of educational experts. The County Councils should likewise be empowered to co-opt men of special knowledge to help in the preparation of their schemes. But on such points the representatives of Wales—a country where, as all who know it well will admit, there is a sincere zeal for educational progress—will not be likely to offer unreasonable opposition.

On the whole, the Bill is a most important step in advance, leading, as we may hope, ultimately to the organization and supervision of secondary schools throughout the Kingdom. All interested in the advance of scientific and technical teaching know how higher institutions are crippled by want of better teaching in secondary schools. The teachers in technical schools and higher colleges in England constantly complain of the want of preparation of those who come to their institutions from private schools. In Wales much of the work which the University Colleges are now compelled to do ought to be done in intermediate schools. We hail the fact that the Bill was read a second time as a sign that the public are waking up to the very great importance of this side of the educational problem.

FLORA ORIENTALIS.

Flora Orientalis, sive Enumeratio Plantarum in Oriente a Græcia et Ægypto ad Indiæ Fines hucusque Observatarum. Auctore Edmond Boissier. Supplementum, editore R. Buser. (Genevæ et Basileæ apud H. Georg, Bibliopolam, 1888.)

A BRIEF notice of the eminent author of the monumental work which the present volume brings to a close appeared in NATURE (vol. xxxii. p. 540), a day or two after his decease, and it is there mentioned that he had for some time been engaged on a supplement to his "Flora Orientalis," the body of which was completed in 1881. That supplement is now fortunately in the hands of botanists, and an opportunity is offered for a more comprehensive notice of the author and his work, as a whole, than has hitherto been published in this country. Apart from the value of the work to the systematist and phytogeographer, it possesses an interest for a wide circle, inasmuch as it deals with the vegetation of those countries of the greatest historical attractions. As the title indicates, the eastern limit of the area of the "Flora Orientalis" is India, and now there are other works actually in progress, which, although they will not by any means exhaust the flora of the rest of Asia, will add vastly to what is known. Sir Joseph Hooker's "Flora of British India" has reached the sixth volume, and the indefatigable author is now engaged on the Orchideæ (the largest order in the British Indian flora, represented by upwards of 1000 species); and we may reasonably hope, now that he is free from official duties, that he will finish it in the course of four or five years. But the energy and perseverance required to get through such an amount of descriptive botany as that accomplished by such men as Bentham, Boissier, and Hooker, can be estimated by few except those similarly engaged.

Regel and Maximowicz's elaboration of the collections of Russian travellers in Central and Eastern Asia, Franchet's "Plantæ Davidianæ" and "Plantæ Yunnanenses," and Forbes and Hemsley's "Index Floræ Sinensis," are jointly bringing together the materials for a flora of Central Asia and China, so that it will soon be possible to survey and analyze the composition of the vegetation in its various aspects from the Atlantic across Europe and Asia to the Pacific.

The "Flora Orientalis" consists of five octavo volumes, with an aggregate of 5387 pages, independently of the present supplement of 499 pages, making a total of 5886 pages; and, on the authority of Dr. H. Christ, the author of a notice of the life and works of Boissier appended to the supplement, the number of species described amounts to 11,876! To these descriptions are added the localities of the plants within the limits of the "Flora," and the geographical area of each species. In giving the former, the author takes the countries in the following order: Greece, Macedonia and Thrace, Asia Minor and Armenia, Egypt and Arabia, Palestine, Syria, and Mesopotamia, Crimea and Caucasus, Persia, Turkestan, Afghanistan and Baluchistan.

Before proceeding to a further examination of the nature and quality of Boissier's "Flora Orientalis," I will extract some particulars of his life from Dr. Christ's memoir, more especially such as relate to his botanical career.

Pierre Edmond Boissier, a descendant of a Huguenot family, was born at Geneva in 1810, and early developed a love for botanical pursuits. This inclination was stimulated and cultivated by the eminent Augustine Pyramus De Candolle, whose admirable teaching resulted in Boissier's life-long devotion to botanical research. Boissier was a man of great mental attainments, of a most amiable disposition, and at the same time of noble stature and fine physique.

Botanizing in the field, which is undoubtedly the best of all training, was his great delight, and his home excursions subsequently extended into distant travels. He was a good walker and a good mountaineer, and retained his great physical power until quite late in life. On his first visit to the Maritime Alps in 1832, he walked the whole distance, some forty miles, from Nice to Tenda in a single journey, and as lately as 1871 he accomplished in one day on foot the longer and much more difficult journey from La Madone delle Finestre to Tenda. The distance is estimated at about forty-five miles, and entails an ascent from 1900 to 2336 metres, then a descent to 1500 metres, upwards again to 2600, and finally down to 750 metres. And this exertion was undertaken to rediscover the rare and singular *Saxifraga florulenta*, originally discovered by an English tourist. This, Boissier's fourth excursion for this object, proved successful.

After finishing his studies at Geneva, Boissier went to Paris, where he met with our countryman Philip Barker Webb, who had botanized extensively in Spain, chiefly in the Kingdom of Granada, though he had published almost nothing thereon. It is supposed that Webb influenced Boissier in his determination to make Spain the field of his next botanical work, and it is certain that he gave him the whole of the materials he had collected, having himself made the Canary Islands the scene of his future labours. Boissier went on his first voyage to Spain in 1836, and continued his investigations for several years, aided more or less by several persons, and greatly by his friend Reuter. Following several preliminary contributions to the botany of Spain, the first part of Boissier's "Voyage botanique dans le midi de l'Espagne" appeared in 1839; and this admirable publication was completed in 1845. It is a botanical work of the first rank, and an enduring monument of the industry and munificence of the author. It consists of two quarto volumes containing a most interesting narrative of his travels; an essay on the geographical distribution of the plants of the region under consideration; descriptions of all the plants, and last, though by no means least, upwards of 200 beautifully drawn, hand-coloured plates by Heyland, one of the most accomplished botanical artists of his time.

Previous to the appearance of this work, the flora of no country of Europe was so little known as that of Spain. The enumeration numbers nearly 2000 species, about one-eighth of which were previously unknown. Since its appearance the flora of the whole of Spain has been elaborated by Willkomm and Lange—by foreigners again, and not by Spaniards! As a noteworthy exception to the botanical lethargy of the Spaniards, the learned and valuable works on the botany and botanists of the Iberian Peninsula by Don Miguel Colmeiro deserve special mention in this connection. Boissier himself, although he soon afterwards became engaged upon a work of much greater magnitude, never lost interest in the flora of Spain, and he revisited the country many times. Even before the completion of his "Voyage en Espagne," he commenced travelling and collecting in South-Eastern Europe, subsequently visiting Egypt, Palestine, and Arabia, and other countries; the results of these journeys culminating in his *magnum opus*, the "Flora Orientalis." Preliminary to this work he published a vast number of new species in fascicles, from time to time, between 1842 and 1859, under the title of "Diagnoses Plantarum Orientalium Novarum." Another important contribution to systematic botany was his "Icones Euphorbiarum," a large quarto, containing figures and descriptive letter-press of 120 species of Euphorbia. This was published in 1866, and in the same year the author furnished descriptions of the seven hundred species of this genus for De Candolle's "Prodromus."

Apart from its size, the "Flora Orientalis" is incontestably one of the most masterly pieces of descriptive botany ever executed, and although many botanists will not agree with the illustrious author in his limitation of species, all will recognize the excellence of the descriptions, and admit that by their aid a botanist can actually "determine" his plants. On this point I can speak from successful personal experience. The analytical keys to the species of some of the larger genera are admirably constructed, and display a marvellously acute knowledge, as well as great power of discrimination Take such genera as *Campanula* (125 species), *Cousinia* (136 species), Centaurea (183 species), Silene (204 species), and Astragalus (757 species), as examples of the work, and it will be admitted that few approach it in quality.

With regard to his conception of species, Boissier rejected the Darwinian theory altogether, believing that species were not arbitrary congeries of individuals, but direct creations of God at different periods. And although he by no means carried subdivision to the absurd extent that some modern botanists have done, yet he went much farther in this direction than most authors who have dealt with the vegetation of so wide an area as that of the "Flora Orientalis."

The supplement, issued towards the end of last year, is brought down to a very recent date, and contains all Dr. Aitchison's additions to the Afghan flora, except those in his last paper, of course, which was not published till the spring of last year. It also includes an index to all the collectors' numbers cited throughout the work, which will be very useful to persons possessing these numbered collections. A portrait of the author late in life forms the frontispiece to this volume, and there are several views of the new building erected on the bank of the lake, not far from Geneva, to contain the fine herbarium amassed by Boissier.

Thus Geneva now possesses the remarkably rich herbaria of De Candolle, De Lessert, and Boissier.

W. BOTTING HEMSLEY.

A TREATISE ON MANURES.

A Treatise on Manures. By A. B. Griffiths, Ph.D. (London: Whittaker and Co., 1889.)

IN this substantial little volume of nearly 400 pages the author treats of natural and artificial fertilizers, with a decided leaning towards the latter. The work is intended to be useful to manure manufacturers as well as to farmers and students of agriculture, and must be regarded as a useful addition to our information. The subject is introduced by two chapters upon the soil and the plant, after which all the leading and the suggested fertilizers are reviewed, and analyses are furnished. It is convenient to have at hand a book written up to date in which the newest sources of phosphatic materials, guanos and alkalies, are brought under notice. The chief interest of Dr. Griffiths's book centres in his chapter upon the use of iron sulphate as a manure. It is well known that Dr. Griffiths first pointed out that the iron sulphate, used in small quantities of about half a hundredweight per acre, exerts a beneficial effect on many crops; and this fact is distinctly brought before the reader in the book before us. The value of sulphate of iron lies in the fact that many soils do not contain a sufficiency of iron in a form to be readily taken up by plants, and Dr. Griffiths considers that when added to such soils it tends to increase the amount of chlorophyll in the leaf, and that this is followed by increased vigour in the elaboration of starch, woody fibre, fats, carbohydrates, and albuminoids. The amounts of increase of crop in the cases cited are remarkable, and the greater percentage of iron in the ashes of plants top-dressed with this substance is decided. It would be unjust to Dr. Griffiths to detract from the value of this observation, which, as he tells us, has been the cause of hundreds of letters on the subject from all parts of the world. The results are indeed open to the criticism that they are almost too satisfactory, for an increase of 19,313 pounds per acre of mangel owing to the use of half a hundredweight of sulphate of iron seems almost too good to be true. Nine tons of mangel are worth something like £6 sterling to the farmer as food for stock, a sum which would effectually turn an unprofitable into a profitable crop. The season is still young, and it would be well if agriculturists would put Dr. Griffiths's results to the test of a simple experiment during the coming summer, upon root crops.

Dr. Griffiths is no great partisan of farmyard manure, and he is scarcely fair in his argument when he touches upon this important subject. We cannot agree with him that farmyard manure is "far from being a perfect manure," or that "the farmer who uses nothing but farmyard manure exhausts his land," or that "farmyard manure does not return to the soil all the nitrogen which was originally extracted from it by growing crops." In pursuing this argument he asks, "Whence comes the fertilizing matter contained in the dung of animals? An ox or a sheep cannot create nitrogen, phosphorus, or potash. All of these substances, which are to be found in its liquid and solid excrements, have been derived from its food. That food has been grown upon the farm."

This is doubtless true if the farm actually does produce all the food of the animals it supports; but every farmer knows that this is not the case. The believers in the value of farmyard manure know perfectly well that the sale of lambs, of young stock, and of dairy produce, as well as of beef, mutton, and wool, exhausts land; but, in order to counteract this tendency, they invariably (we speak of good farmers) purchase oil-cake, hay, and corn in large quantities, sometimes to the extent of from £1 to £2 per acre over the entire farm, and it is this fact which is ignored by Dr. Griffiths. As to whether farmyard manure is a cheap manure or the reverse depends greatly upon the skill of the farmer, but we may be sure that when it is produced by well-bred animals, of high value, or when purchases of stock are made judiciously, farmyard manure may be properly regarded as a by-product.

It is questionable teaching on the part of an agricultural chemist to run counter to the experience of practical men, and we fear that Dr. Griffiths will not carry his agricultural readers with him in his opinions regarding the exhausting nature and expensive character of farmyard dung. Warming with his subject, Dr. Griffiths asks, "Why will the farmer still go sinking in the Slough of Despond, while faithful and willing hands are continually being stretched out in every direction to help him? Let him take a word of warning. Be up and doing, and—whatever you (*sic*) do—be up to the times. Do not let German, French, Belgian, or American agriculturists, simply by dint of superior scientific knowledge and methods, outstrip you in that great competition which is now going on amongst the nations of the world." As in the previous quotation given, we see once more the learned Doctor arguing upon wrong premises. In what respects do German, French, Belgian, or American agriculturists outstrip the English farmer? The average yields of corn and the average results of stock-feeding obtained by British farmers are far superior to those obtained by German, French, and American farmers. The manner in which our farmers have stood the shock of rapidly falling grain prices is extraordinary. Farming has not ceased to be a profitable occupation, but times have recently been very difficult, partly on account of the fall in the value of corn, and partly because the seasons have been remarkably unfavourable for the last fifteen years.

Dr. Griffiths proceeds to point out that in 1884 Germany boasted 158 colleges and schools of agriculture, attended by 17,844 students, and contrasts this fact with the very few colleges and the 240 students of agriculture in England. "If, says he, "Old England is to hold her own, we must have these necessities. It may be said, Is not England already taxed enough? where is the money to come from to support the colleges, schools, and experimental farms? We all admit that England is the *richest* country in the world. Very well, then, if *poor* Germany can support at least 158 agricultural colleges, and give instruction to 17,844 students, surely England need not grumble or be so mean." Does not Dr. Griffiths know that the farmers, as a rule, in Germany and France, do not care about the agricultural colleges? that there is the greatest possible difficulty in inducing them to send their sons to them? that it is only by offering exemption from the galling military service exacted from all men in those countries, and by conferring upon students the rank necessary for serving as officers in the army, that the colleges and schools are filled at all? Does he not know that the colleges and schools are chiefly useful as a means of training the great army of professors and teachers in those countries? Does he not know that a certificate of proficiency gained at a college is, in those countries, absolutely necessary before a man can give evidence in a court of justice on an agricultural question? Does he wish to introduce artificial restrictions such as this into England, and to substitute a patriarchal system for that free enterprise which is the true reason of the wealth and the excellence of England?

A very short time ago £5000 was put aside by the Government for grants on account of agricultural education. No sooner was this offered than a struggle ensued for participation in this small sum. Share lists have been opened, in which one source of profit put before the investing public is a share of this same £5000 as a means of increasing the dividends of the promoters! It is more than likely that this same £5000 will do more harm than good, by encouraging bogus schemes and paralyzing the natural enterprise which is the life-blood of English supremacy.

Dr. Griffiths has issued his book, and farmers are free to read, mark, learn, and inwardly digest it. The agricultural press is open, and there is that great body of good practical farmers who are more fully alive to the situation than Dr. Griffiths imagines, who, if not "scientific" in their instincts, are shrewd men of business, and the possessors of a knowledge of rural matters which comes not from books, but through contact and experience.

Dr. Griffiths is a disciple of Ville, and the main object of his work is to substitute a system of artificial fertilizers for manuring through live stock. Farmyard manure, he says, is imperfect, full of seeds of weeds and germs of disease; it is expensive to produce and to apply; it exhausts the land; it is inferior to artificial manures; and its good properties, such as they are, are not easily recoverable. Such is Dr. Griffiths's indictment, which is calculated to make farmers rub their eyes, and, having made sure they had read aright, lay the book down. If experience is of any value at all in regulating practice, it teaches us that in our climate, and with our natural and acquired advantages in races of cattle, the strength of our position is our live stock; that the fertility of the soil is not only kept up but rapidly and durably increased by the importation of purchased foods; and that it is better for the farmer to pay a "cake" bill than a manure bill.

OUR BOOK SHELF.

Elementary and Synthetic Geometry of the Point, Line, and Circle in the Plane. By N. F. Dupuis, M.A. (London: Macmillan, 1889.)

THIS is a work which we have read with considerable interest. As the author states, "it is not an edition of Euclid's 'Elements,' in fact it has little relation to that celebrated ancient work except in the subject matter." Its alliances are with such treatises as Casey's "Sequel to Euclid" and McDowell's "Exercises on Euclid and in Modern Geometry," but it appears to us to be better adapted in some respects than either of these works to the use of junior students. These are too condensed for some readers, whereas the book before us, without being too diffuse, enters into greater detail, and leads the pupil up, by a course of sound teaching, so as to enable him to attack with success the subject of modern analytical geometry. Mr. Dupuis looks at a triangle not as "the three-cornered portion of the plane inclosed within its sides, but the combination of the three points and three lines forming what are usually termed its vertices and its sides and sides produced." His object is to lead up to the idea of a figure as a locus, with a view to preparing the way for the study of Cartesian geometry. Here the necessity for a careful distinction between congruence and equality arises. He introduces freely the principle of motion in the transformation of geometric figures, and devotes some space to the principle of continuity. Further, he connects geometry with algebraic forms and symbols, "(1) by an elementary study of the modes of representing geometric ideas in the symbols of algebra, and (2) by determining the consequent geometric interpretation which is to be given to each interpretable algebraic form." The subject of proportion is treated on the method of *measures*, and the term *tensor* is freely used. The first part (pp. 1–90) traverses the point, line, parallels, the triangle and circle. The second part (pp. 91–146) considers the measurement of lengths and areas: each part closes with a section devoted to illustrative matter drawn from constructive geometry. The third part (pp. 147–177) consists of two sections—the first on proportion amongst line-segments, and the second on functions of angles and their applications in geometry. Some instruments are described, as the proportional compasses, the sector, the pantagraph, and the diagonal scale. In the fourth part (pp. 178–251) there are seven sections, which are taken up with such matters as the centre of mean position, inversion and inverse figures, pole and polar, radical axis, and centres and axes of perspective. The closing part (pp. 252–290) introduces the student to harmonic and anharmonic properties, polar reciprocals and reciprocation, and to homography and involution. The author discusses all these points in a lucid style, and illustrates them with full store of carefully selected solutions: in addition there are a great number of unworked exercises in all the subjects. These good results are the outcome of many years' teaching of geometry to the junior classes in the University of Queen's College, Kingston, Canada. The book is closed with a full index, and clearly drawn figures accompany the text.

A Vertebrate Fauna of the Outer Hebrides. By J. A. Harvie-Brown, F.R.S.E., F.Z.S., and T. E. Buckley, B.A., F.Z.S. (Edinburgh: David Douglas, 1889).

THIS is a sister volume to "A Fauna of Sutherland, Caithness, and West Cromarty," which was published by the same authors in 1887, and reviewed in NATURE at that time. It may be remembered that in the preface to this work, the authors expressed their intention of following it up with others, dealing in a similarly exhaustive manner with the vertebrate faunas of other parts of Great Britain. We are glad to receive at so early a date so substantial a fulfilment of this intention; for we cannot give higher praise to "A Fauna of the Outer Hebrides" than by saying that it is in all respects worthy of its predecessor. Moreover, when we have regard to the immense amount of labour which the production of these volumes must have involved, we cannot refrain from congratulating the authors on the rapidity with which their works have followed one another. This second member of the series runs to over 250 pages, and, like the first member, is embellished by a few beautifully executed drawings of landscape scenery. Like the first member, also, it gives an exhaustive account of all the Vertebrata which occur within the area specified, together with several introductory chapters dealing with the topography of the district, and the relation (palæontological and otherwise) of its fauna to that of the rest of Great Britain. As the value of such a work consists mainly in the number and the accuracy of its details, little need be said of it in a review, save in general terms. And, as we have already indicated, the painstaking labour which has been bestowed upon this Fauna appears to us to leave nothing that can be desired in the way either of addition or subtraction. We heartily recommend both these Faunas to all systematic zoologists, and sincerely hope that their authors may be able to continue their researches through other areas of Great Britain.

G. J. R.

Dictionary of Photography. By E. J. Wall. (London: Hazell, Watson, and Viney, Limited, 1889.)

THIS work is practically a complete encyclopædia o photography, and will form a very useful addition to photographic literature. It is written throughout in plain and straightforward language, each heading being thoroughly treated. The subject-matter under the heading of "Lens" is accompanied by excellent illustrations of the various forms of lenses, showing by shaded lines the different combinations of crown and flint glass. Developing, printing, &c., receive their full share in the work, and under "toning" no less than twenty-nine different baths are discussed. At the end there is a collection of miscellaneous tables that have not been inserted in the dictionary part of the book, such as sizes of French and Italian dry plates, a list of dry plates and sensitometer numbers, solubilities, freezing mixtures, &c.

For photographers in general this work ought to prove most useful. It will make it unnecessary for them to refer to other works for a hint or remedy, or anything else that may be wanted at a moment's notice.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Upper Wind Currents over the Equator in the Atlantic Ocean.

IN January last I addressed you a letter from the Straits of Magellan, with an account of the upper wind currents observed over the equator during a voyage to South America in the month of December. Then I described how the north-east and south-east trades both turned into a common light surface easterly current along the line of the doldrums; how low clouds from south-east drove over the north-east trade up to 15° N.; how the highest clouds moved from south-west, north of the equator; and how, from 300 miles south of the line, a very high current from north-west prevailed over the south-east trade. No high observations were obtained in that belt of 300 miles, nor were any middle-level clouds seen over the south-east trade.

Now, I have just crossed the same route in the month of May, under a somewhat different wind system. The north-east trade turned to north as it approached the doldrums, instead of towards the east, as in the previous voyage. In the calm belt, it met a light easterly current, without much conflict in the way of rain; while further south the regular south-east trade was experienced as far as 8° S., when the north-east monsoon of the Brazilian coast prevailed nearly down to Rio Janeiro.

No signs of south-east wind could be discovered at any level over the north-east trade, which wind, on the other side, blew at low or middle levels over the south-east trade, till surface, low, and middle currents combined to form the Brazilian monsoon.

Very few observations were obtained of the highest clouds, but in 6° S. a high north-west prevailed; from 2° S. to the equator, both the middle and highest clouds came from the east; and nothing more could be determined till a high south-west current was found over the north-east trade, in 7° N. latitude.

These results confirm in a most striking manner the discovery which I have announced from time to time in your columns, and which was most conclusively proved by the labours of the

Meteorological Section of the Krakatão Committee of the Royal Society—"that the highest air-current over the equatorial doldrums is from the eastward, lying between the south-west current which flows on one side over the north-east trade, and the north-west current which flows on the other side over the south-east trade." RALPH ABERCROMBY.

21 Chapel Street, London, May 27.

The Structure and Distribution of Coral Reefs.

I HAVE to thank Prof. Bonney for pointing out my error in assigning the "90-fathom reef" to Socotra instead of to Rodriguez. It arose from my having been accustomed to associate Prof. Balfour's researches with the former island.

With regard to the depths in which coral reefs can form, there has been without a doubt some little concurrence of testimony as far as the evidence goes. But I contend that all the observers were misled by supposing that the sand and reef *débris*, that nearly always prevent and repress the growth of corals in depths of 20 to 30 fathoms, necessarily represented the lower limit of reef-formation. We know little of the depths beyond this belt of sand and reef *débris*, inasmuch as the observers in question rarely extended their search beyond. The difficulties in examining these depths are much greater, and systematic soundings are greatly needed, being in fact only practicable in the case of a surveying-vessel.

Since writing my letter I have received, through the courtesy of Captain Wharton, a copy of a report of the examination, in 1888, by Commander Moore and Dr. Bassett-Smith, of H.M.S. *Rambler*, of the slopes and zoological condition of the Tizard and Macclesfield Banks. This report is, I believe, to be further extended by Dr. Bassett-Smith, so I will only quote here the suggestive remark of Commander Moore, respecting the Macclesfield Bank: "Coral was found living as far down the slope as 44 fathoms; it may extend further, but darkness put an end to the work." I should also add that a living specimen of an astræan coral was brought up from a depth of 45 fathoms in the lagoon of Tizard Reef.

Through the agency of the officers of Her Majesty's surveying-ships, Captain Wharton will have soon at his disposal a large amount of new material throwing considerable light on the origin of coral reefs. H. B. GUPPY.

Atmospheric Electricity.

IN NATURE of May 16 (p. 55), Mr. Bowlker describes some "curious" and, as he believes, "rare electrical phenomena" which occurred to him and a friend on the Welsh mountains. Such phenomena are rare only because competent observers are so. The effects described are by no means uncommon, and they may be classed under the brush discharge and the glow, the one being an interrupted, and the other a continuous, discharge to the air.

H. de Saussure gives the results of his observations in America, Switzerland, and other places. He remarks that the lighting-up of the rocks at night is analogous to the curious fact of electricity moving over the prairies. It is compared to a kind of miniature lightning discharge, resulting from the electrified cloud brushing over the earth, and discharging itself in thousands of sparks coursing over the meadows. In Mexico he noticed the crepitation of the stones due to electrical discharges, and in Switzerland he describes certain pricking and burning sensations, and sounds like that of simmering water, emitted from sticks laid against the rocks, and from the tops of the alpenstocks. This humming of the mountains is by no means rare, and it seems to indicate a flow of electricity from the ground into the air.

When Prof. James Forbes was at work on the glaciers of Switzerland, he noticed on one occasion, near Mont Cervin, a curious sound proceeding from his alpenstock. The guide referred it to a worm eating the wood; he reversed the stick, and the worm was already at the other end. He raised his hand above his head, and the fingers yielded a fizzing sound, while the angular stones all round were hissing like points near an electrical machine. There was hail at the time, and a thunderstorm soon set in.

M. Trécul relates in the *Comptes rendus* the following curious case:—While writing at an open window in August 1876, between 7 and 8 a.m., he noticed a number of small luminous columns descend obliquely on his paper, each about 2 metres long, and half a decimetre broad at the widest part, obtuse at the farther end, but gradually thinning towards the table. They had mostly a reddish-yellow tint, but near the paper the tints were more intense and varied. In disappearing they left the paper with a slight noise, like that produced by pouring a little water on a hot plate. Loud thunder was heard at the time of the observation.

In June 1880, at Clarens, near the Lake of Geneva, a cherry-tree was struck by lightning, and a little girl who was about thirty paces from the tree appeared to be wrapped in a sheet of fire, while six persons, in three groups, none of them within 250 paces of the cherry-tree, were enveloped in a luminous cloud. They said they felt as if they were being struck in the face with hailstones or fine gravel, and when they touched each other, sparks passed from their fingers' ends. At the same time a luminous column was seen to descend in the direction of Chatelard, and it is stated that the electricity could be distinctly heard as it ran from point to point of the railing of the cemetery.

Mr. Jabez Brown, while ascending one of the sharp hills near Boscastle, in November, at 9 p.m., was suddenly surrounded by a bright and powerful light, which passed him a little quicker than the ordinary pace of a man's walking, leaving it as dark as before. The light was seen by the sailors in the harbour, coming in from the sea, and passing up the valley in a low cloud. A similar one occurred in Scotland last year.

Highgate, N. C. TOMLINSON.

THE electrical phenomenon described by Mr. Bowlker in NATURE of May 16 was doubtless an instance of St. Elmo's Fire; and if it had been dark at the time it was noticed, the post, walking-stick, and other objects affected by it would have been seen to be capped with a glow resembling somewhat the *brush-discharge* of an electrical machine. It has been observed about fifteen times on the summit of Ben Nevis during the last five years, and these cases are described, and the accompanying weather discussed, in a paper by Mr. Rankin, of the Ben Nevis Observatory, published in the last number of the Journal of the Scottish Meteorological Society. When it occurs, all elevated points, whether metallic or not, glow; the light in the more intense cases being several inches in length. It is almost always accompanied by a heavy fall of conical-shaped snow-flakes about a quarter of an inch long, resembling hailstones in shape, but not hard or icy. At all times when it has been seen the barometric pressure has been high over the south or south-west of Europe, and low to the north of Scotland, thus giving steep gradients for westerly winds; and in most cases the temperature on Ben Nevis has been falling, while the barometer after falling considerably has begun to rise again, and the wind to veer from south-west towards north-west. R. T. OMOND.

Ben Nevis Observatory, May 24.

Sailing Flight of the Albatross.

MY attention has been drawn to some correspondence in NATURE, May 2 and 9, on the "Sailing Flight of the Albatross," in which reference is made to my father's letter to Sir William Thomson on the subject. At Sir William Thomson's suggestion, I am now about to condense the rest of my father's correspondence on the subject into a form convenient for publication. In the meantime I will only say that while Mr. Baines's very interesting letter, and his explanation of the phenomenon of "soaring," appear to me perfectly sound in principle (and indeed we have Lord Rayleigh's authority for this view), my father's statements seem to prove that his own solution is also the true explanation of the soaring under the (different) circumstances in which he observed it. It appears to me only reasonable to suppose that the birds instinctively learn to avail themselves of *all* the different natural conditions which under different circumstances may serve them to maintain their flight with the smallest exertion. R. E. FROUDE.

Gosport, May 25.

The Science and Art Examination in Physics.

THE paper set on May 17, in Sound, Light, and Heat, presents several features that must have created dissatisfaction alike among students and teachers.

First, the official Syllabus explicitly states that the paper "will be so arranged that a candidate can secure a first class in either stage by taking up *two* only of the subjects." This has been so for some years past, and there have always been *five* questions in each subject. As the maximum number of questions a candidate may attempt is eight, this gave a choice in each subject of four questions out of five. But this year, without any previous notice, the number of questions in each subject is reduced to *four*, so that a student who only takes up two of the subjects has absolutely no choice. He may be well prepared, yet if he happen to have overlooked *one* of the points dealt with in the questions, his chance of a first class is seriously diminished.

In making this unlooked-for change, the Department practically takes away with one hand what it gives with the other.

Secondly, in the advanced paper, the second question in Sound runs thus: "If a string 24 inches long weighs half an ounce, and is stretched with a weight of 81 pounds find its rate of vibration when bowed or struck."

Now this is a problem not on *comparative* measurements, which are fairly within the grasp of an advanced student, but on *absolute* measurements. To solve this question requires a knowledge not merely of the principles of sound, but also of theoretical mechanics and of numerous mathematical details, besides considerable dexterity in manipulating units, which is about the most perplexing thing a student ever encounters, and has hitherto never been called for except in the honours stage.

To set such a question as one of *four*, and offer no choice, is in effect to condemn the students at the outset, and must have a most depressing effect upon the classes in future years. At any rate, if the Department intended to introduce absolute measurements into the advanced stage, it is only fair that they should have given notice.

Thirdly, the last question in Heat (advanced) asks the student to "sketch an apparatus for determining the *coefficient of expansion* of a gas at constant *volume*." Perhaps the examiners will kindly inform us how a gas can expand, its volume at the same time remaining constant. Possibly the word "expansion" is a misprint for "increase of elasticity," in which case Balfour Stewart's apparatus should be sketched; or, possibly the word "volume" is a misprint for "pressure," in which case Gay-Lussac's apparatus is required; or, possibly there is an intentional confusion of phraseology in order to perplex the candidates.

Misprints occur in one or more papers nearly every year. Last year there was an error in Mathematics, Stage 3, when a certain equation was printed with the figure 4 instead of 1, thus causing candidates to waste time and become flurried, and here again we have the same kind of thing.

A SCIENCE TEACHER OF SEVEN YEARS' STANDING.

May 21.

DR. NANSEN'S JOURNEY ACROSS GREENLAND.

FROM a communication sent us by Dr. Nansen, we are able to give some details of the remarkable journey across Greenland which he accomplished last summer. We need only briefly recall the most important attempts which had previously been made to cross a country which is exactly in the condition of our own islands during the Glacial period. The first serious attempt was made in 1878 by Jensen and Steenstrup, who, from the west coast in lat. 62° 30′ N., managed to get some 40 miles into the interior, after many difficulties and dangers, ascending a mountain to a height of 5000 feet, from which they saw the inland ice rising gradually towards the interior. Then came the famous expedition of Baron Nordenskiöld in 1883. He, with a comparatively large party, started much further north than the previous expedition, a short distance south of Disco Island. The party succeeded in penetrating some 90 miles eastwards, to an altitude of 5000 feet. The Laplanders, however, who accompanied Nordenskiöld went in their snow-shoes 140 miles further, travelling over a continual snow desert to a height of 7000 feet. The next serious attempt was made by an American, Mr. R. E. Peary, in the summer of 1886. Mr. Peary started much further to the north than Nordenskiöld, and his course was due east. He reached 100 miles from the edge of the ice-blink, or inland ice, his highest elevation being 7525 feet.

Dr. Nansen felt sure that the only way to cross the ice was by means of *ski* (a special kind of long snow-shoe) and sledges. He had many applications to be allowed to accompany him; but he selected only five companions—a lieutenant in the army, a shipmaster, a Norwegian peasant, and two Lapps. The expenses of the expedition were generously supplied by Mr. Augustin Gamel, of Copenhagen. The party left Christiania early in May 1888 for Iceland, whence they embarked on board a sealer for the east coast of Greenland. Dr. Nansen's own account of his attempts to land is of interest as showing the condition of the ice and the currents off the East Greenland coast:—

"On June 4 we left Iceland in the *Jason* for Greenland. My hope was that early in June we should be able to reach the coast in the neighbourhood of Cap Dan, in latitude about 65° 30′ N.; but I was disappointed, as large masses of ice stopped us at a distance of 50 miles from the coast. At last, on July 17, we approached the land at the Termilik Fjord, west of Cap Dan, and I determined to leave the ship. In our two boats we had to force our way about ten miles through the ice. The current was, however, very strong, the ice-floes were thrown and pressed against each other, and during such a pressure of the ice one of our boats was broken. We were then very near to the coast, but the boat could not float, and some hours passed before the leak could be restored. In the meantime, the ice was very much pressed, and we went adrift, the speed with which the current carried us off from the coast being much greater than that with which we could advance on the ice. At the great rate of about 28 miles each twenty-four hours we were driven southwards along the coast. We tried to reach land three times, but by a rapid current we were again carried towards the sea.

"At last, on July 29, we succeeded, and reached land at Anoritok, 61° 30 N. lat. Originally, I had thought to land at Inigsalik, in 65° 30′ N. lat. We had consequently come 240 miles too far southwards. Our destination was Christianshaab, in Disco Bay, to reach which we should be obliged to go in our boats northwards, to cross the continent at a more northerly latitude. To get northwards was not, however, very easy. Masses of Polar ice were pressed towards the land, and very often the axe alone could break a way through the tightly pressed ice-floes."

Two parties of heathen Eskimo were met with, who were at first rather distrustful of the strangers, as they had scarcely ever before seen Europeans.

On August 10 (more than a month behind time) the party reached Umiavik, 64° 30′ N., whence the start was to be made across the inland ice. Dr. Nansen and Captain Sverdrup the next day made an excursion to examine the glacier. They got ten miles from the coast, and reached a height of 3000 feet. On August 15 a start was made, there being five sledges to pull, one loaded with 400 pounds, pulled by Dr. Nansen and Captain Sverdrup. Two days later they were stopped by a heavy gale which kept them in their tents for three days. At first the intense heat compelled them to travel only at night. Dr. Nansen goes on to say:—

"At some distance from the coast the snow became, however, very deep and bad for pulling. We were also met by a heavy gale from the north with snow-drift, so that we could advance only very slowly. I hoped that it would soon become better, but each day it became worse. It was only too clear that if it continued in this way we would not be able to reach Disco Bay till the middle of September, when the last ship left for Europe. Though I expected to find more difficult ice in this direction, I changed our route and turned towards Godthaab. That was on August 27. We had then reached about 64° 50′ N., about 40 miles from the coast, and a height of about 7000 feet. By this change of direction, the wind became so favourable that we could use sails on the sledges, and thus they became less heavy to pull. In this manner we advanced during three days, then the wind went down, and we were obliged to lower our sails.

"In the beginning of September we reached a quite flat and extensive plateau, which resembled a frozen ocean. Its height was between 8000 feet and 9000 feet, though towards the north it seemed to be considerably higher. Over this plateau or highland we travelled more than two weeks. The cold was considerable. I am not, however, able to give an exact statement of the temperature, as our thermometers did not go low enough. I believe that on some nights it was between -45° and -50° C. (between 80° and 90° F. below freezing point) In the tent where we (six men) slept, and where we cooked our tea and chocolate, it was even less than -40° C. (72° F. of frost). During one month we found no water. To get drinking-water we were obliged to melt snow either in our cooking apparatus or by our own warmth in iron bottles, which were carried inside our clothes on our bosoms. The sunshine on these white snow-fields was bad for the eyes, but no case of snow-blindness occurred. Only one day, September 8, we were stopped by a snowstorm; the next day, when we wanted to continue our journey, we found the tent was quite buried in the snow.

"On September 19, we got a favourable sailing wind, and then we advanced very rapidly. That day we got the first sight of the mountains of the west coast. In the night we were stopped by dangerous ice with many crevasses, after having very nearly lost several men and sledges in one of them. We met here with very difficult and uneven ice, where we advanced very slowly. At last on September 24, we reached land at a small lake to the south of Kangersunok, a fjord inside Godthaab. On September 26, we reached the sea at the inner end of the Ameralik fjord, in 64° 12′ N. latitude."

This really finished the journey across Greenland. With considerable difficulty the party reached Godthaab, where, as the last ship was gone, they had to spend the winter, reaching Copenhagen only last week. So far Dr. Nansen has not been able to tell us much more than we knew already about the interior ice of Greenland; though he will probably give us full details in the paper which he is to read at the Royal Geographical Society on June 24.

ON THE TELLURIC ORIGIN OF THE OXYGEN LINES IN THE SOLAR SPECTRUM.[1]

M. EIFFEL having very obligingly put the tower in the Champ-de-Mars at my disposal for any experiments and observations that I cared to make there, I decided to take advantage of the powerful electric light which had been installed, to make certain studies of the telluric spectrum, and, in particular ,that which relates to the origin of the lines of the spectrum of oxygen in the solar spectrum.

We know now that there exist in the solar spectrum many groups of lines that are due to the oxygen contained in our atmosphere; but one may ask himself whether these groups are due exclusively to the action of our atmosphere, and the solar atmosphere between counts for nothing, or whether their origin is double—in a word, Are these groups purely telluric or telluric-solar?

To settle this question, one may have recourse to a certain number of methods. One of the most trustworthy is that of displacement, the origin of which rose from the beautiful conception of M. Fizeau, and which has been applied by M. Thollon and perfected by M. Cornu.

[1] Translation of a paper read by M. J. Janssen before the French Academy of Sciences on May 20, 1889 (*Comptes rendus*, cviii. No. 20).

The application of this was too difficult in the present case.

We may also observe the diminution of intensity which the groups undergo when we ascend in the atmosphere, and by careful comparisons when possible, and especially by a great number of observations, we may judge if the diminution of the intensity of the lines would permit us to conclude that they would completely disappear at the limits of the atmosphere. This is the method employed in the last Mont Blanc expedition (Grands-Mulets). Or, we may again proceed with a comparison of the uniformity of the lines by installing a powerful light giving a continuous spectrum at such a distance that the thickness of atmospheric air traversed may have the same action as that of the terrestrial atmosphere on the rays of the sun, when it is near the zenith.

This last circumstance is very fortunately found realized in the respective situations of the Eiffel Tower and the Meudon Observatory. The tower is at a distance from the Observatory of about 7700 metres, which very nearly represents the thickness of an atmosphere having the same weight as the terrestrial atmosphere and a uniform density, and equal to that of the atmospheric layer traversed by the sun's rays.

In addition to this, the considerable power of the magnificent light actually installed on the summit of the tower permits the employment of the instrument that had served me at Meudon and at Grands-Mulets for the sun. I have, however, made use of a condensing lens in front of the slit in order to give the spectrum an intensity quite comparable to that of the solar spectrum in the same instrument.

Under these conditions the spectrum is shown with extreme vividness, and extends beyond A. The B group appeared to me as intense as with the sun on the meridian in summer. The A group was equally well defined. Other groups could be distinguished, and notably those of water-vapour, their intensity showing the hygrometric state of the column of atmosphere traversed.

I should have liked to study the oxygen groups with the great spectrometer of MM. Brunner and a Rowland's grating, but the limited time during which the light was turned on to me did not permit it. I hope to do so another time.

Not one oxygen band is seen in the visible spectrum, although the thickness of the layer of oxygen traversed was equivalent to a column of more than 260 metres of oxygen at a pressure of six atmospheres—that is to say, at the pressure under which the tube in our laboratory shows them with a length of only 60 metres, or four times as small. This well shows that, for oxygen, the lines follow an entirely different law from the bands.

Indeed, whilst for the lines the experiment of last Sunday shows us that it appears indifferent whether we employ a column of gas at constant density or a column equivalent in weight but with variable density; for the bands, on the contrary, the absorption taking place following the square of the density, the calculation shows that there would be required, at the surface of the sun, a thickness of atmosphere of more than 50 kilometres to produce them.

I do not look upon the experiment of last Sunday as more than bringing forward a fact more to a group of studies—a fact which requires to be exact and developed. But it is certain to myself, that the height at which the tower of the Champ-de-Mars makes it possible to place the light source, and its power, will enable me to make other similar experiments of higher interest.

Before concluding, I wish to thank M. Eiffel for the liberality with which he put his beautiful edifice at the disposal of science. I equally thank MM. Sautter and Lemonnier for their kindness.

THE ZOOLOGICAL SOCIETY'S INSECT HOUSE.

ALTHOUGH it has long been the practice of entomologists to keep private collections of the larvæ of insects, for the purpose of studying their metamorphoses and of obtaining perfect specimens of their fully-developed forms, there is, we believe, still only one place where the attempt is made to attract public attention to this most varied and wonderful group of animals by an exhibition of them and of the different stages of their life-history. This place is the Insect House of the Zoological Society of London in the Regent's Park Gardens, which has now been maintained with considerable success for several years.

At this season of the year the Insect House is generally at its best, and examples of the perfect insect are continually to be seen emerging from the chrysalis.

Leaf-insect of the Seychelles (*Phyllium gelonus*).

A very interesting and novel addition has just been made to the collection in the form of a specimen of one of the Leaf-insects, presented by Lord Walsingham, who received it from the Seychelles Islands through Colonel Larking. Though not yet fully developed, there can be no doubt it will prove to be an example of *Phyllium gelonus*, Gray. The insects of this remarkable genus are all Oriental, inhabiting the tropical regions of Asia, and extending to Mauritius and the Seychelles. It has hitherto proved impossible to induce them to continue their species in this country beyond a single generation, so that it is only occasionally that they can be seen alive here. So long ago as 1854 a living specimen of an Indian species, *P. scythe*, was exhibited in the Botanic Gardens at Edinburgh, where it attracted so much attention that it was found necessary to limit its exhibition to four days in each week. This restriction was (as stated by Murray) adopted because, in spite of the old saying that seeing is believing, it was found in the case of this insect that seeing was disbelieving. On those who inspected it insisting that there was no insect on the plant, but only a leaf, it had to be stirred up to convince them of the truth, and this process of continual provocation was found to be very injurious to the constitution of so peaceable a creature.

The resemblance of many of the species of this group of Orthoptera to portions of the plants on which they are found is so extreme that it has given rise to a firm conviction in the minds of the inhabitants of some of the regions in which they are found that they are portions of the actual plant transformed into living insects. There is certainly more to be said for the belief in this metamorphosis than there is for some of the transformations related by Ovid; and M. de Borre, in the *Comptes rendus* of the Belgian Entomological Society (1883), has explained the reasoning by which it is justified. The people having observed the gradual growth of the creature and the development of the appendages of the body, while they have failed to see it when very small and issuing from the egg, maintain stoutly that a young leaf gradually grows into a living insect. The species of the genus *Phyllium* all have a remarkable resemblance to leaves, but it appears as yet not to be known whether the different species have a special resemblance to the foliage on which they feed.

The late Andrew Murray published an account of the Edinburgh specimen in the *Edinburgh New Philosophical Journal* for 1856, and then said that he "should not be at all surprised if, in the course of a few years, the Leaf-insect should be as common an inmate of our conservatories as the canary-bird now is of our dwellings." This hope has, however, not been realized, and for our opportunities of seeing it in the living state we are obliged still to rely on the kindness of naturalists who may be stationed in the tropical regions where these creatures exist, and who will take the trouble of bringing or sending them or their eggs over to us. The difference between a living and a dead insect is not so extreme as that between a live dog and a dead dog, but still it is very great, and one of our older entomologists used to say that he never really knew the species of an insect till he had seen it alive.

The Insect House in the Zoological Gardens affords, as we have said, the only opportunity that the English public have of seeing alive some of the wonderful forms of tropical insects. But, as we have already remarked, the difficulty of perpetuating the life of these examples of exotic Nature's variety and luxury beyond a short period is excessive, and reaches its maximum in London. There is, perhaps, nothing more remarkable in Nature than the pertinacity and rapidity with which the generations of many of the lower forms of insect life are produced. *Phylloxera*, *Aphis*, scale-insects almost defy the efforts of mankind to control them, and the resources of even scientific civilization contend with them as yet almost in vain. But in many of the more evoluted forms of insects we find a very different condition prevalent. Even mating can, in a large number of cases, be induced only when the creatures are placed in exactly appropriate circumstances, and afterwards the insects will only deposit their eggs in such places and under such conditions as insure at least a probability of congenial existence for their progeny. In the case of many species the females prefer to die with their eggs undeposited, rather than place them in conditions that are at all inappropriate. Thus the difficulty of keeping up a varied supply of curious forms for the Insect House is very great.

The different kinds of silk-producing moths have attracted much attention for a considerable number of years past, and in the case of several species fertile eggs are readily procured. These insects, being in many cases very large and attractive creatures, excite a good deal of interest in the visitors to the Insect House. Just at present these moths are about commencing their individual life-cycles afresh; eggs of several species have been procured, and will shortly be hatched. The caterpillars are even more interesting than the moths themselves, and their remarkable shapes and forms, and their wonderful spines and thorns, are of much interest to naturalists. Just now, too, there may be seen in the Insect House a delightful example of the early stages of insect-life in the form of the caterpillar and chrysalis of *Limenitis disippus*. This is a North American butterfly, the egg of which is hatched towards the end of summer or in autumn. Its young larva constructs for itself a delicate habitation by joining together the edges of the leaves of the willow on which it feeds, so as to form a cylindrical tube, which it lines with silk and closes at one end. The fragile creature is thus able to outlive the storms of wintry wind and weather, and to evade the ravagers of the animal world in search of food. In the protection of this dwelling it can be transmitted from North America to this country without injury to its vitality. As seen in the Insect House, the caterpillar is a curiously mottled, pale-brown, greenish and grey creature, with head bent down, but bearing on the prominent part just behind it two rather long, erect, slender horns of a deep black colour, each of them numerously spined. The chrysalis is even more remarkable, and hanging down from a twig displays itself in a very prominent manner. On the middle of its body there is an abrupt, elongate, black hump, about as conspicuous a deformity as could be devised, while at the base of this, on each side, there is a band of delicate and beautiful metallic colour. This band is in some way dependent for its tint on the living creature within, for no trace of it can be seen in the pupa-shell after the insect has escaped. This species of butterfly belongs to the family *Nymphalidæ*. The extraordinary spines of the caterpillars of this group have recently been studied, and many of them delineated, in an elaborate and interesting memoir by W. Müller, which will be found in the first volume of the *Zoologische Jahrbücher*.

The Diurnal Lepidoptera are not so well represented in the Insect House as they usually are at this time of year, there having been a great scarcity of pupæ last summer. But, besides the *Limenitis* above referred to, examples of one of the Swallow-tails (*Papilio machaon*), and of one of the large North American Skippers (*Gonioloba tityrus*), are now daily emerging from their pupa stage, and fresh additions are shortly expected.

NOTES.

WE are glad to learn, from the list of birthday honours, that the Companionship of the Bath has been conferred on Dr. James Bell, F.R.S., and the Companionship of St. Michael and St. George on Mr. Ellery. A baronetcy has been granted to Prof. Stokes; but, seeing that Prof. Stokes has been for many years President of the Royal Society, and that the Government never thought of offering him any special honour until he entered the House of Commons, we may conclude that he receives his baronetcy not as an illustrious investigator, but as a politician.

ON Saturday, Sir Frederick Bramwell, as President of the British Association, entertained the President-Elect, Prof. W. H. Flower, C.B., F.R.S., a large number of members of the Association, representatives of science, and other guests being invited to meet him. The dinner was given in the hall of the Goldsmiths' Company, the use of which was granted to him for the purpose by the Wardens of the Company. The list of guests included Lord Bramwell, F.R.S., Mr. Justice Denman and Mr. Justice Manisty, Mr. C. Lucas, Prime Warden of the Goldsmiths' Company, the Mayors of Newcastle and Gateshead, Sir F. A. Abel, C.B., F.R.S., Captain Abney, R.E., C.B., F.R.S., Prof. Roberts-Austen, F.R.S., Prof. Ayrton, F.R.S., the Ven. the Archdeacon of Bath, Sir I. Lowthian Bell, F.R.S., the Rev. Prof. Bonney, F.R.S., Sir J. Crichton Browne, F.R.S., Mr. Brudenell Carter, Mr. C. Cochrane (President of the Institution of Mechanical Engineers), Sir John Coode, K.C.M.G., Mr. W. Crookes, F.R.S., Prof. Boyd Dawkins, F.R.S., Prof. Dewar, F.R.S., Sir James Douglass, F.R.S., Mr. W. T. Thiselton-Dyer, C.M.G., F.R.S., Dr. John Evans, F.R.S., Mr. Francis Galton, F.R.S., Dr. Gamgee, F.R.S., Dr. Geikie, F.R.S., Mr. R. Giffen, Mr. Alfred Giles, M.P., Dr. Gladstone, F.R.S., Mr. G. B. Gregory, Mr. Thomas Hawksley, F.R.S., Prof. Henrici, F.R.S., Mr. Victor Horsley, F.R.S., Major-General Hutchinson, R.E., Prof. Judd, F.R.S., Colonel Laurie, C.B., M.P., Prof. Liveing, F.R.S., Mr. J. Norman Lockyer, F.R.S., Prof. McLeod, F.R.S., Major Marindin, R.E., Mr. Ludwig Mond (President of the Society of Chemical Industry), Mr. J. Fletcher Moulton, Q.C., F.R.S., Admiral Nicholson, C.B., Admiral Sir E. Ommanney, C.B., F.R.S., Sir P. Cunliffe-Owen, K.C.B., K.C.M.G., Dr. William Pole, F.R.S., Mr. W. H. Preece, F.R.S., Colonel Rich, R.E., Prof. Romanes, F.R.S., Sir H. E. Roscoe, M.P., F.R.S., Prof. Rücker, F.R.S., Dr. Russell, F.R.S. (President of the Chemical Society), Prof. J. S. Burdon Sanderson, F.R.S., Prof. Schäfer, F.R.S., Dr. P. L. Sclater, F.R.S., Sir William Thomson, F.R.S., Sir William Turner, F.R.S., Major Tulloch, R.E., Sir C. W. Wilson, R.E., K.C.B., K.C.M.G., Sir Francis de Winton, K.C.M.G., Mr. E. R. Wodehouse, M.P., and many others. In England, which in this respect differs widely from the other leading countries of Europe, men of science, including even those in State employ, are not invited to take part in such State functions on the birthday dinner. It was a happy thought on Sir Frederick Bramwell's part, therefore, to select the Queen's birthday as the day on which his dinner was to be given. Many of the most eminent men of science in the country had thus an opportunity of associating themselves with the expression of the general feeling of the community on an interesting public occasion. By this time it should surely be manifest to everyone that, on all such occasions, science should be prominently represented. The State has nothing to lose, but, on the contrary, has much to gain, by the full recognition of science as one of the most vital elements of national progress.

THE gold medal of the Linnean Society has been awarded this year to Prof. de Candolle, the eminent botanist, in recognition of his distinguished services to botanical science.

IN his Presidential address, delivered at the anniversary meeting of the Linnean Society on the 24th inst., Mr. Carruthers gave an interesting and detailed account of the existing portraits of Linnæus, many of which are in the Society's possession. The result of his inquiries showed that there are seven original and authentic portraits of Linnæus in existence; that the engravings most widely known are from the originals by Inlander and Roslin; and that these give the most faithful representation of the features of the great naturalist.

A NEW departure, likely to be productive of far-reaching results, has recently been taken in connection with the scientific work of the Scotch Fishery Board. Since 1809 the Scotch fisheries have been under special supervision, and at one time the Scotch fishery statistics were in advance of those of any other country. Previous to 1882 occasional scientific inquiries were made by Sir Lyon Playfair and Prof. Allman, and since 1882 investigations have been systematically carried on under the direction of Prof. Ewart and Sir James Maitland. Year by year the scientific work has been extended, and for some time a scientific department has existed in everything but in name.

This department, which seems to enjoy the confidence of the Scotch Office, and all the assistance the importance of the fisheries demands, has now been fully recognized and strengthened by the formation of a Committee of advice and reference, which includes representatives from all the Scotch Universities, and, in addition, an eminent statistician and the distinguished Director of the Edinburgh Science and Art Museum. The Committee, which is expected to advise as to technical and statistical as well as biological and physical questions, consists of Profs. Bayley Balfour, Crum Brown, Dittmar, D'Arcy Thompson, McIntosh, McKendrick, McWilliam, Traill, and Young; Sir R. Murdoch Smith, and Mr. G. A. Jameson. Those responsible for the formation of this Committee are to be congratulated, not only for the bold and enlightened policy displayed, but also for enlisting the active interest of so many distinguished men in the Scottish fisheries. The willingness of the members of this Committee to co-operate with the present directors of the scientific work is the best guarantee that their past labours have been appreciated, the best reward for surmounting the many difficulties that have necessarily been met with in initiating and carrying on fishery investigations.

MR. RICHARD BULLEN NEWTON, of the Geological Department, British Museum, has been presented to an Assistantship of the first class.

MR. MELLUISH succeeds the late Mr. Johnston as Electrician to the Government of India.

MR. HALY, Curator of the Colombo Museum, has published a "first report" on the collection of moths in the Museum. It is compiled from Messrs. Coles and Swinhoe's catalogue of the moths of India and Ceylon, and Mr. Haly has added all that is at present known concerning their local distribution and the times of the year at which the species appear.

THE Johns Hopkins Hospital, Baltimore, was opened on May 7. An address was delivered on the occasion by Dr. Daniel C. Gilman, who spoke eloquently of the close relationship between the advancement of knowledge and the progress of charity.

MESSRS. TRÜBNER have issued the first number of what ought to be a useful monthly periodical—*The Periodical Press Index*. The aim of the editor is to present a record of the more important subjects dealt with in periodical literature at home and abroad. As it would become irksome in course of time to consult a monthly index, arrangements are being made for the publication of an additional yearly volume on a plan which will render it unnecessary for students to refer to each part month by month.

PROF. H. G. SEELEY, F.R.S., will conduct the London Geological Field Class to sections on the North Downs, showing Gault and Lower Greensand, on Saturdays in June and on Whit Monday. Communications should be addressed to the Hon. Sec., Mr. R. H. Bentley, 31 Adolphus Road, Brownswood Park, South Hornsey.

A NEW substance, singular alike in its chemical nature and in its properties, has been discovered by M. Péchard. It is a mixed acid derived from oxalic and molybdic acids, and is therefore termed oxalomolybdic acid. It is a solid, crystallizing in large monoclinic prisms, and forms a well-defined series of salts. Berzelius long ago found that molybdenum trioxide readily dissolved in a hot solution of oxalic acid, but appears never to have investigated the nature of the reaction. When the molybdic acid has been added almost to saturation the liquid becomes syrupy, and on evaporation yields crystals of the new oxalomolybdic acid, which on analysis give numbers corresponding to the formula $C_2H_2O_4 . MoO_3 . H_2O$. The finest crystals are obtained by dissolving the viscous mass, formed on evaporating the saturated solution of the acid, in dilute nitric acid, and allowing it to evaporate in a desiccator. Oxalomolybdic acid is almost totally insoluble in strong nitric acid, and if an excess of nitric acid be added to a saturated solution of the new acid, small crystals at once separate; but if dilute nitric acid be employed, the crystals form more slowly, and are consequently much larger and more perfect. The crystals dissolve in cold water, more rapidly on warming, yielding a colourless and strongly acid liquid. That it is a true mixed acid is shown by the fact that it forms crystalline salts with metals. If a solution of silver nitrate is added to a warm solution of the acid in water, a yellow crystalline precipitate of the silver salt, $C_2Ag_2O_4 . MoO_3$, is thrown down. This salt is insoluble in water, but, like many other silver salts, is readily dissolved by ammonia. Barium chloride or baryta water precipitate in a similar manner the barium salt $C_2BaO_4 . MoO_3$, in the form of small colourless crystals. The sodium salt, $C_2Na_2O_4 . MoO_3 . 5H_2O$, is readily obtained in good crystals by neutralizing the acid with soda. The crystals of oxalomolybdic acid, when dry, may be preserved unchanged either in sunshine or in the dark. But, if moist, they quickly become coloured blue when exposed to the sun's rays. If characters be written on paper with the solution, they remain invisible in a weak light; but, when exposed to sunshine, they rapidly become visible, turning to a deep indigo colour. It is curious that this effect only happens when the solution is spread over paper or other surfaces, for the solution itself may be kept unaltered in the bottle for any length of time, except for a trace of blue at the edge of the meniscus, where, by surface action, a little is spread against the interior glass walls. If a sheet of paper be immersed in a saturated solution of the acid, dried in the dark, and then exposed behind an ordinary photographic negative, a very sharp print in blue may be obtained by exposure to sunlight for about ten minutes. The colour instantly disappears in contact with water, so that if a piece of this sensitized paper be wholly exposed to sunlight, one may write in white upon the blue ground by using a pen dipped in water. If, however, the paper with its blue markings be exposed to a gentle heat for a few minutes, the blue changes to black, and the characters are then no longer destroyed by water.

THE Pilot Chart of the North Atlantic Ocean for the month of May shows that the month of April commenced with generally high barometer and moderate weather over the greater part of the trans-Atlantic routes, followed by easterly gales on the 3rd, and continuing in the eastern regions until the 11th. On the 7th and 15th, areas of high barometer left the American coast, and slowly traversed the ocean, reaching Europe on the 15th and 26th respectively. Several storms visited the American coast, one off Hatteras on the 7th and 8th being of marked severity, causing the water to rise a foot higher than ever known before at Norfolk, and doing great damage both on shore and at sea. There was a great increase of fog, especially off the coast of the United States. A large iceberg was seen on the 9th, in lat. 48° N., and long. 44° 40′ W.

A LIMITED number of copies of the first part of the "Bibliography of Meteorology," which has been for many years in course of preparation by the Washington Signal Office, has been issued in a lithographic form by General Greely. It contains 382 quarto pages, and includes all the titles of books and articles bearing upon the subject of temperature from the origin of printing to the close of 1881. Similar titles covering the period from 1882 to 1887 have also been prepared, but are not included in the present volume. The classification of the titles is based upon a scheme furnished by Dr. A. Lancaster, of Brussels, and is arranged under nineteen subdivisions, the arrangement of each subdivision being chronological under the authors' names, and, at the end, a list of authors' names is given, with references to the pages on which their works are found. We think that, considering the large amount of materials to be dealt with, this is the best arrangement that could be made, although, whenever a minor classification is attempted, it invariably leads to difficulties of arrangement, and to corresponding difficulties in turning up any particular work. We should like to have seen some reference to the libraries in which the older works are to be found, as has been done for all titles given in the Brussels catalogue. The work is one of the greatest importance to all meteorologists, and we can only hope that the favourable reception it is sure to meet with in all countries will induce Congress to order its regular publication, and that of the volumes relating to all other meteorological subjects, the materials for which are already prepared. It was on this distinct understanding that Mr. G. J. Symons handed over his 20,000 titles to General Hazen, some years ago.

AT a recent meeting of the New York Academy of Sciences, General Andrews, commenting on a paper about the proposed Tehuantepec ship railway, made some interesting remarks on the general subject of ship railways. Estimates which he regards as incontrovertible show that a ship can be hauled by a locomotive over a ship-railway, or, as he prefers to designate it, a ship-tramway, with the expenditure of only one-half the amount of coal which the same ship must burn to propel herself through the water of a canal. The most frequent objection urged against the practicability of the scheme is that it would rack the ship; but General Andrews explained that the weight is so distributed among the numerous supports that no one need sustain a greater weight than a man presses upon his foot in walking. The gradients of the route will be very slight, not exceeding 2 inches in 400 feet, the entire length of a vessel. He had made observations, during a voyage aboard the steamer *Britannic*, to measure the amount of strain to which she was exposed in a sea of no very great roughness, and found by stretching cords that the steamer was bent sixteen inches by the waves, but without the slightest injury: hence he infers that the stress on a vessel in crossing the isthmus would be inappreciable and harmless.

MR. ALEXANDER DURLACHER has presented to the Royal Colonial Institute an interesting collection of native weapons and implements from Western Australia.

A RESOLUTION has been issued by the Government of India, dealing with the preservation of antiquarian treasures, with the view of making known the conditions under which the Government can claim articles of archæological interest, and to provide for their better preservation for the public by holding out the prospect of sufficient reward to finders of treasures. The resolution lays especial stress on the importance of paying proper consideration to the claims and expectations of these latter, as the end in view will be defeated if those who discover objects of antiquarian value are not induced by the hope of sufficient reward to make their discoveries known to the public authorities.

CAPTAIN A. P. MADSEN lately communicated to the Northern Antiquarian Society of Copenhagen an account of his examination of the celebrated great "kitchen-midden" at Meilgaard, in Jutland, which has only once before (in 1869) been slightly examined. It is now situated several miles inland, but the configuration of the country showed that at the time of its formation a bay existed there. The midden was at one time some 12 feet in depth, but is now only 6. Oyster-shells predominated, then came the common blue mussel and winkles. There were also shells of three kinds of other mussels, of which two are extinct, but the third species is still found in the Limfjord. There were three places with remnants of charcoal and ashes. The bones found were those of water rats, ring seals, grey seals, dogs, pigs, foxes, martens, otters, boars, roe-deer, stags, bullocks; common swans, wild ducks, the great loon, sea-gulls, ring-doves, and crows; and of fishes, those of salmon, jack, eel, cod, and flounder. Of implements from the Stone Age were flint chisels, hooks of bone, a flint wedge, arrow-heads, drills, &c. The quantity of the remains indicated that a considerable population had lived in the vicinity, who no doubt brought the spoils of the chase thither. The land was now 20 feet above sea-level, but there was every appearance of the site having once been on a promontory by the sea. Many of the middens in Jutland were now situated from five to six miles inland, but had undoubtedly once lain by the sea. In one midden, Captain Madsen had found split marrow-bones, ornamented pottery, and polished implements, together with bones of sheep and goats, but no marine shells, indicating that there were also middens from a more recent period. Commenting upon these explorations, Prof. Japetus Steenstrup maintained that Captain Madsen's account of the rising of the land was exaggerated.

THE last number of the *Rendiconti della R. Accademia dei Lincei* contains a reference to an Italian precursor of Franklin, the Venetian physician Eusebio Sguario, reputed author of a work on "Electricity, or the Electrical Forces of Bodies," published in 1746. In this work occurs the following passage:—"Still it seems impossible for the violence of a subtle effluvium to acquire such intensity, however increased we may suppose it to be, unless by this means we should succeed in discovering the tremendous velocity of that subtle igneous matter which constitutes lightning. And who will ever venture boldly to deny that lightning is nothing else than a subtle electrical substance impelled to the last degree of its violence? It would certainly be a fatal surprise for that experimenter, who, finding in this way a means of producing artificial lightning, might fall a victim to his curiosity." This was written two years before the appearance of the work on physics by Nollet (Paris, 1748), who has hitherto been supposed to be the first writer who has expressed in clear language the close relation existing between the phenomena of electricity and lightning.

THE British Secretary of Legation in Rio de Janeiro, in a recent report states that for many years, though with varied intensity, a destructive disease has existed in the best zone of territory for coffee in the province of Rio de Janeiro. It has never been so bad as the coffee-leaf disease in Ceylon and Java, but still has done much harm. A scientific Government *employé*, Dr. E. Gölde, in correspondence with Dr. Soltmedel, of Java, has now almost proved that the Brazilian root-disease and the Ceylon leaf-disease have the same origin—namely, a small worm in the root, belonging to the group of Nematoids, similar to the worm in beetroots in Europe.

THE Hydrographical Department of Russia has devoted, since 1837, a good deal of attention to the secular rising of the coasts of the Baltic Sea, and a number of marks have been made on the rocky coasts of the Gulfs of Bothnia and Finland in order to obtain trustworthy data as to the rate of the upheaval of the coasts. Since 1869, observations have been carried on in a systematic way for measuring the changes in the level of the Baltic at several of the above-mentioned marks, and the results of the observations are now summed up by Colonel Mikhailoff in the *Izvestia* of the Russian Geographical Society (vol. xxiv. 3). Taking only those stations at which the secular change could be determined for a number of years varying from thirty-one to thirty-nine years (1839-78), the rise of the coast in a century would appear to be as follows: Aspö, 20·3 inches; Lehtö, 11·5 inches; Island of Kotkö, 26·7; Sveaborg, 22·8 and 25·1; Hangöudd, 33·7; Island of Skotland, 12·5; Island of Jussari, 31·6; Tverminö, 36·2; Island of Gloskär at Redhamn, 12·2. It thus appears that the figure of about three feet in a century, which was deduced from former observations, cannot be very far from the truth. As to local anomalies, they remain still unexplained.

The additions to the Zoological Society's Gardens during the past week include two Yellow-fronted Tanagers (*Euphonia flavifrons*) from Dominica, presented by Mrs. Herbert; two Manx Shearwaters (*Puffinus anglorum*) from the Scilly Islands, presented by Mr. F. Hensman; an Ocelot (*Felis pardalis*) from South America, deposited; four Black-tailed Godwits (*Limosa ægocephala*), European, purchased; two Indian Muntjacs (*Cervulus muntjac* ♂ ♀) from India, received in exchange; a Persian Gazelle (*Gazella subgutterosa* ♀), two Bennett's Wallabys (*Halmaturus bennetti* ♀ ♀), a Hog Deer (*Cervus porcinus* ♂), a Collared Fruit Bat (*Cynonycteris collaris*), two Grey Wagtails (*Motacilla melanope*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

Comet 1888 *e* (Barnard, September 2).—The following ephemeris for Berlin midnight for this object is in continuation of that given in Nature, vol. xxxix. p. 616:—

1889.	R.A. h. m. s.	Decl. ° ′	Log *r*.	Log Δ.	Brightness.
June 1	22 54 22	2 39·9 N.	0·3730	0·3441	2·1
5	22 47 38	2 40·5	0·3786	0·3317	2·1
9	22 40 4	2 38·1	0·3842	0·3193	2·2
13	22 31 38	2 32·5	0·3898	0·3070	2·3
17	22 22 16	2 23·6	0·3954	0·2952	2·4
21	22 11 57	2 10·7 N.	0·4010	0·2839	2·4

The brightness at discovery is taken as unity.

The Motion of Stars in the Line of Sight.—Prof. H. C. Vogel, noting the difficulty which has been experienced at the Greenwich and Rugby Observatories in making eye-observations of the displacement of the lines in stellar spectra due to the approach or recession of the stars, has endeavoured to solve the problem by means of photography, and has met with very considerable success. The atmospheric tremors, which are so baffling and often misleading to direct eye-observation, counteract each other and produce little or no effect on the photograph; and the feebleness of the light of a star when spread out into a long spectrum is overcome by a lengthened exposure. Prof. Vogel gives the following results (in German miles per second) for five stars, of which four have been observed at Greenwich:—

Star.	Vogel.	Greenwich.
Capella	+3·5	+4·8
Aldebaran	+6·5	+6·8
Polaris	−3·5	not observed
α Persei	−1·5	−4·8
Procyon	−1·5	−0·8

The Greenwich observations for 1888, nearly contemporaneous therefore with the Potsdam observations, give the motion of Procyon as −0·8. The agreement of the individual photographs is very gratifying, and is much closer than that of the eye-measures made on different nights.

The Latitude of Detroit.—A determination of the latitude of the Detroit Observatory has recently been made by Dr. Ludovic Estes.[1] The zenith telescope was employed, and the results were discussed by the method of least squares. The value arrived at after all corrections is 42° 16′ 48″·66 ± 0″·051. An interesting point in connection with the observations is that smaller values were obtained from low stars, which seems "to indicate that northern stars are refracted less than southern, for the same zenith distance; and that, therefore, the layers of the atmosphere, instead of being parallel to the surface of the earth, are depressed more rapidly toward the north" (p. 54).

The Minor Planet Victoria.—A programme has been prepared by Dr. Gill, of the Royal Observatory, Cape of Good Hope, for observations of the minor planet Victoria at its opposition in 1889; the opposition in right ascension occurring on July 16, and the primary object of these observations being to determine the parallax of the sun from heliometric measures. A list of comparison stars is given, and is so arranged that when the planet is situated at the greatest zenith distance where good observations may be made, one comparison star may be below and another above it, the measurement by the heliometer of the difference of two nearly equal and opposite distances giving the most accurate result obtainable.

[1] Ann Arbor, Mich.: The Register Printing and Publishing Company, 1888.

Victoria has a zenith distance of 62° at an hour-angle of 4h. for the Cape, 2h. for European Observatories, and 3h. for Newhaven. A list is given of the limits of hour-angle during which observations of the planet may be made from June 10 to August 29.

The corrected ephemeris of the planet has been computed, and it is hoped that co-operating meridian Observatories will determine the places of the thirty-seven comparison stars with the meridian circle, and at the same time procure as many meridian observations of the planet as possible. Provided that means exist for determining the distortion of the photographic film, and the optical distortion of the field, photographs taken in both hemispheres showing the planet lengthened out so as to form a straight line, whilst neighbouring stars are well defined, are available for the determination of parallax. Dates are also given when photographic observations of Victoria may be advantageously combined with heliometer observations.

Meridian Observations of Iris.—A similar programme to the above was issued by Dr. Gill, in September 1888, for observations of the minor planet Iris; and Mr. Arthur A. Rambaut, assistant astronomer at Dunsink Observatory, has made observations, with the meridian circle, of the places of the planet and the twenty-eight comparison stars given. The measures will be found in *Monthly Notices R.A.S.*, March 1889, and extend from September 7, 1888, to January 10, 1889. Between these dates twenty-six observations of Iris were made, and its apparent right ascension and declination found. During the progress of the work two comparison stars were added to Dr. Gill's list.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1889 *JUNE* 2–8.

(For the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on June 2

Sun rises, 3h. 50m.; souths, 11h. 57m. 45·8s.; daily increase of southing, 9·6s.; sets, 20h. 6m.: right asc. on meridian, 4h. 42·3m.; decl. 22° 15′ N. Sidereal Time at Sunset, 12h. 52m.

Moon (at First Quarter on June 6, 20h.) rises, 6h. 42m.; souths, 15h. 2m.; sets, 23h. 17m.: right asc. on meridian, 7h. 46·8m.; decl. 22° 19′ N.

GEOGRAPHICAL NOTES.

AT the anniversary meeting of the Royal Geographical Society on Monday, the medals and other honours already announced in NATURE were awarded. Dr. Radde, of Tiflis, appeared in person to receive his medal, which he acknowledged briefly and appreciatively. The address of the President, General Strachey, was of more than usual interest. After referring to the geographical events of the year, he took up the subject of Central Africa, its future exploration, and its subjection to the commercial and civilizing influence of Europe. General Strachey reviewed the results of European contact with the various other parts of the world, savage and semi-civilized. "There is no room to doubt," he said, "that the occupation of the earth by man in the many various modes presented to us has been determined mainly by the physical conditions of the surface, the distribution of land and sea, and the nature of the climate, operating in conjunction with the particular inherited capacities of the several branches of the human race, which have themselves been largely determined by these same physical conditions. The diffusion of races, and their more or less permanent occupation of various parts of the earth, have necessarily been regulated by their relative powers of adapting themselves to, and taking advantage of, the facilities for existence offered by the regions they occupied, and of resisting adverse pressure of all sorts brought to bear upon them from without. Among the best safeguards against that form of pressure which consists of the intrusion of other races, have ever been isolation by the ocean, or by high mountains, great land distances, forests and deserts; and hence it has been that the interiors of the great continents have for the most part been last explored, and their inhabitants least disturbed. As the first of these defences was weakened by the development of the art of navigation, the progressive races of Europe began to seek for fresh scope for their activities in many distant regions, thus for the first time rendered accessible to them. From very small beginnings within the Mediterranean, which for several centuries gained strength only by slow degrees, at length burst forth some 400 years ago the stream of conquest and commercial adventure which has in our time been carried across every part of the ocean; and has beaten on all its shores, throwing open an infinitude of lines of attack for the inroads of European progress upon regions previously resting in various conditions of relatively primitive stagnation." General Strachey then, in a highly suggestive manner, reviewed the methods and results of European conquest or European civilization in North, Central, and South America, Australasia, India, China, North Africa and South Africa, and, coming finally to Central Africa, he pointed out that the conditions there were peculiar and required peculiar treatment. "The vast area of tropical Africa," he said, "its climate, often so hostile to Europeans, and the numbers and character of the population, combined with the peculiar difficulties attending all transport in the interior, have retarded the progress of geographical discovery, and obstructed that intercommunication between neighbouring districts which supplies the natural machinery by which the progress of the less advanced races is carried forward. It is impossible to suppose that the impression to be made on these countries by the mere handful of men of northern race who are now scattered along its coasts or at a few points in its interior, can be anything but extremely slow, and it is hardly less certain that under the wholly different conditions that Central Africa presents from those of any other country hitherto brought within the operation of the process of civilization, the form which that process will take, and its results, will be very different from anything that past experience can suggest. The possibility of any colonization by direct immigration on such a scale as to produce effects in any way analogous to those obtained in North America or Australia is obviously excluded; the condition of the people over the greater part of the continent renders it equally impossible to look forward to a time when systems of administration at all approaching that of India could be established; and amalgamation between European settlers and the indigenous races appears no less out of the question. The operation of bringing a population such as that of Central Africa under the restraints of civilization will necessarily be a long and no doubt in some respects a painful one, for assuredly the conflict with slavery, cannibalism, and massacre cannot be carried to a successful issue by gentle means alone. The dangers that attend precipitation, with consequent reaction, have been already exemplified too plainly, and by the sacrifice of too many noble lives; and in circumstances such as those that here have to be dealt with, toleration of unavoidable evil at the outset may well afford the best and most certain means of introducing permanent improvement. Nor can I see any reason to question the conclusion that the best method of entering on this gigantic task is that which the general sense of Europe has practically resolved to adopt—namely, to form commercial associations intrusted with the exercise of reasonable administrative authority within the several areas assigned to them, hoping that thus the African population may by degrees be taught that the path to social and material comfort and well-being lies through well ordered industry and peaceful occupations; in imparting which lessons the earnest co-operation of the many purely philanthropic missions already established among these people may be most confidently counted on."

BEACON LIGHTS AND FOG SIGNALS.[1]

II.

IN 1876, Mr. Julius Pintsch, of Berlin, patented in this country his system of illuminating buoys or other floating bodies by compressed oil gas, and in 1878 one of these buoys was experimentally tried at sea with success by the Trinity House. The system is similar to that previously adopted by Mr. Pintsch with great success in the lighting of railway carriages, but with the addition for buoys of a specially constructed lantern, containing a small cylindrical lens for fixed light. Through the kindness of the Pintsch's Lighting Company, we have here one of these apparatus, producing an intensity in the beam of about twenty candle units. With the charge of gas contained in the buoy, the light is shown continuously, night and day, from two to four months, according to the dimensions of the buoy, without refilling or requiring any other attention except occasional cleaning of the lens and the glazing of the lantern. In 1883, Mr. William B. Rickman patented a very ingenious addition to this apparatus for producing occulting or flashing light. The apparatus is automatically worked by the issuing compressed gas on its way from the buoy to the burner. After passing the regulator where the pressure of the gas is reduced for burning, it enters a cylindrical chamber covered with a diaphragm of very flexible specially prepared leather, this diaphragm, on being slightly raised by the in-flowing gas, communicates motion to a lever, which, assisted by a spiral spring, closes the inlet pipe, and opens at the same time the passage to the burner. As the gas passes on and is consumed at the burner, the diaphragm by its own weight, assisted by the spring, sinks, and touching the lever, closes the outlet aperture to the burner, and at the same moment opens the inlet of the gas from the buoy for another charge. Thus the light is extinguished while the gas is entering the chamber, and until the latter is refilled, when the passage from the buoy is again closed by the rising of the diaphragm. A small pilot jet is constantly burning to insure the re-ignition of the gas when re-admitted to the burner. It is evident that several characteristic distinctions of light may be obtained by modifications of this ingenious apparatus. About 150 buoys lighted on the Pintsch system are already rendering valuable

[1] Friday evening discourse delivered at the Royal Institution by Sir James N. Douglass, F.R.S., on March 15. Continued from p. 91.

service to mariners in various parts of the world. For the more important stations at sea where light-vessels are now employed the system is considered to be yet wanting in that trustworthiness which should be the leading characteristic of all coast lighting. Very important experiments have lately been made by the Lighthouse Board of the United States, at their General Depot at Tompkinsville, New York, with buoys lighted electrically by glow lamps, operated through submarine conductors from the shore. These experiments have proved so successful that an installation for marking the Gedney's Channel entrance of Lower Bay, New York Harbour, with six buoys and 100-candle glow lamps, was lighted on November 7 last. Gas buoys were considered inapplicable for this special case, owing to their form and size rendering them liable to break adrift, particularly when struck by floating ice or passing vessels. The buoy adopted for the service consists of a spar 46 feet long, having its lower end shackled direct to a heavy iron sinker, resting on the bottom. At the upper end the buoy is fitted with an iron cage inclosing a heavy glass jar, in which is placed the glow lamp of 100 candle units intensity. The cable is secured by wire staples in a deep groove cut in the buoy and covered by a strip of wood. For a distance of several feet at the lower end of the buoy the cable is closely served with iron wire, over which is wound spun yarn to prevent injury from chafing on the shackle and sinker. The central station on shore, with steam-engines and dynamos in duplicate, is on Sandy Hook, at a distance from the extreme buoys of about 3 nautical miles. The installation is reported to be working continuously and successfully. For auxiliary or port lights on shore where no collisions can occur, the Pintsch gas system is found to be very perfect. At Broadness, on the Thames, near Gravesend, the Trinity House erected in 1885, an automatic lighthouse illuminated on Pintsch's system, as shown by the diagram. This small lighthouse shows a single flashing light at periods of ten seconds, the flashes having an intensity of 500 candle units. The flashes and eclipses are produced with perfect regularity by special clockwork, which also turns on the gas supply to the burner at sunset and off again at sunrise. It is also arranged for periodic adjustment for the lengthening and shortening of the nights throughout the year. This automatic light is in the charge of a boatman, who visits it once a week, when he cleans and adjusts the apparatus, and cleans the glazing of the lantern. An automatic lighthouse similar to that at Broadness has been lately installed at Sunderland by the River Wear Commissioners, on a pier which is inaccessible during stormy weather. In 1881–82 several beacons automatically lighted by petroleum spirit, on the system of Herr Lindberg and Herr Lyth, of Stockholm, were established by the Swedish lighthouse authorities, and are reported to be working efficiently. In 1885 a beacon or automatic lighthouse on this system was installed by the Trinity House on the Thames, near Gravesend, and has been found to work efficiently. The light is occulting at periods of about two seconds; the occultations are produced by an opaque screen, rotated around the light by the ascending currents of heated air from the lamp acting on a horizontal fan. As there is no governor to the apparatus, the periods of the occultations are subject to slight errors compared with those of the gas light controlled by clockwork. In 1844 an iron beacon lighted by a glow lamp and the current from a secondary battery was erected on a tidal rock near Cadiz. Contact is made and broken by a small clock, which runs for twenty-eight days, and causes the light to flash for five seconds at periods of half a minute. The clock is also arranged for eclipsing the light between sunrise and sunset. The apparatus is the invention of Don Isaas Lavaden, of Cadiz, to whom I am indebted for kindly showing me the light in action when on a visit to Cadiz in 1885. There is every probability that automatic beacons lighted either by electricity, gas, or petroleum spirit, will in consequence of their economy in maintenance be extensively adopted in the future.

Coal and wood fires, the flames produced by the combustion of tallow, nearly all the animal, vegetable, and mineral oils, coal and oil gas, and the lime-light, have been employed from time to time in lighthouse illumination, and last but not least, the electric light. None of these illuminants have received such universal application in all positions both ashore and afloat as mineral oil at the present moment, and justly so, when we consider its efficiency and economy for the purpose. So recently as 1822, the last beacon coal fire in this country was replaced by a catoptric oil light, at Saint Bees Lighthouse, on the coast of Cumberland. We have here diagrams of two of these coal fire beacons, one of them designed and erected by Smeaton in 1767 on his lighthouse at the Spurn Point, on the east side of the entrance to the Humber. So late as 1845, sperm oil was entirely used in the lighthouses and light-vessels of the Trinity House; but, shortly afterwards, colza was adopted with the same efficiency, and with a saving in annual cost of about 44 per cent. In 1861, experiments were made by the Trinity House for determining the relative efficiency and economy of colza and mineral oil for lighthouse illumination; but owing to the imperfect refinement of the best samples of the latter then procurable in the market, together with its high price, the result of the investigation was not so satisfactory as to justify a change from colza. In 1869, the price of mineral oil of good illuminating quality, and safe flashing-point, was found to be procurable at about half the price of colza, when the Trinity House determined to make a further series of experiments, and by these it was ascertained that, with a few simple modifications of the argand burners then in use, they were rendered very efficient for the purpose; it was also found that these burners were thus considerably improved for the combustion of colza. A change from colza to mineral oil was then commenced, and mineral oil is now generally adopted in the lighthouses and light-vessels of the Trinity House service; and with even greater economy than was at first anticipated, the price of this illuminant being now rather less than one-third that of colza. The most powerful oil burner then in use was one of four concentric wicks, the joint production of Arago and Fresnel, and adopted by the French lighthouse authorities about the year 1825, in conjunction with the then new dioptric system of optical apparatus of Fresnel. The standard intensity of the combined flames of this burner, one of which we have here, was 260 candle units. A further development was made during the experiments of the Trinity House in 1871, by increasing the number of wicks from four to six, which more than doubled the intensity of the light, while effecting a condensation of the luminary per unit of focal area, or, in other words, improved the optical efficiency 70 per cent. We have here also one of these burners.

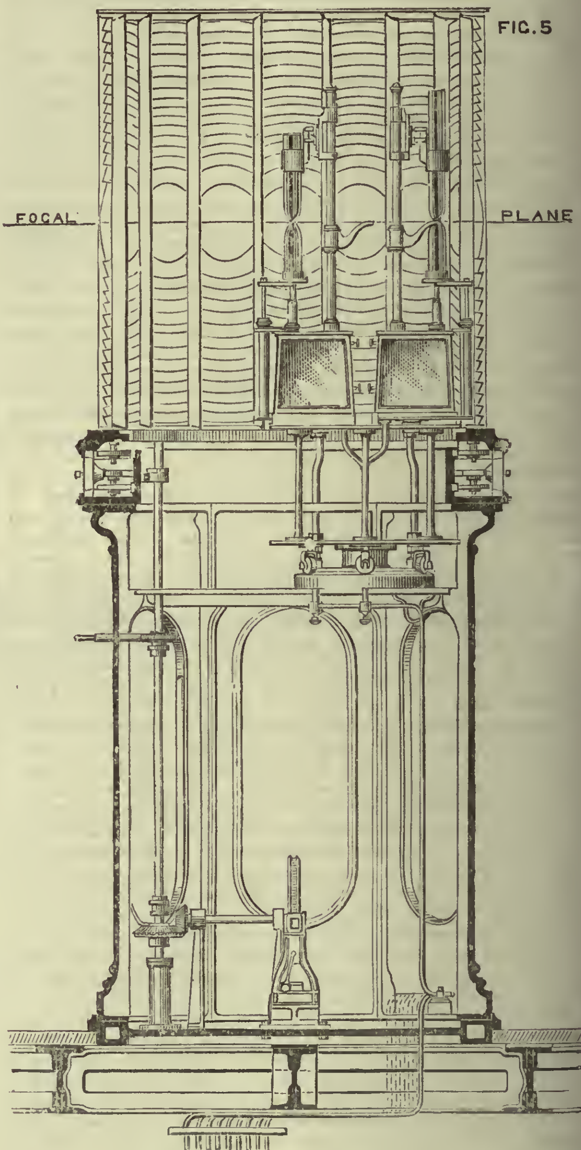
I have since devised an argand burner for the combustion of all illuminating gases and oils, whereby still further condensation of the flames, together with greater intensity and economy of combustion, is obtained, and the glass chimney is protected from breakage. These improvements are effected by a special arrangement and distribution of the air currents through the rings of flame, and between them and the glass chimney. We are thus enabled on this system to increase the dimensions of lighthouse burners, for gas and oil, for ten or more rings of flame. With ten rings, we obtain an aggregate intensity, when burning cannel gas and good mineral oil, of considerably over 2000 candle units, while the improved efficiency of the luminary for optical cendensation of the radiant light per unit of focal area, as compared with the luminary of the Fresnel four-wick oil burner, has been in each case increased 109 per cent. With reference to the perfect combustion of these highly condensed flames, I may state that the efficiency for gas is exactly double that of the London standard argand burner, viz. when consuming gas of the London standard of sixteen candles, the light produced is at the rate of 6·4 instead of 3·2 candles per cubic foot. In addition to a single ring gas burner of this type we have two burners of the ten rings of flames, and models of their flames, one for gas and the other for mineral oil. These burners are all of the Trinity House new pattern, both gas and oil, and they are of the same general arrangement for combustion, except that the oil burner is provided with cotton wicks. Both produce flames of nearly the same form, dimensions, intensity, and colour.

The first application of coal gas to lighthouse illumination was made at the Troon Lighthouse, Ayrshire, in 1827; and in 1847 it was adopted at the Hartlepool Lighthouse, Durham, where for the first time it was employed in combination with dioptric apparatus of the first order of Fresnel. The slow progress made with coal gas in lighthouses, except for harbour lights, where the gas could be obtained in their vicinity, as at Hartlepool, was chiefly due to the great cost incurred in the manufacture of the small quantity required, and at the usual isolated positions occupied by coast lighthouses, involving extra cost both for labour, and for the extra transport of the coal. In 1865, the attention of lighthouse authorities was directed to gas, as an illuminant for lighthouses, by Mr. John R. Wigham, of Dublin, whose system was tried in that year, at the Howth Bailey Lighthouse, Dublin Bay. The gas burner of Mr. Wigham, one of which we have here, consists of seven concentric rings, of single flat-flame burners, amounting in the aggregate to 108. The burner is used without a glass chimney, and thus there is no appreciable condensation of the group of flames, for their employment at the focus of optical apparatus, and the relative aggregate intensity of the seven rings of flat flames per unit of focal area, as compared with the four concentric flames of the old four-wick oil burner of Fresnel, is only 2½ per cent. higher than the latter. The burner has five powers, for varying states of the atmosphere. For the minimum intensity, 28 jets are employed; and with the whole 108 jets there is a maximum aggregate intensity of the flames with cannel gas of about 2500 candle units. Several lighthouses on the coast of Ireland have been illuminated with gas, on the system of Mr. Wigham, and two at Haisborough, on the coast of Norfolk. In 1878, Mr. Wigham installed at the Galley Head Lighthouse, County Cork, his system of superposed gas flames, and group-flashing light, which consisted of four of his large gas burners vertically superposed. In conjunction with these were four tiers of first order annular lenses, eight in each tier. By successive lowering and raising of the gas flames at the focus of each tier of lenses, he produced his group-flashing distinction. This light shows, at periods of one minute, instead of the usual single flash from each lens, or vertical group of lenses, a group of short flashes, varying in number between six and seven. The unavoidable uncertainty with this system in the number of flashes contained in each group is unfortunate for the mariner, who, with the continued increase in the number of coast lights, requires the utmost precision in the distinctive character adopted for each.

In 1857, an experimental trial of the first magneto-electric machine of Holmes, for the practical application of the electric light, was made by the Trinity House at Blackwall, under the direction and to the great delight of their scientific adviser, Faraday; and after a series of experiments the satisfactory report of Faraday encouraged the Trinity House to order a practical trial of a pair of the Holmes machines. The trial was made at the South Foreland High Lighthouse by Faraday and Holmes on December 8, 1858, when electricity was found to be a formidable rival to oil and gas for lighthouse illumination, and this position it maintains to the present day. The trials of this arc light were made at the focus of the first order dioptric apparatus for oil light, which was very imperfect for the purpose, but they were sufficiently encouraging to lead the Trinity House, under the advice of Faraday, to proceed further with the electric light for lighthouses. Faraday thus wrote in his report to the Trinity House:—"I beg to state that, in my opinion, Prof. Holmes has practically established the fitness and sufficiency of the magneto-electric light for lighthouse purposes, so far as its nature and management are concerned. The light produced is powerful beyond any other that I have yet seen so applied, and in principle may be accumulated to any degree; its regularity in the lantern is great, its management easy, and its care, there may be confided to attentive keepers of the ordinary intellect and knowledge."

These truly prophetic words of Faraday's have been entirely realized. Electricity still stands foremost in the illumination of our coasts, and appears destined to be one of the greatest blessings ever conferred on humanity, and more especially on "those who go down to the sea in ships." On February 1, 1862, Holmes's machines and apparatus for electric light were installed at Dungeness Lighthouse; and in 1863, the French lighthouse authorities followed, by an installation of the Alliance Company's magneto-electric machines and apparatus for fixed lights at each of the two lighthouses at Cape La Hève. We have here the first dioptric apparatus designed and manufactured by Messrs. Chance Brothers and Co., of Birmingham, for the electric fixed light at Dungeness. We have also one of the Holmes lamps employed there. The lamp used at the previous experiments was devised by M. Duboscq, of Paris. This lamp of Holmes's is similar to those of Duboscq and Serrin, excepting that the upper and lower carbons and holders are balanced and regulated through pulleys and small catgut cords, instead of by rack and pinions. The carbons are ¼ inch square, and the mean intensity of the light in the arc was 670 candle units nearly. We have here samples of the carbons employed from time to time in the development of the electric light in lighthouses; we have also a Bergot lamp fitted with the fluted form of carbons I have recently devised. They are of the dimensions now in use in the optical apparatus at the St. Catharine's Lighthouse, and are giving a mean intensity in the arc of 40,000 candle units (Fig. 5). Cylindrical compressed carbons were soon manufactured for the electric light, and were found to be more homogeneous in quality, and the flickering of the light less, than with the original square carbons, which were simply sawn from the residual carbon of gas retorts; but there was still the objectionable crater at the points, whether direct or alternating currents were employed, involving flickering from the incessant shifting of position at the points. A considerable loss of radiant light was also involved, particularly when condensing it optically. The flickering was somewhat reduced by an improvement of Messrs. Siemens', in providing the carbons with a graphite core, but with the increasing powers of currents,

FIG. 5



and in the necessary dimensions of carbons, the results were far from satisfactory. With the fluted form of carbon shown on the diagram, the formation of the crater is prevented, and the arc is held centrally at the points of the carbons; there is thus, in addition to comparatively steady light, nearly uniform radiation in azimuth, and over a greater vertical angle for optical condensation. It now appears to me, after some practical experience with this form of carbon, that it is impossible to determine a practical limit to the dimensions of carbons that may be efficiently employed. With carbons of the actual size shown on the diagram, an intensity of about a million candle units should be produced in the arc, and about 150 millions of candle units in the condensed flashes from the optical apparatus of the dimensions now employed for oil and gas flames in lighthouses. Such an intensity is about four hundred times that possible at the focus of such apparatus with a flame luminary. Such results as these were probably in the mind of Faraday when he reported that "in principle this light may be accumulated to any degree." Flashes of the great intensity here referred to could only be employed in atmosphere impaired for the transmission of light. In clear weather they would be found to be far too dazzling to the eyes of the mariner, when an intensity of about 50,000 candle units is found to be sufficient for his guidance, and in thick fog no possible intensity can be of practical value for navigation. There are, however, various gradations of impaired atmosphere between clear weather and thick fog, in which the highest available intensity is doubtless desirable at many important landfall stations for obtaining the greatest possible range of visibility. On the other hand, at the majority of stations in narrow waters, the maximum intensity now obtained with flame light is found to be more generally efficient for navigation than higher intensities.

In 1881, the question of the relative merits of the three lighthouse illuminants—electricity, gas, and mineral oil—was receiving the attention of the lighthouse authorities of this country, which resulted in the Trinity House accepting the responsibility of carrying out an investigation at the South Foreland, of universal importance to the mariner. In the photometrical and electrical portions of this work, the Trinity House were aided by the labours of Prof. Harold Dixon, F.R.S., and Prof. W. Grylls Adams, F.R.S., which contributed very largely to the success of the investigation. The experiments were carried on during a period of over twelve months, and a vast amount of very valuable evidence was collected from numerous observers, trained and untrained, scientific and practical. The Report of the Committee was presented to both Houses of Parliament, by command of Her Majesty, in 1885. The final conclusions of the Committee are given in the following words: "That, for the ordinary necessities of lighthouse illumination, mineral oil is the most suitable and economical illuminant, and that for salient headlands, important landfalls, and places where a very powerful light is required, electricity offers the greatest advantages."

I have already referred to the necessity, with the present development of maritime commerce, that every beacon light maintain a clearly distinctive character. When the optically unaided flames of coal fires were the illuminants of our lighthouses, distinctive characters, owing to the small number of lights then employed, were of little importance, and the only distinctions then possible were the costly ones of single, double, or triple lighthouses at one station; but, with the enormous increase that has since occurred in the floating commerce of the world, and with the necessary laws now in operation, requiring all vessels to carry lights, trustworthy individuality in coast beacon lights has become a positive necessity. Until very recently, the distinctive characters consisted of the following, viz. fixed white, fixed red, revolving white, revolving red, and revolving white and red alternately. The revolving lights showed a flash at periods of ten seconds, twenty seconds, thirty seconds, one minute, two minutes, three minutes, and four minutes. There were also intermittent or occulting lights, having an eclipse at periods of half a minute, one minute, or two minutes. It is now generally considered that fixed lights are no longer trustworthy coast signals, owing to their liability to confusion with other lights, both ashore and afloat. It is also considered that, in these days of high speed vessels, the period of the character of a coast light should not, if possible, exceed half a minute. The revolving or flashing class of lights are probably the most valuable, on account of their superior intensity as compared with the fixed or occulting class, the light during the intervals of eclipse being condensed into each succeeding flash, by the revolving lenses or reflectors, and thus, with the same expenditure of the illuminant, an intensity is obtained in the flashes of five to eight times that of the fixed or occulting class. Where local dangers are required to be guarded by coloured sectors of danger light with well defined limits, this can only be accomplished with the fixed or occulting class of lights. We will illustrate this with the model before us. We will also show the clear difference of character, not generally realized, between flashing and occulting lights. A system of occulting lights for lighthouses was proposed by the late Charles Babbage, F.R.S., in 1851, but as it excluded the flashing or most powerful of the existing lights, it did not receive much favour from lighthouse authorities. In 1872, distinctive characters for coast lights was the subject of a paper by Sir William Thomson, F.R.S., at the Brighton meeting of the British Association for the Advancement of Science, when he directed attention to the extreme importance of ready identification of lights at sea, and proposed the use of quick-flashing lights, their flashes being of longer or shorter duration; the short and long flashes representing the dot and dash of the Morse alphabet as used in telegraphy. It was found, however, that the number of symbols in our alphabetical code would not be sufficient, on a thickly lighted coast, to insure individuality, and render each distinction perfectly trustworthy. Further, that very rapid repetition of each symbol is not required by the mariner, and would involve loss of accumulative power in the flashes, besides incurring unnecessary wear and tear in rotating heavy optical apparatus. Yet much is to be done in the direction of simple distinction. At the Montreal meeting of the British Association, in 1884, I submitted a paper on "Improvements in Coast Signals," in which were suggested, two alphabetical codes of flashing lights, and one of occulting, all having the same period of the symbol, viz. half a minute. In one of the codes of flashing lights, long and short flashes were proposed, as previously by Sir William Thomson; and in the other there were proposed white and red flashes. In the occulting series, long and short eclipses were proposed to be substituted for the long and short, or white and red, flashes, of the flashing codes. The system has the advantage of application to all existing lighthouse apparatus, and many lights have been altered to selected symbols of each of these series.

Little was ever accomplished in the way of warning or guidance to the mariner, during fog, until about the middle of this century. Previously, a few bells had been established at lighthouses in this country and abroad, and gongs of Chinese manufacture had been in general use on board our light-vessels, but both instruments are now acknowledged to be wanting in the efficiency now demanded in fog, to meet the requirements of navigation. The first important improvement in fog signals for the service of mariners was made by the late Mr. Daboll in 1851, who submitted to the United States Lighthouse Board, in that year, a powerful trumpet, sounded by air compressed by horse-power. The apparatus was installed at Beaver Tail Point, Rhode Island, and the favourable results obtained with it stimulated Mr. Daboll, under the encouragement of the United States lighthouse authorities, to the further development of the apparatus; and ultimately he employed Ericsson's caloric engine as the motive power, with automatic gearing for regulating the blasts. In 1854, some experiments on different means of producing sounds for coast signals were made by the engineers of the French Lighthouse Department, and in 1861–62 MM. Le Gros and Saint-Ange Allard, of the Corps des Ponts et Chaussées, conducted a series of experiments upon the sound of bells, and the various methods of striking them. In 1862, Mr. Daboll submitted his improved fog trumpet apparatus, of about three horse-power in the blasts, to the Trinity House, who, under the advice of Faraday, made experimental trials with it in London, and afterwards gave it a practical trial at the Dungeness Lighthouse, where experiments were made with it, against bells, guns, and a reed fog-horn of Prof. Holmes, whose services have been already referred to in connection with the first practical application of the electric light. This fog-horn of Holmes was sounded by steam, direct from one of the boilers employed at the station for his electric light. The results of these experiments were in favour of Daboll's trumpet; and in 1869, one of these instruments was installed on board the *Newarp* light-vessel. In the same year, Holmes having effected further improvements with his steam horn, his apparatus was fitted on board two light-vessels, and sent out to the coast of China, where they were found to give great satisfaction, as compared with gong signals. In 1863, a Committee of the British Association for the Advancement of Science memorialized the President of the Board of Trade, with the view of inducing him to institute a series of experiments upon fog signals. The memorial, after briefly setting forth a statement of the nature and importance of the subject, described what was then known respecting it, and several suggestions were made relative to the nature of the experiments recommended. The proposal does not appear to have been favourably entertained by the authorities to whom it was referred, and the experiments were not carried out. In 1864, a series of experiments was undertaken, by a commission appointed by the Lighthouse Board of the United States, to determine the relative powers of various fog signals which were submitted to the notice of the Board. In 1872, a Committee of the Trinity House, with the object of ascertaining the actual efficiency of various fog signals then in operation on the North American continent, visited the United States and Canada, where they found in service, Daboll's trumpets, steam whistles, and siren apparatus, sounded by steam and compressed air; these latter apparatus were devised by Mr. Felix Brown, of Progress Works, New York; and from the report of the Trinity House Committee, it does not appear that they were greatly impressed with this instrument, but probably they had not an opportunity of testing its real merits as compared with other signals. The late Prof. Henry, of the United States Lighthouse Board, entertained a very high opinion of the siren; and on his advice, and the urgent recommendation of Prof. Tyndall, one of these instruments was sent to England, and included in the fog signal experiments at the South Foreland in 1873–74. This investigation was carried out by the Trinity House, with the view of obtaining definite knowledge as to the relative merits of various sound-producing instruments then in use, and also of ascertaining how the propagation of sound is affected by meteorological phenomena. Prof. Tyndall, as scientific adviser of the Trinity House, conducted the investigation, aided by a Committee of the Trinity House, and their engineer. These experiments were extended over a lengthened period, in all conditions of weather, and the well-known scientific and practical results obtained, together with the ascertained relative merits of sound-producing instruments for the service of the mariner, have proved to be of the highest scientific interest and practical importance. The investigation at the South Foreland was followed up by the Trinity House with further explosive fog signal experiments, in which they were assisted by the authorities at Woolwich Arsenal with guns of various forms, weight of charges, and descriptions of gunpowder. The powders tested were (1) fine grain, (2) larger grain, (3) rifle large grain, and (4) pebble. The result placed the sound-producing powers of these powders exactly in the order above stated; the fine grain, or most rapidly burning powder, gave indisputably the loudest sound, while the report of the slowly burning pebble powder was weakest of all. Here again the greater value of increased rapidity of combustion in producing sound was demonstrated. It was found that charges of gun-cotton yielded reports louder at all ranges than equal charges of the best gunpowder; and further experiments proved that the explosion of half a pound of gun-cotton gave a sound equal in intensity to that produced by three pounds of the best gunpowder. These investigations led the Trinity House to adopt gun-cotton for fog signals at isolated stations on rocks and shoals, as already described, where, from want of space, nothing better than a ball, or gong, it had hitherto been possible to apply. Of all the sound signals now employed for the warning and guidance of mariners during fog, viz. bells, gongs, guns, whistles, reed trumpets, sirens, and sounds produced by the explosion of gun-cotton, the blasts of the siren and explosions of gun-cotton have been found to be the most efficient for coast fog signals; therefore these signals have received the greatest care and attention in their development. The siren doubtless ranks first for stations wherever it can be applied, chiefly on account of its economy in maintenance, and the facility it affords for giving prolonged blasts of any desired intensity or pitch, and thus providing any number of trustworthy distinctive characters that may be required to insure individuality in the signal. Sirens are now employed at many floating and shore stations of the Trinity House; and one, recently installed at Saint Catharine's Lighthouse, Isle of Wight, of the automatic Holmes type, of which we have here a model, absorbs during its blasts not less than 600 horse-power. The audibility of the blasts of this instrument may be considered to be trustworthy at a range of two miles under all conditions of foggy atmosphere, on the sea surface, over which it is intended to be sounded. It is very desirable that for many landfall stations a greater trustworthy range be provided for the mariner, but this can only be afforded by such increased power as would be required for a more powerful electric light installation, to serve the mariner in other gradations of thick atmosphere. A very important improvement and economy has lately been effected in the sirens of the Trinity House, by rendering them always instantaneously available for sounding at their maximum power. This is accomplished by the storage of a sufficient quantity of compressed air, at a pressure considerably above that required for sounding, to work the siren during the time required for raising steam and starting the engine. The signal is thus always in readiness for immediate action day or night, with an expenditure of fuel only incurred during fog, which fortunately on the coast of this country does not exceed an average of 440 hours per annum. The experience yet gained with the most powerful fog signals now in use, although these apparatus far exceed in efficiency for the service of the mariner in fog any light that science can provide, is not yet so satisfactory as we could desire. The best signal is, as I have already stated, occasionally not heard, under certain atmospheric conditions, beyond two miles; while under other conditions, not apparent to the mariner, the signal is distinctly audible at ten miles; therefore there is much to be desired in the development of the means of propagating sound waves, and in rendering them audible to the mariner. In conclusion I would venture to state that, with the best light and sound signals that can be provided, there are conditions of the atmosphere in which the mariner will earnestly look and listen in vain for the desired light or sound signal, and he must still, under such circumstances, exercise caution in availing himself of their guidance, and never neglect the assistance always at hand of his old trusty friend the lead.

PRELIMINARY REPORT OF THE NEWALL TELESCOPE SYNDICATE.[1]

AT the end of the Lent Term the Syndicate met for the first time and drew up a Report to the Council of the Senate, recommending that a Committee of experts should go to Gateshead to view Mr. Newall's telescope and report on its condition and capabilities. A letter of acknowledgment was also sent to Mr. Newall thanking him for his generous offer.

In consequence of their recommendation, Mr. Christie, Astronomer Royal, Mr. Common, F.R.S., and Mr. Graham, First Assistant at our Observatory, went to Gateshead and made a thorough examination of the telescope and of its accessories. They reported to the Syndicate as follows:—

Report on Mr. Newall's 25-inch Refractor.

We the undersigned, being the Committee appointed by the Newall Telescope Syndicate to inquire into and report on the condition and capabilities of the above instrument, beg to submit the following report as the result of an examination made on March 28 and 29. For convenience of reference we have divided the report under three heads:—

1. On the present condition of the telescope and dome.
2. On the necessary work to be done in removing and re-erecting, to put the whole in an efficient state.
3. The capabilities of the instrument when re-erected.

I. On the evening of March 28, the sky being overcast, the quality of the object-glass was tested by artificial stars, formed by the light of a lamp shining through holes in a metal screen, placed at a distance of about 1500 yards. The result of those tests, which it is unnecessary to specify more fully, was sufficient to enable the Committee to come to the conclusion that the object-glass is a remarkably fine one, entirely free from any defect. On the conclusion of those tests about midnight, and as the Committee were about to leave, the sky cleared to a slight extent, and at intervals the telescope was turned upon some stars and upon Saturn. Owing to the state of the atmosphere, the definition was very variable, but the Committee saw enough to confirm them in the opinion they had already formed as to the excellent quality of the object-glass. During these examinations and tests the mounting showed itself to be extremely steady and quite free from vibration. On the morning of the 29th the Committee again met at Ferndene to complete the examination of the instrument and dome by daylight. The telescope is no doubt so well known that it is not necessary to state further than that it is a first-class instrument, mounted on the plan of the elder Cooke, and that it is fully provided with all the necessary appliances to make it an extremely convenient and easily managed instrument.

The condition is such that the necessary cleaning, painting, lacquering, &c., more fully described in the next section, will not be an expensive matter.

The dome and substructure were next inspected. From the brick wall, which rises to a height of about 2 feet, the whole is of iron, the various parts, including the dome, being bolted

[1] Reprinted from the *Cambridge University Reporter*, May 21.

together in such a way as to render taking down and removal a comparatively easy matter. In addition to the circular inclosure supporting the dome, the height of which is about 20 feet, the dome itself being 40 feet diameter, there are two or three rooms and an entrance porch, available as a dark room and computing room. The mechanism for moving the dome and the dome itself are in good order, but in the opinion of the Committee, it would be advisable to go to some expense in providing brackets for the wheels on which the dome runs with horizontal rollers as guides instead of the flanges on the wheels. The observing platform is a first-rate one and will need no alteration. It is suitable for general observational work, or for work where the use of a large spectroscope renders considerable space necessary in any direction.

The shutters of the dome will require some slight repair.

As regards the apparatus with this telescope there are the usual battery of eye-pieces suitable to the telescope; a series of parallel bar, ring, and other fixed micrometers, a very fine parallel wire micrometer, all complete in mahogany boxes; a fine barrel chronograph in glass case, and a good sidereal clock with compensated pendulum. These with sundry apparatus belonging to the telescope complete the outfit.

We had no opportunity of thoroughly testing the clockwork. We consider that it might be advisable to add an electric control and slow-motion gear of the modern pattern in order to render the telescope more efficient in this respect.

II. We have drawn up a specification showing more fully the work required to be done in order to put the telescope simply into an efficient state, but we would recommend that the opportunity be taken to add electric lighting to the circles and micrometer, to provide an electric control to the clock and an electric slow-motion gear. We would further recommend that 12 cast-iron brackets be added to the dome as supports for the wheels, that one or both of the flanges be turned off these wheels, and that horizontal rollers carried by the brackets be added as guides to keep the wheels on the rail. This, we think, would render the turning of the dome much more easy. We would retain the iron circular wall under the dome in preference to a brick or stone wall, as offering more favourable conditions for the telescope. We have added in the appendix our estimate of the cost of this work.

III. When erected and in working order, this telescope will be specially adapted to any work in observational astronomy for which a large aperture is required, and if it is decided to restrict the use of the telescope to micrometric measures of faint satellites, or to the scrutiny of planetary details, no outlay will be required for additional apparatus, beyond an efficient system of lighting the circles and micrometer with small electric lamps. Should it be determined, however, to undertake work in stellar physics, which we understand, from the letter published in NATURE, is the wish of the donor, and which we would strongly recommend as the most useful systematic work to take up, then the necessary spectroscopic outfit, at present wanting, would have to be provided. We estimate the cost of this at about £100. So equipped the telescope would at once be capable of commencing systematic work of first-class importance that would amply repay the cost of keeping such an instrument regularly employed, and in carrying on such systematic work no further outlay in buildings would be required, the computing and dark rooms attached to the dome being sufficient for the work to be done at the telescope. But in our view it would greatly increase the usefulness of this instrument for spectroscopic research if it were placed within easy reach of a physical laboratory where apparatus would be available for experimental investigations in connection with the telescopic observations. As regards the selection of a site we consider it a matter of great importance that the instrument should be located where it would be easy of access to members of the University engaged in making observations with it. It is essential for the effective use of an instrument in a variable climate that the observer should be as near his work as practicable.

W. H. M. CHRISTIE.
A. AINSLIE COMMON.
April 3, 1889. A. GRAHAM.

The previous experience of these gentlemen has also enabled them to give an approximate estimate of the expense of the removal and re erection of the telescope at Cambridge. It appears unnecessary to quote the details of their estimate, but the total sum is given by them as £770.

At the time when Mr. Newall had in contemplation his offer to the University, he was already very ill, and the Syndicate heard with deep regret of his death on the 21st of April. They have reason to believe that he was gratified, before his death, with the prospect that his valuable instrument would probably contribute to the advancement of astronomical science at Cambridge.

Since his death, the executors, with the full approval of his family, have renewed the offer to the University. The Syndicate are of opinion that the University should avail itself of the opportunity of possessing this fine instrument, and they are at present occupied with schemes for its proper maintenance and use.

SOME PROPERTIES OF THE NUMBER 7.

1. MY attention was recently drawn by a pupil to the following property, which will be best illustrated by working out a particular example:

$$\begin{array}{rrl} \text{Let N} = & 342544\;3 & \\ u_2 = & 34253\;8 & \textit{i.e.}\; u_2 = 342544 - 2 \times 3 \\ u_3 = & 3423\;7 & \phantom{\textit{i.e.}\;} u_3 = 34253 - 2 \times 8 \\ u_4 = & 340\;9 & \phantom{\textit{i.e.}\;} u_4 = 3423 - 2 \times 7 \\ & 32\;2 & \text{and so on:} \\ & 2\;8 & \end{array}$$

if any one of the quantities u_2, u_3, u_4, &c., is divisible by 7, then N is so divisible.[1]

$$\begin{aligned} \text{For, let N} &= 10P_1 + p_0 \\ u_2 &= 10P_2 + q_1 \\ u_3 &= 10P_3 + q_2 \\ u_4 &= 10P_4 + q_3 \\ u_{n-1} &= 10P_{n-1} + q_{n-2} \\ u_n &= 10P_n + q_{n-1} \qquad = 7Q, \text{ by hypothesis.} \\ \text{Now, } 10P_1 &= 10^2P_2 + 10(q_1 + 2p_0) \\ 10^2P_2 &= 10^3P_3 + 10^2(q_2 + 2q_1) \\ 10^2P_3 &= 10^4P_4 + 10^3(q_3 + 2q_2) \\ 10^{n-1}P_{n-1} &= 10^nP_n + 10^{n-1}(q_{n-1} + 2q_{n-2}); \end{aligned}$$

$$\begin{aligned} \therefore N = 10P_1 + p_0 &= 21[p_0 + 10q_1 + \ldots + 10^{n-2}q_{n-2}] \\ &\qquad + 10^{n-1}(10P_n + q_{n-1}) \\ &= 21M + 10^{n-1}(7Q) = 7Q^1. \end{aligned}$$

Or we may proceed thus:—

$u_2 = P_1 - 2p_0$; $\therefore N = 10(u_2 + 2p_0) + p_0 = 10u_2 + 21p_0$; hence, if N is divisible by 7, so also is u_2, and so on.

If for 2 we substitute 1, 3, 4, 5, ... n, then if N is divisible by 11, 31, 41, 51(3, 17), ... $10n + 1$, so also are (the corresponding) u_2, u_3, ... u_n.

In like manner, if we strike off 2, 3, ... n figures, then if N is divisible by (101, 201, ... $10^2n + 1$), (1001, 2001, ... $10^3n + 1$), ... and so on, so are u_2, u_3, ... u_n.

2. This property was suggested by the question, "Prove that a number consisting of six like figures (111111) is divisible by 7."

Let x be the digit, and let it be repeated n times, then if N be of the form $(7p - nx)10^n + (10^{n-1} + 10^{n-2} + \ldots + 10 + 1)x$, *i.e.* such a number as 5733, in which we have $57 + 2 \times 3$ = multiple of 7, it will be divisible by 7, if $-n \cdot 10^n + (10^n - 1)/9$ is, *i.e.* if $(9n - 1)10^n + 1$ is, *i.e.* if $(2n - 1)10^n + 1$ is, *i.e.* if $(k =) (2n - 1) 3^n + 1$ is.

Omitting the case of six like digits, we write down the following table for an inferior number, the use of which is explained subsequently.

(1)		(2)		(3)		(4)		(5)	
$7p+2 \ldots 2$	1	$7p+5 \ldots 5$	11	$7p+6 \ldots$	111	$7p+4 \ldots$	1111	$7p+1 \ldots$	11111
$7p+4 \ldots 4$	2	$7p+3 \ldots 3$	22	$7p+5 \ldots$	222	$7p+1 \ldots$	2222	$7p+2 \ldots$	22222
$7p+6 \ldots 6$	3	$7p+1 \ldots 1$	33	$7p+4 \ldots$	333	$7p+5 \ldots$	3333	$7p+3 \ldots$	33333
$7p+1 \ldots 1$	4	$7p+6 \ldots 6$	44	$7p+3 \ldots$	444	$7p+2 \ldots$	4444	$7p+4 \ldots$	44444
$7p+3 \ldots 3$	5	$7p+4 \ldots 4$	55	$7p+2 \ldots$	555	$7p+6 \ldots$	5555	$7p+5 \ldots$	55555
$7p+5 \ldots 5$	6	$7p+2 \ldots 2$	66	$7p+1 \ldots$	666	$7p+3 \ldots$	6666	$7p+6 \ldots$	6666

[1] In fact, 21 may be substituted for 7.

That is, third line of (3) say, 67333, 781333, &c. (note $67 = 7 \times 9 + 4$, $781 = 7 \times 111 + 4$), are multiples of 7. We may preface any one of the above series of numbers with, or affix to them, sextets of digits, like or unlike to those of the number we select. I confine my attention to sextets of like figures affixed, as in this way I am able to find what values of n make k a multiple of 7.

The series in (1) is, of course, $n = 1, 7, 13, 19$, and so on: and so for the other sets. The values of n to be taken are:—

for (1), $n = 19, 61, 103, 145, \ldots$

(*i.e.* if we write down 19 3's, we must preface these with a number of the form $7p + 6$.)

(2), $n = 2, 44, 86, 128, \ldots$
(3), $n = 15, 57, 99, 141, \ldots$
(4), $n = 10, 52, 94, 136, \ldots$
(5), $n = 41, 83, 125, 167, \ldots$

University College School. R. TUCKER.

THE BHILS AND THEIR COUNTRY.

IN the current number of the *Asiatic Quarterly Review*, Sir Lepel Griffin has a long and most interesting article on the Bhils, an aboriginal tribe of Central India living in the jungle and rough country around the Vindhya Mountains. Sir Lepel says that for eight years he presided over the province which includes the Bhil country, and he had ample opportunity in that time of studying the habits and language of this interesting people. The people themselves claim that they represent the aboriginal races of India who were forced to retire before the Aryan conquerors. Through their country flows the sacred Nerbudda River with all its Hindu shrines. The Bhils, however, seem to care very little for the Hindu deities; they have been forced by the Hindus, who treat them with profound scorn and contempt, to give a sort of half-hearted acceptance of the chief Hindu deities, but in fact they never worship the gods of their superiors. In one respect, however, they agree with the Hindus, and that is in regarding the Nerbudda with feelings of terror and veneration. From the earliest days of the Aryan conquest of India, the Bhils have been looked on as wild animals, deserving of no protection or kindness. In a few States, such as Barwani and Rajpur, they were so numerous, that their conquerors found it more profitable to tolerate them, keeping them, however, at the same time, in the most abject poverty and subjection. Since the advent of the British Government, the condition of these simple and harmless people has much improved, so that the poor Bhils are gradually becoming less and less savage. Their knowledge of woodcraft and of the habits of birds and beasts makes them invaluable to English officers. Unlike the orthodox Hindu, the Bhil has always eaten the flesh of the cow and the buffalo and other abhorred animals. In fact, he eats every wild animal except the monkey, which is universally worshipped in the form of the forest god Hanumán. The tiger is held in great respect, and the people are very unwilling to kill it, unless it is a man-eater. If a beast has thus become obnoxious, a trial is held with religious rites, and if the animal is found guilty, sentence is passed upon him, he is pursued, killed, and hung up on a tree over the main road as a warning to all evil-doers of his species. It is very curious, and shows the antiquity of this race, that at the coronation of the highest Rajput chiefs, in States where the Bhils live, the sacred mark of kingship is impressed on the forehead of the new chief by the head of the Bhil family to which this hereditary privilege belongs, and the Bhils do not regard him as their king till this ceremony is performed. The Bhils are noted for their endurance, for their capacity of living where others would starve, their indifference to the greatest changes of temperature. Not even to save his life will a Bhil tell a falsehood. Their most solemn oath is by the dog, their most valuable companion in the chase. They are gay and of a light-hearted disposition, and take every opportunity of having a feast and a drinking-bout. Their drink is made from the Mowra, a tree which abounds in Central India, the white flowers of which, when pounded and mixed with grain, form a palatable food, and when distilled by a simple process produce a highly intoxicating spirit. Their priests are not of any particular caste, but the office is an hereditary one. The deities most generally worshipped are the ordinary Vedic deities of water, fire, and the heavens, and each village has its presiding deity, who is a different personage in each village. Like Hindus they burn their dead, except unmarried children of both sexes, who are buried, as also those who die from small-pox. In case of cholera they also bury the dead, believing that the smoke from the pyre disseminates the disease. The dead are worshipped and propitiated by offerings; tree worship is unusual; witchcraft and omens are implicitly believed in; charms of various kinds are universally used.

SCIENTIFIC SERIALS.

THE *Quarterly Journal of Microscopical Science* for April 1889 contains the following:—Contributions to the knowledge of *Amphioxus lanceolatus*, Yarrell, by Prof. E. Ray Lankester, F.R.S. (plates xxxiv.–xxxvi.*b*). Referring to his notes on the anatomy of Amphioxus published in 1875, the author withdraws his confirmation of Johann Müller's statement that there is a pair of apertures on either side of the oral sphincter (velum of Huxley). In reality there are no such apertures at all. Those important structures, described as the "brown funnels," are fully described and excellently illustrated; some few numerical data of importance for the anatomical discussion of Amphioxus are given; some errors which appear to be current as to the existence or non-existence of spaces of one kind or another in the body and gill bars are corrected; and some drawings are given, which represent in a semi-diagrammatic form the structure of Amphioxus, not merely as seen in sections or dissections, with all their obvious drawbacks, but as reconstructed and corrected from the examination of numerous specimens, so that they present as nearly as might be a true conception of the living organism. This excellent paper will be welcomed by all students.—Studies in the embryology of the Echinoderms, by H. Bury (plates xxxvii.–xxxix.). In this memoir the author confines his attention;—to the primary divisions of the cœlom, starting from a stage in which at least two enterocœle pouches are already present;—the hydrocœle; its development and connections;—and to the skeleton, so far as it is developed in the dipleurula stage.—On the ancestral development of the respiratory organs in the Decapodous Crustacea, by Florence Buchanan (plate xl.).

The *Journal* for May 1889 is a special issue, and contains a memoir on the maturation of the ovum in the Cape and New Zealand species of Peripatus, by Lilian Sheldon, Bathurst Student, Newnham (plates i.–iii.). The ovarian structures are fully described in *Peripatus capensis*, *P. balfouri*, and *P. novæ-zealandiæ*. A summary of events in the maturation and fertilization of the ovum in these three species is also given; these are followed by some details of the origin of the ova from the germinal epithelium; the disappearance of the germinal vesicle; the formation of the polar bodies, and the formation of the yolk. Among the many interesting facts mentioned are those in reference to the polar bodies: in *P. novæ-zealandiæ* they appear to be completely absent, but two very prominent bodies are present in the Cape species; they are also in these species exactly similar to one another—a series of facts at variance with Weismann's theories.—With this number is given a series of very valuable indexes: an index to the *Journal* from 1853 to 1888; and one to the Transactions of the Microscopical Society from 1853 to 1868; also to the Proceedings of the Dublin Microscopical Club from 1865 to 1880. These indexes are paged separately, so that they may be bound up as an independent volume.

Engler's Jahrbücher, vol. x., includes the following articles:—The first part of the description of the plants collected by Dr. Marloth in South Africa in 1885–86 (with six plates). The descriptions are prepared by Dr. Engler, with the help of other botanists, and include the Monocotyledons, and Archichlamydeous (Choripetalous and Apetalous) Dicotyledons.—On the anatomical characters of the *Monimiaceæ*, by M. Hobein. This natural order is one as to the position of which various opinions have held; the author's observations strengthen the alliance to Laurineæ, inasmuch as in both orders secretory cells are constantly present.—A monographic review of the species of the genus Primula, by Dr. F. Pax. An attempt to trace the phylogenetic relationships of the species of this large genus.—The second part of the description of Dr. Marloth's plants from

South Africa (with four plates), including the Gamopetalous Dicotyledons, by Dr. Engler, &c.—The Piperaceæ collected by Lehmann in Guatemala, Costarica, Columbia, and Ecuador, described by Casimir de Candolle.—A new plant belonging to the Olacineæ (*Tetrastylidium Engleri*, Schwacke), by W. Schwacke.—An anatomical study of *Scirpus* and allied genera (with one plate), and a key for distinguishing them on anatomical grounds, by Dr. Ed. Palla.—On some mistaken, or little-known Rubiaceæ of South America, by Karl Schumann.—On the flora of Greenland, by Eug. Warming. Including interesting descriptions of the general appearance of the vegetation, as well as the habit of certain species, with a discussion of the origin and relations of the flora. The author concludes that Greenland is not a European province, from the point of view of botanical geography, but has nearer relations to America.—Contributions to the comparative anatomy of the *Aristolochiaceæ* (with three plates), by Dr. H. Solereder. A comprehensive investigation of the structure of both vegetative and reproductive organs.—The volume also includes the usual personal notices, and abstracts of current literature, together with a list of works recently published on geographical and descriptive botany.

Journal of the Russian Chemical and Physical Society, vol. xxi. No 1.—On hexabromtetramethylene, by A. Sabaneyeff.—On the heat of solution of lithium bromide. It is equal to 11·351, and thus occupies an intermediate position between those of LiCl (8·440) and LiI (14·886).—On the action of ethyl iodide and zinc upon paraldehyde, by W. Wedensky.—On the oxidation of erucic and ricinoleic acids by means of permanganate of potassium, by L. Urvantzoff and W. Dieff.—On the formation of cane-sugar from starch in plants, by F. Selivanoff. It was observed in tubercles of potatoes.—Notes by MM. Moltchanoffsky, Alexeyeff, and Kondakoff.—Theoretical researches into the motion of water in the subsoil, by N. Joukovsky. The author concludes from his mathematical inquiry and some experiments that the law of Darcy remains satisfactory if the secondary causes are also taken into consideration and the results are not extended to great distances from the well. As to the corrections of Darcy's law proposed by Kröber and Smreker, they do not yet correspond to all facts noticed during pumpings.—Note by W. Rosenberg on cyclonic movements.

No. 2.—Yearly reports of the Society.—Notes on primary, secondary, and tertiary nitro-compounds, by J. Bevad.—On the general law of contraction which takes place during the formation of solutions of salts, by A. Gueritch; second paper, containing data relative to H_2SO_4 and HCN.—On the action of chlorides and hydrochloric acid upon the photochemical decomposition of chlorine-water, by E. Klimenko and G. Pecatoros. They slacken the decomposition.—On the vapour density of ethyl isocyanurate at various temperatures, by S. Krapivine and N. Zelinsky.—On the dilatation of solutions of salts, by N. Tchernay; third paper, containing tables relative to nine different nitrates.—Note on electrical phenomena due to actinic influences, by J. Borgmann.

In the *American Meteorological Journal* for March, Mr. A. L. Rotch continues his interesting articles on the meteorological services in Europe, dealing in this number with the Paris and Montsouris Observatories. The interest of the Paris Observatory, from a meteorological point of view, is now chiefly in its long series of observations, which date from the year 1666; since the establishment of the Central Meteorological Office, meteorology has not been actively pursued at the Observatory. The Montsouris Observatory was founded in 1871, and deals chiefly with the collection of hygienic statistics, and the application of meteorology to agriculture. It publishes an *Annuaire*, and also a monthly summary in the *Comptes rendus* of the French Academy. Prof. H. A. Hazen contributes an article on anemometer comparisons, and discusses the results of recent experiments in America and in this country, with the view of determining the ratio between the motion of the wind and that of the centre of the cups. The results of the American experiments have been discussed by Prof. Marvin, and will shortly be published *in extenso*. The chief difficulty lies in the determination of a constant factor for all velocities, and of constants for different sizes of cups and arms. Prof. Hazen thinks it possible to construct an anemometer with arms and cups so proportioned as to give a constant factor at all velocities. Lieutenant Finley discusses the frequency of tornadoes in the State of Georgia during the last ninety-four years.

SOCIETIES AND ACADEMIES.

London.

Royal Society, May 9.—"On the Magnetic Rotation of the Plane of Polarization of Light in doubly refracting Bodies." By A. W. Ward. Communicated by Prof. J. J. Thomson, F.R.S.

In repeating Villari's experiment on the rotation of the plane of polarization of light in a spinning disk of heavy glass, placed with its axis of rotation perpendicular to the lines of force in a magnetic field, it was observed that the incident plane-polarized light became elliptically polarized. The elliptic polarization was due to the centrifugal force, which had the effect of stretching the glass along the radii of the disk and compressing it parallel to the axis of rotation. The strained glass in the magnetic field has, therefore, the double property of elliptically polarizing plane-polarized light, and at the same time rotating the plane of polarization. The strained glass therefore acted like a crystal placed in a magnetic field, and so, before Villari's experiment could be properly interpreted, it is necessary to examine how the elliptic polarization and magnetic rotation affect each other. The following investigation is an attempt to solve this question, and its conclusions show that the apparent magnetic rotation in a doubly refractive medium is a periodic function of the length of the path of light in the medium. This hitherto unsuspected result entirely accounts for the effects observed by Villari, and those observed by Lüdtge in a piece of compressed glass.

Villari's results are very similar to Lüdtge's. Villari, by spinning a disk of glass very rapidly, strained it, and on observing the magnetic rotation found it get less and less as the strain got greater and greater. There is, however, one noticeable difference between Villari's strained disk and Lüdtge's strained prism. The disk was free from strain in the middle, the prism free from strain at the ends.

I have repeated Villari's experiment at the Cavendish Laboratory, using, at Mr. Glazebrook's suggestion, an elliptic analyzer to determine the magnetic rotation. With the disk spinning about 200 times a second, the magnetic rotation was reduced from 10° to 6°. This is not so great a diminution as Villari observed, but his glass may have been softer and more easily strained.

Villari thought that the effect he observed was due to the time required to magnetize the glass. That this supposition was erroneous has been clearly established by the experiments of Bichat and Blondlot, and recently repeated by Dr. Lodge. In these experiments the oscillating discharge of a Leyden jar was found to rotate the plane of polarization in time with the oscillations. Before hearing of these results I had myself attacked the problem in a somewhat similar manner. A coil of wire was wound round a piece of heavy glass, and a current alternated 250 times a second by a tuning-fork was sent through the coil. The current was measured by a dynamometer and a tangent galvanometer. The first gave the measure of the current independently of its sign, the second showed that the integral current was zero. When the current was passing it was found impossible to extinguish the light, owing to the rapid alternations of the plane of polarization.

May 16.—"Physiological Action of the Active Principle of the Seeds of *Abrus precatorius* (Jequirity)." By Sidney Martin, M.D. London, British Medical Association Research Scholar, Assistant Physician to the Victoria Park Chest Hospital; and R. Norris Wolfenden, M.D. Cantab. (From the Physiological Laboratory, University College, London.) Communicated by E. A. Schäfer, F.R.S.

"The Toxic Action of the Albumose from the Seeds of *Abrus precatorius*." By Sidney Martin, M.D. London, British Medical Association Research Scholar, Assistant Physician to the Victoria Park Chest Hospital. (From the Physiological Laboratory, University College.) Communicated by E. A. Schäfer, F.R.S.

From numerous experiments, the following conclusions were arrived at:—

(1) The poisonous activity of the seeds of *Abrus precatorius*, the jequirity, resides in the two proteids present in the seeds—a paraglobulin and an albumose.

(2) Both of these proteids have practically the same action. They produce severe conjunctivitis when applied to the eye; and when subcutaneously injected, they cause local inflamma-

tion, œdema, and ecchymosis, and gastro-intestinal irritation, with extrusion of fæces and blood; the general symptoms being, first, a great fall of body temperature, and a condition of stupor, ending in death.

(3) The activity of both these proteids is destroyed by moist heat. In solution, the activity of the globulin is destroyed at between 75° and 80° C., and that of the albumose between 80° and 85° C.

(4) That abrus-poison resembles snake-venom in chemical composition, in the local lesions produced, in producing a fall of body temperature, in causing semi-fluidity or fluidity of the blood after death, and, to some extent, in the effect of moist heat on it. Abrus-poison is, however, much less active than snake-venom.

The following table shows a comparison between the activity of the venom of various snakes and of Abrus:—

Vipera berus (common adder)	Fatal dose in man, 0·0021 gramme per kilogramme of body weight (Fontana).
Hyplocephalus curtus (Australian tiger-snake)	Fatal dose in dog, 0·00485 gramme per kilogramme of body weight; ½ grain in medium size dog (15 pounds).
Cobra	Fatal dose in dog, 0·000079 gramme per kilogramme of body weight; $\frac{1}{10}$ grain in dog weighing 18 pounds (Vincent Richards).
Abrus-poison—	
Globulin	Fatal dose, 0·01 gramme per kilogramme of body weight.
Albumose	Fatal dose, 0·06 gramme per kilogramme of body weight.
Peptic albumoses ...	Fatal dose in dog, any dose over 0·3 gramme per kilogramme of body weight (Pollitzer).

"Appendix to paper on Descending Degenerations following Lesions in the Gyrus marginalis and Gyrus fornicatus in Monkeys." By E. P. France. Communicated by E. A. Schäfer, F.R.S.

Linnean Society, May 24.—Anniversary Meeting.—Mr. Carruthers, F.R.S., President, in the chair.—A portrait of John Jacob Dillenius (1687-1747), the first Professor of Botany at Oxford, copied from the original picture at Oxford, was presented to the Society by the President, who gave a brief outline of his career, and of his personal acquaintance with Linnæus.—The Treasurer having made his annual statement of accounts, and the Librarian's and other reports having been read, a ballot took place for the election of officers and Council for the ensuing year. The President, Treasurer, and Secretaries were re-elected, and the changes recommended in the Council were adopted.—The President then delivered his annual address, to which we refer elsewhere.—A unanimous vote of thanks to the President for his address, coupled with a request that it might be printed, having been passed, the ceremony of awarding the Society's gold medal took place. This medal, having on the obverse a fine bust of Linnæus and on the reverse the arms of the Society, below which is engraved the name of the recipient, was founded last year in commemoration of the Society's centenary anniversary, and is bestowed upon a botanist and zoologist alternately, for distinguished services to biological science. This year it was awarded to the eminent botanist Prof. Alphonse de Candolle, and in his unavoidable absence was handed to his grandson M. Austin de Candolle, who attended on his behalf to receive it. Addressing his representative, the President said:—"Monsieur de Candolle, it is a great satisfaction to me to place in your hands, for transmission to your distinguished grandfather, the Linnean gold medal, in recognition of his many important services to botanical science. These services have been so great, and are so universally acknowledged, that it is unnecessary for me to do more than to refer to them. His many systematic monographs justify his being awarded any honour that botanists can confer. His philosophical treatment of the geographical distribution of plants has greatly advanced this department of science, and his successful codification of the laws of botanical nomenclature has been of the greatest practical service to systematists. But botanists will always look with gratitude to Alphonse de Candolle for the successful carrying on of the gigantic enterprise inaugurated by his father when he undertook the publication of the 'Prodromus Systematis Naturalis Regni Vegetabilis.' By his own work, by securing the aid of accomplished *collaborateurs*, and perhaps not least by the plodding toil of reading the proof-sheets of volume after volume of dry systematic descriptions during the thirty-two years in which he took charge of the 'Prodromus,' he has laid science under a debt which cannot be estimated. The work as now completed contains descriptions of all the Dicotyledonous Phanerogams, and of Gymnosperms, which were known when the different volumes were published, amounting to nearly 60,000 species. By his numerous labours Alphonse de Candolle has added lustre to a name that had already obtained a first place amongst botanists. His son Casimir, by his scientific researches, maintains the credit of that name; and now, in handing this medal to you, Monsieur Austin de Candolle, the representative of the fourth generation, may I venture to hope that this imperfect estimate of the services rendered to science by Alphonse de Candolle may help you to realize the honour of the name you inherit, and encourage you by similar true and honest labour to transmit it with added renown to posterity."—The presentation having been suitably acknowledged by Dr. Marcet, F.R.S., a countryman and relative of the recipient, the proceedings terminated with a vote of thanks to the President and officers.

Anthropological Institute, May 14.—Prof. Flower, C.B., F.R.S., Vice-President, in the chair.—Mr. Arthur Thomson read a paper on the osteology of the Veddahs of Ceylon, and exhibited a complete skeleton and several skulls of these people, Although the skeleton was said to be that of a man of twenty-six years of age, many parts were not completely ossified. The fifth lumbar vertebra was less wedge-shaped than amongst the higher races of man, and hence there was a distinct tendency to a backward curve in this region. Attention was drawn to the fact that the left clavicle was longer than the right by no less than 10 mm., and this may probably be explained by the employment of the left arm in the use of the bow; the left arm was also slightly larger than the right. The scapulæ were small and slender, and the high index, 71·1, indicates a marked difference in shape from that of Europeans. The femora and tibiæ were remarkable for their great length, and in each case the left was the longer. On the anterior borders of the lower extremities of both tibiæ were semilunar facets articulating, in extreme dorsiflexion of the foot, with corresponding surfaces on the necks of the astragali. The extreme length of the articulated skeleton was 1578 mm., which was somewhat above that of the average Veddah, as calculated by Virchow. It appeared from examination of all the available crania that the average capacity of the Veddah male skull is 1321 cc., and that of the female skull 1229 cc. The cephalic index is 70·9. From the data given in the paper the author inferred that, if the Veddahs be not of the same stock as the so-called aborigines of Southern India, they at least present very strong points of resemblance both as regards stature, proportions of limbs, cranial capacity, and form of skull; and that, if physical features alone be taken into account, their affinities with the hill tribes of the Neilgherries, and the natives of the Coromandel Coast and the country near Cape Comorin, are fairly well established.—Some notes by Mrs. R. Braithwaite Batty, on the Yoruba country, and a paper by Mr. H. Ling Roth, on salutations, were also read.

PARIS.

Academy of Sciences, May 20.—M. Des Cloizeaux, President, in the chair.—On the telluric origin of the oxygen rays in the solar spectrum, by M. J. Janssen.—On the complete correspondence between the continuous fractions which express the two roots of a quadratic equation whose coefficients are rational numbers, by Prof. Sylvester.—On the impossibility of diamagnetic bodies, by M. P. Duhem. The author's researches lead to the general inference that the existence of diamagnetic bodies is incompatible with the principles of thermodynamics. The so-called diamagnetic bodies are simply magnetic bodies plunged in a more powerful magnetic medium, in accordance with Becquerel's hypothesis, which assumes that for these bodies there exists one distribution of equilibrium and one only, that this distribution is stable, and that a diamagnetic body is always repelled by permanent magnets.—On the artificial reproduction of the mirage, and on the interference fringes that may accompany this phenomenon, by MM. J. Macé de Lépinay and A. Perot. A process is described, by means of which conditions are realized which are analogous but inverse to those that give rise to the natural mirage.—On the expansion of quartz, by M. H. Le Chatelier. The experiments here described show that quartz undoubtedly undergoes considerable expansion between 480° and 570° C. Above the critical temperature of 570°, it ceases to expand, and on the contrary undergoes a slight contraction. The phenomenon is analogous to that observed in the dimorphic transformations of litharge, of potassium sulphate, and especially of dicalcic silicate.—On the variations of the acid function in stannic oxide, by M. Léo Vignon. The author here resumes his study of the polymerization of stannic acid, dealing more especially with stannic acid prepared by means of stannic chloride; with metastannic acid obtained by the reaction of nitric acid on tin; and with calcined stannic oxide. He finds that there must exist a complete series of stannic acids, whose first term would appear to be the soluble acid, and the last the calcined metastannic acid.—On oxalomolybdic acid and the oxalomolybdates, by M. E. Péchard.—On phosphorous acid, by M. L. Amat. In a previous note (*Comptes rendus*, cvi. p. 1400) the author showed that, under the action of heat, the acid phosphite of soda may lose water, and be transformed to a pyrophosphite of soda. His present researches make it probable that the other acid phosphites behave like the salt of soda, only the dehydratation in their case is much more difficult.—Action of the alkaline meta-, pyro-, and ortho-arseniates on the alkaline earthy oxides, by M. Lefèvre. These researches, which are confined to baryta, strontia, and lime, show that lime has a greater tendency to form chloro-arseniates than baryta, while baryta yields simple compounds more readily than lime. Strontia is intermediate between these two bases.—On the malonates of ammonia, by M. Massol. Here the author describes the method of preparation, composition, and properties of the acid and neutral malonates.—On the proportion of nitrates contained in the rains of tropical regions, by MM. A. Muntz and V. Marcano. Observations taken at Caracas (Venezuela) and at Saint-Denis (Réunion), compared with those recorded by Messrs. Lawes and Gilbert at Rothamsted and by M. Boussingault at Liebfrauenberg (Alsace), show that the quantity of nitrates contained in tropical rains is from five to thirteen times greater than in those of temperate zones. To this abundance of nitrogen under a form easily assimilated must doubtless be partly attributed the exuberance of tropical vegetation.—On the richness of wheat in gluten, by MM. E. Gatellier and L. L'Hôte. Continuing their researches on this subject, the authors arrive at the general conclusion that by careful selection and treatment wheat may be made to yield a high proportion of gluten without any reduction in the abundance of the harvest.—Papers were contributed by M. Martinand, on the alcoholic fermentation of milk; by Dom Pedro Augusto de Saxe-Cobourg-Gotha, on a specimen of crystallized iron glance from Bahia (Brazil), and on the albite of Morro Velho; and by M. P. Termier, on leverrierite (a new phyllite), and on the Bacillarites of the coal-measures.

Astronomical Society, April 3.—The following were elected officers for the ensuing year:—President, M. Faye; Vice-Presidents, M. C. Flammarion, Colonel Laussedat, General Parmentier, and M. Trouvelot; Secretary, M. Gérigny; Vice-Secretaries, MM. C. Detaille and E. Bertaux; Treasurer, M. A. Hentsch; Librarian, M. Mabire. Council: MM. Bischoffsheim, Bossert, Charton, Gunziger, Heman, Hirn, Moussette, Secretan, Oppert, Trépied, Armelin (Admiral), Cloué, Bardou, Moureaux, and Schmoll.—M. C. Flammarion summed up the progress of astronomy during the past year.—M. Faye then took the chair, and remarked that in founding this Society M. Flammarion and his collaborators had created something durable, and had rendered a great service in so doing. M. Faye proposed that the Society should hold an extraordinary meeting in September this year, on account of the Exhibition, which will bring many foreign astronomers to Paris. This proposition was adopted.—M. Guiot sent an observation of shadow cast by Venus.—M. Dumesnil, same observation; also observations of Venus, with the naked eye, on March 6, 9, 15, 23, and 28, from 3 to 4 p.m.—M. Faye made some remarks on the Samoa cyclone, and explained the parabolic path of cyclones in both hemispheres.—M. Junod sent some remarks on the attraction between rotating spheres.

Berlin.

Physiological Society, May 3.—Prof. du Bois Reymond, President, in the chair.—Dr. Blaschko gave an account of his anatomical researches on the formation of the horny layer of the skin. According to his observations the Malpighian layer consists of polygonal cells, which are pierced by so considerable a number of fibres that the cell-substance of each consists of a network of fibres. These fibres pass through two or three cells in succession, thus uniting them one to the other; between them, and external to the cells, is found the intercellular fluid, and similarly a fluid substance in the interior of the cells. The growth of the horny layer begins in the *stratum granulosum*, with the appearance of Waldeyer's keratohyalin granules in the fibres; these granules then become larger, and the fibres disappear. In the *stratum corneum* fibres again make their appearance in the dried cells, which have now entirely lost the nucleus which they possessed when they formed part of the Malpighian layer. The speaker supported his statements by drawings and preparations which he exhibited.—Dr. Goldscheider spoke on the muscular sense, and on the experiments he had made with a view to its analysis. To assist him in his researches he made use of localized anæsthesia, produced by Faradic currents, and of the exclusion of conscious volitional impulses. Perception of motion takes place at the joints, and is unaffected by want of sensitiveness in the skin. The liminal value for the sensation of motion varies greatly for various joints, lying between 1°·30 and 0°·27. The time required for the perception of the motion is very short, and is unaffected by the position of the limb. The muscles are not concerned in perceiving the position of the limb, this being dependent on the visual centre, which is stimulated by local sensory impulses. The perception of weight is similarly dependent on the central nervous system, and the recognition of resistance experienced in raising and lowering weights is brought about by means of the varying presssure exerted by the surfaces of the joints against each other. Owing to the lateness of the hour the conclusion of this communication was postponed to the next meeting.

[*Note.*—In the report of the Physiological Society, NATURE, May 2, p. 24, line 22, *for* "ventral" *read* "dorsal."

May 17.—Prof. du Bois-Reymond, President, in the chair.—Dr. Goldscheider concluded his communication on the muscular sense. He brought forward a mass of evidence in opposition to the view, which has up to the present time been widely spread, that innervation-sensations play an important part in connection with muscular sense. Thus, for instance, the following experiment is opposed to the current view: a given muscle is stimulated electrically (the will thus being excluded), lifts a weight, and gives rise to a distinct sensation of the accompanying movement. On the other hand, a movement may be intended, the innervation-sensation being at the same time distinctly prominent, and still the sensation of movement may be subminimal and not reach its liminal value, so long as the movement when executed is very small. As regards the raising of weights, it must be borne in mind that this is performed by limbs made up of several parts connected by joints; the rigid joints give rise to the sensation of resistance. The speaker summed up the outcome of his researches as a whole in the conclusion that the muscular sense is compounded of three peripheral sensations: of a sensation of *movement* resulting from the displacement of the condyles, of a sensation of *weight* produced by the tension of the tendons, and of a sensation of *resistance* due to the pressure of the articular surfaces against each other. In addition to the above there is still another sensation—namely, of *position*, resulting from pressure, tension, and stretching of the skin and other local stimuli. Prof. Gad gave strong expression to his own view, in opposition to the conclusions of Dr. Goldscheider, that the perception of resistance is not directly a sensation but a judgment, based upon the relation of the movement to the innervation and muscular tension.—Prof. Kossel then expressed his opposition to the views of Prof. Leo Liebermann on nuclein, which he regards as a mixed precipitate of metaphosphoric acid, albumen, and bases of the xanthin series.—He next gave an account of the researches of Schindler, who had sought in the tissues for the bases of adenin, hypoxanthin, guanin, and xanthin, which are all products of the decomposition of nuclein. He found no adenin in the semen of bulls, but only the other three bases, whereas in that of the carp and in the thyroid gland not only adenin but the other three are plentifully present. Schindler had further exposed adenin and guanin to putrefactive decomposition. After prolonged exposure both these bases were entirely decomposed, hypoxanthin having taken the place of adenin, and xanthin that of guanin. In both cases the result is explained by the assumption of one molecule of water and the elimination of one molecule of ammonia.

Meteorological Society, May 7.—Dr. Vettin, President, in the chair.—Prof. von Bezold discussed the modern views on the formation of atmospheric precipitates, which, in opposition to the older views, are based upon strictly scientific principles. At one time it was thought that the precipitates are formed by the mixing of cold air with warm moist air, and since the temperature of the mixture falls to the arithmetical mean of the other two, so much moisture must be condensed as corresponds to the considerably lowered saturation-point which results from the above process. Now, however, it is known that both the rise in temperature of the cold air and the heat set free by the condensation of the moisture must be taken into account, so that in reality very little moisture is precipitated: this was clearly shown by the speaker in a series of examples, both by calculation and by graphic representation. Thus appreciable precipitations occur either very seldom or not at all when masses of air of differing temperatures are mixed together. Precipitation only occurs when a saturated mass of air is directly cooled, such cooling being brought about in nature chiefly by radiation and by the upward flow of currents of air. Hence the precipitations which take place on the lofty sides of mountains as the air rises along them, as a result of its having been warmed, and in cyclones. Since warm dry air is carried into the cyclone from the anticyclone, the clouds formed at the edge of the cyclone are subsequently absorbed; thus the clouds are most dense in the centre where the pressure is a minimum, and are progressively less dense towards the periphery. Dr. Vettin showed several experiments on the movement of smoke inside a glass case which was slowly rotating about its centre. Small vessels filled with ice were suspended in the case, causing downward currents of air, and towards these places the smoke made its way from the periphery in a whirling, screw-like formation.

Vienna.

Imperial Academy of Sciences, March 14.—The following papers were read:—On the oxidation of β-naphthol, by E. Ehrlich.—On the encysting of protoplasm with regard to the function of the cell-nucleus, by G. Haberlandt.—Contribution to the anatomy of the aërial roots of Orchidea, by E. Palla.—Results of comparative researches on the spectra of cobalt and nickel (sealed), by A. Grünwald.—Contribution to the systematic knowledge of Muscaria (sealed), by F. Brauer.—On the intestinal mesenteries and omenta in their normal and abnormal state, by C. Toldt.—On the oxidation of paraphenylenediamine and paramido-phenol, by E. von Bandrowski.—On some phenomena of electrical discharges and their photographic fixation, by A. von Obermayer and A. von Hübl.—On the elements of the geological structure of Rhodus, by G. von Bukowski.—Determination of the orbit of the Andromeda (175) planet, by F. Bidschof.

Amsterdam.

Royal Academy of Sciences, April 20.—Prof. van de Sande Bakhuigzen in the chair.—M. Martin read a paper on the so-called "old-slate formation of Borneo." This formation is known among others in the western parts of the island, where a few fossils were collected by the mining engineer, C. J. van Schelle, viz. at the Soengli Molsong, and near Boedoek and Sepang, in the "Chinese districts." It appeared, on examination, that these fossils belong to the genera Gervillia and Corbula, and as neither genus ever occurs in Palæozoic strata, the "old slate" here cannot be Palæozoic. The slates are, moreover, covered by Tertiary strata, so that the only alternative is to assume that they belong to the Mesozoic age. A further confirmation of this hypothesis he found in the fact that he had succeeded in finding, in a grey limestone of the Bojan, in the Upper Kapoes dominion, *Orbitulina centicularis*. As this fossil is Cretaceous, and the limestone in question occurs likewise in company with clay-slate, he concluded that the strata with Gervillia and Corbula are of the same age as those with Orbitulina, and that they all belong to the Cretaceous period. M. Martin feels persuaded that the Cretaceous formation is widely spread in the Indian Archipelago, and, on account of the absence of fossils, has been partly included among the "old slate," and partly among the Tertiary system.

Stockholm.

Royal Academy of Sciences, May 8.—Prof. S. Lovén gave an account of a recently published memoir, by Prof. J. Steenstrup in Copenhagen, with the title, "On the Station of the Mammoth Hunters at Tredmort in Moravia."—Baron Nordenskiöld exhibited the first copy, now ready, of his great work, "Facsimile Atlas to the Oldest History of Chartography, containing copies of the best maps printed before the year 1600," a volume in folio, with fifty-one large maps, and eighty-four maps and figures inserted in the descriptive letterpress. The interesting manuscript map of Northern Europe from 1467, discovered by Baron Nordenskiöld in the library of Count Zamoiski at Warsaw, is also copied.—He also exhibited a large meteoric stone, 10½ kilogrammes in weight, which fell on April 3, this year, in the province of Scania.—Contributions to the knowledge of the absorption of the radii of heat through the various components of the atmosphere, by Dr. Ångström.—On the construction of the integrals of the linear differential equations, by Prof. Mittag-Leffler.—Note sur la série généralisée de Riemann, by Dr. A. Jonquière, of Bern.—On the action of cyanium on phenyl-sulpho-urinate, by Herr D. S. Hector.—On the action of some oxidating bodies on phenyl-sulpho-urinate, by the same.—On integration of differential equations in the problem of the n bodies, by Prof. Dillner.—The singular generatrices of the binormal and principal surfaces, by Prof. Björling.—Studies on the peat bogs of Southern Scania, by Herr G. Andersson.—Zoological notes from Northern Bohuslän, by Herr C. A. Hansson.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

CONTENTS.

THURSDAY, JUNE 6, 1889.

REPORT OF THE ROYAL COMMISSION ON A UNIVERSITY FOR LONDON.

THIS Report is a disappointment. The spectacle of three eminent lawyers taking an eminently legal view of a question, and three teachers an educational view, is instructive and amusing, but it is not business. Passing over, for the present, the question how far its conclusions are discredited beforehand, by the dissent, on the material point at issue, of all the Commissioners who have had experience of teaching, we shall consider the principal Report from our own standpoint; which is that of a complete impartiality as between the University of London, the petitioning Colleges, and the other institutions and interests concerned, and of an earnest desire to see established in London a real University for teaching and research—that is to say, one of which the function is the dissemination and advancement of knowledge, while the examinations are relegated to their proper place, as accessories to study, not fetters on the teaching.

At first sight the impression is favourable. "The general case for a teaching University is," in the Commissioners' opinion, "made out." The limitation of its area to London, so far as concerns its teaching functions, is strongly insisted on, and reiterated in several paragraphs. The rejection of a separate University for Medicine is good in itself, and is of good omen, when the position of the two leading Commissioners is considered, for a future association with the University of the only possible London School of Law, that of the Inns of Court. The Commissioners have adopted some excellent ideas as to the constitution of Faculties, consisting exclusively of actual teachers, and as to the formation from the Faculties of Boards of Studies. They further "think it desirable to give a definite value to the training and teaching which those students will obtain who go through the prescribed courses of constituent colleges and teaching institutions connected with the University," and they formulate certain proposals for their exemption from specified examinations, which at least serve to show that the recognition thus given to the value of systematic study under competent guidance is not, in their minds, a purely nominal one. There cannot be a doubt that, if their recommendations were adopted, the administration of the University of London would be improved, and the influence of its examinations upon study, in London at all events, greatly modified for the better. We do not see why, subject to some further consideration for the case of students elsewhere than the Commissioners have cared to give, the reforms suggested in the Report should not now be carried out, as it proposes, by the independent action of the University of London, with hearty support and approval from the University Colleges, and without in the smallest degree impairing their case for the simultaneous establishment as a separate institution of a real teaching University for London.

But this, of course, is not the intention of the Commissioners. On the contrary, they recommend, in so many terms, that if this reform should take place in the University of London, "the prayer of University College and King's College be not granted." This obliges us to examine whether the reform in question will insure to us that further benefit to be expected from the establishment of a teaching University which lies apart from any possible good results to follow upon the mere perfecting of the machinery of examinations. Upon this head it is our deliberate judgment that they will fall short of what is needed. It is not the somewhat stinted amount of representation upon the Senate which is offered to University College and King's College; not the representation on a more liberal scale of teachers in the University Colleges and schools, arranged in Faculties for the purpose, upon the same body; not even the appointment by these Faculties of so-called Boards of Studies, limited to the function of advising the examining body; nor yet all these concessions taken together, which will transform a general examining body into a teaching University for London, as we understand the term. Far less will such a University be constituted by "confederating" or "co-ordinating," for examining purposes only, all the "various societies and institutions in London which profess to give advanced teaching," such as, for example, "the Birkbeck Institution, the City of London College, and the Working Men's College." In the Charter of the Victoria University it is expressly provided that the affiliated Colleges shall be, for teaching purposes, efficient. This necessary safeguard has been overlooked by the Commissioners. There remains the recommendation that "the University should have power to teach by professors and lecturers of its own, attached or unattached to particular Colleges or institutions, and to receive endowments for that purpose." Assuming the necessary endowment to be forthcoming, the bearing of this proposal depends on its application. If the University Colleges are willing to allow of the "attachment" to them of University professors—that is to say, to allow the University to appoint the leading members of their teaching staff—and if further they permit the University "Boards of Studies" to arrange their prospectuses, then, indeed, the result will be that the Colleges, for teaching purposes, will become merged in the University; and we shall have, at the expense of the sacrifice of their individuality, and not without considerable violence to their traditions, a strong and homogeneous teaching University in London. Otherwise, one of two things will happen: the separate University staff may be a mere peripatetic staff of lecturers, doing what is known as "University extension" work; or else it will constitute a third University College, with a privileged position, competing with others for their students. In neither of these cases shall we have reaped the characteristic benefit of a teaching University, which is, shortly, the organization of teaching power.

Thus, on the most careful examination we have been able to give to the proposals of the Report, we are brought to the conclusion that only on one condition—a condition very unlikely to be realized—will they result in giving us a real teaching University for London. In default, we shall have a general examining University as before, but one largely under the control of London teachers. The change will entail a violence to the traditions of the University, and perhaps a disparagement of its Imperial position. The Commissioners, indeed, say: "For other parts of the Kingdom, as for the Colonies, it is sufficient that there should be access, as heretofore, to examinations and to degrees." This dictum, a curiously inaccurate one, if we consider the recent foundation of the Victoria University, not to speak of Colonial and Indian teaching Universities, will hardly be accepted by the country Colleges which still look, and must for some time continue to look, to the University of London for degrees. They will claim representation on its governing body, if not also on its Faculties and Boards of Studies; and if its functions are restricted to the control of examinations, we do not see on what principle the claim can be refused. The refusal to admit institutions at a distance is justifiable if the first business of the University is to teach; but hardly plausible if its function is only to examine.

Nor is this all. In order to obviate "the risk of practical injustice being done to candidates for degrees from country Colleges or from no Colleges at all," the Commissioners propose to establish what they call a "balance in the government of the University and in determining the course of the examinations and the choice of examiners," between the associated institutions and "independent elements." This they attempt by assigning a majority in the governing body to Crown nominees and the representatives of Convocation. This provision will in no way help to keep the University in touch with the teaching of the country Colleges; but it will undoubtedly entail the risk, which has been overlooked by the Commissioners, of producing a want of flexibility in the administration of the examinations, considered as accessories to study in the London Colleges. The University will thus start on its teaching career with a clog about its movements. Differences of opinion are sure to arise among its administrators, as often as an alteration of its programme is proposed in the interests of the London teaching; and these will be differences which no wisdom or moderation will entirely obviate, because they will be due to a fundamental difference in the point of view. We strongly apprehend that an institution so framed will be found to contain within itself the seeds of failure. In any case it will hardly obtain that large measure of confidence from the Colleges which would lead them to intrust it with any power over their teaching.

The initial fallacy of the whole Report may be traced to a little word in the twelfth page of it, paragraph 15. The Commissioners say: "Whatever difficulties there may be in the way of establishment of such form of connection as may be desirable between a teaching University for London and the different bodies and agencies now engaged in kindred work on an independent footing, we think it probable that these difficulties may be more easily overcome if *the ground* were occupied by one University only, and not by two." The ground proposed to be covered is not one field of work, but two. There is the work of affording by means of a general examination a test of attainment for students in institutions of as yet imperfect efficiency, and for private students. There is also the work of organizing the teaching, with its examinations closely following and dependent on the teaching, in the efficient Colleges of London. The two differ essentially, not merely in area, but in purpose. The attempt to devise an instrument competent to regulate both at once has failed, as it was bound to fail. Whatever line is now taken by the University of London, we trust that the promoters of the movement, who have succeeded hitherto so far beyond expectation, will stand fast by their principles, and not forfeit, by a too great eagerness for immediate results, the success which is certain ultimately to crown their efforts.

TASMANIAN GEOLOGY.

Systematic Account of the Geology of Tasmania. By Robert M. Johnston, F.L.S. Pp. 408, with Geological Map and Sections, and 57 Plates of Fossils. (Hobart: Published by the authority of the Government, 1888.)

NEARLY forty-five years have elapsed since Count Strzelecki and Prof. J. Beete Jukes, working independently, made known to geologists the main features of the important island of Van Diemen's Land. In the interval between the publication of their researches and the present day, numerous papers treating on questions of local geology have been published by Mr. Charles Gould—who for a time was engaged in making a geological survey of the colony—and by many amateur geological investigators. No complete description of the geology of the whole colony has as yet appeared, however; and we therefore heartily welcome the large and comprehensive volume now lying before us, as supplying a long-felt and pressing want.

The author of this work, Mr. Robert M. Johnston is the Government Statistician and Registrar-General of Tasmania; and during the last sixteen years he has devoted much time and labour to the study of the geology and natural history of the colony in which he resides, and has published numerous papers dealing with questions of stratigraphical geology and palæontology, as well as of botany and zoology. In the year 1884, Mr. Johnston was requested by the Tasmanian Government to write a general treatise on the geology of the island; and the present work has been prepared during the leisure hours of a busy Government official.

The Island of Tasmania has an area of a little more than 26,000 square miles, or between four and five times that of Yorkshire. Over large parts of the island there is a covering of almost impenetrable scrub; while the rivers are large enough to make traverses of the country by no means an easy task; and the rainfall is heavy. The interesting details of the methods of exploration, given in the introductory chapter of this work, illustrate the nature of the difficulties which have had to be overcome in making the researches upon which the work is based. We cannot but admire the energy and zeal which have been exhibited in carrying out the numerous and valuable observations that have made the present work possible.

The excellent sketch-map of the geology of Tasmania, drawn on a scale of 15 miles to the inch, gives a very good idea of the general distribution of the several rock-masses. The oldest formations appear on the west and on the north-east of the island, and consist of crystalline schists, apparently belonging to the Archæan periods, associated with clayslates, quartzites, sandstones, and limestones of Cambrian, Ordovician, and Silurian age, with some small and doubtful representatives of the Devonian. The palæontological evidence concerning the age of the different Lower Palæozoic rocks appears to be of a fairly satisfactory character.

Lying in the district between the two areas of older rocks, we have, in the central parts of the island, a tract of great extent, which is occupied by the important coal-bearing strata. These strata have, however, been greatly invaded by igneous extrusions, and are, over a considerable area, covered up by Tertiary deposits. While the lower series of these coal-bearing strata contain the remains of plants, like those of the Carboniferous strata of Europe and the United States, the higher Coal-measures yield many plants having Mesozoic affinities.

Mr. Johnston, like all who have had to deal with the geology of countries in the East and in the southern hemisphere, has been compelled to confront a very serious difficulty—that of making his nomenclature and classification fit in with the scheme that has been adopted in the countries which happen to have been the first systematically studied by geologists. His biological training and knowledge have here, however, stood him in good stead; and there are few contributions to this difficult question more worthy of attentive consideration than the chapter of this work which deals with nomenclature and classification, and the suggestions offered by the author on the subject of the "distribution of genera in time, from independent or widely separated geographical centres."

Mr. Johnston divides his Tertiary strata into the two groups called by him Palæogene (including perhaps the Eocene, Oligocene, and Miocene of European geologists) and Neogene (corresponding with our Pliocene). It is perhaps unfortunate that in the latter case a name is employed which has also been used by the geologists of Eastern Europe with a somewhat different signification.

Coming down to post-Tertiary times, the author gives an excellent account of the caverns and native shell-mounds, containing the rude flint-implements of the aboriginal inhabitants. Portraits are given of the last surviving man and woman of the Tasmanian race (King Billy and Truganini), the former of whom died in 1869 and the latter as recently as 1876. Drawings of the rude instruments made of chert which were used by this interesting race of human beings, and details concerning the mode in which the natives employed the different kinds of weapons, will prove of great service to those engaged in studying the remains left by various ancient races in Europe and America.

Full justice is done to the different kinds of igneous rocks, so far as they have yet been studied; to the various economical products; and especially to the useful ores, of the island. Interesting details are given concerning the mode of occurrence of the "Tasmanite," or "white-coal," which attracted so much attention a few years ago, and first led to the investigation of many similar "spore-coals" in Europe and America. The character of the deposits from which stream-tin and gold have been obtained is also described, and their importance is indicated by accurate statistics: the value of the tin obtained in Tasmania is now shown to be between £300,000 and 400,000 per annum. Nor are more purely scientific and theoretical questions neglected. An interesting discussion of the probable distribution of land and water in the Australasian region before and during the Tertiary period is illustrated by sketch-maps; and here, too, the author's biological knowledge has aided him greatly in dealing with a very complex and difficult problem.

But quite independently of the scientific value of the work, which as we have seen is certainly very great, we think the Government and people of Tasmania are to be congratulated upon the character of this remarkable and handsome volume. It aims at being above all things of practical use, and its great object is to direct the attention of the colonists to questions of pressing interest and importance, as well as to secure their aid and co-operation in solving the important problems presented by the geology of the country.

The bibliography of Tasmanian geology has, with the assistance of Mr. Robert Etheridge, Jun., been very amply dealt with. Chapters containing a key to the determination of rocks, and instructions for the blowpipe examination of minerals, together with an excellent glossary of geological terms, which might seem out of place in a memoir on European geology, will make this work of service to many colonists who have not had the advantage of a scientific training or access to libraries. The numerous plates, too, if not so highly finished in some instances as we are accustomed to in works of the kind, serve their purpose admirably; and the plan of giving side by side with the imperfect fossils found in the colony a number of well-marked types from the other Australian colonies, and even from Europe, can scarcely fail to prove of the greatest service to many a traveller or resident in the country, whose only work of reference may be this volume.

In the execution of his task, which has evidently been a labour of love, the author has received much assistance from the geologists in other Australian colonies and in New Zealand, and this he warmly acknowledges. No less valuable has been the co-operation of many of his fellow-colonists, who have aided him by drawing plates, in making special inquiries, and in many other ways.

When invited to undertake the work, the author was requested to prepare a volume which should be "specially suited for the guidance of local students, mining prospectors, and others." We can heartily congratulate Mr. Johnston, and the Government which have so liberally paid for the publishing of the book, upon having not only completely accomplished their primary object, but of having at the same time issued a work which is of the highest scientific value. It is not often that the wants of the general public and of the scientific specialist have been so admirably met; or that a book has been produced, which is at the same time accurate and thorough in its treatment of technical questions, while it is not wanting in the more elementary details required by those who have not had the advantages of a scientific training.

JOHN W. JUDD.

CACTUS CULTURE FOR AMATEURS.

Cactus Culture for Amateurs. By W. Watson. Profusely Illustrated. (London: L. Upcott Gill, 1889.)

QUAINTNESS of form, extraordinary brilliancy of colour in the flowers, facility of cultivation, all supply reasons why these plants, independently of the scientific interest attaching to them, should be extensively cultivated. At one time succulents were fashionable. They were grown, and grown well too, in the most unpromising localities—on the leads of London houses, in back yards, in cottage windows. They may still be found in the latter position, where the conditions often seem to suit them better than in more specialized habitations, probably because the plants get full exposure to light, and a dry atmosphere, while they are at the same time relatively impervious to dust. Barring occasional survivals, succulents have, however, "gone out." A collector recently dead did his best to galvanize the public taste. Regardless of expense, he got together a superb collection. With unwonted generosity he lent large assortments to public institutions, where they might be seen of many. With even greater liberality he gave away great numbers of plants to schools and other institutions, as well as to private individuals. He hoped by so doing to revive the public taste for this class of plants. Vain hope! They are no more abundant now than they have been for the last quarter of a century; the nurseries have mostly discarded them as unprofitable lumber; the great collections are broken up. Even the assemblage to which we have just alluded has been recently sold under the hammer, and, despite its excellence, realized scarcely more than enough to pay for the hammer. Under these circumstances it was with no little astonishment that we saw a series of articles in the *Bazaar* some time since, and it is with even greater surprise and pleasure that we now welcome their republication. The publisher, it seems, noting the general absence of cactuses in English gardens, came to the conclusion that the reason for their exclusion was to be found in the absence of adequate knowledge as to their cultivation and management. He thereupon commissioned Mr. Watson, Assistant Curator of the Royal Gardens at Kew, to write a series of chapters on the subject. Brave publisher! may he be amply compensated for his chivalrous efforts! At any rate, he pursued a wise instinct when he secured the services of Mr. Watson. While private collections have, as we have said, almost disappeared, these plants have always been very well represented at Kew. The succulent house indeed is, and always has been, one of the most striking features of that grand establishment. While of exceptional interest to the naturalist, the cactus house appeals to the attention of the general public more forcibly, if not always more pleasurably, than any other department of the Gardens. Ten years' experience in the care and cultivation of these plants at Kew is alleged by the author as his justification in publishing the present book. But, in truth, the book furnishes its own vindication. It is written for gardeners, not for botanists, but it will be acceptable to both, and we shall not be greatly surprised if the book is more appreciated by the naturalist than by the gardener. Fashion rules in gardening as in other things, and Fashion says now we will have cut flowers and roses, and we will have orchids; by and by, perhaps, it will demand cactuses, although they do not furnish "cut flowers," and this demand will, we trust, be furthered by the book before us.

The naturalist is, if not wholly, still largely, beyond the influence of the caprices of Fashion. For him the limited geographical distribution and the extraordinary forms of these plants, their surprising adaptations to the conditions under which they grow, their remarkable metamorphoses, the absence or extremely reduced condition of their leaves, the co-relative thickness of stem and expansion of surface, offer a never-ending source of interest and investigation. The wonderful provision against undue evaporation, the protection against the ill effects of radiation, the amount of green surface exposed to the sun even in the practical absence of leaves, the defence against thirsty marauders afforded by the spines, the singular nature and arrangement of those spines—all these points, to say nothing of the, in many cases, incomparably gorgeous flowers, give these plants claims on the attention of philosophic naturalists beyond those offered by most others. Further, with occasional exceptions they are easily grown, demand relatively little space, attention, or expense, and are therefore specially fitted for the naturalist of moderate means.

Lastly, we may commend them to the attention of those botanists who have the management of botanic gardens. Those who have visited the smaller University Gardens in Germany or France know what depressing establishments they generally are, and how little they seem to contribute to the advancement of science; but if the managers of each garden were to take up the cultivation, one of one genus of plants, one of another, as means and opportunities permitted, they might do excellent service to botany at little cost, and in these specialties achieve results not possible of attainment in larger and more exacting establishments. The Bromeliads were taken up in this manner in the Liége Botanic Garden by Prof. Morren, who unfortunately did not live to complete his monograph. We allude to the subject here because no group of plants affords better opportunities for a thorough and comparative study of the inter-relations of structure, development, and life-history generally than does the order Cactaceæ. Whilst fashion fades and palls, the interest of scientific investigation is not only continuous but progressive. The cactuses are replete with problems of deep import to naturalists, and we trust that Mr. Watson's book may be the means of bringing about the solution of some of them.

OUR BOOK SHELF.

Lehrbuch der Vergleichenden Anatomie zum Gebrauche bei vergleichend anatomischen und zoologischen Vorlesungen. Von Dr. Arnold Lang, Inhaber der Ritter-Professur für Phylogenie an der Universität Jena. Erste Abtheilung. (Jena: Gustav Fischer, 1888.)

THIS "Lehrbuch" is the ninth edition of E. Oscar Schmidt's well-known "Handbuch." It has been thoroughly revised—indeed, in parts rewritten. As might be expected from the Professor of Phylogeny at Jena, the subject is treated from a quite modern standpoint. We have first the systematic arrangement of the tribes, orders, and classes of each group or sub-kingdom, with the characteristics of each. This is succeeded by some general observations on the group, then the general morphology is described, next we have the details of the various systems; the illustrations to the descriptive part of each chapter being selected with great care and judgment, and being in most cases refreshingly new. This first part of the volume commences with the Protozoa and ends with the Vermes. With the immense advance of zoological knowledge it may be regarded as impossible that any one person can have an equal knowledge of all the groups into which the animal kingdom is now divided; and while at once acknowledging the care which has been shown in the compilation before us, one has only to study the chapters on the Plathelminthes and Vermes to find how the author's special and great knowledge of these groups has made this the most valuable portion of the present part. The Protozoa are divided into three classes—the Monera, Sarcodina, and Flagellata; among these last, such genera as Pandorina, Stephanosphæra, and Volvox are included without a hint being given that many regard them as plant forms. The Cœlenterata are divided into the Gastræadæ, Porifera, and Cnidaria, and the former class is made to include not only the Orthonectidæ and Dicyemidæ, but also the Physemaridæ. In the quoted literature on this group no reference is made to Prof. Ray Lankester's very impartial paper on a species of Haliphysema. These facts are referred to, not as criticisms on this valuable addition to an already large list of introductions to a study of the comparative anatomy of the animal kingdom, but rather as in their way indicating the standpoint from which this one has been written. The printing is excellent, and the style of the work is worthy of the house of Gustav Fischer, of Jena.

A Manual of Practical Solid Geometry. By William Gordon Ross, Major R.E. (London: Cassell and Co., Limited, 1888.)

THIS book follows in the main the lines of geometrical drawing as studied at the Royal Military Academy, Woolwich. It will be found to be a useful help to those who desire to have the power of producing accurate and workmanlike drawings. Orthographic projection of points, lines, and planes, system of vertical indices, and projection of curves and solids, are first dealt with, and are followed by simple cases of regular solids and solids of revolution, illustrated by drawings in elevation and plan. A series of solid geometry problems are next worked out on the index system, figures being drawn in the more difficult cases. Problems in connection with irregular surfaces, and relating to the defilade of works of fortification, are worked out, and also illustrated by drawings. The appendix contains a collection of examples of different kinds, and various hints and suggestions useful for draughtsmen.

Key to Lock's Elementary Trigonometry. By Henry Carr, B.A. (London: Macmillan and Co., 1889.)

THE examples given in this book are fully and clearly worked out, and in the elementary examples the author has added considerable detail to enable those reading the subject for the first time, and those who are studying it without the help of a teacher, to obtain a clear insight into the working of them. Great care seems to have been taken to insure accuracy, and from beginning to end a teacher would find it hard to add much in the way of supplementary explanation.

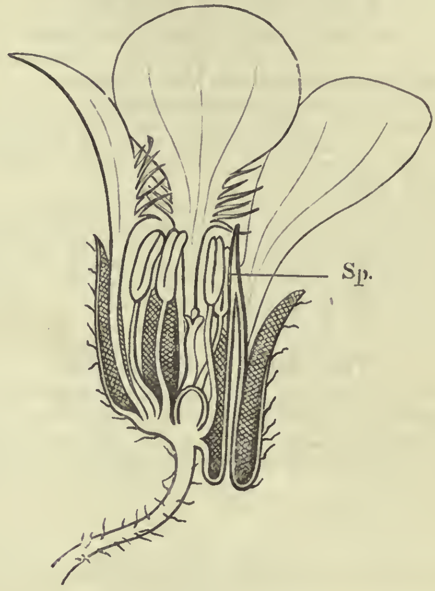
LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Abnormality in Tropæolum.

IN the early summer of last year my attention was directed to a case of abnormality in flowers of Tropæolum, which I think is sufficiently interesting and rare to be worthy of record.

I observed three distinct plants of several years' growth (in a conservatory) to be producing flowers in considerable numbers which were peculiar in having the spur either completely or partially *invaginated*, as shown in the figure.



In examples where the invagination is complete, the intruded spur occupies the exact position of the stamens, and it is a fact of some significance that it is not uncommonly double.

Flowers of the normal form were also developed, and I noticed that as the summer advanced the proportion of these increased until eventually the plants produced only flowers of the ordinary kind. They are again flowering this season, and are repeating their behaviour of last year in every detail.

I am not aware of any similar case having been recorded either in Maxwell Masters's "Vegetable Teratology" or elsewhere. The facts brought to light by the examination of numerous examples seem to me to suggest a new interpretation of the nature of the "spur" in this flower, which I purpose discussing at a later period. In the meantime I shall be very glad to hear of any similar instances either in this or any other "spurred" flowers. ALFRED DENNY.

Firth College, Sheffield, May 27.

The Structure and Distribution of Coral Reefs.

IN reply to Mr. Guppy's letter permit me to state that (owing to Captain Wharton's kindness) I had before me, when writing, the Report on the Survey of the Tizard and Macclesfield Banks. That reef-building corals occasionally grow at depths considerably greater than 25 fathoms was already known (see "Coral Reefs," second edition, p. 115, note), and Commander Moore's investigations did not appear to me to do more than confirm this. Mr. Guppy, I think, must have read his copy of the Report rather hastily, or he would hardly have failed to quote the following "suggestive remark" which occurs on p. 16:—"This fact [a living astræan at 45 fathoms] proves that the fine sand of the lagoon is not necessarily fatal to the solid reef-building astræan, and helps to explain how individual coral heads appear in the deep waters of these atolls, but it cannot be doubted that their growth is very limited. . . Coral growth is most luxuriant between 2 and 12 fathoms." T. G. BONNEY.

Atmospheric Electricity.

NOT once only, but on several occasions, I have been alarmed by the fizzing of my ice-axe in the Alps.

Twice in one neighbourhood—the Riffelberg—I have been in company with several tourists who have (as I myself) been considerably frightened.

It must be remembered that the Riffelberg and the Gorner Grat contain so much iron as to affect the compass observations of surveyors. How often may this be a determining cause?

Alpine Club, May 28. MARSHALL HALL.

Unusually Large Hail.

SOME very large hailstones fell here about 3.30 p.m. on Sunday, June 2, during a short but sharp thunder-storm. Most of them were ellipsoidal in outline; some were mammillated, and some were evidently compound, formed of several hailstones partially fused together. Ten picked up at random as being fairly large ones measured from $\frac{7}{8}$ to $1\frac{3}{4}$ inches ($\frac{7}{8}$, $\frac{7}{8}$, 1, $1\frac{1}{8}$, $1\frac{1}{8}$, $1\frac{1}{8}$, $1\frac{1}{2}$, $1\frac{1}{2}$, $1\frac{3}{4}$, $1\frac{3}{4}$ inches) in greatest diameter. Many of them were formed of four, five, or six concentric layers, which were alternately clear and snow white. Some of these hailstones lying on the grass took more than an hour and a half to melt away (temp. 65° F.)

Mr. I. C. Thompson has just drawn my attention to the residue which they leave when melted on a clean glass slide. This, when examined under a high power of the microscope, is found to contain, along with inorganic particles, a number of minute plant spores.

W. A. HERDMAN.

University College, Liverpool, June 2.

The Muybridge Photographs.

ALLOW me to state, in order to save correspondence due to the omission of a publisher's name in connection with the Muybridge photographs (NATURE, May 23, p. 78), that they may be seen and ordered of Mr. Muybridge, at 38 Craven Street, Strand, London.

E. RAY LANKESTER.

University College, London.

THE VICES OF OUR SCIENTIFIC EDUCATION.[1]

THE subject which I desire to bring to the notice of the Association to-day must necessarily remind you of the attack which was recently made on our competitive examination system in the *Nineteenth Century*.

In some respects the writers of the article, or articles, in the *Nineteenth Century*, appear to me to have right on their side when they object to the existing state of our competitive system.

They begin by complaining against the dangerous mental pressure, and the resulting physical mischief, which accompany the working of nearly all parts of our present educational system. This complaint seems to me to be just.

The fact is, in my opinion, that nearly all our examinations are much too difficult—too much beyond the mental and physical abilities of the examined.

Let me take, as a supreme instance, the examination for the Mathematical Tripos at Cambridge. Ever since I have known anything of this examination, I have wondered how it can be possible that young men, three years after leaving school, can successfully grapple with problems, a great number of which are of transcendent difficulty, in such an immense range of mathematical and physical subjects as this Tripos contains. Indeed, when we are admitted behind the scenes by reading the solutions of these problems by those who have set them, our wonder is increased; for we find frequently that the discussion of a single problem occupies four, five, or six (and sometimes more) pages of small print. Such problems have a very great value for the student who has plenty of time to consider them in the solitude of his study; but I should think that the attempt to attain the amount of knowledge and adroitness necessary to deal with them on the spur of the moment in the Senate House must often produce mental and physical injury. Are we really to believe that a young man of twenty-one or twenty-three has made himself master of nearly everything given to the scientific world by Newton, Laplace, Gauss, Jacobi, Helmholtz, Cayley, Thomson, and Clerk Maxwell?

The desire to place before a student a standard which (I suppose I am right in assuming) he can never reach is, of course, quite defensible; and it is one which appears in every educational competition. But it is not in all cases carried out with a regard for rightness of method. For, this desire to be always in advance of the student leads some examining bodies to hurry him through a large number of subjects in a short time. It is, I think, a marked characteristic of our very modern method that we require half a dozen branches of mathematics and physics to be got through in a time which, say, twenty years ago, would have been devoted to the study of two or three. Is there, for example, nearly so much time now devoted to the study of pure Geometry as there was then? Is Trigonometry so thoroughly and leisurely studied now in the schools?

With the rage which now exists for rushing students through elementary mathematics in order that they may in the shortest possible time reach physics, both experimental and mathematical, the necessary foundations of scientific knowledge are seldom properly laid. Boys who ought to be learning skill in Algebraical manipulation, in assimilating Trigonometrical formulæ, and in applying them to various problems of Mensuration, are, I find, endeavouring to limp through Statics, Hydrostatics, and Kinetics. When to these comparatively advanced subjects we add some Chemistry, the phenomena (at least) of Heat, Optics, Sound, Electricity, and Magnetism—to say nothing of languages—the result is inevitable that the less showy subjects of elementary pure Mathematics must be insufficiently studied—must, in fact, be merely skimmed.

There is no subject in which the result of this overhaste is so easily recognized as Trigonometry; for, at the outset, the student's work in this branch must largely consist in committing to memory a number of formulæ, and nothing but long-continued practice in application will fix them in the mind. Hence, as the necessary time must be given to several other subjects, I find very many students exceedingly slow in repeating, and even in recognizing, some of the most elementary and frequently useful formulæ in Trigonometry. Hence also a large portion of the knowledge brought out in competitive examinations consists of what is called "Cram," and it is, therefore, customary to heap odium on the "Crammers." I do not think, however, that the fault rests with the Crammers, who do merely what they are invited to do by educational authorities.

I shall take as an instance of the excessive haste with which students are pushed on through various branches of Science the Matriculation Examination of London University; and what I say with reference thereto is the result of a present experience which I have in assisting a young relative in his reading for this examination. In last year's Regulations for Matriculation you will find that the course of Mathematics consists of Arithmetic, Algebra as far as easy quadratic equations with questions involving their use, Geometry to the extent of the first four books of Euclid, with simple deductions; and in Mechanics the requisites are "elementary notions as to Velocity, Acceleration, Force, Mass, Momentum, Work, and Energy, Composition and Resolution of Velocities, Accelerations, and Forces in one plane. Moments and Couples in one plane. Centre of Gravity, or Mass-centre. Transmission of Pressure in Liquids; variation with depth of the pressure due to weight of liquids. Specific Gravity and modes of determining it. Pressure of gases, and laws relating thereto. Atmospheric pressure. Common instruments and apparatus whose action depends upon the pressure of liquids, or of the atmosphere, or both." In addition to this, the candidate must take up either Chemistry, or Heat and Light, or Electricity and Magnetism.

Now you will observe particularly two things about this prescribed course. Firstly, the candidate is not supposed to have any knowledge of the fifth and sixth books of Euclid, and therefore no knowledge of the propositions relating to the ratios of linear or other magnitudes; and, secondly, that all knowledge of Trigonometry is excluded.

[1] A Paper read before the Association for the Improvement of Geometrical Teaching, January 19, 1889, by Prof. Minchin, President.

What boy with this slender knowledge of pure Mathematics is likely to have a correct notion of the nature of Acceleration? And, without knowing the meaning of a sine or a tangent, to what can his knowledge of the Composition and Resolution of Forces and of the method of taking Moments amount?

A course of reading in Mechanics and Hydrostatics, specially constructed so as to avoid Trigonometry and the sixth book of Euclid, is a curious object to contemplate. It reminds one of a number of large boulders thrown out into a stream, with painfully and dangerously wide intervals between them, their tops barely above the water, to enable a man to get across by a series of courageous jumps; and, as in the case of such a traveller, not all the caution nor the acrobatic deftness of balancing on the point of one foot which he possesses will prevent him from tumbling off his flimsy and rickety supports, so in the case of the student for whom knowledge has been packed up into a number of scientific boluses, it is impossible to avoid the acquisition of erroneous notions and fallacious rule-of-thumb principles, which, assimilated thus early, have a strong tendency to remain rooted in the mind.

In the case of my young friend I found it quite impossible to impart anything that could with propriety be called a knowledge of Mechanics without the aid of Trigonometry. In the Composition and Resolution of Forces a few questions made specially to order, which usually depended on the facts that the sine and cosine of 45° are equal, and that the sine of 30° is $\frac{1}{2}$—although, of course, the mention of a sine or cosine was inadmissible—exhausted the field; and the same restrictions were imposed on the treatment of Moments, so that I was obliged to abandon the task, and to insist on a small knowledge of Trigonometry and the sixth book.

In such a cramped and stunted knowledge there is nothing of spontaneity, nothing of power, but much of danger. It is far better to give no encouragement to it, to defer the attempt to study the elements of mathematical physics until the old and well-recognized branches of elementary pure mathematics have been studied with some thoroughness.

The want of thoroughness which seems to me to be so prominently characteristic of our works on mathematical physics sometimes exhibits itself, quite unconsciously on an author's part, in a ludicrous manner. It may, perhaps, be best described as "Calculus dodging." For some curious reason, which I have never discovered, it has been generally assumed that a student can possess a very extensive knowledge of the results and principles of Dynamics—of the composition and resolution of forces and couples in three dimensions, of the principle of work and energy, of the nature and properties of tubes of force, Potential, &c.—without any knowledge of the Differential or Integral Calculus. This is, surely, a piece of self-deception. The processes of differentiation and of elementary integration are not difficult of acquirement, and it seems to me that they ought to be studied before such an extensive inroad is attempted into Dynamics. But, presuming that such knowledge is not possessed by the reader, we find the author performing such an integration, for example, as that of $\frac{dx}{x}$ between specified limits by a process which must strike an intelligent student as at once most ingenious and most unnatural. Special devices exhibited "for this occasion only" confer no independent power on the student, and, moreover, require him to possess an amount of ability which would be much better and more successfully employed in acquiring a knowledge of the principles of that Calculus which is thus evaded by artifice.

In all such cases it may be said, I think, that a student who is capable of understanding the notions involved will arrive at the results by other than the special artificial methods employed by the author; while in the case of a student for whom such methods are necessary, most probably the notions are unsuitable, and the method of proof is apt to puzzle him with what seems to be mathematical jugglery.

If more time were spent in teaching the mathematical principles on which quantitative physics depends, there would be less need for such methods, and in the long run the student of physics would be a gainer.

But, while advocating a more thorough and leisurely study of the elements of pure mathematics before the study of physics, it seems to me that many of our elementary text-books in mathematical physics make the mistake of occupying the student's attention with questions which, being far removed from physical reality, and being, in fact, merely disguised mathematics, had much better be omitted. We should make the effort to make our works on physics as physical as possible, to use Mathematics for the sake of Physics, and not *vice versâ*; and it is time to recognize that the field of physics is now so extensive as to supply subject-matter for calculation and for illustration of mathematical principles, and to permit us to curtail greatly the space which is now devoted to things comparatively useless.

Let me take one or two examples. Is anything gained by teaching students the very numerous properties of the curve which a particle would describe if it were projected with any velocity, under the influence of gravity, if the Earth had no atmosphere?

Again, let us turn to any work on Hydrostatics, and we are certain to find a very large number of mathematical trivialities. I say nothing of a number of liquids, whose densities are in some kind of progression, superposed in very fine tubes of peculiar shapes. These are harmless; but what about that notion of *whole pressure* on a curved surface—the sum of all the normal pressures, or, more strictly, the surface-integral of pressure over the curved surface?

Numerous, indeed, are the mathematical problems to which this notion gives rise; but what about the physical idea involved? It is easy to comprehend the trouble which a teacher lays in store for himself if he practises his students in the process of adding together the magnitudes of a number of forces whose lines of action are in all directions in space. And remember that, in most cases, very few students who are taught to calculate the whole pressure of a fluid on a curved surface will subsequently learn that a similar process has a physical meaning only in the case of the normal flux of Newtonian gravitation through a curved surface. Let us see, however, the physical meaning which is actually attributed to the whole pressure of a curved surface by the author of one of our very elementary text-books for students. The following is the literal statement:—"It should be observed that these pressures act in different directions, the pressure at each point being perpendicular to the surface at that point. The whole pressure is the sum of all these pressures, and represents the total strain to which the vessel containing the fluid, or the body immersed, is exposed." Now in this statement, besides the addition of the magnitudes of a number of non-co-planar forces, we have the misuse of the term *strain* and the completely unintelligible expression "total strain" of the vessel. And, in illustration of this definition, we are given the following example: "Show that if a sphere or a cube be filled with liquid, the total strain to which it is subjected is three times the weight of the liquid it contains." You will, I hope, agree with me in holding that such teaching is in the highest degree erroneous and objectionable, and that the efforts of those who have to teach should be directed against it.

So far as my observation goes, the principle making Physics a mere disguise—and a very unskilful one—for pure mathematics is much too largely adopted by writers on mathematical physics, with the result that many students receive very insufficient practice in acquiring and developing physical conceptions.

To this cause, also, must be attributed the fact that proficiency in mathematical physics is a much rarer thing than proficiency in pure mathematics, the former being made, to such a great extent, subservient to the latter. Indeed it was not, I think, until the publication of Thomson and Tait's "Natural Philosophy" that the ancient problem-grinding system, which hindered the progress of exact Physics, received a severe blow, and Cambridge, under the influence of the ideas and methods of Thomson and Clerk Maxwell, produced a plentiful supply of physicists.

But the good that was effected by Thomson and Tait is confined almost entirely to advanced students; in the hands of those of a lower standard are still to be found text-books of the old sort, teaching Mathematics under the guise of Physics, presenting nothing but the dry husks of the latter, and, by inaccurate language, laying an early foundation of erroneous notions. Some people of the older school—not a few—express, indeed, a strong impatience with us if we protest against the use of slipshod and inaccurate language in our text-books. They tell us that we are doing the matter of nomenclature to death, and that, after all, we need not be very particular about the choice of exact terms. This is a most unfortunate attitude; it is one, however, which this Association has done, and is doing, something to counteract. Surely it must be admitted that if the conceptions of Physics are presented to the beginner in erroneous language, there is a danger that in many instances these conceptions will never be properly acquired. And is not accurate language as cheap as inaccurate?

I know of several text-books still in the hands of schoolboys and others in which, in whole pages of answers to problems on the motion of a particle, *velocity* is always spoken of as so many feet, and *acceleration* also as so many feet—no reference being made to *time*, and the fact that acceleration has a double reference to time being never mentioned. I assume it as evident that the progress of such students is seriously hindered and delayed by such teaching.

If the writers of such text-books as those to which I refer have really clear and correct notions themselves, they ought to take pains to present them accurately to beginners who have to learn from them. Not to do so is to ignore the fact that a great deal of the difficulty of learning any branch of science is removed if only the student is started upon it with clear and correct notions as to the various entities with which the science deals, and with its fundamental principles expressed in accurate language.

Let us take, as another example of exceedingly erroneous teaching, the following exercise—one of a great many, all similarly expressed—from a text-book still in the hands of beginners: "The time occupied by a body in describing uniformly a complete revolution in a circle, whose radius is 11 feet, is 16 seconds, calculate the centrifugal force which acts upon it. *Ans.* 1·696 feet per second."

In this we have two bewildering errors instilled into the student's mind, viz. that *force* is measured in feet per second, and that when a body is revolving in a curve, it is acted upon by an *outward* normal force—the old time-honoured fallacy about centrifugal force. It is almost miraculous that any accurate scientific knowledge is acquired in spite of such fallacious teaching as this.

I wish to emphasize this teaching about *centrifugal force*, because, no matter how often it is condemned and shown to be erroneous, it still flourishes in our scientific text-books. In another elementary work which is extensively used, we find the nature of centrifugal force more fully explained in the following manner. "In order to keep a body moving in a circle, there must be a force acting upon it which will produce a constant acceleration towards the centre, equal to $\frac{v^2}{r}$. Hence, if W be the weight of the body, P the pressure tending towards the centre, $P = W\frac{v^2}{gr}$." This is, of course, all right; but then follows the mysterious statement, "a pressure equal and opposite to P is sometimes spoken of as the centrifugal force."

I call this a mysterious statement, because it does not tell us on what this pressure equal and opposite to P acts, or whether it really acts on anything at all or not. We know, of course, that this reversed force is the reaction of the moving particle on the agent or surrounding medium; but how is a beginner to know this? Will he not naturally fall into the error of supposing that it acts on the moving body itself? Or, if he possessed a little intelligence, would he not ask, "Why do you require me to think of a force equal *and opposite* to one which acts on the body? I have nothing to do, when considering the motion of the body, with any forces except those which act on the body itself; and why do you not ask me to consider a force equal and opposite to some of the other forces acting on the body—a force equal and opposite to its weight, for instance? It would be just as sensible to do so, since this reversed weight is the body's reaction against the Earth."

The only true reply to such a student is to confess that it is quite a mistake to introduce the conception at all; but instead of this, we find that the discussion proceeds to encourage the erroneous notion that centrifugal force acts on the moving body by taking the case of a carriage describing a curve of small radius.

Now, what is it that has given rise to this fallacy about centrifugal force? Is it the fact, so often adduced, that, if we tie a stone to one end of a string and, holding the other end in the hand, whirl it round, we feel an outward force pulling the hand? But then, if we imagine the stone to be attached to an elastic string, one end of which is tied to the hand, while the stone is projected vertically upwards, the hand would experience an *upward* pull; and are we thence to conclude that the stone is continually acted upon by an *upward* force?

Possibly the whole fallacy is traceable to D'Alembert, who gave us a sort of dynamical *memoria technica*, usually expressed in the words, "forces equal and opposite to the effective moving forces of a material system are in equilibrium with the external forces,"—a very imperfect and misleading statement for the principle obviously contained in Newton's first and second axioms, viz., "the mass-accelerations of the particles of any material system have at each instant *the same* total component along any line, and *the same* total moment round any axis as the external forces acting on the system."

D'Alembert's fictitious reversal is unnatural and unnecessary; and, in introducing fictitious forces and reducing the state of the moving material system to one of equilibrium, he ignored the actual state of affairs. He should have faced the state of motion as it exists, and recognized the fact that the production and maintaining of a given state of motion requires the action of a definite system of forces assisting the motion, instead of concentrating his attention on something which would stop the motion. It is this determination to fix the mind on a state of equilibrium, and to ignore the actual motional state that is, I think, responsible for the fallacy of centrifugal force.

[Other examples of erroneous teaching with regard to centrifugal force, the confusion of *work* with *horse power*, &c., were then given.]

We must remember, also, that a teacher who has often to correct the erroneous language of the text-book which he employs with his class is by no means certain of inspiring confidence in himself and convincing his pupils that the teaching of the author is at fault; for, young students, very unlike Prince Bismarck, have a profound respect for printer's ink; hence they are always disposed to believe that the book is right, and if you tell them that an acceleration is not so many *feet*—as the book says it is—but so many *feet per second per second*, they accept the correction for politeness or for peace sake, but not with any conviction.

In addition to numerical calculation as an important aid in the teaching of Mathematical Physics, I would also advocate the employment of *graphic methods of solution* in cases in which exact solution is not possible. The graphic method of solution is scarcely recognized at all in our text-books. Every text-book of Statics gives us, indeed, its modicum of graphic representation, which is usually exhausted in a bare and barren exposition of the principle of the *triangle of forces* and the *polygon of forces*, which has long since become stale "book-work."

But this is by no means what I advocate. I intend graphic solution at once as an aid to calculation, as a means of strengthening the student's interest in the subject, and as a representation to the eye of the possibilities and limitations of any particular problem under discussion.

[The problem of the equilibrium of a camp-stool was then given as an illustration of the graphic method.]

In Statics and Hydrostatics we have abundant instances of this kind, and their solutions by the graphic method furnish excellent practice for the ingenuity of the student, giving to each problem the interest which a vivid picture always gives, as well as strengthening his knowledge of the results and methods of pure Mathematics.

The sum total, then, of what I have said with reference to our elementary text-books comes to this—that, while we are abundantly supplied with high-class scientific works of an advanced character, a corresponding improvement has not generally taken place in the books from which school-boys and other beginners have to learn; that these books are often marred, not only by inaccurate language and fallacious teaching, but by a certain scrappiness in their mode of treatment which is encouraged by the desire of examining bodies to hurry through and skim over a large number of scientific subjects at the expense of a more leisurely study of the foundations of Science.

I should like, in conclusion, to say a few words with regard to the way in which the cramming of Science is encouraged by examinations.

Wherever well-worn book-work is set at an Examination, it is extremely likely that cram will find its opportunity, and it may be impossible for an examiner to detect it. Assuming that book-work must be set, I do not know of any reliable safeguard against cramming except *vivâ voce* examination. But a *vivâ voce* examination which is made a part of the competition, and in which the candidates do not all get the same questions, is, I think, essentially unfair. Whenever such an examination is possible, its function should be to discuss with each candidate the several questions with which the written paper deals. In this way, when his knowledge of any particular question or method appears to the examiner of the written paper to be doubtful, the doubt is very speedily settled one way or the other. But, in the absence of such a corrective, an examiner who is, after all, dissatisfied with the candidate's working of any particular question, and yet disinclined to allow him no credit whatever, is obliged to resort (at least in many instances) to some systematic method of cutting off marks, and this method is not infrequently a system of elaborate trifling.

As a particular example, take a question which is sometimes set at examinations in Science—the method of determining H, the horizontal intensity of the Earth's magnetic force. A part of the process consists in the discussion of the vibrations of a uniform magnet bar round a vertical axis under the influence of the horizontal magnetic force. Such a bar is a compound pendulum, and its motion involves a knowledge of its moment of inertia and the integration of a differential equation of the second order. If at any instant θ is the angle made by the axis of the bar with the magnetic meridian, the expression $\frac{d^2\theta}{dt^2}$ is involved in the equation.

Now, I know a case in which the whole of this process was crammed up by a candidate who, although he had a good practical knowledge of Physics, did not know how to resolve a force along a line, did not know the meaning of the moment of a force about an axis or of the moment of inertia of a body about an axis, and, of course, was wholly ignorant of the meaning of the expression $\frac{d^2\theta}{dt^2}$. Indeed, this last was a puzzle to him, for he always failed to place the two figures "2" in their proper places. Yet the whole thing was crammed up with sufficient success to obtain credit for the question.

In such a case as this an examiner may have very grave suspicions, but he may be obliged to give a large measure of credit, nevertheless. Frequently the method of marking such an answer is something like this—the expression $\frac{d^2\theta}{dt^2}$ involves two *d*'s, two 2's, a *t*, and a θ; if the candidate uses all these symbols, each in its proper place, give him full marks; if he uses all the symbols, but *one* is misplaced, take off *one* mark; if *two* are misplaced, take off *two* marks; and so on. This is of course an exaggeration, but it is the *kind* of system adopted—necessary, perhaps, but extremely unsatisfactory.

Now a *vivâ voce* examination of the candidate on this question would, in a few seconds, have decided his mark to be *zero*.

In cases in which the number of candidates is very large, it would seem to be impossible to apply a *vivâ voce* test; but there are cases in which it could be used, and used, I have no doubt, with good effect.

The setting of book-work at examinations is, I think, much too frequent. It gives a hope of success to candidates who really have no vocation for a subject, but who load their memories sometimes with whole pages of work of which they understand almost nothing.

Our examination system has its defects; but these defects are almost wholly due to the shortcomings either of individual examiners or of the directors of education.

I have spoken of the excessive haste with which educating bodies compel students to attempt the acquisition of a large and varied assortment of knowledge; but I must not omit to add that the evils of examination are greatly aggravated by the prodigious haste which is imposed on examiners themselves in some public competitions. Nothing can justify a system which requires an examiner to read over and determine the numerical value of every one of 1200 papers in little more than a fortnight. The thing is utterly impossible, and the results must be untrustworthy.

But, whatever the defects of the examination system may be, I hold that the *principle* of examination is good.

[Some of the objections of the writers in the *Nineteenth Century* were then dealt with in detail. Referring to the unsatisfactory method by which professors and lecturers are now appointed, Prof. Minchin continued:—]

Mr. Frederic Harrison says, "Trust the teacher; trust him to teach, trust him to examine;" and I should say that, if we did, we should find our trust far more often misplaced than it would be by trusting wholly to the independent examiner. If the teachers were always people who could teach, the case would be different; but what is the method of appointing teachers, as a rule, in England? People make inquiries as to what scholarships, prizes, and degrees, have been obtained at the University by a candidate for a teaching post; but of his capacity for imparting successfully any of his own knowledge to others there does not, in most instances, exist the slightest proof; and hence we are often presented with such lamentable teaching failures. Under these circumstances it would be ridiculous to "trust the teacher, trust him to teach, trust him to examine;" for, bad as examiners are, teachers are worse—partly for the same reason as that for which white sheep eat more than black, viz. that there are more of them.

And is it not also vain to attempt to replace the Examination system, even at the Universities, by a system of Thesis writing on some particular subject selected by the candidate, the Thesis being written by him at home, with ample opportunity for composing it out of works of reference, or with the assistance of his friends, with the addition of a small make-believe of "original research?"

We are told by one of the writers in the *Nineteenth Century* that, under our Examination system, England is losing her intellectual giants, men who are a head and shoulders above their contemporaries; but I ask is the writer aware that we have still among us Sir William Thomson, and that we have only recently lost Clerk Maxwell? People who speak thus seem to think that we are to expect a crop of intellectual giants to sprout up like a crop of mushrooms, and to be ready whenever we want them.

I would say in conclusion—let us retain Examinations, make them tests of a knowledge of the applications of principles, so that they will be real tests of intelligence, and not of cram; do not make them so difficult and so high-flown as they often are; and, finally, do not encourage the hurrying and skimming through a large number of different subjects, but make sure of the foundations by a more thorough and leisurely system of study.

THE LIFE-HISTORY OF A MARINE FOOD-FISH.[1]

I.

It is but a few years since the life-history of our most important marine food-fishes was involved in considerable obscurity—not only as regards popular views, but even in respect to the knowledge of men of science. Thus, for instance, in the years 1883 and 1884 the almost unanimous opinion of British fishermen was that our common food-fishes sought the shallow water of the bays and inshore ground generally for the purpose of depositing their eggs on the bottom. No observations specially bearing on this point had been made by British zoologists, and a series had to be undertaken for a public inquiry then in progress—with a result which demonstrated how extensive the reverse of the popular notion was. Again, certain comparatively recent authors on British fishes speak of a common fish like the gurnard as spawning twice a year, whereas, after careful observation, no evidence in support of this view has been obtained. The same obscurity veiled the larval and post-larval conditions of most of the food-fishes, even G. O. Sars—in regard to the latter stage—describing no intermediate forms between the larva of 6 mm. and the post-larval stage of 24 mm. in the cod, almost the only fish to which some attention had been paid.

On the other hand, our knowledge of the development and life-history of the fresh-water fishes—such as the salmon, trout, and charr—has for many years been well understood—thanks to the labours of Louis Agassiz and Vogt in Switzerland, Coste and Lereboullet in France, Ransom in England, and Shaw in Scotland, on the scientific side, and of the noblemen and gentlemen of Perthshire (ably seconded by Robert Buist) in connection with Stormont Field Ponds on the Tay, on the popular side. Much information has also been recently obtained by Dr. Day and Sir J. Gibson Maitland at the excellent ponds of the latter at Howietoun.

[1] A Discourse delivered by Prof. W. C. McIntosh, F.R.S., at the Royal Institution, on Friday, February 1, 1889.

A short time ago, relying on experience derived from fresh-water fishes, not a few imagined the eggs of marine fishes as readily visible and tangible objects—possibly associated in their minds with certain practices in trout-fishing, or it may be with the manufacture of caviare. Recent investigations, however, have shown that in most marine food-fishes the eggs are minute glassy spheres which float freely in the ocean. For a knowledge of this fact we are indebted in the first instance to Prof. G. O. Sars, of Christiania, a naturalist trained from boyhood under a distinguished father, and who, by a fortunate appointment to a fishery post in Norway, was enabled to discover that the eggs of the cod, haddock, and gurnard, floated in the water, or, as we term it, were pelagic. He thus opened up a new field in the economy of the food-fishes, which in a great maritime country like ours ought not to have remained so long unexplored.

Lately, however, attention has been earnestly directed to the subject, and the labours of Cunningham, Brook, Prince, and others have made considerable advances in this department.

It is now known that the great majority of our British marine food-fishes—indeed, all our most valuable kinds (including even the sprat and the pilchard amongst the Clupeoids) produce minute eggs—as transparent as crystal, and which float freely throughout the water. These eggs, moreover, are not all shed at once, as in the case of the

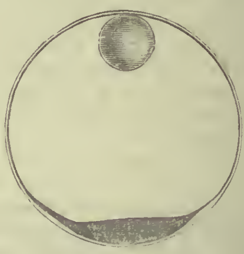


Fig. 1.[1]—Pelagic egg of the ling (enlarged).

salmon, but successive portions of the ovary become ripe, and the eggs then issue externally. If by any accident or irregularity—as for instance the confinement of a flounder in an unhealthy tank—this gradational issue is interfered with, the animal dies from the great distention of the body caused by the pent-up eggs. In the case of the cod this gradual issue of the eggs continues probably for a week or two, so that the progeny of a single fish in one season may vary considerably in size.

From the early months of the year onward to late autumn the sea off our shores thus abounds with pelagic eggs, those of the rockling, haddock, and sprat being amongst the earlier forms, while the later include those of the sole. As indicated in the Trawling Report, and now supported by further experience, it would be a very difficult matter indeed to arrange for a close time in the sea—that is to say, for a limited period during which the mature fishes might be permitted to spawn in peace. This, however, in the case of individual species, such as the cod, might more readily be carried out, so as to save the mature fishes at the spawning period.

In a vessel of still sea-water these transparent glassy spheres rise at once on issuing from the fish, and form a stratum on the surface. Even the ripe portions of ovaries removed from the rejected viscera on a pier will show the same features, and thus, indeed, they first came before the lamented Lord Dalhousie at Anstruther. In the sea, however, they are seldom met with on the surface, and the tow-nets require to be sunk a fathom or two for their capture, their specific gravity being so little less than that of sea-water that they are carried hither and thither by the

[1] I am indebted to Mr. E. E. Prince, B.A., for kindly aiding me with sketches for the woodcuts. The sketch of *Motella* is by Dr. Scharff.

currents in every direction. Some indeed are captured near the bottom by nets attached to the trawl-beam, while experience with the large net of the St. Andrews Laboratory has proved that a great number are carried in mid-water.

When these glassy eggs issue from the female fish, they are soon fertilized in the surrounding water; so that in British waters, at any rate, non-fertilization is one of the rarest conditions in these pelagic eggs. It is indeed more likely to happen in the case of the herring, which deposits its eggs in masses on the bottom, or in artificial circumstances in tanks. The unfertilized egg soon becomes opaque and sinks, so that it is readily recognized.

In this connection I would again refer to the notion not long ago firmly rooted in the minds of many—especially those practically engaged in fishing—that the fishes at the spawning season seek the shallow water in which to deposit their eggs. Now there is little in Nature to support this idea. Shore-fishes, it is true, such as the lump-sucker and sea-scorpion (*Cottus scorpius*), do deposit their eggs there (and there cannot be a doubt that some of the masses of eggs thus deposited have been mistaken for those of the food-fishes); but the edible fishes proper, such as the cod, haddock, whiting, flounders, and others, appear to produce their eggs just where they happen to be feeding at the season. Their eggs are taken in charge by the ocean generally, and hence are independent of any imaginary protection or privilege pertaining to the shallow waters.

Moreover it does not follow that the fishes of an inclosed bay[1] will increase of themselves. As in the case of the plaice, in shallow sandy bays, it may happen that most of the large mature female fishes are beyond the limits, the half-grown or immature forms mainly occurring within; pelagic ova therefore must be borne inward, and still more the pelagic young, while the post-larval stages likewise migrate shorewards; a counter-migration of the older forms subsequently taking place to the deeper water. Such bays, therefore, have to depend for their stock of fishes on the unprotected off shore. If by any chance the latter waters were depopulated, the inshore would seriously suffer.[2]

The minute size of the eggs of all the important marine food-fishes enables a fish like the cod, for instance, to produce an enormous number—probably about 9,000,000, as against the 18,000 to 25,000 of the salmon or the 10,000 to 30,000 of the herring, both of which fishes deposit their eggs on the bottom. In the same way the very small eggs of the dab provide for a large annual increase of the species.

The translucent eggs, which, unless they contain a globule of oil, as in Fig. 1, are difficult to see in some instances even in a glass vessel, thus escape (by floating throughout the water) the vicissitudes to which a purely surface-life would expose them, such as the admixture of the surface-water with rain, and the attacks of gulls, ducks, and other forms; and they also are less at the mercy of the active predatory races living on the bottom, not to allude to the risks of being swept by storms on the beach or captured and destroyed by the ground-rope of the trawler. Nature, indeed, could have devised no method more secure than this for the safe propagation of those valuable fishes which for ages have peopled our waters, and I venture to say, with Prof. Huxley, will perhaps people them for ages yet to come, notwithstanding the persistent efforts of man to annihilate them.

Some good observers, for example Prof. Ryder in America, have attached much importance to the oil-globule in eggs which are pelagic, but its buoyant influence has been slightly over-estimated, for some contain no oil-globule, while the massive oil-globules in the eggs of the salmon and cat-fish have no such effect. They float, as well shown by my friend Mr. Edward E. Prince, Secretary to the Mussel and Bait Committee, solely in virtue of their specific gravity, which is somewhat less than that of sea-water. The moment fresh-water is added they sink, as they likewise often do when transferred from a vessel filled at sea into one containing shore-water.

[1] For example, closed by a Fishery Order.

[2] This feature was pointed out in the Report of H.M. Trawling Commission, under Lord Dalhousie.

While immediately after deposition these minute spheres are prone to accident from impurity and sudden changes in the temperature of the water, such would not seem to be the case after development has made some progress. Thus many living eggs will be found in odoriferous vessels brought from sea by the fishermen if the inclosed embryos have reached an advanced stage. Again, while carrying out some experiments on temperature (at the suggestion of Prof. Huxley) during the trawling expeditions, I had occasion to heat a test-tube containing some of the eggs of the flounder, so as to make them rush up and down the vessel most actively. Considerable heat was applied, and, under the impression that the eggs were irretrievably injured, the tube was set aside. Some days afterwards, when explaining the nature of the experiment to Prof. Ewart, he noticed motion in the tube, and further examination showed that after all this exposure to heat the little flounders had emerged as usual, and were alternately floating and swimming about in the water. On the other hand, severe frosts are fatal to ova crowded in shallow vessels, in many cases actual rupture taking place;[1] and the same occurs in large eggs, for example those of the cat-fish deposited on the bottom of the vessel.

Out of the little glassy sphere, after a longer or shorter interval (varying from a few days to a few weeks, according to temperature), comes a minute and nearly transparent fish which at first is often as passive in the currents as the eggs themselves.[2] It soon, however, uses its tail for swimming and its pectoral fins for balancing. Its shape

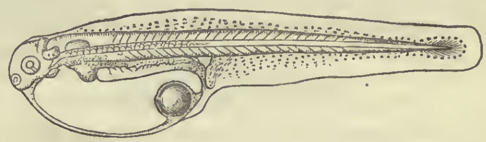

FIG. 2.—Larval ling immediately after hatching.

is somewhat like that of a tadpole, partly from the large head, but mainly from the great size of the yolk-sac, which contains a store of nourishment on which the little mouthless creature, about 3 mm. long, sustains itself for a week or ten days. In this respect it somewhat resembles the young salmon, in which a much larger collection of the same food supports it for about six weeks amongst the gravel in the spawning-bed of the river, though a closer scrutiny reveals certain essential differences. Thus the store of nourishment in the yolk-sac of the salmon is taken up by the blood-vessels which branch in a complex manner over the whole yolk, whereas in the young cod, though the heart is present and pulsating, not a blood-vessel at first is seen, and none ever enters the yolk-sac. The absorption of this nourishment therefore must take place by aid of the cells and tissues themselves, and there is nothing specially wonderful in this, when the condition in the endoderm of *Hydra* and other instances of intracellular digestion are considered.

It has been mentioned that these minute and most delicate little fishes are nearly transparent, and this is more or less the case throughout, though in the majority—even before they leave the egg—points of pigment appear here and there in the skin, so as to give them a distinctive character. After hatching, these pigment-spots branch out in a stellate manner, thus becoming more evident, and it is found that in most cases each little food-fish has

[1] NATURE, June 1886.

[2] For some years the development of fishes has been studied by able workers: amongst others, on the Continent, by Götte, Kupffer, Hoffman, Henneguy, E. Van Beneden, Osjannikov, and Rafaele; in America, by Alex. Agassiz, Ryder, and Whitman; while in our own country, Ransom, Klein, Cunningham, Prince, and Brook have carried out similar researches.

colours of its own. Thus the cod is known by its four somewhat regular black bands, the pigment on the haddock being less defined, the whiting by its canary-yellowish hue, the gurnard by its chrome-yellow, the ling by its gamboge-yellow, the flounder by its yellow and black, and

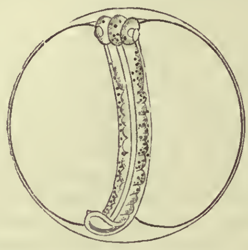

FIG. 3.—Flounder showing pigment *in ovo*.

so on. All these hues, however, become greatly modified during subsequent development; indeed, the pigment in no group of vertebrates shows more remarkable changes between the young and adult states than certain of our food-fishes. Thus for instance the cod is characteristically

FIG. 4.—Larval cod with black spots or bands.

speckled in its tiny youth (Fig. 4), next it becomes more or less uniformly tinted, then the pigment groups itself somewhat irregularly on the sides (Fig. 5); thereafter it is boldly tessellated, subsequently blotched with reddish-

FIG. 5.—Aggregations of pigment in post-larval cod.

brown, and finally in its adult condition it again puts on more or less uniform tints. The ling shows a similar series of transformations, the colours, however, differing in their arrangement, being marked with gamboge-

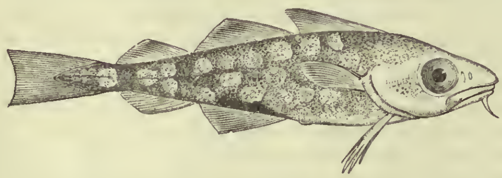

FIG. 6.—Tessellated condition of young cod (spirit-preparation).

yellow in its larval, slightly banded in its early post-larval stage, then the body becomes more or less uniformly tinted in its post-larval phase, and the little fish is furnished with a pair of enormously developed and bright yellow

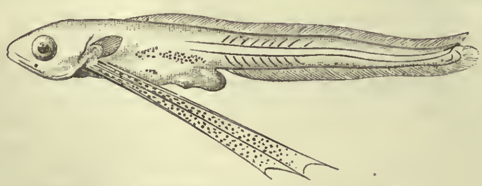

FIG. 7.—Long-finned post-larval ling (enlarged).

ventral fins (Fig. 7)—so different from the short ones of the adult. It is next striped conspicuously when about 3 inches long (Fig. 8), thus affording a great contrast to the tessellated condition of the young cod. In this stage an olive-brown band passes from the tip of the snout in a line with the middle of the eye, straight backward to the base of the caudal fin-rays. The pale ventral surface bounds it inferiorly, while a dorsal stripe with a beautiful opaline lustre runs from the tip of the snout, over the upper part of each eye to the tail, on which it is opaque white, thus giving the fish a characteristic appearance. The dorsal line from the brain backward is distinguished by a narrow edge of dull orange or pale olive, which relieves the colours formerly mentioned, and the general effect is varied by two black specks in the dorsals. When it is double the length (*i.e.* 6 or 7 inches), a complete

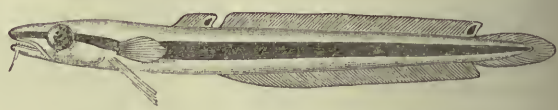

FIG. 8.—Young ling about 3 inches long (in spirit).

change has taken place in its coloration (Fig. 9). Instead of being striped, the fish is now boldly and irregularly blotched—both dorsally and laterally, the region of the white stripe being indicated by the pale and somewhat scalloped area dividing the dorsal from the lateral blotches. Fourteen or fifteen brownish blotches occur between the pectorals and the base of the tail, and they are separated by the whitish areas, which thus assume a reticulated appearance, and both kinds of pigment invade the dorsal fins. Other touches of dark pigment on the fins and tail increase the complexity of the coloration at this stage.

FIG. 9.—Young ling in the barred stage (about half natural size).

Again, some species, like the gurnard, have pigment over the yolk-sac before they are hatched, others have not. The dragonet in its post-larval (and pelagic) stage has its ventral surface deeply tinted with black pigment, while in the adult (a ground-loving fish) it is white. The St. Andrews cross in the eye of the post-larval four-horned Cottus (*C. quadricornis*) is another remarkable feature (Fig. 10). No more interesting or more novel field, indeed, than this exists in the whole range of zoology; but the investigations need ships and boats, with expensive appliances, as well as persevering work for several seasons. We have only been able to open the field at

FIG. 10.—Head of *Cottus quadricornis*, with St. Andrews cross in eyes.

St. Andrews by the help of the Trawling Commission under Lord Dalhousie, and subsequently by the aid of the Fishery Board. It may be asked, Why is all this remarkable variation in colour? Just for the same reason that the young tapirs and wild pigs are striped, or the young red deer spotted—the adults in each case being uniformly tinted. Such features indicate their genetic relation with ancestral forms having these marks; and, moreover, in the struggle for existence, such variations in tint conduce to the safety of the young.

The view of Eimer that the markings in animals are primitively longitudinal would not suit for many fishes, notably for the young cod, ling, and Pleuronectids, and, indeed, Haacke has already pointed this out from a study of the Australian fish *Helotes scotus*,[1] the adult of which is marked by eight longitudinal bands, while young specimens present in addition a row of clear transverse bands which subsequently disappear.

(*To be continued.*)

[1] One of the Pristipomatidæ.

NOTES.

On account of the severe illness of his child, Prof. Mendeleeff was obliged to leave London early on Tuesday morning, very greatly to the regret of those who assembled in the evening to hear him deliver the Faraday Lecture, which was read by the Secretary. It was announced that the dinner, at which the Fellows of the Chemical Society proposed to entertain Prof. Mendeleeff on Wednesday evening, would not take place, but that the President, Dr. Russell, and Miss Russell would receive at the Grosvenor Gallery on Friday evening, as before arranged.

The Ladies' *Conversazione* of the Royal Society will be held on Wednesday, June 19.

The *conversazione* of the Society of Arts will take place at the South Kensington Museum on Friday, June 28.

It has been decided that a statue shall be erected in honour of the late John Ericsson in Stockholm. His biography, papers, and letters will be edited by one of his most intimate friends, Colonel Church, of the American *Army and Navy Journal*.

Dr. George Owen Rees, F.R.S., died at Mayfield, Watford, Herts, on May 27. Dr. Rees took his degree of M.D. at Glasgow in 1837, and became a Fellow of the Royal Society in 1843.

It is requested that all persons having in their possession letters from the late President of Columbia College, Frederick A. P. Barnard, will be kind enough to send them to Prof. Nicholas Murray Butler, Columbia College, New York, U.S.A., at their early convenience. The letters will be returned after copies have been made.

Sir Lyon Playfair, who recently resigned the secretaryship of the Royal Commission of the Exhibition of 1851, has been succeeded by Major-General Ellis, Equerry to the Prince of Wales.

Allen's Indian Mail reports that Dr. Burgess, Director of the Archæological Survey of India, will come home immediately, and that he is retiring from his appointment.

The foundation-stone of the Framjee Dinshaw Petit Laboratory of Scientific Research, in Bombay, was laid on April 8 by Lord Reay. Mr. Petit, the son of the donor, explained that it had appeared to his father desirable, in the interests of medical education, that a laboratory for scientific research in biological and physical sciences should be established. He had long cherished the wish to have the properties of Indian drugs investigated, and made known to medical students. The laboratory, which will be connected with the Grant Medical College, was described by Lord Reay as the only missing link in the educational programme he had sketched out for Bombay.

The Allan Line steamer *Caspian*, which arrived from Halifax at Queenstown on Tuesday evening, reported having passed in the North Atlantic no fewer than thirteen large icebergs. The ship steamed quite close to one of them on Thursday last.

We are glad to be able to report the publication of synoptic weather maps twice a day by the Central Physical Observatory at St. Petersburg, beginning with May 12. The stations for which information is given extend from the west of Ireland to the Ural Mountains and the western shores of the Caspian, and from the north of Norway to the Trans-Caucasus, showing the weather-conditions at a glance, over nearly the whole of Europe. The atmospheric pressure is represented by isobars, and other elements by figures and symbols; the charts being printed on the back of the tabular reports, which have been issued since 1872. A general summary of the weather is given in Russian and French.

We print elsewhere a letter by Prof. Herdman on unusually large hailstones which fell at Liverpool on June 2. A correspondent writes to us from Rock Ferry about the same hailstones. "Five minutes after they fell," says our correspondent, "when the rain had subsided, I examined some. They were then all quite transparent outside, and had a spherical opaque centre surrounded by concentric rings alternately transparent and opaque. Some were flat: the largest I picked up measured one inch by three-quarters of an inch, and a quarter of an inch thick; its edge was very irregular. Others were more spherical in general form, but some still had rhombohedral faces very well defined. It was half an hour before all were melted."

On April 30, about 7 a.m., an earthquake was felt at Sokendal, in Dalerne, on the west coast of Norway. It was accompanied by a rumbling noise like distant thunder, going from east to west. The weather was clear and the wind north-west.

Serious efforts are being made to establish a great National Home-reading Circle Union, and we are glad to learn that they are likely to be successful. One object of the Union will be to publish courses of reading for three classes of readers—young persons, artisans, and general readers. The various courses will be approved by experts, and so planned as to interest and liberalize the mind as well as to convey useful information. Local circles will be formed under suitable leaders, and encouraged to meet frequently for the discussion of the subjects they have been studying. In many different ways the Union will try to aid the readers, and there can be little doubt that the scheme will be of real service to a very large number of persons who have often felt the need of guidance in their attempts at intellectual work. In all the courses science will receive the place which properly belongs to it, but adequate attention will also be given to literature and history.

Does the cuckoo ever hatch its own eggs? Herr Adolf Müller answers this question in the affirmative, and has given in the *Gartenlaube* a full account of a case which he himself claims to have observed. A translation of this account has appeared in the *Ibis*, and is reproduced in the new number of the *Zoologist*. The latter periodical prints also a translation of an article in which Herr Adolf Walter disputes the statements of Dr. Müller, who, he thinks, must have made a mistake. The same subject is dealt with in the June number of the *Selborne Magazine* by Mr. C. Roberts, who quotes from "Zoonomia" an interesting passage, in which Dr. Erasmus Darwin expresses his belief that the cuckoo sometimes makes a nest and hatches its own young. In this passage Dr. Darwin gives an extract from a letter of the Rev. Mr. Wilmot, of Morley, near Derby, describing an instance brought to Mr. Wilmot's notice in July 1792 by one of his labourers, and afterwards closely watched by Mr. Wilmot himself. Mr. Wilmot was confident that the bird was a cuckoo, but this is a point about which most ornithologists would no doubt like to have a little more evidence.

Everyone who takes the slightest interest in natural history will be sorry to learn that the kangaroo is in danger of being extinguished. Its skin is so valuable that large numbers of young kangaroos are killed, and high authorities are of opinion that, unless the process is stopped, Australians will soon have seen the last specimen of this interesting animal. Mr. R. G. Salomon, one of the largest tanners in the United States, whither kangaroo-skin is chiefly sent, urges that a fine should be imposed for the killing of any kangaroo whose skin weighs less than ten-twelfths of a pound; and, from a note on the subject in the *Zoologist*, by Mr. A. F. Robin, of Adelaide, we are glad to see that a serious attempt is being made to secure the enforcement of this restriction throughout Australia and Tasmania, and the proclamation of a close season between January 1 and May 1. We must hope that the Australian Legislatures will understand the necessity of taking speedy action in this matter. It would be scandalous if, in deference to the wishes of a few greedy traders, they were to allow Australia to lose the most famous and most interesting of its characteristic fauna.

AT the concluding meeting of the thirty-first session of the Geological Society of Glasgow, which was held last week, Mr. John Young read a paper on "The Occurrence of Spines within Spines on the Shells of the Carboniferous Productidæ." He said that, though long familiar with the spines themselves, it was only recently he had discovered the peculiar structure he was about to describe. He pointed out that the spines of the Productidæ were tubular, and referred to the varied opinions expressed by those palæontologists who had previously taken up the group for investigation respecting the functions of these spines. Mr. Young said he had now discovered that within the tubes of the spines, of at least four species, there existed a barrier of small spines of microscopic size placed in the tubes just above the junction of the spines with the shell itself. These small spines were planted deeply within the walls of the large spines, and radiated to the centre of the tubes, varying from twenty to forty or more in number. He was inclined to believe that the detection of these minute spines favours the view held by De Verneuil, that the spines themselves conveyed water to the interior of the shell. In illustration of his paper, Mr. Young exhibited under the Society's microscope several beautifully prepared slides showing the presence and arrangement of these remarkable "spines within spines."

A SERIES of new aromatic compounds of bismuth have been prepared by Drs. Michaelis and Marquardt. The first member of the series, bismuth triphenyl, $Bi(C_6H_5)_3$, is a solid, crystallizing in two distinct forms of the monoclinic system, thus forming an example of dimorphism in the same system. In order to obtain it a quantity of the sodium-bismuth alloy is first prepared by melting 500 grammes of bismuth in a Hessian crucible and gradually adding 50 grammes of sodium in small pieces. The resulting hard alloy is then powdered in a warmed metallic mortar, and heated for two days to 160° C. in an oil bath with an equal weight of brom-benzene, C_6H_5Br, a little acetic ether being from time to time added. The filtered product is afterwards distilled until benzene ceases to pass over; water is then added, and the excess of brom-benzene distilled off in steam, the bismuth triphenyl remaining behind unaltered. The cooled residue in the distilling flask is next extracted with chloroform, the chloroform solution separated and dried over calcium chloride. After removal of the greater part of the chloroform by distillation, the bismuth triphenyl is thrown out of solution, by addition of absolute alcohol, as a brown oil. On standing the oil soon crystallizes, and on recrystallization from a mixture of alcohol and chloroform the bismuth triphenyl is obtained in beautiful long colourless monoclinic prisms of brilliant lustre. The prism angle of these crystals is 109° 40′, and the plane of the optic axes is perpendicular to the plane of symmetry. On the other hand, if pure warm alcohol be employed as the solvent, the crystals are found to be quite different, being tabular in habit, but still belonging to the monoclinic system. The principal prism angle is much less than that of the other form, being 100° 23′, and the plane of the optic axes is parallel to the plane of symmetry. No difference of composition could be detected, but the melting-point of the prismatic variety was found to be 78°, while that of the tabular form was 75°. Both varieties are converted by concentrated hydrochloric acid to benzene and bismuth trichloride—

$$Bi(C_6H_5)_3 + 3HCl = 3C_6H_6 + BiCl_3.$$

In a similar manner two higher homologues of the series, bismuth tritolyl, $Bi(C_6H_4 . CH_3)_3$, and bismuth trixylyl, $Bi[C_6H_3 . (CH_3)_2]_3$, were obtained by heating the bismuth sodium alloy with brom-toluene and brom-xylene respectively. Both form good crystals, but no dimorphism was observed. Perhaps the most important property of the compounds is their affinity for chlorine or bromine, for by direct addition they take up two atoms of either halogen, with production of compounds in which bismuth assumes its full pentad atomicity, thus supplying an additional proof of the similarity of bismuth to antimony, arsenic, phosphorus, and nitrogen. For instance, bismuth triphenyl forms $Bi(C_6H_5)_3Cl_2$ and $Bi(C_6H_5)_3Br_2$, the tolyl and xylyl compounds acting precisely analogously. Not only is this the case, but with nitric acid they form dinitrates of the type $Bi(C_6H_5)_3(NO_3)_2$, neutralizing two equivalents of the acid. It is interesting to note that the preparation of these aromatic compounds of bismuth completes a wider series, for the preparation of which we are mainly indebted to Dr. Michaelis and his assistants, as we are now acquainted with analogous compounds of antimony, arsenic, phosphorus, and nitrogen.

A VIPER and a lizard in spirit were lately sent, for examination, to the British Museum by Mr. R. H. Ramsbotham, Waterside, Todmorden, with the following remarks:—"This adder was caught at Trowbers Warren, Sussex, on April 24, 1889, about noon. It was kept in this bottle without spirit till the following morning, between nine and ten, when the bottle was filled. Immediately after this was done, the lizard (which is still in the bottle, and has not been touched) crawled out of the snake's mouth, and was quite lively for a short time." Commenting in the *Zoologist* on this statement, Mr. G. A. Boulenger points out that it includes three facts well worthy of record: (1) that vipers do occasionally swallow lizards, although their food normally consists of small rodents; (2) that in this instance the snake did not avail itself of its poison-apparatus in seizing its prey; (3) that a lizard retained life for nearly twenty-four hours in the gullet of a viper. The lizard is an adult female, *Lacerta vivipara*.

AMONG the contents of the new number of the Journal of the Anthropological Institute is an interesting paper, by Mr. T. W. Shore, on the distribution and density of the old British population of Hampshire. Miss Buckland has an instructive paper on the monument known as King Orry's grave, in the Isle of Man, compared with tumuli in Gloucestershire. There are also valuable papers on Australian message sticks and messengers, by Mr. A. W. Howitt; on social regulations in Melanesia, by the Rev. R. H. Codrington; and on the Nicobar islanders, by Mr. E. H. Man. The number contains Mr. Galton's Presidential address, which our readers have already had an opportunity of studying.

THE "Medical Register" and the "Dentists' Register," for 1889, have been issued. Both are published under the direction of the General Council of Medical Education and Registration of the United Kingdom.

THE Cambridge University Press has issued a second edition of Mr. M. M. Pattison Muir's "Treatise on the Principles of Chemistry." In the preface, Mr. Muir states that the whole has been thoroughly revised, and that Book II., dealing with chemical kinetics, has been entirely re-written.

MESSRS. LONGMANS AND CO. announce as nearly ready, "Physical and Chemical Studies in Rock-Metamorphism, based on the Thesis written for the D.Sc. Degree in the University of

London, 1888," by the Rev. A. Irving, D.Sc. Lond., Senior Science Master at Wellington College. The same publishers have in preparation seven new volumes of their "Elementary Science Manuals."

THE Smithsonian Institution has published a new edition of Mr. Frank Wigglesworth Clarke's "Tables of Specific Gravity for Solids and Liquids." It is, in effect, a new edition of Part I. of the work called "The Constants of Nature." The tables in this "part" have been revised, rearranged, and as nearly as possible brought up to date. The work is issued in England by Messrs. Macmillan and Co.

THE Abbé Armand David, whose writings on the natural history of China are well known in France, is contributing a series of articles to *Les Missions Catholiques* of Lyons on the fauna of China. In the last issue of that journal he completed the papers on Carnivora.

THE *Publishers' Circular* states that a work entitled "The Ice Age of North America, and its Bearings on the Antiquity of Man," by Prof. G. F. Wright, is announced for early publication by Messrs. Appleton and Co., of New York. It will be amply illustrated from photographs taken by various members of the United States Geological Survey during the past ten years.

A WORK on the Island of Saghalin and its vertebrate fauna, by Dr. Nikolsky, has just been published. The author, a native of Astrakhan, is well acquainted with the fauna of the Altai and West Turkestan, and is known as the writer of an interesting work on the fauna of Lake Balkhash. In his new book he has utilized, besides his own collections, the very rich collections formed by the late M. Polakoff.

MR. W. P. COLLINS has issued a catalogue of works on *Cryptogamia*. He claims to possess a more complete set of books on Diatoms than have ever been advertised in a bookseller's catalogue.

WE have received vol. iii., Part 4 (second series), of the Proceedings of the Linnean Society of New South Wales. It contains the following papers:—Revision of the genus *Heteronyx*, with descriptions of new species, Part 1, by the Rev. T. Blackburn; Diptera of Australia—Part 4, the Simulidæ and Bibionidæ, by Frederick A. A. Skuse (Plate xxxix.); further notes on Australian Coleoptera, with descriptions of new genera and species, by the Rev. T. Blackburn; contributions towards a knowledge of the Coleoptera of Australia—No. 5, on certain species belonging to unrecorded genera, by A. Sidney Olliff; descriptions of hitherto undescribed Australian Lepidoptera (Rhopalocera), by W. H. Miskin; notes on Australian earthworms, Part 5, by J. J. Fletcher; descriptions of Australian Micro-Lepidoptera—Part 15, Œcophoridæ (continued), by E. Meyrick; on simple striated muscular fibres, by W. A. Haswell; jottings from the Biological Laboratory of Sydney University, by W. A. Haswell; Diptera of Australia—Part 5, the Culicidæ, by Frederick A. A. Skuse (Plate xl.); list of the Australian Palæichthyes, with notes on their synonymy and distribution, Part 1, by J. Douglas Ogilby; a list of the birds found in the county of Cumberland, N.S.W., by A. J. North.

THE additions to the Zoological Society's Gardens during the past week include a Grey Ichneumon (*Herpestes griseus*) from India, presented by Mrs. Walter Boden; a Serval (*Felis serval* ♂) from Zambesi, presented by Mr. John Walker; an Ocelot (*Felis pardalis* ♂) from America, a Red Brocket (*Cariacus rufus*), two White-eared Conures (*Conurus leucotis*) from Brazil, an Acouchy (*Dasyprocta acouchy*) from British Guiana, a Brazilian Tree-Porcupine (*Sphingurus prehensilis*), a Blue fronted Amazon (*Chrysotis æstiva*), a Yellow Hangnest (*Cassicus persicus*) from South America, a Hairy Armadillo (*Dasypus villosus*), a Pileated Jay (*Cyanocorax pileatus*) from La Plata, presented by Mrs. Wolfe; a Diana Monkey (*Cercopithecus diana*, var. *ignita* ♀), a Campbell's Monkey (*Cercopithecus campbelli* ♂) from West Africa, a Musanga Paradoxure (*Paradoxurus musanga*) from the Indian Archipelago, presented by Colonel Wethered; a Nightingale (*Daulias luscinia*), British, presented by Mr. John Young; a Bar-tailed Pheasant (*Phasianus reevesi*) from North China, presented by Mr. Charles J. Lucas; a Yellow-headed Conure (*Conure jendaya*) from South-East Brazil, a Blue-and-Yellow Macaw (*Ara ararauna*), a Blue-fronted Amazon (*Chrysotis æstiva*) from South America, deposited; an American Jabiru (*Mycteria americana*) from Para, an American Tantalus (*Tantalus loculator*) from America, purchased.

OUR ASTRONOMICAL COLUMN.

NEW MINOR PLANET.—A new minor planet, No. 284, was discovered by M. Charlois, of the Nice Observatory, on May 29.

THE SPECTRUM OF χ CYGNI.—At the Wolsingham Observatory, bright lines were seen in the spectrum of χ Cygni on May 19 and 21; D_3 very plain. Confirmed by Mr. Taylor at Ealing.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1889 *JUNE* 9–15.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on June 9

Sun rises, 3h. 46m.; souths, 11h. 59m. 0·6s.; daily increase of southing, 11·6s.; sets, 20h. 12m.: right asc. on meridian, 5h. 11·2m.; decl. 22° 59′ N. Sidereal Time at Sunset, 13h. 26m.

Moon (Full on June 13, 14h.) rises, 14h. 48m.; souths, 20h. 35m.; sets, 2h. 9m.*: right asc. on meridian, 13h. 48·4m.; decl. 5° 45′ S.

NOTES ON METEORITES.[1]

IX.

Did these Swarms or Comets always belong to the System?

MUST we assume that the members of the swarms to which we have referred and of all the other swarms similar to it have always been thus crossing the earth's orbit periodically; that the November swarm, to take an instance, has *always* been crossing it every thirty-three years? Must they of necessity have started their existence with the planets and other more stable members of the system?

This point has been well inquired into, and it is certain that it is not at all necessary that such a state of things should have existed from all time.

It is a matter of common knowledge that all stars are in motion. The so-called "fixed" stars are not really fixed: they are only relatively fixed. The sun is a star, and therefore like the other stars it is also in movement with its attendant bodies in space.

If we have a swarm of meteorites moving in space, as the sun is doing, at a very considerable distance from the sun, the directions of movement being not parallel but inclined to each other, a time will come when the two bodies, taking the swarm as representing one body, and the sun another, will begin to have an attractive influence on each other. If the attractive energy of the sun is considerable as compared with that of the swarm, the swarm will begin to change its direction obviously towards the sun. If, in changing its direction towards the sun and increasing its velocity in consequence of this increased gravitational stress, that swarm can get round the sun without any loss of momentum the two bodies will say good-bye to each other and will go different ways; but supposing there has been a loss of momentum the loss may mean that for the future the swarm of meteorites must perform its journey *round the sun*.

It does not therefore follow that when a particular group of meteorites has been watched for 900 years that these meteorites which give rise to the appearance of shooting stars always formed part of the solar system. What we do know is that *at the present moment* this particular swarm to which the November meteors are due and another swarm which is called the Biela swarm, to mention two instances, do really move round the sun in closed cometary orbits, and the chronicle of the appearances of both these swarms is so complete that very definite statements may be made about them.

With regard to the November swarm it is known that a thousand millions of miles of its orbit have been pierced by the earth in its successive passages through it since the year 902, each time the earth must have filched many millions of the small constituents of the swarm and used them up as shooting stars, and yet the swarm does not seem to be very much the worse, and enormous though the numbers are, it is known that the distances between the meteorites is so considerable that no obvious mutual gravitational effect can be noted, so that their combined or common movement is a clear indication of a common origin.

In the case of the orbit of the Biela swarm we know that more than half of it, or a length of 500 million miles, contains these meteorites; a long thin line, say a mile long and an inch in section, represents, according to Prof. Newton, the distribution of the meteorites along the orbit.

The great Laplace was the first to suggest that many comets, especially those of high inclination and great eccentricities, represented introductions of matter into the solar system from external space. But on this, as on many other points, we owe our present views chiefly to Schiaparelli, who, in 1867, attacked the problem[1] in connection with his researches on the November swarm.

[1] Continued from vol. xxxix. p. 402.

He commenced by referring to the point made by Laplace as to the phenomena presented by cometary orbits, suggesting that the planets are truly indigenous to the system; have always followed the sun in his movement through space; and had taken part in all the evolutionary changes which have finally brought the solar system to its present condition. In these characters common to planets the comets are lacking, while the eccentricities of their orbits generally is so great that the greater part of their journey is performed outside the known limits of our system. Schiaparelli considers that these facts demonstrate that the comets were not members of the solar system during its early stages, but that they are really messengers from the stellar void. Cloudlike masses wandering in parts of space where there was no star sufficient to dominate them have fallen gradually under the empire of our own by the effect of their movement relatively to our system. This movement, combined with the acceleration produced by the large mass of the sun has determined the relative orbits of these bodies in relation to the sun, which is very different from their absolute orbit in space. He next examined all the circumstances of the movement of the external mass under these conditions. First, there is no doubt that the movement of the solar system in space is comparable to that of the planets in their respective orbits, while it is possible—indeed certain—that many of the stars are in more rapid movement than our sun. Hence when it is affirmed that the relative movement of the sun and of other bodies disseminated through space is comparable in rapidity to the orbital movement of the planets, the statement is not a surprising one.

That being so, let us next suppose that one of these cloudlike masses—let us call them external swarms—wandering in space in consequence of its initial movement, penetrates eventually into a region where the attraction of the sun is much greater than that of any other star. It might be situated at a very great distance from the sun, where the annual parallax is only a small number of seconds. The relative movement will take place in a conic section. To define it, let us suppose the sun stopped, and let us give to the comet, instead of its real velocity in space, its relative velocity to the sun; and let us further imagine a perpendicular dropped from the sun in the direction of this relative velocity. It is evident that the area described by the comet round the sun in unit time will be equal to the half of the product of this perpendicular by its relative velocity.

Now as in general this velocity is of the order of planetary velocities, and since most frequently the perpendicular in question will be very much greater than the distance of the planet from the sun, we must conclude that the areas described by the comet round the sun in unit time will be incomparably greater than the corresponding areas described by the planets. But when many bodies move in conic sections round a central body, the areas described in unit time are, among themselves, as the square roots of the parameters of their respective orbits; therefore, the ratio of the parameters of cometary orbits to those of planetary orbits will be much greater than the ratio of the areas described by comets to the areas described by planets in unit time. Whence it follows that, in general, cometary orbits will have enormous dimensions in every direction, and that bodies which describe them will remain perpetually invisible to us, in consequence of their enormous distance. Nevertheless, among the infinite combinations possible in cometary orbits, there are two which may bring the cometary cloud within our ken: one, when the comet is moving directly towards the sun, describing a hyperbolic orbit very little different from a right line; and the other, when the relative movement of the comet and sun is almost zero, that is, when the two bodies are moving through the stellar space along parallel lines with nearly equal velocities.

Schiaparelli then goes on to show that when these cosmic clouds are attracted by the centre of our system, the constituent particles of the cloud must be drawn out into a parabolic current; thus, for instance, supposing a cosmic cloud equal in volume to the sun and at such a distance that its apparent diameter is 1′, the sun's attraction upon this would result in the formation of a parabolic chain or stream of such a length that it would require 636 years to pass through perihelion. When the centre was close to the sun, the beginning and the end of it would be distant from it 263 times the earth's distance from the

[1] *Les Mondes*, vol. xiii. p. 147.

sun. There are nebulæ of which the apparent diameter is greater than that of the sun. If we assume such a nebula, with the sun's apparent diameter, 1924″, it would be transformed into a parabolic chain which would require 20,000 years to pass perihelion, its transversal dimension still being such that the earth could traverse it in one or two days at the most. In this way, then, Schiaparelli shows not only that external swarms can be attracted from external space into our system, but that when so drawn out their constituent particles must take the form which we know such swarms as that of November to possess.

More recently this subject has been treated by Prof. H. A. Newton, and some results at which he arrived have been thus stated by Prof. A. S. Herschel :—[1]

"The evidence so strongly and distinctly shown in favour of the theory of the original motion of most, if not of all, of our recorded comets in spaces far external to the solar nebula, rests upon the assumption that the comet-yielding matter of the primitive nebula, if it existed, was confined, like that which formed the planets, to the neighbourhood of the ecliptic plane. This ground for the conclusion may admit of an exception that a similar distribution of the inclinations of the orbits to that which Laplace's hypothesis requires, would have been produced were this matter otherwise spread uniformly on a very distant sphere, instead of in the distant portions of a disk or annulus. But the plane of the planetary motions in the solar system, and the analogy which they present to spiral and disk-like nebulæ in the heavens, scarcely allows us to assume with reasonable probability such a different disposition of the matter of the outer part of the nebula from what the courses of the planets show us must have been its original mode of distribution and of gradual contraction near the centre ; and with no evidence before us of the past or present existence of a distant spherical envelope of nebular matter inclosing the solar system, we may certainly prefer to accept, with Prof. Newton, the much simpler conclusion to which he is finally conducted by his well-executed labours, that, with the exception of a few, perhaps, of the zodiacal comets, and comets of the shortest periods, all the comets which have been recorded are originally denizens of the interstellar spaces, pursuing unknown orbits like the stars, and separated at least and dissevered in their primitive astronomical relations from any connection with the nebular matter which, in the process of concentration supposed by the nebular hypothesis, formed the sun, the planets, and the asteroids."

Most Comets have once existed as External Nebulæ.

We now come to an important question : we have noted the extreme probability that the comets which now form part of the solar system did not always belong to it, but that they were drawn into it by the sun's attractive energy in its course through regions of space which contained the meteorites of which they are composed.

Then, instead of considering the case of a cloud of meteorites at a great distance from the sun, we have to consider one moving in an orbit round it ; and we must attempt to inquire into the conditions of that cloud, both before and after it began to fall under the sun's attraction. Into what conditions must we inquire in order to compare comets with external swarms ? They are mainly these—

(1) It is agreed that a comet is a swarm of meteorites, each meteorite being on an average far from its neighbours. This follows from an inquiry into the masses of comets. These are very small, for they have never been known to appreciably disturb any of the planets, or even the satellites, by their gravitational attraction.

In 1776, Jupiter and his satellites were entangled in a comet, yet the satellites pursued their courses as if the comet had no existence. The comet itself, however, was thrown entirely out of its course by the gravitational influence of the enormous mass of Jupiter, and its time of revolution changed from a long period to a short one of twenty years or so.

Biela's comet, first seen in 1826, appeared as a double comet in 1845. The extreme lightness of the two portions was shown by the fact that their mutual attraction was imperceptible, and each performed its revolution independently of the other.

The mass of a comet probably never exceeds 1/5000 of that of our globe. The meteorites composing them must therefore be very far apart, seeing that this small mass is distributed through spaces millions of miles in extent.

[1] *Monthly Notices*, vol. xxxix. p. 279.

(2) We next assume that a comet's luminosity is to a large extent produced by collisions of meteorites.

It is certain that one of the principal causes of the increase of temperature of a comet during its approach to perihelion is the increased number of collisions due to the greater tidal action which takes place. Hence the larger the swarm, the greater the difference between the attractions of the sun upon opposite sides of it, and therefore the greater the disturbance set up. Also, the shorter the perihelion distance, the greater fraction of it is the diameter of the swarm, and the greater therefore the differential attraction.

The initial movements of the individual members of the swarm, and these superadded by tidal action, may be defined as producing *internal* work.

If all the heat of a comet is produced by such internal work, it is clear that the temperature of the comet will depend (1) upon the velocity of orbital motion of the particles, (2) upon the size of the swarm of which it is composed, and (3) upon its perihelion distance. It will practically be independent of the velocity of the comet in its orbit round the sun.

If the luminosity be due entirely to internal collisions brought about by the increase of solar action, then large comets, or those best visible, should begin to be brilliant long before smaller or more distant ones. But this does not seem to be so. Mr. Hind has pointed out that proximity to the earth is not so important a condition for visibility of a comet in the daytime as close approach to the sun (Nature, vol. x. p. 286); and M. Faye is the authority for the statement that no comet has been seen beyond the orbit of Jupiter (*ibid.* p. 228). "It is assuredly not on account of their smallness that they thus escape our notice in regions where the most distant planets, Saturn, Uranus, and Neptune, shine so clearly with the light which they borrow from the sun ; this is because the rare and nebulous matter of comets reflects much less light than the solid and compact surfaces of the planets of which we speak, much less even than the smallest cloud of our atmosphere."

On the latter part of this quotation it may be remarked that it is not necessary to assume that comets at a great distance from the sun, any more than nebulæ, are visible by means of reflected light.

Another possible cause is that of collisions with bodies external to the comet. If external work is done on a comet by meteorites in space—that is to say, if there are collisions with external bodies—the velocity of the comet must be considered in the first place, and the equal or unequal distribution of the masses which it encounters can be tested by the phenomena observed.

The discussion of the recorded observations shows, indeed, that in addition to the constantly increasing action which takes place in a comet during its approach to perihelion passage, there are at times temporary increases in temperature.

We know that meteorites are scattered through space, and here and there are gathered into swarms. It is only to be expected, therefore, that at times a comet will meet with such swarms just as our own planet does, and in that case its temperature would be increased by the collisions which would occur. The increase of temperature would depend upon (1) the dimensions and density of the swarm ; and (2) upon its velocity. The larger and denser the swarm the more collisions would be likely to occur, and the greater the velocity of the comet, the greater the amount of kinetic energy available for transformation into heat energy.

If we assume that the increased brightness of comets as the sun is approached depends to any extent on collisions with meteorites external to the swarm, we must conclude that such meteorites exist nearer together nearer the sun. This we should expect. A test of this view would be great and irregular variations of intensity, as we know that the meteorites which the comet is liable to meet are not equally distributed. Such a variation was noticed in Sawerthal's comet in 1888, amounting to three magnitudes (Nature, vol. xxxviii. p. 258) in two days.

Such variations, however, would be more likely to be observed in the tails in consequence of the enormous dimensions of some of them ; and indeed they have been observed from the time of Kepler.

The fact that these variations so strongly resemble at times auroral displays is an additional argument in favour of the meteoric origin of the latter.

Another result of a different order produced by a comet moving through a meteoric plenum would be the gradual shortening of a comet's periodic time, and this shortening should not be absolutely regular, as in a homogeneous gas, for the reason that the meteorites are not equally distributed.

That there is such a shortening was proved by Encke for the comet which bears his name, as the following table will show:—

Returns of Encke's Comet, showing Reduced Period of Revolution.

Here, then, we have three possible sources of collisions. In any case, if any light be produced by collisions, we have the spectroscope as a sure guide to enable us to determine its chemical origin.

We have already seen that the telescopic appearance of a comet when far away from the sun and when close to it are very different. We must now introduce the verdict of the spectroscope. It was observed by Dr. Huggins in the comets of 1866 and 1867 that when they were very far away from the sun the spectrum consisted chiefly of a line seen in the spectrum of those nebulæ which he had up to that time examined. Unless, then, Dr. Huggins has withdrawn this observation, there is a *spectroscopic* connection between nebulæ and comets away from the sun.

The phenomena of comets revealed by the telescope show, as we have seen, that as a matter of fact a good many of them seem to be connected in some way or other with the production of luminous concentric or eccentric envelopes.

In the case of a comet gradually getting nearer the sun, and getting very excited as it gets there, we pass from the spectrum already described to a very different one. There is a considerable change similar to that observed in experiments with meteorites, the spectrum of carbon produced from some compound of carbon or another. In nineteen cases out of twenty when the comet gets near the sun and near enough to the earth for us to have a good look at it, the spectrum is a spectrum of carbon.

On its first appearance in a cometary spectrum, carbon is represented by the flutings which are special to low temperatures. In the most visible part of the spectrum these flutings differ very little in position from those which appear at a higher temperature, but in the blue there is a low-temperature fluting about wave-length 483, whilst the nearest high-temperature fluting is 474. If, therefore, this fluting be observed, the presence of cool carbon may be safely inferred, although it would not be quite safe to infer its presence from observations of the green flutings. This has certainly been observed in two comets—namely, Winnecke's comet (1868) on June 17 (the perihelion passage occurring on June 24), and in Brorsen's comet (1879) on March 25 (the perihelion passage occurring on March 30). The limited number of recorded appearances of cool carbon in comets is doubtless due to the same cause as in the case of the line near λ 500, which Dr. Huggins ascribed to an unknown form of nitrogen, while I ascribe it to magnesium, since we know that there is magnesium in meteorites, and we do not know that there is an unknown form of nitrogen. The reason is that the temperature being low, the light is excessively feeble and observations therefore difficult. When nearer perihelion passage, the comets get hotter, and the spectrum of cool carbon is replaced by that of hot carbon. Under these conditions of increased temperature, comets lend themselves best to spectroscopic study, and hence it happens that in the majority of cases the spectrum of a comet (if the temperature be increasing) has not been observed until it has arrived at this stage.

Manganese is the next substance which writes its record in the spectroscope. It is first represented by a fluting at 558,[1] which is the brightest fluting in its spectrum at a low temperature. This fluting is very persistent, and becomes visible even when there is only a very small percentage of manganese present in the substance examined. The fluting is always seen before the iron lines in the spectrum of ordinary iron at the temperature of the oxyhydrogen flame, and this is the case even with the purest specimens of electrolytic iron which has yet been prepared. The effect of the addition of this fluting to the spectrum of carbon is to modify the appearance of the citron band in the cometary spectrum in a very definite manner.

At a still higher temperature, the radiation of lead is added to that of manganese and carbon, which still further modifies the appearance of the citron band. The brightest lead fluting is at wave-length 546, and when this is present in the spectrum of a comet the citron band has three maxima of brightness, one at 564 (carbon), one at 558 (manganese), and one at 546 (lead).

Afterwards, the temperature having increased, the radiations of manganese and lead give way to the absorption flutings of these substances, carbon radiation from the interspaces still remaining. The result is again a very definite modification of the appearance of the citron cometary band, the general effect being an apparent shifting of the carbon fluting from wave-length 564 to a more refrangible part of the spectrum—namely, to 558, when only manganese absorption is added, and to 546 when both manganese and lead absorptions are added.

Until quite recently, the variations in the position of the citron band in different comets, or in the same comet at different periods, have been attributed to faulty observations, it being supposed that carbon pure and simple was in question. It is now certain, however, that this is not so in all cases. The variations are real, and are simply dependent upon the temperature, or indirectly upon the distance from perihelion.

In some cases iron fluting absorption has also been observed under these conditions of high temperature.

The spectral conditions brought about in the comets which in our time have got nearest to the sun were very similar to those observed in the electric arc, and the recorded observations of the spectrum show that we were dealing with a considerable number of lines of iron, manganese, and other substances.

We see in the telescope that a comet puts on the appearance of a central nucleus with surrounding envelopes or jets, so that we must understand that in the spectroscope the spectrum of the nucleus is seen distinct from the spectrum of the envelopes and jets, because the former is made to fall upon one part of the slit of the spectroscope and the latter upon another.

When a comet approaches very near to the sun we get in addition to the usual flutings of carbon, bright lines, *especially in the spectrum of the nucleus*, so that in addition to the long flutings of carbon as visible in the spectroscope we have short lines added along the nucleus in the red, yellow, green, and so on.

In those comets which have reached a very high temperature, like Comet Wells and the Great Comet of 1882, there is evidence of line absorption. At the same time there were bright lines, proceeding from the incandescent vapours driven away from the meteoritic nuclei by the solar repulsion. Without this repulsion, it is highly probable that there would be line absorption pure and simple, and this has to be taken into account in comparing the spectra of comets with the spectra of other meteor-swarms.

During the passage of a comet from perihelion to aphelion, the temperature decreasing, these changes take place in inverse order.

In spectral phenomena, then, we have another term of comparison to apply, and it may be stated that the sequence of spectral changes are now known to us in a very definite way, so that the chemical changes which take place in the composition of the vapours of comets produced by collisions at various distances from the sun have been ascertained.

Whether we take form, distance apart of component parts, or spectrum, there is now ample proof that the external bodies which supply us with these shreds and patches which we term comets are the nebulæ.

It has already been stated that if we can rely upon Dr. Huggins's observations, in some comets at aphelion and in some planetary nebulæ we get a single line at the same wave-length, so that from

[1] Students of spectrum analysis will understand that this is a "short title," and does not represent the *exact* wave-length, which with adequate instruments might require something between 10 and 100 numerals.

this observation alone it would seem extremely probable that when a comet enters our system for the first time it simply means that a swarm of meteorites in that part of space through which the sun was passing at the time began to feel the sun's attraction, and ultimately became a member of our system, and also that when we see the appearance which we call a nebula in space, since its spectrum is the same as the spectrum of a comet, the nebula is simply a swarm of meteorites if it be true that a comet is a swarm of meteorites.

These nebulous masses, visible in all parts of the heavens, but in some parts of the heavens very much more numerously than in others, were very early observed and imagined to be very different in nature from the so-called fixed stars.

Ptolemy was the first to point out, when he was making his map of the stars that there were certain "cloudy" stars of which he gave 5 on his map, and Tycho Brahé, whose work was done before the invention of the telescope, although he did not notice any bodies which we now class as nebulæ, was firmly convinced that that nebulous luminosity, which we call the Milky Way, was something entirely different in its nature from the stars. He imagined it to be what he called an ethereal essence, a sort of fire mist, so that when in his time, in the year 1572, a new star appeared, he supposed it to be a considerable agglomeration of this ethereal fluid. Galileo was able to show that the Milky Way, the "ethereal substance" of Tycho, was only an appearance due to enormous numbers of stars lying in the same visual ray, the stars of which the Milky Way is composed can indeed be seen with very small optical power. It was not till 1612, a few years after the introduction of the telescope, that we got the first real definition of a body which we now call a nebula.

The first observation we owe to Simon Marius, who stated that some of the bodies visible exactly resembled the appearance produced by the flame of a candle seen through horn. It was not till 1656 that the nebula in Orion was discovered, although now to the trained eye it is very easily visible, so that it seems rather wonderful that it was not discovered before. In 1714, in England, attention began to by paid to these bodies, but it was not until the time of Sir Wm. Herschel that the most magnificent revelations were made. He was the first to construct very large telescopes, the function of very large telescopes being to collect light, so that objects which appear to the eye as excessively dim may be brought into full visibility.

After not only Sir Wm. Herschel but his son, Sir John Herschel, had accumulated vast stores of facts, Lord Rosse took up the story, and made a telescope very much more powerful than any which had been employed by the Herschels. His telescope has a light-grasping power compared with the eye of 130,000. One of the results of Lord Rosse's work to which we need here refer is the idea that in a great many bodies which had been classed as nebulæ this enormous increase of optical power suggested that we were only dealing with very distant clusters of stars.

Lord Rosse was able to get the suggestion of "resolvability" in so many bodies which had been classed as nebulæ by Sir Wm. Herschel and others, that gradually the idea came to be held that the most nebulous nebula, if we could get sufficient optical power to bear upon it, would be broken up into stars, just as certainly as the Milky Way had been.

This would mean that the nebulæ were simply clusters of stars so infinitely remote from our ken that even with the power of Lord Rosse's instrument they put on the appearance of an ethereal essence.

This was the general opinion in 1864, in the early days of spectrum analysis, when Dr. Huggins turned his spectroscope one night to one of the planetary nebulæ. At first he thought that something had gone wrong in the apparatus because he could only see a bright line instead of the usual sort of spectrum obtained from a star. The spectroscope, however, was doing its level best, and the cause, the anomaly, was really that the nebula gave out monochromatic light.

In some cases another line was seen, stated to be due to hydrogen. It now appears that the dispersion employed was so small that the discoverer had no right to allocate any line, so that it is fortunate that other observers have since shown that there is another hydrogen line visible.

Dr. Huggins came to the conclusion that the first line was very nearly, if not exactly, in the position of the chief line seen in the spectrum of nitrogen, and the suggestion was therefore made that these nebulæ were masses of nitrogen and hydrogen gases mixed, or, if not nitrogen, some constituent of nitrogen mixed with hydrogen. That result made the idea of Lord Rosse concerning the possibility of the resolvability of nebulæ into stars untenable. We had to consider from that time that the light of the nebulæ came from a gas, and hence it was held that the nebulæ were masses of gas.

Another explanation of the origin of the green line has already been given. If we study the spectrum of magnesium we find a very bright fluting with its less refrangible edge absolutely in the position of the green line with the dispersion generally employed; in nebulæ and in comets the same line appears, if, as I said before, Dr. Huggins's observations are to be relied upon.

We are therefore justified in holding the view that nebulæ, like the comets, consist of meteorites.

J. NORMAN LOCKYER.

(To be continued.)

THE ANNUAL VISITATION OF THE GREENWICH OBSERVATORY.

THE Report of the Astronomer-Royal to the Board of Visitors of the Royal Observatory, Greenwich, was received at the annual visitation on Saturday last, June 1.

As regards buildings, it is noted that the new 18-foot dome is completed, together with the photographic dark rooms, in preparation for work with the 13-inch photographic equatorial which is to be erected this year. As regards transit-circle observations, we read:—

"The regular subjects of observation with the transit-circle are the sun, moon, planets, and fundamental stars, with other stars from a working catalogue, which includes all the stars in Groombridge's Catalogue and in the Harvard Photometry not observed since 1867, and a selection from Piazzi's Catalogue. Ten close circumpolar stars taken from the *Connaissance des Temps*, or from M. Lœwy's list of stars for longitude determinations, have been observed regularly, in addition to the four standard azimuth stars. The observation of these close circumpolars has been much facilitated by the adoption (since 1889 January 1) of the method used by the officers of the French Service Géographique, which consists in making a number of bisections of the star with the R.A. micrometer during its transit, the exact time for each bisection being recorded on the chronograph. The Annual Catalogue of stars observed in 1888 contains about 1820 stars.

"Special attention has been given to the observation of the minor planet Iris and comparison stars in connection with the determination of its parallax at the late favourable opposition, eighteen observations of the planet and 113 of twenty-eight comparison stars having been made last autumn."

As regards computations, the transits have been completely reduced so as to exhibit mean Right Ascension 1889 January 1, and also the circle observations to exhibit mean North Polar distance for the same period. Two determinations of the astronomical flexure of the transit-circle telescope have been made since the last Report, the resulting values being 0"·08 and 0"·52. It has been found that the correction for discordance between reflection and direct observations of stars was erroneously applied in 1887, and hence the results for colatitude and for position of the ecliptic are also erroneous. The correct values are now given, with those recently found for 1888.

The ecliptic investigations from 1877 to 1886 have been revised to reduce the results to the same system of flexure, R—D correction, refraction and colatitude; so the computations for the ten-year Catalogue, containing 40,000 observations of 4059 stars, are now practically complete.

It has been found that the mean error of the moon's tabular place (computed from Hansen's lunar tables with Newcomb's corrections) is + 0·090s. in R.A., and + 1"·21 in longitude, as deduced from seventy-four meridian observations in 1888. The mean error in tabular N.P.D. is − 1"·19, indicating that the mean of the observed N.P.D.'s is too great. A number of altazimuth observations has been made and reduced to April 8, so as to exhibit errors of moon's tabular R.A., N.P.D., longitude, and E.N.P.D.

The object-glass for the new 28-inch refractor is now being worked, and, as it is to be of a special form, equally suitable for photographic and eye observations, an experimental object-glass is being mounted on the Sheepshanks equatorial for trial. A number of photographs of stars have been taken with the experimental 6-inch object-glass, supplied as a preliminary to the construction of the 13-inch, which is to take part in the construction of the photographic map of the heavens. Only inconclusive results have, however, as yet been obtained. The spectroscopic work has mainly consisted of observations of motion of stars in line of sight. We read :—

"For determination of motions of approach or recession of stars, 236 measures have been made of the displacement of the F line in the spectra of 38 stars, and 18 of the *b* line in the spectra of 8 stars, besides 5 of the *b* line in the spectrum of Saturn's ring, and comparisons with the spectra of the moon, Venus, the sun, or the sky, as a check on the general accuracy of the results. Observations of Algol on three nights during the past year confirm the previous results indicating orbital motion, but further evidence is required to establish the fact. The spectra of γ Cassiopeiæ, *o* Ceti, β Lyræ, P Cygni, R Cygni, and β Pegasi, have been examined on several occasions, and Comet *e* 1888 has been spectroscopically observed on one night, the spectrum being chiefly continuous. The spectroscopic observations of all kinds are completely reduced."

Photographs of the sun have been taken 182 days in the year ending on May 10, 1889. Indian and Mauritius sun photographs have been received from the Solar Physics Committee as far as 1888 December 31 and December 9 respectively, and it is noted that, by means of photographs from these two places supplementing the Greenwich series, the daily photographic record of the sun's surface is practically complete since the beginning of 1882. For earlier years 118 photographs of the sun taken at Harvard College, Cambridge, U.S.A., between 1874 December 9 and 1875 December 31, and ten photographs taken at Ely, between January 1 and February 25, 1874, have been received from the Solar Physics Committee.

The photographs of the sun for 1888 show that it has been free from spots on 155 days in the year 1888, the longest spotless periods being February 4 to 17, May 24 to June 8, and October 5 to 25. The mean spotted area in 1888 was half that of the preceding year, and corresponded closely to that for 1877, so that the minimum may be expected to occur during the present year. The mean distance of spots from the equator has also diminished to 7°·38 in 1888, being very little larger than it was in 1878, just before the last minimum, and this is a further indication that the sun-spot minimum is close at hand. The faculæ in 1888 show a diminution in correspondence with that of sun-spots, their area for 1888 being intermediate between those for 1876 and 1877.

Continuous observations of the changes in the three magnetic elements of declination, horizontal force, and vertical force have been photographically recorded.

The following are the principal results for the magnetic elements for 1888 :—

Approximate mean declination	17° 40′ W.
Mean horizontal force ...	3·9480 (in British units). 1·8204 (in Metric units).
Mean dip	67° 24′ 26″ (by 9-inch needles). 67° 25′ 33″ (by 6-inch needles). 67° 26′ 16″ (by 3-inch needles).

In the year 1888 there were only three days of great magnetic disturbance, but there were also about twenty other days of lesser disturbance, for which tracings of the photographic curves will be published, as well as tracings of the registers on four typical quiet days.

The meteorological results are as follows :—

"The mean temperature of the year 1888 was 47°·7, being 1°·6 below the average of the preceding forty-seven years. The highest air temperature in the shade was 87°·7 on August 10, and the lowest 18°·4 on February 2. The mean monthly temperature in 1888 was below the average in all months excepting May, November, and December. In March, April, July, and October it was below the average by 3°·6, 3°·6, 4°·4, and 3°·9 respectively, and in November it was 4°·0 above the average.

"The mean daily motion of the air in 1888 was 296 miles, being 12 miles above the average of the preceding twenty-one years. The greatest daily motion was 790 miles on March 11, and the least 57 miles on December 31. The only recorded pressures exceeding 20 lbs. on the square foot were 31 lbs. on March 11, and 21 lbs. on August 28.

"During the year 1888 Osler's anemometer showed an excess of about nineteen revolutions of the vane in the positive direction north, east, south, west, north, excluding the turnings which are evidently accidental.

"The number of hours of bright sunshine recorded during 1888 by the Campbell-Stokes sunshine instrument was 1068, which is about 250 hours below the average of the preceding eleven years, after making allowance for difference of the indications with the Campbell and Campbell-Stokes instruments respectively, and it is 333 hours below that of 1887 recorded with the same instrument. The aggregate number of hours during which the sun was above the horizon was 4465, so that the mean proportion of sunshine for the year was 0·239, constant sunshine being represented by 1. A comparison has been made of the records of the Campbell and Campbell-Stokes instruments for the twelve months from 1886 June 1 to 1887 May 31, with the result that the former registered 1256 hours of bright sunshine, while the latter registered 1364. It would appear, therefore, that the indications of the former instrument require to be multiplied by the factor 1·086 to make them comparable with those of the latter.

"The rainfall in 1888 was 27·5 inches, being 2·9 inches above the average of the preceding forty-seven years."

The average daily number of chronometers and deck watches being rated is 212, and the total number received up to May 10, 1889, was 668. The Astronomer-Royal notes that in future the duration of the trial of deck watches will be increased from twelve to sixteen weeks, viz. six weeks in the ordinary temperature of the room, four weeks in the oven (temperature 80° to 85°), and finally six weeks in the room.

The Report concluded with a note on the re-determination of the difference of longitude between Greenwich and Paris :—

"Observations were made in four groups of three nights each (or the equivalent in half nights). An English and a French observer were stationed at each end, each with a separate instrument and chronograph, and the pairs of observers were interchanged twice, to eliminate any change in the personal equations during the progress of the work. The pairs of English and French instruments were similar, and the signals as well as the star transits were recorded on similar chronographs. On a full night each observer recorded about forty star transits, reversing his instrument three times, and exchanged signals twice (near the beginning and end of the evening) with his compatriot at the other end of the line, and once with the other observer. At Greenwich the transits were referred to the sidereal standard clock, and comparisons with the large Greenwich chronograph enable the ordinary determinations of clock-error with the transit-circle to be utilized as well as those specially made with the portable transits. With this object transits of clock stars with the transit-circle were usually taken by four observers on each night during the longitude operations. The actual stations were the Front Court of the Royal Observatory and the Observatory of the Service Géographique de l'Armée at Paris, the position of which reference to the Paris Observatory has been accurately determined. Commandants Bassot and Defforges were the French observers, and Mr. Turner and Mr. Lewis the English. The observations lasted from September 23 to November 15, and 18 nights of observation at both stations are available, the two English observers having observed at Greenwich 653 transits of clock stars and 165 of azimuth stars, and at Paris 778 transits of clock stars and 165 of azimuth stars. All of these, as well as the signals exchanged, have been read out from the chronograph registers and the reductions are far advanced. Subsidiary investigations of the value of a revolution of micrometer screw, of intervals of wires, of form of pivots, and of errors of the axis-level have consumed much time, the last-named having been a long and tedious discussion."

The difference in longitude between Greenwich and Dunkerque will be determined this month, and Commandant Defforges also proposes to determine the latitude between these two places.

THE EARTHQUAKE.

ON the evening of Thursday, May 30, a considerable seismic disturbance was noticed over the English Channel and in the neighbouring districts. Its area cannot yet be precisely determined. It seems to have been felt most strongly in the Channel Islands, but it was also very distinctly noticed over wide districts in the south of England and the north of France. We bring together various facts relating to the earthquake, some of which have been communicated to us by correspondents.

In Guernsey four successive vibrations were felt at 8.15 p.m. It is said that the houses in St. Peter-Port trembled for several seconds, and that most of the occupants rushed into the streets. The weather had been very sultry for some hours previously.

The shock was felt not less severely in Jersey, as the two following letters will show. The first, which has been sent to us from the Meteorological Office, is by the correspondent of that Office at Jersey, and is dated St. Aubin's, May 31:—"Last evening, at 8.15 p.m., there was a rather severe shock of earthquake here; in fact, it visited the greater part of the island, as far as I can learn. But what I heard myself was a loud rumbling noise, and everything began to shake and tremble, even the buildings; it so frightened a great many that they ran out of their houses, not knowing what was the matter. It appeared to me to travel from north to south, and lasted for about two to three minutes. The barometer at the time was steady, the wind south-south-west, force 4, and a fine night with a clear starlit sky; this morning the weather was gloomy. There was a mock sun, and afterwards a solar halo, but it has been a fine day, with a deal of cirro clouds moving from a southerly direction and looking very heavy in the westward all day, and at present we have cold nights." The second letter has been sent to us by the Rev. W. Clement Ley, to whom it was written, on May 30, by a friend at St. Helier's, Jersey:—"A series of earthquake waves passed here at 8.14 this evening: I could not be quite sure of the direction, but I think from south-west to north-east. They continued for forty seconds at least. I was in my room at the top of the house, and so felt the full force. The whole room trembled, windows rattled, and at the same time the room swayed gently. Some one at the time ran along the road shrieking, 'Earthquake! earthquake!' I think that this is the most severe shock that has been felt in Jersey for many years."

At Sark, also, the earthquake was noticed. Major R. D. Gibney, writing to us from that island on May 30, says:—"This evening I felt two distinct shocks of earthquake, the whole lasting about three seconds, the direction being from south to north-west. Time (believed to be Greenwich) 8.25 p.m. The night was clear, but the setting sun and angry clouds hanging on the horizon presaged rough weather. The shock or shocks were sufficiently severe to shake furniture and to rattle crockery on shelves in almost every house in the island. A low rumbling noise, somewhat like distant thunder, accompanied the vibrations."

Three sharp shocks were felt on the same evening at Cherbourg, but the time has not been exactly noted. The cornice of the doorway of the Church of the Holy Trinity was thrown to the ground. The earthquake is said to have been distinctly felt at Havre, Granville, Caen, and Rouen; and it is stated that it was also felt in Paris at certain points on the left bank of the Seine.

Correspondents have written on the subject to NATURE and the daily papers from many different parts of the southern coast of England. A writer at Penzance testifies that three or four shocks were felt there at 8.21, the direction being from west to east. Mr. J. M. Hayward, writing to us from Sidmouth, on May 31, says:—"As I was sitting here alone quietly reading yesterday evening, I felt a very decided shock of earthquake, three distinct vibrations, each of which shook my chair to and fro several times, and made the things on the table—a china plate with a small glass of flowers in it—rattle; the last was strong enough to make me put down my paper, take off my glasses, and wonder whether the room would tip over. I immediately made a note of the time, 8.20, but I cannot answer for my clock being exactly right." At Blandford, Dorset, a vibration, which is said to have occurred at 8.18, lasted about ten seconds; and Mr. G. J. Groves states that the glass and china ornaments in the room in which he was sitting rattled audibly. According to the Rev. L. Lester, a distinct shock was felt at Wareham, Dorset, "about a quarter past 8." "It happened," he says, "while we were in church. There was first of all a very slight shock, which caused the roof to crack, as it does sometimes in a strong gale; but immediately after there was one much more severe, strong enough not only to make the roof-timbers crack in a far greater degree, but also to set the lamps in the chancel swinging. Those of the congregation who happened to be sitting in seats attached to the main piers or pillars of the church felt a distinct movement. The direction of the shocks seemed, by the way in which the noise ran along the roof, to be from north-west to south-east." At Poole the shock was so severe that many persons rushed from their houses in alarm. Colonel L. S. Venner, writing from St. Rode, Bournemouth, says that at 8.20 p.m. a shock of earthquake passed through the house, travelling from south to north. "The features of it were a strong quivering of the floor, with an up and down movement, accompanied by a hollow noise underneath, and the shaking of shutters and crockery. An invalid's bed was a good deal oscillated, and a dog on it was alarmed. The shock was not at all violent. The wind, which was cold and fresh from south, became still just before the shock, and then freshened up again. The sky was clear." Mr. J. Grey, also writing from Bournemouth, fixes the time at 8.18. He and three others were in a ground-floor room facing the sea, when they felt two shocks: it seemed as if the floor was upheaving. The servants at the back part of the house did not notice it. At Portsmouth, Havant, and the surrounding district the shock is said to have been felt about 8.25; and at Havant, where articles were visibly moved, there was "considerable alarm." In many parts of the Isle of Wight the earthquake attracted notice, and at Sandown and Shanklin the residents are said to have been "greatly alarmed." Dr. F. M. Burton, the senior curate of Newport, writes:—"We were in church, attending the evensong of Ascension Day. It was about the middle of the sermon, when a tremor passed through the church, apparently from north to south. The roof groaned and cracked; the reading-desk in which I was seated (a solid old oak structure, of 1636) perceptibly and very unpleasantly moved, and the gas standards shook for some minutes after. Our vicar, the archdeacon of the island, and several members of the choir and congregation observed it. One lady (Mrs. Haigh) had the presence of mind to time the shock, which took place about twenty-three minutes past eight. Several people told me next morning that they felt the shock more or less severely in their houses." Writing from St. Laurence, Ventnor, Mr. W. E. Kilburn says:—"A very distinct shock of earthquake occurred here at 8h. 21m. 30s. p.m. The shock was not sufficient to overthrow anything or to stop the clocks; but the long pendulous drops, 8 inches long, of the glass lustres on the solid marble chimney-piece formed admirable seismometers, vibrating freely for twenty minutes afterwards, and showing the direction apparently from the south-west. The aneroid and barometer indicated 29·73 at the time; they were 29·80 at 9 o'clock in the morning. The temperature in the open air was 53° by Casella thermometer, and the wind south-south-west. The duration of the shock was about three seconds." The Rev. A. Conder says that at Bognor there were two severe shocks at 8.20, with an interval of about three seconds between them:—"An invalid in an adjoining house called for assistance, as some one was under her bed lifting it. I distinctly felt the shocks, which caused the window-frames to rattle." At Littlehampton, at 8.22, cranes were seen to swing suddenly, and an oscillation was felt in different parts of the town. At Arundel, while reading on a sofa, Mr. E. Goldsmith suddenly "felt a peculiar movement, and distinctly saw the sofa vibrate for three or four seconds." "At the same time," he says, "the windows shook, not as they had occasionally done during the evening on account of the wind, but with a quite different and more continuous movement. I called to my daughter, who was at the moment in the dining-room, to know what was the matter; but she had only heard the windows shake in the room where she was (but in the same peculiar manner), and had not felt any movement. My little boy, who was in bed upstairs, felt his bed move; and my two little girls, who were going to bed, were quite frightened, and ran down to know if it was an earthquake. The servant with them felt it too. The time was 8.20." At Brighton a distinct shock was felt, especially in the western part of the town; and at Rudgwick, near Horsham, two persons in a room noticed a movement "which caused a rocking of chairs, cracking of woodwork, and the sound of rumbling, apparently exhausting itself to the westward." Captain H. King, R.N., writes to us from Petersfield:—"On the evening of May 30, at 8.20 p.m., I was leaning upon a spring mattress, when I felt it vibrating in a peculiar manner. We could only account for it by an earthquake; and surely enough the newspaper of next day described one at Guernsey, which appears to have been similar to one which I witnessed in Jersey in April 1853." Mrs. Lane, also writing to us from Petersfield, says that she and her children's governess, while sitting together, "were startled by a most peculiar vibration seeming to shake the house, which quivered perceptibly for some seconds."

Several correspondents of the *Times* testify that they felt the shock in London. Mr. Ernest Myers writes from 31 Inverness Terrace, W.:—"A slight but unmistakable shock was felt here about 8.20 p.m. There was no rattling of windows or other sound. The vibration seemed to be from side to side." Mr. E. W. Haines, of Alexandra Road, St. John's Wood, says:—"The earthquake was distinctly, though slightly, felt here last evening at 8.30." A member of the firm of Yates, Crighton, and Co., of Cannon Street, E.C., while working in their offices on Thursday evening, distinctly felt four shocks just before 8.30. He says:—"It was the more noticeable as our offices are situated in a huge building, on the third floor, and the sensation was just as if the whole block were rocked by the wind from south to north." "C. W. H." writes from the General Post Office:—"Last evening I was sitting in my room, situated in the south-west corner, top story of the General Post Office, when I felt my chair oscillate with a slight tremulous motion, which lasted perhaps four seconds. Thinking it was a slight shock of earthquake, I stood up, and looking at my watch saw the time was 8.20." A person living at West Kensington reports having felt the shock at 8.15. Mr. F. Yates, writing from Park Street, Southwark, S.E., May 31, says:—"Yesterday evening, between 8.20 and 8.25, while sitting in my library at Surbiton, I distinctly felt two light shocks, which I attributed to earthquake. The shocks were also observed by other members of my family."

Mr. J. Lloyd Bozward writes to us from Henwick, Worcester, that the earthquake was perceptible there. While seated in a room on the second floor of his house at about 8.23 p.m. on Thursday, all being still, he felt five distinct tremors in rapid succession, the third being the most notable. "On making immediate inquiries," he says, "I learned that the tremors had not been felt on the other floors, but my son, who happened to be in the basement on the occasion, says that at the time referred to by me he noticed that the flame of a lamp burning on the table suddenly shot up above the top of the glass chimney."

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The Annual Report of the Museums and Lecture Rooms Syndicate, just issued, contains much interesting information about the progress of natural science studies and collections.

Prof. Babington announces that the late Prof. Churchill Babington's extensive herbarium has been presented to the Botanical Museum by his widow, including the typical specimens of lichens described by him. The type collection has been enlarged. and demonstrations in organography and histology are regularly given. Mr. Potter has just returned from Ceylon with a fine collection. A series of germinating seedlings (prepared by Mr. Barber), specimens showing the injuries caused to plants by insects (by Mr. Shipley), and Kny's diagrams, given by Mr. Thiselton Dyer, are among the valuable acquisitions.

Mr. J. W. Clark, Superintendent of the Museum of Comparative Anatomy, reports the gift of a beautiful collection of spiders, with accompanying drawings, by Mr. Warburton; the mounting of the skeleton of *Rhytina gigas*; the deposit of a valuable collection of skulls and bones of Bovidæ and Cervidæ, by Mrs. Stewart, widow of Surgeon-General L. C. Stewart; Surgeon-General Day has given 357 birdskins from India and Burmah; and Messrs. Cordeaux have given over 100 valuable Indian specimens.

Two parts of the "Morphological Studies" have been issued by Mr. Sedgwick since the last Report. The Elementary Biology Class numbered 167 in the Easter term of 1888, and 139 in the Lent term of 1889. The Morphology Class varied from 77 to 42; with a smaller advanced class.

Prof. Macalister reports the addition of 131 Egyptian skulls, 25 skulls from the Saxon burial-place at Hauxton, and many from that behind St. John's College. The Rev. J. Sanborn, of Lockport, N.Y., has given valuable skulls from a burying-place of the Seneca Indians.

Prof. Roy describes the careful and systematic arrangement he has adopted in his Pathological Laboratory (late the Chemical Laboratory).

Prof. Hughes once more deplores the long postponement of the new Geological Museum. It certainly is not just to allow the donors of the funds to die out and never see the erection of the Museum towards which they contributed such large sums. Important additions have been made to the Cambrian and Silurian fossils by Mr. Marr, and many of them have been described and figured by him. Thirty-four figured types from the Inferior Oolite of Dorsetshire have been presented by the Rev. G. F. Whidborne. About 130 slides have been added to the cabinet of microscopical preparations of rocks. Much progress has been made in palæobotany, and two courses of lectures have been given by the lecturer, Mr. Seward. Mr. Strickland's collection of fossils, numbering 7000 specimens, has been presented by the late Mrs. Strickland.

The new Chemical Laboratory proves to be very satisfactory in working.

The demonstrations in the Cavendish Laboratory were attended by 136 students last Michaelmas term and 144 in the Lent term. Twelve persons have been doing original work in the Laboratory during the year. Some important new apparatus has been acquired.

SCIENTIFIC SERIALS.

Mémoires de là Société d'Anthropologie de Paris, série ii., tome iv., fasc. 1 (Paris, 1889).—Pre-Columbian ethnography of Venezuela, by Dr. Marcano. The author prefaces his special ethnographical remarks with a short geographical notice of the Venezuelian territory, entering more particularly into the physiographical character of the fertile valleys of Aragua and Caracas. The special feature of the landscape in these picturesque regions is the range of low hills locally characterized as "Cerritos," which extend over a large area near the beautiful lake of Valencia, first known to the Spaniards as Lake Tacarigua, and which were regarded by the native Indians as natural features of the soil. It has been discovered, however, by recent explorers, that they are artificial elevations, raised in past ages by some aboriginal Indian race long extinct, whose very name is unknown to the present inhabitants of the district, although the shores and bottom of the lake testify, through their vast accumulations of bones and other *débris*, that the country must have been densely populated at some remote prehistoric period. Dr. Marcano, who devoted several years to the exploration of the Cerritos, near Lake Valencia, has succeeded in laying bare the interiors of twenty of these mounds, which prove to be sepulchral caves filled with bone and other detritus. All present a uniform plan of arrangement, and consist of a central circular walled-in space, containing an enormous mass of whole and fractured bones, and marine and fresh-water shells, with fragments of stone, bone, and wood implements, and sherds of pottery, most of which bear traces of the action of fire. The human remains were deposited in round earthen jars or urns, each of which contained only the separate bones of one body, the skull resting at the base of the vessel, while the sacrum, with the long and the small bones, was laid above it so as to fit into all the available space. The appearance of these bones indicates that the flesh had been detached from the dead body before its interment, but their brittle condition rendered a minute examination impossible in some cases, although Dr. Marcano was able to recover forty crania which admitted of sufficiently exact investigation to warrant the conclusion that they represent two distinct types of brachycephalism. About half of these crania showed signs of deformity, due to artificial pressure over the frontal bones. The most remarkable characteristic was their prognathism, which exceeded that of any skull previously examined by him, although his observations were based on the examination of more than 2000 crania, of which some belonged to New Caledonians, who have hitherto ranked as belonging to the most prognathic race extant. The implements found in the Cerritos caves are nearly identical with those associated with the Neolithic age in Europe, while the animal remains are composed of types belonging to the local terrestrial and aqueous faunas, including the broken skull of a cebus; while so enormous a mass of the bones of a caïman (*Crocodilus bava*, which is peculiar to the Lake of Valencia and its affluents) was found, that it is evident the flesh of this animal must have served as food. A number of detailed craniological tables, and numerous illustrations of the crania and of the curious figurines and idols, the urns, tools, ornaments, and other objects interred with the human bones, add greatly to the value of Dr. Marcano's exhaustive memoir.—The superstitions prevalent in Wales, by M. Maricourt. In this article the author has drawn his materials so indiscriminately from casual travelling companions, and from writers of the most various degrees of authority, that his statements can lay no claim to the serious attention of students of folk-lore, and present no interest for the English reader.

SOCIETIES AND ACADEMIES.

LONDON.

Physical Society, May 25.—Prof. Reinold, President, in the chair.—The following papers were read:—On a relation existing between the density and refraction of gaseous elements and some of their compounds, by Rev. T. Pelham Dale. In a previous communication the author pointed out a relation between the specific refractive energies of sulphur and selenium, and the present paper deals with similar relations in gaseous bodies. On calculating out the values of $\frac{\mu - 1}{d}$ for the elements H, O, N, Cl, S, P, it was noticed that the logarithms were nearly integral multiples of half the logarithm for H, those for N, Cl, and P being double, and S and O three times that number. The value of $\mu - 1$ for different elements is compared with the $\mu - 1$ for H, the resulting numbers being, for oxygen 2, mercury 7, arsenic 8, and sulphur 12 nearly. Similar calculations are made for the compounds N_2O, NO, CO, SO_2, Cy, NH_3, HCl, H_2S, CH_4, and C_2H_4, but as the data obtainable are very rough, the numbers are not so closely integral. The author hopes that better data will be furnished by persons having greater facilities than himself for experimental research. Prof. Rücker thought the results obtained pointed towards some relation between the volumes of the molecules of different elements, and at the close of the meeting announced that on working out the relation he found the relative volumes to be a series of numbers in geometrical progression.—On a water-spray influence machine, by Mr. George Fuller. The apparatus is made up of four similar sections, each consisting of a nozzle, a metal ring, and a metal dish or receiver, arranged about a vertical axis. Pressure-water issues from perforations 1/100 inch in diameter in the nozzles, and passes through the rings into the insulated receivers below. The rings are placed at such a distance below the nozzles as to be about the point where the streams break into spray, and the receivers empty themselves automatically. Calling the consecutive sections 1, 2, 3, 4, respectively, the rings of 1 and 3 are connected to the receiver of 4, and those of 2 and 4 to the receiver of 1. The discharge-points are connected with the receivers 2 and 3, and a rapid succession of sparks passes when the water is turned on. Prof. S. P. Thompson inquired whether the length of the spark was limited by leakage along the glass rods or by the spray passing between the receivers, and in reply Mr. Fuller said he thought the former leakage the most important.—Notes on polarized light: (*a*) on the transition tints of various orders; (*b*) lecture illustrations of the rotation of circularly-polarized light; (*c*) on the rotation of circularly-polarized and non-polarized light, by Prof. S. P. Thompson. The first note described an inquiry as to what thickness of quartz gives the best "sensitive tint" for polarimetric work. Biot gave the name to the tint produced by a quartz 3¾ millimetres thick in a bright field, whereas in most modern polarimeters the name is given to that produced by 7½ millimetres of quartz in a dark field. The transition-tints of various orders were exhibited on a diagram of Newton's scale of colours, and by a wedge of selenite. Experiments were made on quartzes of 3¾ and 11¼ mm., giving tints of the first and second order respectively in the bright field, and with a 7½ mm. quartz in a dark field. The 3¾ was more sensitive than the 11¼ to small rotations, but the 7½ mm. seemed the best of the three. Prismatic analysis of the light transmitted by each led to the same conclusion—a new square-ended direct-vision prism built up of a glass prism (angle 140°) immersed in cinnamic ether being used for that purpose. The author pointed out that the "sensitive tints" of German opticians are decidedly redder than Biot's, and those generally used in England. In the first apparatus devised under (*b*), the ray of light is represented by a stretched cord thrown into promiscuous vibration by a tuning-fork, and the polarizer and analyzer are each represented by two plates of glass mounted parallel to each other about a millimetre apart, between which the cord passes. Between the polarizer and analyzer the vibrations are in one plane, and they are transmitted or cut off by the analyzer according as its plates are parallel or perpendicular to those of the polarizer. By blowing across one side of the spindle-shaped vibrating segment between the crossed plates, the plane of vibration is slightly rotated, and part is transmitted through the analyzer. Other experiments illustrating rotation of the plane of polarization were shown or described, the most conclusive being a bar of heavy glass placed along with a fish-eye lens between crossed Nicols. On starting a current in a helix surrounding the glass, the black cross formed by the fish-lens is seen to turn round as the current grows. Another piece of apparatus to illustrate Fresnel's view of the circularly polarized waves in quartz consists of two equal coplanar disks rotating in opposite directions, and carrying pins on which the extremities of a double pantograph arrangement are pivoted. The middle point of the link-work describes a line perpendicular or inclined to the line of centres of the disks according as the phases of the pins are the same or different. (*c*) In speaking of rotary polarization it is customary to say that the plane of polarization is rotated, but the author thinks it is equally correct to say that the light itself is rotated. Prof. Stefan's and Prof. Abbe's experiments bearing on the subject were described, and to demonstrate that ordinary light may be rotated, a biquartz was placed between a Fresnel biprism and the screen on which the interference fringes were formed. By using quartzes of thickness sufficient to rotate each beam 45°, the interference fringes are caused to disappear, and on inserting a bar of heavy glass in each of the pencils, and magnetizing one of them, the fringes reappear. Mr. Glazebrook thought the reason why 3¾ mm. quartzes were more sensitive than 11¼ might be seen by considering the sector-shaped spectrum in which the rays are spread out by the quartz, for with the thick piece the angle of the sector will be three times that with the thin one, and hence, in the latter case, a greater change of colour is produced by a given small rotation. Mr. Ward strongly condemned the use of biquartzes for rotation measurements, for he found it impossible to get them cut with such accuracy as to give a uniform tint; and if the light be slightly elliptically polarized, considerable error may be introduced. Speaking of magnetic rotation, he thought Fresnel's explanation unsatisfactory, and considered it probable that the rotary character of the magnetic field increases the period of one and decreases that of the other circular wave, their velocities remaining the same. As regards quartz, he believes the rotary action due to the light itself (probably an effect of the longitudinal wave), and not to any peculiar crystalline structure of the quartz, for liquids exhibit similar phenomena. Dr. Thompson, in reply, said Mr. Glazebrook's explanation of the difference in sensibility of the quartzes of various thicknesses was not quite satisfactory, for the reasoning would lead one to expect the 3¾ millimetres to be most sensitive, whereas experiment showed that the 7½ millimetres was best. He quite agreed with Mr. Ward about the defects of the biquartz, and thought the shadow method preferable in many cases. On the other hand, he was disposed to believe that the rotary power of quartz was a result of its crystalline structure, for fused quartz possessed no such property. As regards liquids, Dr. Thompson thought the rotation due to some kind of skew symmetry possessed by the molecules, the average effect of which is observed.—On the molecular weight of caoutchouc and other colloid bodies, by Dr. J. H. Gladstone, F.R.S., and Mr. W. Hibbert. This paper gives the results of determinations made by Raoult's method, the reliability of which was first tested by preliminary experiments on substances of known molecular weights, and found to be fairly satisfactory. The experiments on caoutchouc give a very high value (above 6000), thus confirming the author's previous impression that it was a colloid. Similar experiments were made on gum-arabic, caramel, albumen, and ferric and aluminic hydrates, all of which were found to have high molecular weights. All the experiments confirm the belief that the molecule of a colloidal substance is an aggregate of a very great number of atoms.

EDINBURGH.

Royal Society, May 20.—Sheriff Forbes Irvine, Vice-President, in the chair.—A paper, by Prof. Letts and Mr. R. F. Blake, on the identity of Hofmann's "dibenzyl phosphine" with oxide of tribenzyl-phosphine, and on some other points connected with the phosphorized derivatives of benzyl, was read.—Sir W. Turner communicated a paper by Dr. D. Hepburn, on the development of diarthrodial joints in birds and mammals.—Dr. G. Sims Woodhead communicated observations by Mr. D. McAlpine on the progressive movement of detached ciliated portions of frogs and tortoises, and also observations on the progression, pulsation, and quivering of excised hearts of fish, frogs, reptiles, birds, and mammals.—Dr. John Murray read a paper by Mr. W. S. Anderson, on the solubility of carbonate of lime in fresh and sea water.

PARIS.

Academy of Sciences, May 27.—M. Des Cloizeaux, President, in the chair.—On the radicular nature of the stolons of *Nephrolepis*, by M. A. Trécul. In reply to M. Van Tieghem, the author argues that the so-called stolons of this fossil plant were not shoots or runners, but had the constitution of true roots; hence he was fully justified in describing them as "radicular stolons."—On the representation of the continuous fractions expressing the two roots of a quadratic equation, by Prof. Sylvester. In continuation of his previous paper (May 20), the author shows how the twin formulas there worked out for the two roots x and x' may be considerably simplified and generalized.—On the Calamariæ, *Arthropitus* and *Calamodendron*, by M. Grand'Eury. In this paper the author sums up his reasons for believing that these Carboniferous plants were highly organized Cryptogams. Their representatives or descendants in the Secondary formations were of smaller size, less varied, and more nearly related to *Equisetum*, the last degenerate survivor of the family.—Exact determination of the quantity of water contained in the blood, by MM. Gréhant and Quinquaud. Experiments made on the dog and rabbit show generally that the quantity of water is less in the venous than in the arterial blood. For the dog, the respective proportions were found to be: water, 77·09; dry residuum, 22·91; and 78·01 and 21·99 per cent.—Quantitative analysis of the urea contained in the blood and in the muscles, by the same physiologists. From these experiments, made with the rabbit and the skate, it would appear that the muscles of this fish contain fifty times more urea than those of mammals, and that the urea is formed in the muscles, in which it is present in larger quantity than in the blood.—Distribution in latitude of the solar phenomena during the year 1888, and solar observations for the first quarter of 1889, by M. Tacchini. The results of the observations here tabulated show that in 1888 the solar phenomena were much more frequent in the southern than in the northern hemisphere. The maximum zone for the spots, faculæ, and metallic eruptions lay between 0° and −10°, as in 1886 and 1887. But the maximum for protuberances does not correspond with that for the other phenomena, as it lay in higher latitudes (+30 to +40 and −40 to −50). The observations for the first three months of 1889 show a perceptible diminution of the spots and faculæ as compared with the last quarter of 1888, while the protuberances were somewhat more frequent in the former than in the latter period.—On the expansion of the metals at high temperatures, by M. H. Le Chatelier. In continuation of his previous communication the author here tabulates the results obtained for iron, steel, copper, aluminium, silver, nickel, platinum, and sundry alloys, concluding generally that for all metals the coefficient of expansion increases with the temperature. The law of increase is generally regular except for certain alloys of silver and for all varieties of iron.—Researches on the phenomenon of magnetic rotatory polarization in Iceland spar, by M. Chauvin. In a previous note (April 27, 1886) the author showed, against the opinion of Wertheim, that this substance possesses magnetic rotatory power not only in the direction of the axis but also in the neighbouring directions. His further researches here summarized generally confirm this conclusion, the phenomena observed being identical with those presented by natural quartz.—On the electric conductivity of saline solutions: reciprocal displacements of the acids, by M. P. Chroutschoff. A tabulation of the chief results already obtained of the reactions between salts in solution and acids other than those entering into the composition of the salt under examination.—Researches on the electric resistance of bismuth, by M. Edmond van Aubel. The author here studies the influence of temperature on the electric resistance of bars of bismuth, and examines this metal under two molecular states: melted and slowly cooled; melted and very rapidly cooled or tempered.—On the heat of combustion of some organic bodies, by M. J. Ossipoff. Continuing his determinations of the heat of combustion of organic bodies, the author here deals with racemic acid and its anhydride, and with methyl racemate and tartrate.—On some metallic sulphides, by MM. Armand Gautier and L. Hallopeau. Continuing their last memoir (April 15), the authors here describe the action of carbon disulphide on nickel, chromium, and lead.—Papers were contributed by M. F. Parmentier, on the presence of sulphate of soda in the atmosphere; by M. A. Haller, on a general method of synthesis for the β-acetonic acids of the aromatic series; and by M. E. Sorel, on the rectification of alcohol.—The President announced the death of M. Halphen at Versailles; and M. Hermite paid an eloquent tribute to the memory of the illustrious geometrician at his obsequies on May 23.—The death was also announced of the distinguished physicist and electrician, M. Gaston Planté.

VIENNA.

Imperial Academy of Sciences, March 21.—The following papers were read:—On Van Deen's blood-test and Vitali's pus-test, by E. Bruecke.—On some problems of the theory of the conduction of heat, by T. Stefan.—On the alterations of the pigment in the insect's eye, caused by the influence of light and its physiological meaning, by S. Exner.—New observations on the change of combinations in phenols (third communication), by T. Herzig and S. Zeisel.—On ortho-dicarbonic acids of pyridine, by G. Goldschmidt and H. Strache.

BOOKS, PAMPHLETS, and SERIALS RECEIVED

Petrographical Tables: H. Rosenbusch, translated by F. H. Hatch (Sonnenschein).—An Elementary Treatise on Mechanics: I. Warren (Longmans).—The Metallurgy of Silver: M. Eissler (Lockwood).—A Treatise on Geometrical Conics: A. Cockshott and F. B. Walters (Macmillan).—An Elementary Text-book of Chemistry: W. G. Mixter, 2nd edition (Macmillan).—A Practical Guide to the Climates and Weather of India, Ceylon and Burmah, &c.: H. F. Blanford (Macmillan).—Papers on Alternating Currents of Electricity: T. H. Blakesley, 2nd edition (Whittaker).—A Graduated Course of Natural Science, Part 1, 1st Year's Course: B. Lœwy (Macmillan).—International Annual of Anthony's Photographic Bulletin, vol. ii., 1889-90 (Illiffe).—British Dogs, No. 31: H. Dalziel (U. Gill).—La Période Glaciaire: A Falsan (Paris, Alcan).—Indian Meteorological Memoirs, vol. iii. Parts 3 and 4, and vol. iv. Part 5 (Calcutta).—Report on the Meteorology of India in 1887 (Calcutta).—An Elementary Treatise on Dynamics: B. Williamson and F. A. Tarleton, 2nd edition (Longmans).—Questions on Stewart's Lessons in Elementary Physics: T. H. Core (Macmillan).—The Middle Lias of Northamptonshire: B. Thompson: (Simpkin).—Essays upon Heredity and Kindred Biological Problems: A. Weismann; authorized Translation by Poulton, Schönland, and Shipley (Clarendon Press).—Himmel und Erde, Heft 9 (Berlin, Paetel).—Aus dem Archiv der Deutschen Seewarte, viii. Jahrgang, 1885 (Hamburg).—Observaciones Magnéticas y Meteorológicas del Real Colegio de Belen, 1er Semestre, 1887 (Habana).—Veröffentlichungen aus dem Königlichen Museum für Völkerkunde, i. Band, 1 Heft (Berlin, Spemann).

THURSDAY, JUNE 13, 1889.

THE ELEMENTS OF VITAL STATISTICS.

The Elements of Vital Statistics. By A. Newsholme, M.D. (London: Sonnenschein, 1889.)

DR. NEWSHOLME has written a book which, though intended primarily as a guide to medical officers of health and students preparing for the various sanitary examinations, will be found by the general reader to form a convenient compendium of useful facts and of the conclusions deducible therefrom. For the writing of such a book the author was well qualified, having been distinguished as University Scholar in Medicine, and having had, in addition to the ordinary practice of a medical man, considerable experience as a medical officer of health, formerly at Clapham and recently at Brighton. A work of this kind must necessarily consist largely of information derived from the census returns, public registers, and reports; and an author's ability is shown in the selection of the information, its arrangement, and verbal presentation.

Like many persons who have given attention to the subject of vital statistics, whether for sanitary or financial purposes, Dr. Newsholme attaches great value to a correct and more frequent census, and to a complete and accurate registration of births, marriages, and deaths, the cause of death being in all cases carefully ascertained and recorded. He also desires a systematic and extended registration of sickness, its nature and duration; urging that the concurrent publication of information furnished by such registration, and involving the announcement of the outbreak, the spread, and the subsequent contraction of epidemics, would lead to results of the highest public benefit.

The requirements of a good census from a sanitarian's standpoint are said to be that the enumeration shall be accurate and complete—to this we may say, of course—and that it shall be simultaneous throughout the country, in order to avoid the disturbing influences of migration—again, of course. It is suggested that the particulars demanded at the taking of the census should comprise the following items as a minimum: name, sex, age (children under two years stated in months), relation to head of household, conjugal condition, calling, religious persuasion, illiteracy, birthplace and nationality, language, residence, infirmities, this last term meaning, we presume, serious infirmities, such as those of the blind, the deaf, and the dumb, and the several forms of insanity. We ourselves do not see in what way a sanitarian is concerned with the religious persuasions of the people, or with language as apart from and independent of nationality; nor do we think a sanitarian, or any other student or scientific worker, could extract any useful knowledge out of the untested declarations of uneducated persons relative to the ability or inability of themselves and their families to read and write. We do not altogether agree with our author in advocating inquiry on these points; but we entirely agree with him on the remaining points he mentions, to which, in the main, however, the country at large may be considered already to have assented. We would emphasize, with him, the desirability of taking the ages of the youngest children in months; at any rate, for the first year of life. Considering the heavy mortality prevailing during infancy—about one-fifth of all the births being followed by death within two years—and considering its rapid change from month to month, as the development of the infant progresses, it is an obvious requirement of this branch of the subject that steps should be taken to ascertain the mortality for each succeeding month of a child's life, and thus verify the estimates and partial results that have already been published. We would also emphasize, with our author, the desirability that the calling or occupation of each person should be given with sufficient definiteness to obviate confusion. At present one experiences some difficulty in manipulating the figures of the Registrar-General's Office; a difficulty arising not only from the classification of occupation, and partly unavoidable, but also from the inclusion in one figure of masters with workmen, and sometimes of those who have retired from an employment with those actively engaged in it. There is, as is self-evident, the greatest difficulty in obtaining precise information from the millions of an entire population; but the Registrar-General has, no doubt, turned his attention in the directions now indicated with a view to future action.

The Civil Registration Act was passed in 1837, but for a long while the registration of births was defective, it having been estimated that as many as 5 per cent. of the births were lost sight of. This is a fact not to be forgotten in dealing with earlier years. The registration of births was made compulsory by the Births and Deaths Registration Act of 1874; but the record gives neither the age of the mother at the date of the birth of the child, nor the order of its birth (first, second, third, &c.); so that we can know neither the number of children borne by mothers at each year of the mother's age, nor the average number borne in the course of a mother's lifetime. The birth-rate in a community is commonly represented by the ratio of births to population, so many per thousand; but the basis of 1000 living, including, as it does, a varying proportion of men, women, and children, is not a perfect basis; and, to get the true birth-rate, the number of births should be compared with the number of women between the ages of about 16 and 45. The population basis is, as a rule, however, adequate for practical purposes, and tables, so constructed, display, throughout Europe generally, a tendency in the birth-rate to decline. In the United Kingdom the decline has been fairly regular and continuous for some years past, the decline amounting to almost 3 per thousand in seven years.

The chapter on births contains, under the head of "The Malthusian Hypothesis," some remarks respecting the famous essay on the theory of population published in 1798. As popularly understood, the hypothesis was to the effect that the growth of a population must be circumscribed by the means of subsistence. The remarks are especially directed against the doctrine that "the population is increasing in a geometrical progression, the means of subsistence in an arithmetical progression; and unless wars, destructive epidemics, marshes, dense towns, close workshops, and other deadly agents, carry off the excess of the numbers born, . . . the whole people must be exposed to a slow process of starvation." Our author is quite right in attacking this theory, but it is substantially no answer to the theory to say that a geometrical progression may progress so slowly as hardly to progress at all; or that, when the number of births falls below the number of deaths, there is a decreasing geometrical ratio instead of an increasing one. Such an argument is, doubtless, the correct statement of a purely theoretical truth of abstract mathematics, but it does not meet the case as popularly understood. Also inconclusive, in our opinion, are some of the comments on increase of subsistence. To define subsistence as "all that supplies men's wants" is to adopt a definition of the term which calls for definition more loudly than the word defined; and to suggest that we may look to human industry and scientific discovery for the increase of food is to open up before us a very doubtful and probably disappointing prospect. The teachings of Malthus may have been more or less refuted by the history of the present century, but we all agree that the danger of population outrunning subsistence is one that common-sense demands should always be kept in view.

The marriage-rate is usually obtained by comparing the number of marriages with the number of the population in which they occur. This method is exact enough for many purposes, but to attain theoretical accuracy the comparison should be made with the number of eligible bachelors, spinsters, widowers, and widows. Like the birth-rate, the marriage-rate appears to be on the decline, not only in this Kingdom, but also throughout Europe. In England and Wales, bachelors now marry at a mean age of 26·2 years and spinsters at 24·6 years, the age at marriage exhibiting a tendency to increase. The average number of births to a marriage is for England and Wales about 4½; the average for Italy being 5·15; Prussia, 4·92; Austria, 3·73; and France, 3·42. In England and Wales the average duration of ordinary married life has been computed at about 27 years.

It is customary to state the death-rate by comparing the number of deaths with the number living, but the results require to be received with caution. The population of a place may vary in its age and sex composition with the arrival of immigrants and the departure of emigrants; also from an excess or defect of births over or under deaths; also from other and special causes; and these disturbing elements cannot always be left out of consideration. Thus, the general death-rate in England and Wales in 1881 was 18·9, for all ages, while the general death-rate in France was 22·0; but had the age-distribution in France been the same as in England, the French rate would have been 20·9, and it is clearly with this figure, and not with the 22·0, that the English figure is justly to be placed in comparison. With respect to the registration of death, and with a view to obtain better information as to the cause of death, Dr. Newsholme favours the appointment of medical registrars, and thinks the certificate of the medical attendant on the deceased should be withheld from the family and sent direct to the registrar.

To the general reader the discussion of the influence exerted on mortality by climatic and social conditions, by recent sanitary legislation, by density of population, and by occupation, is sure to prove attractive. Figures are adduced to demonstrate that mortality is usually highest in the first quarter of the year and lowest in the third; and we are told that mild winters and cool summers both lower the mortality, the former especially of the old, and the latter of the young. Pervious subsoils apparently afford a better protection against lung-disease and diphtheria than retentive ones, as might naturally be expected; but not so with phthisis, which, according to the figures quoted, is no great respecter of subsoil. As is popularly understood, the death-rates for married persons of both sexes are more favourable than for the single or widowed, but it must not be forgotten that in marrying and giving in marriage a process of natural selection takes place, and that it is only the more or less healthy, if not also the more or less strong, that enter the married state. The aggregation of an ever-increasing proportion of the population in towns has an unfavourable effect on mortality; for the general death-rate in the urban districts, which, according to the mean rates for the country, and making due allowance for age and sex, should have been 20·4, was as high as 23·1, while in the rural districts, where it would have been estimated at 22·83, it was only 19·0. However, the inferiority of town to country, in this respect, is, apparently, becoming less marked. Next to the subject of crowding in towns, comes up for consideration the subject of crowding in houses. Some observations in Glasgow tended to show that among those living in one and two roomed houses the death-rate was 27·74 per 1000; among the occupants of three and four roomed houses, 19·45; and among those living in houses of five rooms and upwards only 11·23; but such results cannot be attributed solely to the extent of house accommodation. The fewer the rooms, as a rule, the poorer the person, and therefore the less able to procure a supply of good and sufficient nourishment, suitable clothing for summer and winter, healthful occupation and recreation, and, in times of sickness, efficient medical attendance and comforts. Of the increased mortality to the poor man, one cannot say what portion is to be ascribed to the narrowness of his habitation, and what portion to the combination of various other and accompanying causes. A whole chapter of the book under notice is devoted to the effect of occupation on the death-rate, but we have not the space to allow of quoting from it. The chapters on the mortality due to each of the seven chief infectious diseases, and to certain other special diseases that flesh is heir to, will prove little less interesting to the reader than those to which we have more fully referred.

Dr. Newsholme is evidently very earnest in his advocacy of the national registration of sickness, *i.e.* sickness of a disabling character. The number of deaths registered as due to a specified disease may or may not give an indication of the prevalence of that disease. The prompt registration of sickness would result in various advantages to the public health. Prophylactic measures could and would be taken to prevent the spread of threatening epidemics; the isolation of patients and suspects would be more generally provided for; the children of an infected family would be debarred from attending school; while the public excitement consequent on any unusual warning given by the registration would lead to the discovery of conditions conducive to disease, to the thorough inspection of houses, workshops, public drains, clothing, and the food and water supplies. Such periods of excitement would have an educational value among parents and householders, and teachers of all kinds, and a better knowledge of sanitary principles would manifest its presence amongst us in a greater freedom from sickness and in an enhanced vigour of mind and body. If the registration of sickness, by informing us, warning us, and alarming us, will compel public attention, and direct it to matters of public health, and enable us to resist our worst and deadliest foes, by all means let us have registration.

When one reflects on the attention given to sanitation for, at least, the last twenty years, and on the labour and money devoted to it since 1872, when the Public Health Act came into operation, one naturally asks what has been the effect on the national death-rate of all the sacrifices we have made. The answer is, on the whole, satisfactory. The mean annual death-rate per 1000 in England and Wales, at all ages, males and females taken separately, has fallen in each of the last three quinquennia, as under:—

	Males.	Females.
30 years, 1841—70	23·3 ...	21·4
5 years, 1871—75	23·3 ...	20·7
5 years, 1876—80	22·2 ...	19·5
5 years, 1881—85	20·4 ...	18·2

Here there is manifested a striking reduction in the general death-rate, both for males and females. But it is desirable to examine this improvement more in detail, and to differentiate for age as well as sex. When this is done, the change in the death-rate stands out very distinctly.

Mean Annual Death-rates in England and Wales for Periods of Years and Groups of Ages; Males and Females separately.

Ages.	Males.				Females.			
	1841—70	1871—75	1876—80	1881—85	1841—70	1871—75	1876—80	1881—85
0— 5	72·5	70·0	67·2	59·6	62·7	60·0	57·0	50·5
5—10	8·6	7·2	6·4	5·8	8·4	6·6	6·0	5·6
10—15	4·8	4·0	3·5	3·2	5·0	4·0	3·6	3·3
15—20	6·7	5·7	5·0	4·6	7·3	6·0	5·1	4·7
20—25	8·9	8·1	6 8	6·0	8·6	7·5	6·3	5·9
25—35	9·8	10·1	8·7	8·2	10·1	9·2	7·9	7·9
35—45	13·0	14·3	13·5	12·7	12·4	12·0	11·2	10·9
45—55	18·5	20·1	19·0	19·4	15·7	15·8	14·9	15·2
55—65	32·0	34·7	34·6	33·6	27·8	28·8	28·9	27·8
65—75	66·7	69·4	67·6	68·8	59·7	61·0	60·2	59·5
75—85	147·4	148·0	146·7	144·6	135·1	134·3	132·3	129·4
85 and upwards	311·6	315·0	304·1	296·4	288·8	285·9	274·0	267·8

From this table it is seen at a glance that the improvement in the death-rate has been very considerable for all ages up to 25; less considerable from 25 to 45 in the case of males, and 25 to 55 in the case of females; and that for subsequent ages the change is, on the whole, somewhat adverse. The proportion of urban population to rural has increased till at the present moment it may be stated as 2 : 1, but despite this fact there has been a striking and continuous fall in the mortality. Of course, it may be argued that the spread of education, and the diffusion of a knowledge of elementary physiological facts, have had something to do with bringing about this result, and the argument is admissible; but they cannot account either for the suddenness with which the fall set in or the persistency with which it has continued. To sanitary works and operations is, probably in a large measure, to be attributed the improvement in the death-rate as shown above, an improvement that gives 1,800,047 additional years of life to the 858,878 children annually born in England, extending the average lifetime of the 437,492 males by nearly a year and a half, and of the 421,386 females by not less than two years and three-quarters. Apparently, we are taking care of the women and children, especially the latter, and if anything could now be done to alleviate the wear and tear of adult life, arising from the increasing severity of competition, especially among men, and to check the evil effects of crowding together in great towns, these remarkable figures might become more remarkable, and human life healthier, happier, and still better worth living.

In conclusion, we may say that the book is clearly and pleasantly written, that the arrangement of the work is excellent, and that, although it cannot contain much that is new, it is interesting from the first page to the last.

BIRD-LIFE OF THE BORDERS.

Bird-Life of the Borders: Records of Wild Sport and Natural History on Moorland and Sea. By Abel Chapman. (London: Gurney and Jackson, 1889.)

THIS is an admirable book of its kind. On the one hand, its "records of wild sport" will be full of interest to devotees of the gun and rod; while, on the other hand, the trustworthiness of its "natural history" is guaranteed by a statement in the preface that the proofs have been revised by Mr. Howard Saunders. But it is not enough to say that the natural history is trustworthy: it is also full of original observations, interesting alike to the bird-lover and the scientific ornithologist. In particular, we may instance a very suggestive chapter on migration, which shows among other things the importance in this connection of distinguishing between a species and its constituent individuals. Certain birds occur in certain regions all the year round, and therefore in those regions might be regarded as non-migratory; but, as a matter of fact, such regions constitute "overlapping zones" doubly crossed by the birds in question during their migrations north and south, so that although the species occupies such a region all the year round, it does so only in virtue of a continual changing of its representative individuals; "those individuals which occupied this area in summer will be wintering 1000 miles south, while their vacated places are occupied by others which had passed the summer 1000 miles north."

Again, there are some curious observations on what the author calls "pseudo-erotism," by which he means a display of amatory instincts which occurs on the part of black-game, plovers, gulls, &c., in October, or even later.

"On wet, foggy mornings in particular, one hears the old blackcocks 'crooning,' 'bubbling,' and 'sneezing,' as excitedly as on a fine day in spring. With a glass, I have watched one surrounded by his harem, strutting round some bare little knowe in the fullest 'play.' . . . Whether this is merely a chronological miscalculation, or arises from some specific cause, the origin of which may be lost in the mists of a remote past, the instinct certainly exists," &c.

There is another point to which we would like to draw attention. It is, of course, well known that telegraph-wires are very destructive of bird life upon open moors; but it is generally supposed that, after the wires have been set up for a year or two, the birds learn by experience to avoid them, and so do not come to grief in nearly such large numbers as they do when the wires are first erected. Now, whether or not this supposition is well founded, it appears certain, from Mr. Chapman's systematic observations upon the mortality thus occasioned, that it occurs perennially to an astonishing degree. The observations were conducted along a line of telegraph wires (nineteen in number), and are as follows:—

"I have heard it estimated by farmers and shepherds (and believe they are not far wrong) that more grouse meet their deaths annually from these mischievous wires than are killed by all the shooters on the moor around. . . . This destruction is going on at all seasons of the year. It is no exaggeration to say that the roadside is, at certain seasons, strewn with remains. Besides grouse, I have picked up black-game, partridge, curlew, golden plover, snipe, peewits, and other birds. Every morning, at break of day, come out the marauding bands of rooks from the lowland woods, reconnoitering along the roadside, and feasting on the dead and dying."

As evidence of the cruelty inflicted by the wires, quotations are made from the author's note-book, of which the following is an example:—

"October 6.—Found to-day four grouse which had been severely damaged by flying against the telegraph wires on Elsdon Hill. Two were already dead, and pulled to bits by the crows. The third had evidently received his wound late the night before, and the blow had completely carried away his crop, which at that time would be full of heather. The poor bird had been hungry this morning, and, regardless or oblivious of having no crop, had been feeding—his throat, down to the huge gash, being crammed with heather-shoots. I never saw anything more pitiable in my life. This bird could still fly, but very weakly, and could not possibly long have survived. The fourth grouse had been injured some time before. He also had received a horrible gash across the breast, but it appeared to be slowly healing."

Now, as Mr. Chapman says "it would be easy to adduce hundreds of similar instances" from his own neighbourhood alone, every sensible man must agree with him when he adds—

"Surely, in these days of ultra-humanitarianism, of R.S.P.C.A. Associations, and of 'Wild Bird Protection Acts'—when a maudlin sentimentality comforts itself by fining a poor man for shooting a wild goose in March, or for overworking his horse on which perhaps depends his daily bread—surely, in these days, the wanton cruelty and useless waste above described (carried on for a national profit) should not be permitted."

Of course the answer to this is, that telegraph wires are nowadays an absolute necessity; but, on the other hand, there is a simple solution of the difficulty, which we will mention in the hope that it may be taken up by the "R.S.P.C.A.," or some private M.P. in search of material out of which to construct a Bill. Let an Act be passed, enjoining that all telegraph-wires extending over moorlands, or other open spaces frequented by birds, shall be run underground.

"Bird-Life of the Borders" is profusely illustrated, and in all respects well deserves the patronage both of sportsmen and field-naturalists.

OUR BOOK SHELF.

Curiosa Mathematica. Part I. A New Theory of Parallels. By Charles L. Dodgson, M.A. Second Edition. (London: Macmillan and Co., 1889.)

WE noticed the first edition of this *brochure* in NATURE (vol. xxxix. p. 124) at some length; and now merely wish to touch upon one or two points which our author animadverts upon in his new preface. Mr. Dodgson apparently fails even now, after our letter in NATURE (*l.c.*, p. 175), to realize our difficulty with the construction in Prop. vi. He says:—"Bisect the angle: that gives halves. Bisect the halves: that gives quarters. Bisect again: that gives eighths. Bisect once more: that gives sixteenths. *Voilà tout!*" Shade of Euclid! who knows not such things? We admitted the same (*l.c.*, p. 175), but stated that our difficulty in the construction was the condition imposed in the enunciation: viz., "the chord of each such sector not less than the radius of the circle." Take Mr. Dodgson's illustration of a sixteenth, this would necessitate that the original angle should be at least 960°. We do not object to that or to any other size. But this, or what is tantamount thereto, we have already brought forward, and have further noted that no one of the chords in Mr. Dodgson's figures is even equal to the radius. But this is not a point touching the author's argument; and we notice it only because he has pilloried us therefor in his new preface, which *some* people will read, contrary to his recorded experience. We thought the remarks we wrote (p. 175) touching viii. and xi. would have amply satisfied him, but he returns to the subject. We need only say that the present enunciations of these propositions, had they been given in the first edition, would have saved us from any misapprehension of the author's argument. This edition is little more than a slightly corrected (there was very little need of correction) and so improved edition. The proof of Prop. i. is new: on p. 9, line 4, an = might advantageously, we think, precede AB. The new forms of viii. and xi. are: "It is not true that the angles of every triangle are together greater than two right angles," and "It is not true that the angles of every triangle are together less than two right angles." On p. 23 there is an uncorrected false reference in line 5 up: for iii. read iv. The proof of xii. has been recast, and in the appendix ii. (pp. 43, 44) about a page of matter, with Euclid's definitions of ratio, has been interpolated. On p. 56 the name R. Simpson occurs twice: it should be R. Simson or T. Simpson. It would be possible now, we should suppose, after a year's interval, to speak in somewhat clearer language ("I understand") of Mr. (now Prof.) Cook Wilson's investigations. After a hasty re-examination of Mr. Dodgson's argument, we can only reiterate our admiration for this first part of the "Curiosa Mathematica." We hope other parts are on the way. R. T.

Longmans' New Atlas. Edited by George Chisholm, M.A., B.Sc., Fellow of the Royal Geographical and Statistical Societies. (London: Longmans, Green, and Co., 1889.)

THIS atlas, although primarily designed for use in schools, aims at being a school and a reference atlas in one, and the attempt to effect a compromise between the two is certainly laudable. It contains 40 quarto and 16 octavo maps, illustrating the physical conditions of the earth, and dealing with climate, vegetation, products, distribution of population, ethnography, and religion. The maps are finished in a good style, and reference to them is considerably facilitated by the system of ledger indexing that has been adopted. In only a few cases has the rainfall been given. It would have been well if a map had been constructed to show the mean annual rainfall over the entire globe.

The magnetic variation map is complete as far as it goes, but since it does not reach below lat. 60° S., the two foci in the southern hemisphere are not shown, and to a beginner it would appear as if such foci existed only in the northern hemisphere.

The physical features of different parts of the earth are generally well illustrated; but in an attempt to eliminate names that have been considered superfluous, it is doubtful whether in some cases the line of demarcation has not been overstepped and the maps left comparatively bare. The two ethnological plates, and the full explanatory note contributed by Mr. A. H. Keane, are worthy of commendation. Some of the subjects of the plates containing typical scenes from different parts of the world seem rather out of place in an atlas like this. We refer to such small cuts as "Children enjoying a Ride on a Dog Sledge" and "Children tobogganning in Canada." Again, another cut which is supposed to illustrate "An Aurora Borealis" is but a mournful representation of one of the grandest of natural phenomena, and might be omitted altogether for the idea it conveys of the character of an aurora.

Most of these plates, however, exhibit the physiographic aspect of different parts of the globe in a very clear light. Indeed, such an atlas as the one before us should play an important part in public school education, and deserves a high place among the political and physical atlases now in use.

Travels in the Atlas and Southern Morocco. By Joseph Thomson, F.R.G.S. (London: George Philip and Son, 1889.)

WHEN Mr. Thomson began his exploration of Morocco, his intention was to write a complete account of that interesting country. His purpose was, however, thwarted by the fact that he was recalled to England much earlier than he had anticipated; so that he has been able to write only a narrative of his personal experiences during his travels. In order to preserve what he calls "the popular and handy character of the volume," he has omitted many things of general and scientific interest which will see the light through more appropriate channels. The book ought to be cordially welcomed by a large class of readers, for it presents many vivid sketches of places which have hitherto been very inadequately known, and the people of Morocco are not less graphically depicted than the physical features of the country itself. Mr. Thomson, we need scarcely say, is a most careful and exact observer, and he has a vigorous, straightforward style, which makes it pleasant for his readers to attend him from point to point of his story. The interest of the volume is greatly increased by a number of admirable illustrations from photographs.

Eclectic Physical Geography. By Russell Hinman. (London: Sampson Low and Co., 1889.)

WE have much pleasure in drawing attention to an English edition of this admirable text-book, which has already been reviewed in our columns. We can confidently recommend it both to teachers and students. The numerous maps with which the book is illustrated will make it especially useful to teachers.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

"Mithradatism."

I AM anxious to introduce the above word for the purpose of indicating the phenomenon of immunity to poison (whether of bacterial or other origin) induced by administering to an organism gradually increased doses of poison. Mithradates Eupator, the sixth and greatest of that name, King of Pontus, is stated in classical tradition to have so far impregnated his system with poisons on which he experimented, that finally, when he wished to kill himself by some drug, he was unable to do so, having inadvertently rendered himself "immune" or refractory to all known agents of the kind.

I suggested this term in a lecture at the Royal Institution last week; and previously, in conversation with Dr. Roux, in Paris, proposed its use. The utility of the related terms "mithradatize" and "mithradatic" is obvious. The mithradatic theory of inoculations is opposed to the theory of "exhaustion of the soil" and to that of "inhibition by the introduction of chemical substances *directly* inimical to the growth of disease germs."

The Persian god Mithras is not inappropriately associated with the conquest of poisons, since the scorpion was represented as lying at his feet.

E. RAY LANKESTER.

45 Grove End Road, N.W., June 3.

Report of the Royal Commission on the University of London.

WILL you allow me to submit to your readers a somewhat different view of the Report of the Royal Commission from that of the able article which appears in to-day's NATURE?

The writer puts the case clearly and forcibly from the position of University College; and thence, looking down upon the existing University, he recommends it to "afford, by means of a general examination, a test of attainment for students in institutions of as yet imperfect efficiency, and for private students." Those who are justly proud of the work that has been done by the present University (which the Commission fully and unanimously acknowledge) are well aware of its imperfections. More or less "imperfect efficiency" might be asserted of most human institutions. But the University has already elaborated a scheme of reform which in its essentials has been accepted by the Commission; and we may hope that it would grant even more liberal terms in order to secure the great public object of unity. It is beside the mark to propose, not the reform of the University—that both Senate and Convocation desire—not even its destruction, for that would leave the chance of making a better one in its stead; but its perpetuation in a starved, degraded, and hopeless state.

Surely it would be wiser for University and King's Colleges to accept the position offered them of taking the leading part in the reconstituted University, and sharing in its prosperity. For what would they surrender? The faint hope of obtaining a reversal of the Report after an uncertain period of suspense—always trying for a public institution—and then the task of making a new and rival University in London, of providing degrees not inferior in credit and yet not superior in difficulty to those of the older University, of conciliating the antagonistic principles on which the two Colleges were founded and are still supported, and of either persuading richer, larger, and older medical schools to join them, or running great risk of being forsaken by their own medical faculties.

Both Colleges have, under discouragement and undeserved neglect, performed excellent work, and University College in particular has done wonders in the last fifteen or twenty years. They have always had a grievance against the University of London, and were justified in getting tired of waiting on a tardigrade Senate and an amorphous Convocation. They saw a chance of obtaining a new joint charter, and pushed their claims at all hazards, including the loss of some of their most distinguished members. They have not succeeded, and on the whole they will probably be thankful that they have not, for their success would have meant the barter of a splendid birthright for a doubtful immediate triumph.

The writer of the article does not consider the question of the great medical schools of London, except to say that "the rejection of a separate University for Medicine is good in itself"; but in fact the grievance of these bodies is far greater and more pressing than that of University College.

In the real University of London that we all hope to see——teaching, examining, learning, and growing—the three or four best of these schools will form constituents in many respects more academical, more collegiate, and more powerful than the non-medical Faculties of University and King's Colleges. They have traditions, they have endowments, and they have a scientific as well as a purely medical discipline. Their students are for the most part older than those of the Arts Faculties, they have more of a common life, and they are wholly engaged in the studies of the place; whereas a large number of the nominal students in the two Colleges are buyers of scraps of knowledge, rather than University students as the phrase is understood at Oxford, at Edinburgh, or at Leipzig.

The chief difficulty which the minority of the Commissioners have evidently felt is that, by the constitution of the existing University, candidates are admitted to most of its degrees who have passed the several examinations, whether they have been educated in Colleges or no, and whether in London or elsewhere.

But it must be remembered (1) that this was not the original constitution of the University, but a later modification; (2) that the change has never been carried out in the Faculty of Medicine, which is confessedly the most successful of the four, and that practically it has been confined to the Faculty of Arts, which is confessedly the weakest; (3) that there is no insuperable difficulty in the same University granting degrees to collegiate students and to non-collegiate, to local students and to others; for Oxford and Cambridge give the same degrees to men from College and to those who are "unattached," and the University of Dublin has for many years admitted graduates from outside as well as students of Trinity College; (4) that when a teaching University for London has been organized, the number of collegiate students will steadily increase, while that of outsiders will diminish; for local centres will gradually develop and claim independent existence, as they have already at Manchester, at Calcutta, and at Bombay.

Surely, when the first feeling of disappointment has passed away, the Professors of University and of King's Colleges will see that they have still a splendid position waiting for them to occupy. Together with the medical schools, they will enter upon the vantage-ground which fifty years have gained for the present University of London. They will influence, and almost direct, it, if agreed among themselves; and if now and then Doctors and even Teachers find that they cannot have their way in everything, may not the few exceptions be just those in which it is well for the most liberal and enlightened professorial, or clerical, or professional opinion to be moderated by the judgment of laymen?

London needs a University worthy of the greatest city in the world. Three constituents, and three only, are necessary to its formation; and it is not too much to say that no two can make it, but that any one of the three can mar it. To obtain this great public object, the existing University will have to give up many of its prejudices and many of its powers; the medical schools will have to give up some of their independence; University and King's Colleges will give up little but a grievance. In the long run, by united forces, each healthy and vigorous constituent of the renovated University will share in the prosperity and the progress of the whole. The strongest and the best will have the largest share.

June 6. A LONDON TEACHER.

A Lizard Swallowed by a Viper.

As it appears from the "Notes" in the last number of NATURE that the swallowing of a lizard by a viper is not usual, I may mention an instance which came under my own observation. Many years since, I captured a viper on Cannock Chase, in Staffordshire. The animal was rather sluggish, so I got it into a box unhurt, and carried it home. There I shook it out on to the ground. There came out first the slimy body of a *Lacerta vivipara*, followed by a thinner and livelier viper than that which had entered the prison. This result was not surprising, for the victim was about half as long as the swallower, which may explain the ejection of the former when the latter exchanged the fresh air of the Chase for a stuffy box. The lizard, however, in this case was dead, and digestion had begun. T. G. BONNEY.

Remarkable Meteors.

THE spring of 1889 has afforded a very unusual number of fireballs, though it is somewhat rare to find the vernal season prolific in these phenomena. In the autumn, it is true, we frequently hear of conspicuous meteors, but the earlier months of the year are by no means rich in such apparitions.

On March 11, 6h. 36m., a fine meteor of the colour and brilliancy of Venus was seen at London.

March 13, 10h. 25m. Large, bright meteor, without sparks or trail, observed at Dublin.

March 22, 24, 27, and 31. Fireballs appeared at Wexford, Dublin, &c.

April 15, 12h. 24m. Very brilliant fireball observed at Bristol, Bath, Dublin, Lincoln, London, Ramsbury, Worthing, and other places. Though the full moon was shining, the meteor burst out with startling effect, and lit up the sky and landscape for several seconds with a degree nearly equal to daylight.

April 27, 8h. 51m. Fireball equal to Venus seen at Bristol and Trowbridge. It fell vertically and moved slowly from a radiant probably at R.A. 119°, Decl. 28° N., a few degrees east of Castor and Pollux.

May 22, 10h. 8m. A very slow-moving meteor, as bright as Jupiter, and having a great length of path, observed at Bristol, Reading, Clifton, &c.

May 29, 10h. 45m. Fireball, fully 12′ in diameter, and shaped like a club, noticed at Leeds. It travelled with extreme slowness, occupying 9 seconds in traversing the 26° from $141° + 20°$ to $113° + 23\frac{1}{2}°$. Its probable radiant was either at $176° + 9°$ or $210° - 5°$.

Of these various bodies, the most remarkable were those of April 15 and May 22. The former was undoubtedly one of the most brilliant fireballs seen in recent years. The descriptions of its apparent path are not, however, sufficiently precise and accordant to enable its height to be ascertained. It appears to have emanated from a radiant point near Arcturus, and to have been very low in the atmosphere at the time of its final outburst and disappearance.

With regard to the meteor of May 22, it displayed some rather exceptional characteristics, though in point of brilliancy it was certainly inferior to several of the fireballs which have been lately recorded. As observed by the writer at Bristol, it passed about 6° below Vega, and was lost sight of behind buildings, which intercepted the view, when close to η Ophiuchi. Its path of 62° was performed in 16 *seconds*, so that the motion was extremely slow. As the nucleus sailed slowly along, it distributed a train of yellowish sparks in its wake. At Reading, the meteor was seen by Mr. G. T. Davis while observing coloured stars. He noticed its course with particular care as from about 1° west of Corona to between β and δ Scorpii, and gives the points of the observed beginning and ending as $226° + 31°$ and $239° - 24°$, length of track 56°. He notes, however, that this line of flight should probably be extended to include the whole visible arc of the meteor's course. The duration was estimated as 15 *seconds*. A yellow train of 15° in length followed the head of the meteor as it slowly trailed across the sky, and Mr. Davis describes the whole effect as a splendid one. At Clifton an observer watched the object as it passed from the northern [??] sky to the star Vega, and from thence into the north-east confines of Scorpio. He remarks that the most curious point in connection with its career was its long duration, which must have been 18 *or* 20 *seconds*.

Comparing the pair of observations at Bristol and Reading, it is found that the radiant point of this conspicuous meteor was at $63° + 35°$, in azimuth $153\frac{1}{4}°$ (reckoned west from south), and altitude 1°. It was therefore pursuing a course very nearly parallel with that part of the earth's surface above which it appeared. When first seen at Bristol it was passing over a point 6 miles east of Oxford at a height of 50 miles. The Reading observer caught sight of it when 6 miles east by south of Farnham, the height being the same. When the object was obscured by houses at Bristol, its height had increased to about 55 miles. At Reading it was last seen when above a point 10 miles west of Orleans, in France at a height of 58 miles. The rapidly increasing distance of the meteor prior to its disappearance was of course due to the earth's curvature.

The real length of path observed at Bristol was 196 miles, described in 16 seconds, so that the velocity was $12\frac{1}{4}$ miles per second. At Reading the length was 249 miles in 15 seconds—velocity $16\frac{1}{2}$ miles per second. Parabolic velocity would be about 20 miles per second, so that it is probable the meteor was revolving in an ellipse of very slight eccentricity—in fact, the orbit appears to have been nearly circular in form.

The radiant point of this meteor is situated some 7° south-east of ϵ Persei. The position is a very unusual one for a meteor shower occurring at this period of the year. When the effects of zenithal attraction are allowed for, the radiant is found to be several degrees below the position as above assigned from a simple projection of the two paths, and within about

12° of the sun's place. The very slow motion of the meteor, its considerable length of path, and the exceptional point from which it diverged, combine to render it an object of especial interest, and further observations of its apparent path would be valuable. It probably became visible at an earlier part of its path than when first seen at Bristol in Lyra, and it is desirable to ascertain, if possible, a more precise result for its point of appearance. The entire length of its course might then be derived, when it would possibly be found that the distance assigned from present data is much shorter than that really traversed by the meteor. The Bristol and Reading observations indicate the whole length as nearly 300 miles, and this, though undoubtedly under the true value, is yet far greater than the customary tracks over which the flights of these bodies extend.

Bristol, May 31. W. F. DENNING.

Palæolithic Implements from the Hills near Dunstable.

DURING the past twelve months I have found a small number of Palæolithic implements at great elevations in North Hertfordshire and South Bedfordshire, unconnected with existing river valleys. Four of the implements—1386, 1387, 1393, and 1398 in my collection—are from Caddington: height above Ordnance datum, 595 feet 9 inches. The dry valley close by, to the west, is 470 feet, and the ground gradually falls southwards to 409 feet at the source of the Ver, near Markyate Street, at a distance of $1\frac{3}{4}$ mile. The sections at Caddington exhibit red "clay with flints," brick earth (or clay), and tenacious brown clay or loam, surmounted by blackish earth, containing broken white-coated flints, a few ochreous flints, and numerous blackish Tertiary pebbles. The whole deposit rests on chalk, and varies in depth from 2 feet to 50 feet. Aware of the importance of finding the worked flints in the undisturbed material, I have, after long searching, found a single implement and one or two flakes *in situ* at the stony bottom of the upper deposit of tenacious brown clay at a depth of 3 and 4 feet from the surface. A single small Palæolithic implement I have found on the surface at Kensworth: height above Ordnance datum, 759 feet 8 inches. The bottom of the valley, $1\frac{1}{4}$ mile to the west, at the source of the Ouzel, is 414 feet. Half an ovate Palæolithic implement, obviously derived from the hill-tops, I have found in a field at the bottom of a chalky valley near Houghton Regis. The Caddington implements are pointed (or tongue-shaped), slightly abraded, small in size, and cinnamon-brown in colour. The interest attached to these finds rests not only on the great heights mentioned and the positions away from existing river valleys, but in the nature, age, and mode of deposit of the upper tenacious brown clay in which the implements are embedded. The implements themselves agree in make and appearance with the well-known brown or ochreous implements often found in non-ochreous sand, &c., in existing river valleys. I have at present seen no traces of fossil bones or fresh-water shells in the deposits mentioned. WORTHINGTON G. SMITH.

Japanese Clocks.

WITH reference to your notice of the Japanese clocks purchased for this Museum, and described by Mr. A. Rambaut, it may prove of interest to point out in somewhat fuller detail the conclusions at which he has arrived as to the cause of the peculiarities in their construction It was on account of these, to me, unintelligible peculiarities, that I invited Mr. Rambaut to undertake their explanation, and this, I venture to think, he has very thoroughly accomplished as follows. The three clocks agree in having a dial on which the time is indicated by a pointer attached to, and descending with, the weights. In other respects they differ, though all are made more or less on the same principle. The largest of the three appears the most important, and the greater part of the paper is occupied in explaining its construction. The dial of this is divided by vertical lines into six equal spaces, which are crossed by a series of thirteen graceful curves. An examination of these curves leads to the conclusion that they were intended to divide the day and night, at all seasons of the year, into six equal portions each. This system was common enough in ancient times, but the peculiarity of these clocks is that they show the day to have been reckoned, not from sunrise till sunset, but from the first noticeable streak of morning twilight until the sun had reached a corresponding distance below the western horizon. This distance is equal to 13°, and the form of the curves leads to the conclusion that the clock was constructed in a latitude of about 34° 7′, very little less than that of Miako, formerly one of the principal cities in Japan. An examination of the two other clocks, although they differ very much in detail, supports the conclusions derived from a study of the first. V. BALL.

Luminous Night-Clouds.

FOR the first time this year these clouds appeared in this locality last night, between 10 p.m. and midnight. I inclose sketches, as with my reports in former years, made at half-hour intervals, exhibiting development and movement; which latter has been in this case from west to east, a direction the reverse of light local wind. A depression of temperature was noticed, as on former occasions. Minimum (on grass) fell to 40° F.

It may be remembered by some of your readers that when first pointing attention to this annual phenomenon some years ago, and affirming the self-luminous character of these cloudlets, at apparently high altitudes, the name "nubeculæ boreales" was suggested to distinguish them from simple auroral effects. Herr Jesse, of Berlin, has recently (NATURE, vol. xxxix. p. 537) noted their occurrence toward the South Pole also, and pointed to their probable cosmical importance. Detailed observations of any of your correspondents, made during the present reappearance of this phenomenon, would be accepted by the writer thankfully, toward a fuller discussion of the subject. If, as would appear, it is chiefly of a Polar character, the name proposed should be modified to include the South Pole, and these clouds so designated "nubeculæ polares" (or "noctilucæ").

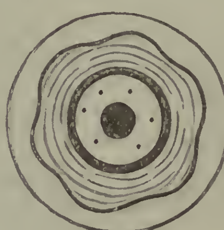
D. J. ROWAN.

Dundrum, Co. Dublin, June 8.

Note on some Hailstones that fell at Liverpool on Sunday, June 2, 1889.

BEING in the Physical Laboratory at about 3.35 p.m., about which time a violent thunderstorm took place, accompanied by hail and rain, I went outside and picked up what seemed to me a fine specimen of hail. I brought it inside, measured its diameter with a pair of calipers, and found it to be 2·9 centimetres.

I then placed it on a slate slab, on which it gradually melted down until it showed a very fine section, a picture of which is given below.



The centre was circular, and consisted of opaque ice, about the size of an ordinary hailstone; this was surrounded by a circle of almost perfectly clear ice, this again by a circle of opaque ice, and this once more was surrounded by almost clear ice, but with fine circular lines in it, and bounded by a beautifully frilled outline of opaque ice, which imitated in shape the spheroidal state of a drop of water. Outside this again was a thick layer of clear ice of crystalline form, the position of whose angles I have not shown, as I did not observe their position with regard to the frill inside sufficiently well.

The diagram is drawn to the right size, omitting the angles on the outer covering of ice, the dark parts represent white opaque ice.

If a hailstone is formed during electric oscillation from cloud to cloud, and if it receives opaque ice from one cloud and clear ice from another, the alternation of layers would be a natural consequence. The violence of the hail scarcely seemed as great as their size justified, and this suggested that electrostatic attraction had upheld them against the force of gravitation down to a moderate height above the ground.

I believe almost all the lightning flashes that occurred were between two clouds, as, although I was looking out for the form of the flashes, I could only see the sky lit up with a brilliant red or pinkish glow. Dr. Howard found some hailstones that were cylindrical in form; those that I found were approximately round but for the sharp edges of crystalline structure. Mr. B. Davies measured one and found it to be 3·5 centimetres in diameter. All the large stones that I found showed the same construction; in every one there was the same frilled appearance of an internal surface: this was also observed by Mr. B. Davies.

THE SUBDIVISION OF THE ELECTRIC LIGHT.

TEN years ago the subdivision of the electric light was the burning question of the day. Again it has been revived, but the present subdivision is a legal and not an electrical problem.

The public interest in electricity roused by the sensational telegrams about Edison's work in 1878–79, and by the wonders seen at the Paris Electrical Exhibition in 1881, as well as at the Exhibition at the Crystal Palace in the following year, made people reflect that the electric lighting of our streets and houses might breed a monster as tyrannical as the water companies; consequently, paternal legislation passed an ill-considered Bill, the "Electric Lighting Act of 1882," to curb electrical repaciousness.

But had our law-givers paid attention to what was taking place in the City, and had they also possessed some acquaintance with the difficulties connected with the problem of electric distribution, they would have seen that it was on the Stock Exchange that the devouring electric Hydra was rampant, and that the general supply of electricity was in 1882 but a weak puny infant, which would require the most tender care to enable it to reach boyhood. Instead, however, of fostering the babe, the framers of the Act of 1882 showed their absolute ignorance of the way in which a new industry grows up, by introducing a clause which specified that at the end of twenty-one years the local authority might take over any installation for electrically lighting a district on paying the simple market value of the land and plant without giving anything for good-will. In view of the improvements in electrical machinery that might be expected to take place in twenty-one years, it might have been anticipated that before the end of this period the dynamos and other apparatus might very properly have been replaced twice over, in each case more efficient apparatus being substituted for less perfect: but the local authorities were still to be empowered to step in, to disregard all that had been done in building up a good business, and purchase the whole as a going concern for the mere market value of the land and plant. Hence the progress of electric lighting in England was strangled at its birth, while vast sums were squandered on the legalized gambling of the Stock Exchange, the public being unmercifully fleeced, and then left without electric lighting or belief in it.

This instance of paternal legislation was but a repetition of the one-sided Act passed to remedy the extortion that sometimes accompanied the operation of bills of sale. In this case the interests of the borrower were alone present in the minds of the framers of the Act, and they quite forgot that by making the recovery of debts on bills of sale very difficult they would introduce a new and even greater hardship, by making the borrowing of money on bills of sale frequently impossible.

This bone of contention, the Electric Lighting Act of 1882, was steadily snarled over and growled at, until last year the two Houses of Parliament saw fit to swallow a new Act, which, by extending the period of compulsory purchase to forty-two years, and by recognizing that the development of an electric light installation might represent something much more valuable than the market value of the land and plant, has at last made the general distribution of the electric current commercially possible.

But in the meantime, over a vast area extending from Regent's Park on the north to the Thames on the south, from the Law Courts on the east to Park Lane on the west, some thousands of electric lamps had been dotted, all fed from one central station in the basement under the restaurant of the Grosvenor Gallery in Bond Street. And to avoid the difficulties that would be introduced by the clauses in the 1882 Electric Lighting Act, if the streets were broken up and the wires put underground, the London Electric Supply Corporation, to whom the Grosvenor Gallery installation belongs, erected their cables, some 50 miles in length, over the tops of the houses. Hence, the legislation that was intended to avoid a vested interest being acquired in street conduits has forced the erection on the house-tops of a network of high-pressure mains which have now to be specially legislated for.

The productive capacity of the Grosvenor Gallery plant having been fully reached, while applications to supply current for thousands of incandescent lamps had to be shelved for want of means of generating the necessary current, the London Electric Supply Association commenced the erection of a vast station on the banks of the Thames at Deptford for the supply of current for some millions of incandescent lamps; and it has been mainly due to the application on the part of the company to obtain powers to run their wires along twenty-seven railways and tramways, and through thirty parishes, that the recent inquiry by the Board of Trade, lasting from April 3 to May 1, has been held to examine into the whole question of the electric lighting of London. The result of this inquiry is contained in a long Report that has just been submitted to the Secretary of the Railway Department of the Board of Trade by Major Marindin, this Report being agreed to by Major Cardew.

Eight companies—viz. the Chelsea Electricity Supply Company, the Electrical Power Storage Company, the House to House Electric Light Supply Company, the Kensington and Knightsbridge Electric Lighting Company, the London Electric Supply Corporation, the Metropolitan Electric Supply Company, the Notting Hill Electric Lighting Company, and the Westminster Electric Supply Corporation—applied for thirteen provisional orders and two licenses. A license is a permission granted for seven years, but it is renewable at the end of this period. The Board of Trade, however, can only grant a license when the consent of the local authority has been previously obtained. A provisional order, on the other hand, requires no consent of the local authority of the district, and is granted for a period of forty-two years. After a provisional order has been approved of by the Board of Trade, it requires to be confirmed by a Bill in Parliament before it can come into force. Neither the license nor the provisional order when granted is exclusive or creates any monopoly.

The first point considered in Major Marindin's Report is the systems of supply proposed to be used by the various companies applying for powers. They may be divided into a supply by direct current, and a supply by alternate current. The direct supply by means of continuous currents is dealt with under three heads:—(*a*) The system adopted by the Chelsea Company—viz. the use of one generating station for a considerable area, supplying current to charge several accumulator stations at different points within the area of supply with a pressure of from 1000 to 2000 volts, each station having a duplicate set of accumulators. The supply mains leading from these accumulator stations are intended to carry the current directly into the houses at a pressure of 100 volts, the supply being entirely from the accumulators. This is the system of transformation that was originally suggested by Sir William Thomson at the meeting of the British Association at York. (*b*) The system adopted by the Kensington and Knightsbridge Company, which is at the present moment supplying partly by accumulators and partly by dynamos—the former doing the whole work during the hours of minimum supply, and the latter being employed in charging the accumulators and supplementing the direct supply from the accumulators during the hours of maximum supply. The accumulators are all stationed at the generating station, and merely serve as a reserve of power. Since they are not employed to effect a transformation from a high to a low pressure, they do not introduce any saving in the size of the distributing mains, as in the case of the Chelsea system. Hence the Kensington system, which the Notting Hill Company proposes also to adopt, would require several generating stations for the lighting of a large area. (*c*) Direct supply at low pressure without the use of accumulators, such as is at present employed by the St. James's and Pall Mall Company. This system is also only suited for distribution over small areas, not exceeding half a mile in radius, since the absence of any system of transformation necessitates the employment of very large conductors. This last system has also the disadvantage of alternate current distribution, as the supply, being directly dependent on the steady working of the machinery, is liable to be seriously affected by even a temporary breakdown, which is, of course, not the case with the direct current systems (*a*) and (*b*).

It is interesting to note that no system of direct current transformation, other than that effected by the use of accumulators, has been proposed by any of the companies or referred to in Major Marindin's Report; probably because all direct current transformers, "motor-dynamos," &c., that have yet been devised, employ moving parts, and are therefore in their present form unsuitable for transformation in private houses. We cannot, however, but think that such direct current transformers might be very economically employed at distributing stations, the energy being received at high pressure from the main generating station, and distributed at low pressure to the houses in the neighbourhood of the distributing stations.

The House to House, the London Electric Supply, and the Metropolitan use high-pressure alternate currents with transformers, except in the case of the Whitehall installation of the last company; and it speaks well for the alternate current system that, while the Metropolitan Company commenced at Whitehall with direct currents and accumulators, which they first thought so superior to the use of alternate currents, they now state in their evidence that in their extensions they propose employing alternate currents and transformers. In the case of the London Electric Company, a *double system of transformation* is to be employed between the current leaving the dynamo and the current in the houses of the consumers. The supply will be obtained from a very large generating station at Deptford, outside the crowded districts of the Metropolis, and carried through trunk mains, at the unprecedentedly high pressure of 10,000 volts, to transforming stations inside, or near, the area of supply, whence the current will be taken by distributing mains, at a pressure of 2500 or 2000 volts, to the consumers' premises, and transformed there to 100 or 50 volts. Or this second transformation may be effected at secondary transforming stations, the currents being conveyed from them to the houses at the pressure of 100 or 50 volts.

In the case of the House to House and Metropolitan Companies only one transformation is proposed to be employed, so that several generating stations must be erected; as even with a pressure of 2000 volts the conductors would have to be inconveniently thick if the electric energy were conveyed very far. The Metropolitan Company have, therefore, selected sites in Sardinia Street, Rathbone Place, South Mews (near Manchester Square), Eccleston Place, and Waterloo Bridge Wharf; from each of which a current at 1000 volts will be sent, to be transformed into 100 or 50 volts inside the consumers' premises.

The Report contains a concise account, written by Major Cardew, of the relative advantages of the direct and of the alternate systems. He refers to the fact that the employment of accumulators by the Chelsea Company at their distributing stations enables small distributing mains to be used; makes the lighting of the district unaffected by even a temporary total breakdown of the machinery, since the accumulators that are at any time supplying current to the houses are quite distinct from those that are being charged; enables a nearly constant pressure to be maintained at the houses, independently of the number of lamps that are turned on; and, lastly, the current being a direct one is applicable for the supply of motive power and for other uses besides the production of light and heat, and can be more easily measured than an alternate current. Major Cardew further adds, as an additional advantage possessed by supplying current from accumulators, that "there is no doubt that a battery current is less destructive to lamps than one supplied from dynamos, whether alternating or continuous." We doubt, however, whether there is sufficient experimental evidence on this subject to justify this conclusion.

As a set-off to these advantages the cost of accumulators is great, as well as that of the skilled attention they require, while their efficiency at maximum output is probably rather low; the automatic switches for switching the accumulators into the charging circuit when discharged and into the discharging circuit when charged, as well as for regulating the discharge from each cell, are, Major Cardew thinks, a weak point, and any failure in their action would probably ruin the accumulators; the insulation of large batteries cannot be maintained at all high; and the numerous joints that have to be maintained good in the presence of acid fumes are a source of weakness.

The special advantages of the high-pressure transformer system Major Cardew considers to be: the smallness of the mains; the absence of difficulty in maintaining constancy of pressure in the mains within 2 per cent. over a large area; the pressure in the houses may be different in different cases according to the needs of the consumer; the system is simple to work; the dynamos are simple, and can be made in easily replaceable parts.

The disadvantages are that the high pressure necessitates great care and expense in insulation; the conveying of this high pressure to at any rate one point on the consumer's premises involves some risk to life; the main cannot be handled nor connection made with it when the pressure is on; the transformers cause the regulation in the houses to be not so good as in the mains; the system cannot at present be efficiently utilized for motive power, or for electric deposition or other chemical uses, such as charging accumulators; "and it is very doubtful whether a practically successful alternating motor is likely to be brought out"; the system depends entirely on running machinery; the general efficiency must be low when the supply is near its minimum, which, so long as it is utilized for lighting alone, obtains during about eighteen hours out of the twenty-four; a serious accident at the generating station might stop the supply. "Alternating machines cannot be so readily connected together to run in parallel circuit as continuous current machines"; the instruments and methods for making measurements are far more restricted in number, and the measurements are more difficult to make, when alternate currents are in question.

The sentences in the preceding paragraph that are placed in inverted commas appear to us to be particularly rash. So far from saying "it is very doubtful whether a practically successful alternating motor is likely to be brought out," we should prefer to say that it is almost certain that, as soon as there is a widespread demand for cheap efficient alternate current motors, such motors will be forthcoming; and, after the experiments shown by Mr.

Mordey at the end of May, at the factory of the Anglo-American Brush Company, on the great facility with which alternate machines can be coupled in parallel, Major Cardew must, we think, wish that he had worded the sentence quoted above somewhat differently.

Major Cardew next criticizes the objections that have been urged against the particular scheme involving two transformations of the pressure, which the London Electric Supply Association are arranging to carry out: that having only one generating station an accident might stop the whole supply of current to hundreds of thousands of incandescent lamps. To avoid, for example, the bursting of a steam-pipe greatly impeding, if not entirely stopping, all work by filling the factory with steam, and by the steam condensing on the dynamos and fittings, and so causing the high-pressure current to flash where it ought not to go, Major Cardew recommends that the Company shall subdivide the station at Deptford so as practically to provide two distinct generating stations, or shall forthwith establish a second generating station in some other locality. With reference to another objection, that the proposed pressure of 10,000 volts is so enormously in excess of anything which has hitherto been worked with, as to cause the scheme to be a gigantic experiment, he very rightly points out that, as there has been successfully used for some time at the Grosvenor Gallery installation over ten times the pressure that was believed to be the limit of safety a few years ago, "and as the so-called experiment of still further raising the limit of pressure would, if successfully carried out, be of immense benefit both to the public and electric light undertakers, I do not consider that, under proper regulations, the London Company should be prevented from carrying out a scheme in which they have shown the greatest confidence, and which the majority of scientific witnesses who have been called approve of in principle." With this recommendation we heartily agree, since all past history has shown that it is better to be guided by experience than by preconceived notions.

The final conclusions arrived at in the Report embrace several pages, but they may be briefly summed up as follows:—"That it must be admitted that the science of electric lighting has now reached the point at which a supply can be made which will be of great benefit to the public, and that the power of obtaining this supply should be within the reach of all persons who may require it," and therefore, although the wishes of local authorities should be consulted, "the mere objection by a local authority to the introduction of a company proposing to supply electric light, upon general grounds, should not be considered sufficient to exclude such company." As the whole Metropolis may be for purposes of lighting and management of roads and streets under the control of one central authority, "the provisional orders granted for the Metropolitan area should, as far as possible, be identical in form, with identical provisions as to supply, compulsory powers, interference with streets, and more than all as to price."

That the scheme adopted in 1883, of dividing a district into two areas (A) and (B)—the former an area that it was compulsory for the company obtaining the provisional order to light; the second an area which the company might light if they thought fit, but which they could not be required to light until after the expiration of two years—be abandoned, as such a distinction of areas is not likely to work well, and is not contained in the Electric Lighting Act, being merely introduced for the purpose of convenience; and that instead the supply shall be compulsory, under requisition, over the whole area on equal terms. That, "taking the (Metropolitan) area as a whole, it does not appear that it would be wise to fix a lower maximum than 8*d*. per unit." One Board of Trade unit is one thousand watts for one hour, so that at three and a half watts per candle, which is a fair average efficiency for an incandescent lamp, if it is to have a decent life, and assuming that a sixteen candle-power gas-burner consumes 5 cubic feet per hour, the maximum price proposed for the electric supply is equivalent to gas at 7*s*. per 1000 cubic feet, or nearly three times the present actual cost of lighting by gas. In the draft provisional orders several companies have asked for the right to make a certain minimum charge irrespective of the amount of electric energy consumed; and in the case of the Metropolitan Company, they ask to be allowed to charge a householder who has electric lamps in his house £5 10*s*. a quarter even if he never turns on a single lamp. Of course such a high minimum charge would be absurd, and even that of 13*s*. 4*d*. per quarter, which the Report appears to consider a reasonable one, appears to us much too high. In fact, we think that the proposal that there should be no minimum price at all if the householder pays for connecting his house with the mains might have been strongly urged in the Report, instead of it being stated that "such a provision would hardly be necessary where the minimum is reduced as in the Metropolitan Orders,"—that is, to 13*s*. 4*d*. a quarter. It is further recommended that there shall be a revision of the prices in the form of a sliding scale based upon the basis of a 10 per cent. dividend, the standard being fixed after the experience gained by the working of the first seven years.

In view of the fact that the laying of the mains of several companies means so much dead capital which the local authority would have to pay for if it elected to purchase at the end of forty-two years, and that no matter what regulations be made as to laying of mains the interference with the street must be to a certain degree proportionate to the number of companies having powers over this street, it is recommended that powers should not be given to more than two companies over the same area, and that one of these companies should be a company using the direct current. The following is very important, since if passed it will entail a vast expense on the London Electric Supply Corporation:—"That wherever a company now supplying a district by means of overhead wires is granted an order for such area, it should be placed under the obligation to remove these overhead wires within a period of two years from the granting of the order; and if such a thing be possible that this company should be prevented from invading a district in which it has not got powers by means of overhead wires."

At this Board of Trade inquiry many arguments *pro* and *con* were advanced as to the large companies being allowed to invade the areas that had begun to be worked by small companies. The large companies raised the "no monopoly" cry, and urged that they ought to be allowed to compete everywhere; whereas the smaller companies alleged that the most certain way to bring about monopoly would be to allow the large companies to enter the areas worked by the small companies, and to use the profits gained by the large companies in non-competing districts to enable them to work for a time at a loss in the competing district, and by underselling the smaller companies to eventually drive them out and have the whole field to themselves. Taking all points into consideration, Majors Marindin and Cardew recommend that there be allotted to—

(1) The London Electric Supply Corporation: the portions of St. Martin-in-the-Fields lying to the south of the Strand and west of St. Martin's Lane; the portion of St. Margaret and St. John, Westminster, lying to the north of Victoria Street, excepting that portion of St. Margaret lying to the west of St. George, Hanover Square; St. James, Westminster; St. George, Hanover Square; Chelsea; the Greenwich District; St. Mary, Rotherhithe; St. Mary, Bermondsey; the district of St. Olave; the district of St. Saviour, Christchurch; and that portion to St. Mary, Lambeth, lying to the north of Westminster Bridge Road.

(2) The Metropolitan Electric Supply Company: St. Giles-in-the-Fields; St. George, Bloomsbury; St. Andrew, Holborn, above Bars; St. George the Martyr; St. Sepulchre, Saffron Hill; Hatton Garden; Ely Rents and Ely Place; the Liberty of Glasshouse Yard; St. Anne, Soho; St. Paul, Covent Garden; St. John the Baptist; Savoy, or precinct of Savoy; St. Mary-le-Srand; St. Clement Danes and the Liberty of the Rolls; together with the extra-parochial places known as the Charter House, Gray's Inn, Lincoln's Inn, Staple Inn, and Furnival's Inn; St. Marylebone; St. Mary, Lambeth; St. Leonard, Streatham, and Clapham; that portion of St. Martin-in-the-Fields which lies to the east of Northumberland Avenue, Charing Cross, and St. Martin's Lane.

(3) The Chelsea Electricity Supply Company: the small portion of the parish of St. Mary Abbotts at the east end of the parish contiguous to Chelsea, which has already been agreed to by the Kensington Vestry; as well as the following, which has up to this time been refused by the Vestry of St. George, Hanover Square, viz. so much of the parish of St. George, Hanover Square, as is between the line formed by the eastern boundary of Chelsea parish on the west, by Knightsbridge, St. George's Place, and Hyde Park Corner, on the north, and by Grosvenor Place, Upper Grosvenor Gardens, Lower Grosvenor Gardens, Buckingham Palace Road, Commercial Road, and Bridge Road, on the east and south-east.

(4) The House to House Electric Light Supply Company: the south-western portion of the parish of St. Mary Abbotts, Kensington, which has been offered to this company by the Vestry, and which it is willing to accept.

(5) The Kensington and Knightsbridge Electric Lighting Company: the portion of the parish of St. Mary Abbotts, Kensington, which this company is at present lighting under licence from the Vestry; so much of the parish of St. Margaret, Westminster, as lies to the west of the parish of St. George, Hanover Square, which is at present worked under licence from the Vestry of St. Margaret and St. John, if the consent of this Vestry, which is at present refused to the issue of a forty-two years' provisional order, can be obtained.

(6) The Notting Hill Electric Lighting Company: the portion of the parish of St. Mary Abbotts, Kensington, which has been allotted to the company by the Vestry.

(7) The Westminster Electric Supply Corporation: the parish of St. George, Hanover Square; and the portions of St. Margaret and St. John, Westminster, lying to the south of Victoria street.

(8) As regards the Electrical Power Storage Company: that as the articles of association of this company do not give it any power to manufacture and supply electricity for house-to-house lighting no provisional orders be given.

Lastly, that the licenses applied for by the Chelsea and House-to-House Companies for areas in the portions of the parish of Kensington already allotted to these companies by the Vestry be granted.

As regards the City itself, the Commissioners of Sewers, acting for the Corporation, are asking for tenders; but Major Marindin says that he sees "no reason why the principle that all such lighting should be done under statutory powers and obligations should be departed from in their case;" and he recommends that the Board of Trade should "urge the Commissioners of Sewers to consider whether the orders as remodelled do not sufficiently provide for all their requirements, and to consent to a division of the area of the City between the two competing companies, viz. the London and Metropolitan Companies, the latter company being allotted the portion nearest the Strand District, and the former the Central and Eastern portions of the City, so that access may be given to the parish of Clerkenwell, the Vestry of which wishes for an order to be granted to this company."

Major Marindin's Report was forwarded on May 18, by the Board of Trade, to the London County Council, for an expression of their opinion on the subject; and the Clerk to the London County Council has within the last few days sent a reply to the Assistant Secretary of the Railway Department of the Board of Trade. In this reply, while expressing the general approval of the Council to the recommendations contained in Major Marindin's Report, he communicates the following important suggestions, among several others, which the London County Council desires to make:—

"That in the case of subways being in future made in streets where wires are already laid, the companies should be under an obligation to remove the wires into such subways, and to pay a rent for the use of them, a reasonable time (say three years) free of rent being allowed as a set-off to the cost of such removal."

Such a regulation it appears to us would be very onerous in the case of companies like the Kensington and Knightsbridge Company, who have gone to a considerable expense in making small special conduits for their own wires.

"That in view of future possible reduction in the cost of production which may be made as the result of experience and invention there should be a provision that the maximum price of 8*d*. per Board of Trade unit, proposed to be adopted, shall be subject to revision at the end of seven years; and that in order to insure healthy competition between the companies during that period no amalgamation or working agreement between companies shall be permitted without the consent of the Council. That clauses should be inserted providing for the application at the end of seven years of a sliding scale of price and dividend, on the basis of a dividend of 8 per cent." (not 10 per cent. as recommended by Major Marindin to the Board of Trade), "leaving the initial price and arrangement of the scale to be determined at the expiration of the term of seven years.

"That the minimum charge for supply should be fixed as low as possible, and that should such minimum be fixed at £1 per quarter or over it should be reckoned by the year and not by the quarter, because of the irregular requirements of the consumer at different seasons of the year."

We presume this is to prevent a company charging a householder by meter in the winter quarters, and levying the minimum rate in the summer quarter.

"The Council considers that it would be to the advantage alike of the public and the companies that there should be one uniform system of regulation and control throughout the entire area of London. The Council is of opinion that, as the representative governing body of the whole of London, it should be appointed the controlling authority. The Council would further suggest that, if it be made the controlling authority, it should be empowered to discharge the following duties, viz.:—

"Inspection of lines and works.

"Testing current.

"Testing and certifying meters."

We do not know whether the London County Council is aware that a Committee of the Institution of Electrical Engineers, and a Committee of the Electrical Section of the London Chamber of Commerce, have for some time past been engaged in advising Major Cardew regarding the details of an electrical standardizing laboratory to be fitted up for the use of the Board of Trade; and we think that, while municipal regulations may very properly be left to the County Council, the standardizing and certifying of meters would more appropriately form part of the work of that body which is already in charge of the national standards of weights and measures, viz. the Board of Trade.

The letter of the Clerk of the Council goes on to say:—

"The Council, in view of the fact that some companies have been, and are now, supplying electricity by overhead wires without statutory powers, and being convinced of the undesirability of allowing this to be continued, would venture to suggest that, in any further legislation on electric lighting, the supply of electricity in any district, before obtaining statutory powers for such district, should be prohibited under penalty."

To this we see no objection, now that the Electric Lighting Act is so modified that it is possible for an electric lighting company to reap commercial success by working under it.

THE LIFE-HISTORY OF A MARINE FOOD-FISH.[1]

II.

THE larval salmon enters the world of a size—though small—that is readily recognizable, viz. about three-fourths of an inch in length, but the marine forms under consideration, from their minute size and glassy translucency, are almost invisible to the naked eye—just a gleam of light broken by the passage of a different medium, or a tinge of pigment, arresting attention. Only in the cat-fish (which is not much—though it ought to be more—of a food-fish) with its large egg, have we a size nearly reaching that of the salmon at birth.

We had left the larval fish tossed about by the currents and unable to struggle against them, now floating with its yolk-sac uppermost, or hanging in the water with its head downward, and again making spasmodic darts hither and thither. Soon, however, it gathers strength, and at the end of a week or ten days it glides actively through the water, and avoids both obstacles and enemies, the young cod nimbly escaping the forceps, poising itself in the water with its large pectoral fins (Fig. 11), and

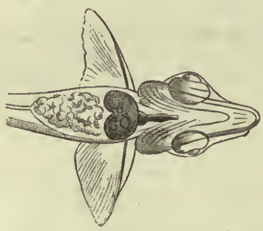

FIG. 11.—Ventral view of the anterior region of larval cod (magnified).

evincing both intelligence and dexterity. Moreover, this activity greatly promotes respiration in those like the gunard with a motionless mandible, the water being thus sent through the mouth and over the branchial region. Its mouth has now opened and the yolk-sac has been absorbed, while it feeds on the most minute of the little Copepods, especially those almost microscopic in size, that swarm in the surrounding water. The provision whereby such tiny fishes find in the ocean food suited to their capacities is one of the most striking features in Nature, but it has only recently been carefully investigated. It is a notion no longer tenable that during the winter and spring the sea, to a large extent, is devoid of the wealth of pelagic life so characteristic of the summer months—just as it is of the genial waters of the tropics. For several years, however, it has been found that a vast abundance of minute life of all kinds is present throughout the entire year—and from the surface to the bottom. Moreover, during the warmer months a constant succession of young forms rises from the eggs both of the sedentary and creeping animals on the bottom to the surface, where they sport in the summer sun, undergo certain changes, and again descend as they assume the form of the adult. The pelagic young food-fishes—swimming freely in the ocean—thus have a double chance at them; first in their very early stage as they rise, and again in their larger and later condition as they descend. The enormous numbers, countless variety, and ever-changing nature of the small animals either directly or indirectly constituting the food of these little fishes form an important feature in the economy of the sea. Such animal forms comprise those long known in the British seas, besides others more familiar to Arctic voyagers, or to the sunny waters of the Mediterranean, for, with modern apparatus and persistent efforts (thanks to the enlightened views of the Government acting through the Fishery Board), our knowledge is always extending.

It is a remarkable fact that it is primarily to plants in inshore waters that the abundance and variety of animals are in many respects due, especially if estuaries also debouch in the neighbourhood. Thus nowhere are the swarms of Sagittæ, Appendicularians, Crustaceans, and other forms of fish-food more conspicuous than in the midst of a sea teeming with Diatoms, Rhizosoleniæ, and other Algoid structures.[1] These nourish many of the lower forms upon which the Crustaceans and other higher types feed, the latter again falling a prey to the fishes. Moreover, while the larger forms of the Copepods and other Crustaceans, for example, afford suitable nourishment for the more advanced post-larval fishes, the multitudes of larval Crustaceans (*Nauplii*) are adapted to the needs of the smallest larval food-fishes. Now this plant-life is specially abundant in April and May, just when the larval and very young post-larval fishes appear more abundantly in the inshore waters, so that the cycle is nearly complete, viz. from the inorganic medium through microscopic plant and larval Crustacean to the post-larval fish. I have mentioned the neighbourhood of an estuary as a prolific source of food for young fishes, and I need only explain further by instancing the case of mussel-beds, which for months pour countless myriads of larval mussels into the adjoining sea, far beyond the needs of the area as regards mussel-culture, but which form a favourite food of the little fishes at all stages, but especially from an inch and a half to three inches in length. These fishes feed on the young mussels as they settle down on the seaweeds, rocks, and zoophytes in August, after a free-swimming larval existence. Like some of the forms indicated above, mussels live to a considerable extent on microscopic plants and various minute organisms contained in the mud of the estuaries and other sites, so that a rich and favourite food, universally liked by fishes, is the product of these uninviting flats. Moreover, in passing, it may be remarked that, while everywhere preyed on by the food-fishes, it occasionally happens that in turn the mussel proves a source of inconvenience to them, for, settling on the gill-arches of haddocks, the mussels flourish on a site so suitable for aëration and food that they by and by press out the gill-cover and impede respiration, just as the shore-crab (which is also fond of mussels) has its eye-stalks wrenched out by the slow but sure growth of the young mussels which have fixed themselves in their sockets. Nemesis thus, by a chance of anchorage, converts a favourite food into a permanent inconvenience.

Again, in connection with the pelagic food of fishes, it is a well-known fact that adult cod are extremely fond of sea-anemones,[2] and some of the rarest species may be procured in their stomachs, a feature by no means surprising when we remember that Abbé Dicquemare cooked and ate his sea-anemones with great relish, and wrote in their favour, as also did Mr. Gosse in our own country. Now, the pelagic young fishes, instead of roaming near

[1] A Discourse delivered by Prof. W. C. McIntosh, F.R.S., at the Royal Institution, on Friday, February 1, 1889.

[1] The fact that certain fishes feed on Infusoria has not been overlooked.
[2] A favourite bait for cod in some parts; and from the fact, amongst others, that star-fishes do not molest them on the hooks, no bait is more successful.

the bottom in proximity to the anemones fixed on the rocks, and running the risk of being themselves captured for food, find in the inshore waters in summer the larval *Peachiæ* in great numbers conveniently attached by the mouth to the little Hydromedusæ (*Thaumantias hemisphærica* and *T. melanops*) which occur in swarms in mid-water. Moreover, the somewhat larger young food-fishes (2 to 3 inches) show the same liking for the Cœlenterate group, by browsing on the zoophytes (*Obelia geniculata*) which cover the stones and rocks with feathery tufts, yet the zoophytes are not much the worse for this treatment, for they by and by shoot afresh, and clothe the area once more with dense forests. The rapidity with which such zoophytes grow is remarkable, though we must remember that in some cases the old stock naturally dies off after having produced swarms of pelagic young.

Under this rich food, the young fishes grow apace; head and eyes, mouth and accessory organs, body and fins—all rapidly increase; and the little fish, hatched in the spring, say from March to May, is soon in what is known as the post-larval stage—that is, has lost its yolk-sac, has assumed a more or less uniform tint, and has gill-fringes and teeth. It is about a quarter of an inch long, and is both active and intelligent, the large head and large eyes of the young food-fishes being at this stage specially conspicuous, and in marked contrast with such as *Cottus*. The marginal fin is quite continuous at a quarter of an inch, and the lancet-like termination of the caudal end of the body is noteworthy.

About this time the ventral fins of the young fishes first make their appearance, for hitherto they have managed to do without them. Moreover, these fins in some, such as the rockling and ling, undergo remarkable development, forming in the latter (Fig. 7) a pair of great ventral wings, conspicuously coloured yellow; yet in the adult (a ground-fish) they attain no greater dimensions than in the cod, both having at a certain stage soft, free filaments or tacile processes at the tip. The ventral fins in the post-larval rockling (Fig. 12) are equally large, the distal half being black,

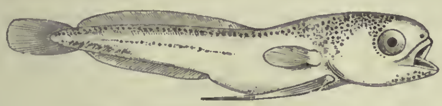

FIG. 12.—Post-larval rockling (enlarged).

so that at first sight the little fish when captured seems to possess a great ventral spine on each side. In the post-larval gurnard again, the huge pectoral fins form a drapery for the entire body when folded back, only the tip of the tail extending beyond them (Fig. 13). They are indeed proportionally as large as in the southern flying gurnards, but in these the fins reach full development only in adult life, while in the young stages they are comparatively small—exactly the reverse happening in the grey gurnard of our seas. The presence of the broad arches of pigment on the pectorals of several forms, such as the present species, green cod, and armed bullhead, is also an interesting feature. We have not yet read the riddle of all these changes, but in the ling the great ventral fins are probably connected with its roaming or pelagic life, and this explanation would also suit in the case of the rockling, both in their mature state seeking their food on the ground.

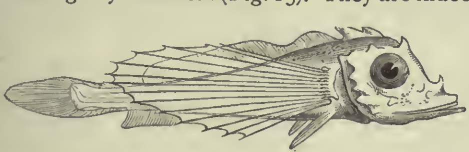

FIG. 13.—Post-larval gurnard (enlarged).

The little fishes at this stage are still more or less translucent, except in the region of the eyes, which are silvery, and on the parts where the pigment occurs. Moreover, their fondness for a minute reddish Copepod (*Calanus finmarchicus*), which occurs in myriads around them, gives the region of the stomach a faint pinkish hue from the translucency of the tissues. By and by, however, pigment appears, foreshadowing in the cod those peculiar squares which give the sides, at a somewhat later stage, their tessellated or tartan-like aspect. Besides, they are found nearer the bottom of the water, so that they can be captured in a naturalist's trawl with a fine gauze bag at the end. There is, therefore, a downward tendency as the little fishes get older and stronger, and thus in many cases a parallelism exists between them and the minute forms on which they prey, for the eggs rise on deposition toward the surface, where the helpless larvæ (or newly hatched young fishes) also often occur, and then they seek the lower regions of the water as their size increases.

There is much that is wonderful in such a life-history, especially in the metamorphoses or changes of form undergone by many of our best fishes, such as the flat fishes (Pleuronectidæ), which come out of the egg just like a haddock or cod, with an eye on each side, yet in after life have both eyes on the same side, as in Fig. 2. Nothing like this occurs in any of the higher vertebrates. Gradually during growth the body of the fish increases in depth (Fig. 14), the right or left eye passes over the ridge of the back to the opposite side (Fig. 15), while the creature, hitherto

FIG. 14.—Young "witch" (*Pleuronectes cynoglossus*) in the third stage (enlarged).

FIG. 15.—Young "witch" at a later stage, the left eye just appearing on the ridge of the head (enlarged).

pelagic, sinks deeper in the water and exhibits a tendency to lie on the side from which the eye has passed, and which gradually loses its dark pigment so as to become white.[1] It finally reaches the bottom, taking up its residence amongst the sand or sandy mud, and lying with the two eyes and the coloured side up, the white underneath. The mode by which the eye travels round has been a fruitful source of discussion with scientific men, and amongst these the names of Steenstrup, Malm, Schiödte, and Alex. Agassiz abroad, Wyville Thomson and especially Traquair in our own country, are well known. The fact is, two methods exist in Nature: in the one the eye travels over the ridge of the head, as just described in the flounder; in the other it traverses the soft and yielding tissues of the tiny fish, and so gains the other side. In *Plagusia*, the species in which the latter remarkable change occurs in the post-larval stage, the general tissues are so transparent that the creature in a glass vessel can only be noticed by the two apparently disembodied eyes, or by the gleam of light caused by its movements; and before the change ensues in its eyes it can look obliquely through its own body and see what passes on the other side.[2]

[1] The tardy disappearance of the pigment in some forms is interesting.
[2] Alex. Agassiz, Proceed. Americ. Acad. Arts. and Sci., vol. xiv. p. 8, 1878.

Up to this stage in the life-history of both round and flat fishes it will have been apparent that the efforts of man can have little effect on the vast multitudes of the eggs and minute fishes. His trawl sweeps beneath them, or they are carried harmlessly through its meshes. Not even in the case of a trawl blocked by a fish-basket and several large skate are any likely to occur. No example, indeed, was procured in the trawling expeditions for the Commission under Lord Dalhousie. The hooks of the liners are too large for the mouth at this stage, and hence they escape capture. Their small size and translucency also seem to afford protection in the case of predatory fishes of their own or other kinds, for they are rare, so far as present observation goes, in the stomach of any fish. Their great numbers are doubtless kept in check by some means, and we know that even jelly-fishes (*e.g. Pleurobrachiæ*) are very fond of post-larval fishes. It is only when they become somewhat larger that they are preyed on by their own and other species, and are swept up in thousands by the destructive shrimp-nets on our sandy shores.

While the little food-fishes are assuming the change of hue indicated in the preceding pages, they in many cases seek the inshore waters; at least systematic use of the mid-water and other nets proves that at certain seasons they are met with in large numbers at the entrance to bays or off-shore, and that a little later, in the case of the cod from the 1st of June onward, they are visible from the rocky margins. The coloration in this species (cod) is now beautifully tessellated, and they swim in groups, often in company with the young green cod, at the margin of the rocks at low water, and in the little tidal bays connected with rock-pools. The latter are often richly clothed with tangles, bladder-weed, red and green seaweeds, and the green *Ulva*, amidst the mazes of which the young fishes find both food and shelter, capturing the little Crustaceans (Copepods, Ostracods, and others) swimming there, and snatching the young mussels and minute univalve mollusks from the blades of the seaweeds. To the zoologist few sights are more interesting than to watch the little cod in these fairy lakes, as they swim in shoals against the current, balancing themselves gracefully in the various eddies by aid of their pectoral fins. In a mixed company, the young cod are easily recognized by their coloration, and the reddish hue of the occiput, for the blood-vessels there shine through the tissues, which generally are more translucent than in the green cod.

Prof. G. O. Sars considered that about this stage there was an intimate connection between them and the hordes of Medusæ (*Aurelia* and *Cyanea*) which abound in the inshore waters towards the end of summer. He thought the young cod approached the Medusa for the sake of the minute pelagic animals stupefied by its poisonous threads, and that the fish repaid this favour by picking off a parasitic Crustacean (*Hyperia medusarum*) which clings to the Medusa. Observations, continued for a long period in this country, show however that this connection is only casual and of very little importance, and that certain *Hyperiæ* are occasionally found in vast numbers in a free condition.

As the season advances, the young cod are joined off the rocky ledges by a few pollack and whiting, but not by the haddock, which appears to have certain social views of its own—keeping probably a little farther out. The size of this cod late in autumn, as in October, varies, some reaching 4 to 5 inches in length. Their food ranges from zoophytes to crustaceans, mollusks, and small fishes, and in confinement the larger are voracious, an example about 5 inches readily attacking a smaller (3 inches), and swallowing it as far as possible, though for some time a considerable portion of the body and tail of the prey projected from the mouth. Moreover, the tessellated condition becomes less marked, and as they approach 8 inches in length a tendency in some to uniformity of tint is noticeable. Many of those, however, that continue to haunt the rocky shores and the tangle-forests beyond low water still retain for some time mottled sides, and they are known by the name of rock-cod. Further, while their growth in the earlier stages is less marked, it is now very rapid—even in confinement. The exact rate of growth in the free condition in the sea is difficult to estimate, but the little cod of an inch and a half to an inch and three-quarters in June reach lengths varying from 3 to 5 inches in autumn, and in the tanks of the laboratory, specimens 5 inches in August attain 8 inches the following March. At Arendal, in Norway, where opportunities for watching the growth of cod in confinement have been supplied with a liberality yet foreign to our country, Dannevig found that the cod of 3 mm. in April reached only 15 mm. in June, a length somewhat at variance with the condition as above stated on our shores. In July they measured 2 inches, in September 3½ inches, and in October about 4½ inches. The second year they attained 14 to 16 inches in length. In artificial circumstances, as well as in nature, it is found that great variation exists in the sizes of the young fishes of the same age, and this variation would not seem to be related to temperature.

At the stages just mentioned they now come under the notice of both liner and trawler, for young cod 5 or 6 inches in length occasionally take a haddock-hook, and those somewhat larger (9 to 18 inches) occur in certain hauls of the trawl, especially off a rocky coast like that of Aberdeenshire, south of Girdleness, as well as on the hooks of the liners on rough ground. Special trips, indeed, were, and perhaps are, made by the liners for the capture of these young cod (termed codling), and thus their numbers are kept in check.

So far as present observations go, therefore, the young cod in a free condition reach the length of from 4 to 10 inches the first year, while in the second they attain from 10 to 20 inches or more. It probably takes 3 or 4 years (and this is the original opinion of Sars) or more, to reach full maturity, and a length of 3 feet or upwards; though he mentions having seen young cod a foot in length, with mature roe and milt in the fish-market of Christiania. These, however, were probably abnormal examples.

Let us now glance at the condition in the whiting. Its earlier post-larval stages immediately following those observed in the tanks at the laboratory (for we failed to rear them) are even now somewhat obscure, but they probably approach those of allied forms such as the cod and haddock. The characteristic nature of the larval pigment, however, would lead to the belief that perhaps in the brighter tints (*e.g.* yellow), differences may occur. Such, however, are lost before they come under observation; for all these delicate and minute forms are dead before reaching the deck, and indeed considerably altered. The pressure to which they are subjected in the large mid-water net by the crowds of Hydromedusæ and Ctenophores alone would suffice for this, and the handling of the heavily laden net increases the dangers to forms so fragile. One about 12 mm. shows in spirit the dorsal and anal fins outlined though not separated from each other, and permanent rays occur in them and in the caudal. Minute ventrals are present, while the pectorals form large mobile fans. Groups of black pigment-corpuscles are distributed along the base of the dorsal and anal fins and over the brain, and a similar series occurs along the ventral median line of the abdomen. The sides have these blackish pigment-corpuscles more generally distributed than in the cod. No barbel is noticeable. When a little longer (15 mm.), the species is distinguished from the young cod by a more abundant distribution of black pigment-specks along the sides of the body and on the fins, and by the greater length and diminished depth of the first anal fin. The median line of pigment still runs along the ventral surface of the abdomen. At 20 mm. the characters that distinguish it from the cod of the same size are better marked, viz. the distribution of dense blackish pigment along the base of the dorsal fins; and it soon spreads downward over the sides. The first anal fin assumes the character of the adult, and a minute papilla indicates a barbel. Between the stage just mentioned and a length of 28 mm. a decided change in the dense dorsal pigment takes place, viz. a tendency to form separate groups or touches (Fig. 16). These differ from

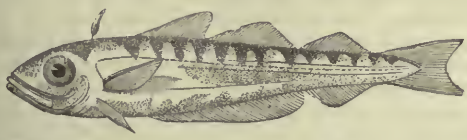

FIG. 16.—Young whiting, with serrated dorsal pigment-band and parasitic *Chalimus*.

the cod in being confined to the dorsal region, though a few bars occur at the base of the tail. The fish is also now minutely flecked, all over the head, sides, snout, and fins with black pigment, and its general outline approaches that of the adult. It is at once distinguished from the young cod by the shortness of the snout, irrespective of the features already pointed out, by the coloration, and by the shape of the first anal fin.

The differentiation of the two species, viz. the cod and the whiting, is very marked in spirit at the length of 34 mm. In the whiting the median dorsal fin is less abruptly elevated than in the cod, and the first anals diverge widely, the elongation of the latter being probably connected with the abbreviation of the abdomen. The body of the whiting is more plump and neatly rounded than in the cod, which is flatter and has generally a more prominent abdomen. The pigment-specks closely cover the sides of the body in the whiting, as well as the membranous webs of the dorsal fins, and are continued on the head. The pigment at the base of the caudal rays is more distinct in the whiting, and the lancet-like caudal termination of the body is longer in this species. The myotomes are coarser in the cod, and the surface has little of the dappled silvery sheen of the whiting. The chromatophores are larger in the cod, and are grouped in blotches over the surface, with intermediate pale patches, and the shoulder and head have much less pigment than in the whiting. Both the pectoral and ventral fins of the cod are shorter than those of the whiting. The snout in the latter is shorter and broader as well as deeper, and the short sub-mental papilla is in contrast with the long barbel of the cod of the same length. The whiting, produced from an egg of larger size, would appear to attain a plump body and finished outline sooner than the cod.

The foregoing stages are very abundant in autumn in the deep water off the Isle of May and the mouth of the Forth, but they also appear west of Inchkeith in the latter estuary. They are indeed more characteristic of the former region, as far as present observations go, than of the shallow water of the open bays, such as St. Andrews, though on reaching a somewhat larger size they are quite common in the latter expanse. Both they and the cod in these early stages are infested by a Crustacean parasite (*Chalimus*), which adheres to various parts of the head and body, just as the larval *Anceus* tenaciously attacks the young flounders in tidal harbours and inshore grounds.

The young whiting at a later stage (3 to 5 inches) joins the young cod at the margins of the rocks, and forms independent shoals in tidal harbours, as well as occurs some distance off shore, being frequently got in the mid-water net in the deeper water. Towards the latter size (6 to 7 inches) it readily takes the hooks of the liner, and in certain bays the multitudes of young whiting prove an inconvenience to the fishermen. As it increases in size great shoals are formed in the offing, though a few small are almost always found in inshore waters.

The young round fishes, such as cod, haddock, and whiting, of similar or nearly similar size, seem respectively to herd together. Thus it happens that in certain hauls of both liners and trawlers the majority agree in size. This is well known to the liners, who in former days specially sought out the young cod as already indicated. The same feature is observed in many other fishes, and probably conduces to their safety.

So far as known, the adult fishes of the three kinds specially alluded to in the preceding paragraph (viz. cod, haddock, and whiting) follow no very definite law in regard to migrations, if we except the apparent congregation in certain regions during the spawning season, as pointed out, for instance, by Sars, off Lofoten, where they occur in vast numbers from January to March. In our own country, again, the appearance of shoals of haddocks and whiting in certain localities is another example. How far such multitudes, however, are influenced by the abundance of food is still an open question. In British seas the herring is the main cause of these congregations in the cod and haddock; the former chiefly pursuing the fishes, the latter their eggs. In the same way, the abundance of Norway lobsters and similar food on the grounds called banks exercise considerable influence on the presence of cod.

It has already been pointed out, however, that in their young stages certain migrations do occur. Thus the post-larval cod by and by seeks the Laminarian region, while the older forms for the most part tend to go seaward. The same occurs even in a more pronounced manner with the ling, the adults of which as a rule are found in deep water. The pelagic post-larval ling seeks downwards as it grows, and is seldom found near the shore till it attains the length of 6 or 7 inches—in short, until it is barred with pigment. As it increases in size it migrates seaward. Similar features are noticed in the plaice. As observed in the trawling expeditions of 1884, only large plaice as a rule are procured in deep water off the east coast, while the sandybays abound with those ranging from 11 inches downward, and none of the females of which appear to be mature. Multitudes of little plaice haunt the margins of these sandy beaches, but it cannot be said that forms which have the length, for example, of 3 inches, are confined to any particular line drawn across a bay, for small forms (2 to 4 inches) occur in hauls all over such a bay as that of St. Andrews. Small turbot and halibut in the same way are often found in the shallow bays, while the large adults are inhabitants of the deeper water. Such would not, however, seem to be the case with certain skate, very large adults of which occur in the shallow water of the sandy voes in Shetland.

On the other hand, the witch (*Pleuronectes cynoglossus*) keeps to its special areas, both as regards the young and the adult condition, so that the movements of eggs, larval and post-larval forms are circumscribed; and the same would seem to be the case with the topknot (*Zeugopterus*) and sail-fluke (*Arnoglossus*). The dab (*Pleuronectes limanda*), again, is found in all stages both in comparatively deep and comparatively shallow water.

Almost all our valuable food-fishes, therefore, are produced from minute pelagic eggs, the enormous numbers of which provide for a vast increase and wide distribution of the species; yet it cannot be said that this habit alone provides for their multiplication when the case of the herring with its demersal eggs, fixed firmly to the bottom, is considered. It has to be borne in mind, however, that the larval herring immediately mounts upward toward the surface as soon as its strength suffices.

Many striking changes occur during growth, both in external form and coloration, but it is difficult at present to lay down any general law that would apply to all cases, though those in which certain migrations take place during growth show such changes very prominently. The young round fishes by and by roam about the sea in shoals, led hither and thither mainly by the presence of food; though in the case of the larger and adult forms, safety or freedom from molestation may have some influence. Though so minute on escaping from the egg, their growth is, by and by, rapid, and the duration of life in such as the cod is considerable. Abundance of food, more than any special instinct, would appear to be the main cause of their migrations in the adult or semi-adult state, and that food is as varied as their haunts; in short, it embraces every sub-kingdom up to their own, for fishes and their eggs form a large share of their diet.

There would be little difficulty in adding to the sea great numbers of larval forms of any species of which eggs can be procured: yet if a few adults can be obtained in such waters at the proper season it is still an open question whether the natural process with its surroundings would not be more successful.

In the foregoing remarks I have but touched on a few of the leading features of the life-history of a food-fish; for the subject is one of vast extent, and some of the points embraced in it are by no means easily solved. We have only earnestly entered on the study of the subject in this country within the last few years, and much yet remains to be done, even in some of the most common marine fishes. However, the zoological investigator is here stimulated by the fact that all his labours directly bear on the public welfare, for it need hardly be pointed out that a thorough knowledge of the development and life-histories of our food-fishes is the first step to sound legislation and effective administration. The State has in past years spent princely sums on more or less pure science, as in the memorable voyage of the *Challenger*. There can be no doubt that at the present moment the public interests demand a searching and long-continued inquiry nearer home, viz. the exhaustive investigation of all that pertains to the food-fishes of our shores, since the problems connected therewith affect the prosperity of so large a portion of the population.

ON THE MENTAL FACULTIES OF ANTHROPOPITHECUS CALVUS.[1]

THE female Chimpanzee which has now been in the Society's Menagerie for nearly six years has attracted general notice, not only on account of her peculiar zoological characters, but perhaps still more on account of her high intelligence. This is conspicuously displayed by the remarkable degree in which she is able to understand the meaning of spoken language—a degree which is fully equal to that presented by an infant a few months before emerging from infancy, and therefore higher than that which is presented by any other brute, so far, at least, as I have met with any evidence to show. Nevertheless, the only attempts that she makes by way of vocal response are three peculiar grunting noises—one indicative of assent or affirmation, another (very closely resembling the first) of dissent or negation, and the third (quite different from the other two) of thanks or recognition of favours. In disposition she is somewhat capricious, though on the whole good-humoured, fond of her keepers, and apparently never tired of a kind of bantering play which off and on they keep up with her continually. By vocalizing in a peculiar monotone (imitative of the beginning of her own "song"), they are usually able to excite her into the performance of a remarkable series of actions. First, she shoots out her lips into the well-known tubular form (depicted in Darwin's "Expression of the Emotions," p. 141), while at the same time she sings a strange howling note interrupted at regular intervals; these, however, rapidly become shorter and shorter, while the vocalization becomes louder and louder, winding up to a climax of shrieks and yells, often accompanied with a drumming of the hind feet and a vigorous shaking of the network which constitutes her cage. The whole performance ends with a few grunts.

A year or two ago it occurred to me that I might try some psychological experiments on the intelligence of this animal. The circumstances in which she is placed, however, did not prove favourable for anything like systematic instruction. Being constantly exposed to the gaze of a number of people coming and going, and having her attention easily distracted by them, the ape was practically available for purposes of tuition only during the early hours of the morning, before the Menagerie is open to the public; and, as a rule, I did not find it convenient to attend at that time. Therefore, the results which I am about to describe do not in my opinion represent what might fairly have been expected under more favourable conditions: if the Chimpanzee could have been kept as a domestic pet for a few months (as I kept the Cebus kindly lent me for the purposes of psychological observation by this Society), there can be no doubt that many much more interesting results might have been obtained. Nevertheless, it appears to me that even those which thus far have been obtained are worthy of being placed on record; and although some of them have already been published a few months ago in my work on "Mental Evolution in Man," since that time some further progress has been made; and therefore in the present paper I will state together all the facts which have been hitherto observed.

Having enlisted the intelligent co-operation of the keepers, I requested them to ask the ape repeatedly for one straw, two straws, or three straws. These she was to pick up and hand out from among the litter in her cage. No constant order was to be observed in making these requests, but, whenever she handed a number not asked for, her offer was refused, while, if she gave the proper number, her offer was accepted, and she received a piece of fruit as payment. In this way the ape was eventually taught to associate these three numbers with their names. Lastly, if two straws or three straws were demanded, she was taught to hold one straw or two straws in her mouth until she had picked up the remaining straw, and then to hand the two straws or the three straws together. This prevented any possible error arising from her interpretation of vocal tones—an error which might well have arisen if each straw had been asked for separately.

As soon as the animal understood what was required, and had learnt to associate these three numbers with their names, she never failed to give the number of straws asked for. Her education was then extended in a similar manner from three to four, and from four to five. Here, for reasons to be presently stated, I allowed her education to terminate. But more recently one of the keepers has endeavoured to advance her instruction as far as ten. The result, however, is what might have been anticipated. Although she very rarely makes any mistake in handing out one, two, three, four, or five straws, according to the number asked for; and although she is usually accurate in handing out as many as six or seven; when the numbers eight, nine, or ten are named, the result becomes more and more uncertain, so as to be suggestive of guess-work. It is evident, however, that she understands the words seven, eight, nine, and ten to betoken numbers higher than those below them; for if she is asked for any of these numbers (*i.e.* above six), she always gives some number that is above six and not more than ten; but there is no such constant accuracy displayed in handing out the exact number named as is the case below six. On the whole, then, while there is no doubt that this animal can accurately compute any number of straws up

[1] Paper read before the Zoological Society on June 4, 1889, by Prof. George J. Romanes, F.R.S.

to five, beyond five the accuracy of her computation becomes progressively diminished.

It is to be noticed that the ape exhibits some idea of multiplication; for she very frequently (especially when dealing with numbers above five) doubles over a long straw so as to make it present two ends, and thus to appear as two straws. Any of the comparatively rare errors which she now makes in dealing with numbers below six are almost invariably due to her thus endeavouring to duplicate her straws. In this connection it is to be remembered that, owing to the method above described (whereby the ape is required to place each straw separately in her mouth until the sum asked for is completed), when any high number is demanded a considerable tax is imposed upon her patience; and, as her movements are deliberate while her store of patience is but small, it is evident to all observers that the doubling of the straws is intended to save trouble by getting the sum completed with greater rapidity than is possible when every straw is picked up separately. Of course we do not recognize these doubled straws as equivalent to two straws, and therefore the persistency with which she endeavours to palm them off as such is the more noteworthy as evidence of her idea of multiplication. Moreover, I am disposed to think that the uncertainty which attends her dealing with the numbers six and seven is more largely due to her losing patience than to her losing count; although after seven I believe that her computation of the numbers themselves becomes vague, or merged in a merely general idea of many. It may also be stated that, while picking up the straws and placing them in her mouth, she looks only at the straws themselves and not at the person who asks for them: therefore she is certainly not actuated in her responses by interpreting facial expression, unconscious gesture, &c., as is no doubt the case with many dogs which on this account are sometimes accredited by their owners with powers of "thought-reading." It is needless to add that, after asking for the number of straws required, we remain silent till the ape has handed them out.

It is not necessary—indeed it would be unreasonable—to suppose that in this process of "counting" the ape employs any system of notation. We know from our own experience that there is counting and counting, *i.e.* distinguishing between low numbers by directly appreciating the difference between two quantities of sensuous perception, and distinguishing between numbers of any amount by marking each perception with a separate sign. The extent to which the former kind of computation can be carried in the case of man has been made the subject of a careful research by Prof. Preyer, of Jena (*Sitz. Ber. d. Gesell. f. Med. u. Naturwiss.*, 1881). His experiments consisted in ascertaining the number of objects (such as dots on a piece of paper) which admit of being simultaneously estimated with accuracy, and it was found that the number admits of being largely increased by practice, until, in the case of some persons, it may rise to more than twenty. But of course in the case of a brute it is not to be expected that such a high degree of proficiency even in this non-notative kind of "counting" should be attainable. The utmost that could here be expected is that a brute should exhibit some such level of ability as is presented by a young child, or by those savages whose powers of accurate computation do not appear to extend further than numbers which we write as units.[1] It was in view of such considerations that I did not attempt to carry the education of this ape beyond the number five; and the result which has attended subsequent endeavours to teach her numbers as high as ten is, as previously remarked, exactly what might have been anticipated. It may here be added that in the only records with which I am acquainted of animals exhibiting any powers of numerical computation, these powers have not extended beyond the number five. Thus, for instance, in his well-known account of these powers as presented by rooks, Leroy says:—"To deceive this suspicious bird, the plan was hit upon of sending two men into the watch-house, one of whom passed out while the other remained to shoot the bird on returning to her nest; but the rook counted and kept her distance. Next day three went, and again she perceived that only two returned. In fine, it was found necessary to send five or six men to the watch-house in order to throw out her calculations."[1] Again, Houzeau tells us that mules used in tramways at New Orleans have to make five journeys from one end of the route to the other before they are released, and that they make four of these journeys without showing any expectation of being released, but begin to bray towards the end of the fifth.[2] Lastly, the keeper of the eared seals now in the Menagerie has recently taught one of these animals to "count" as far as five His method is to throw pieces of fish in regular succession, which the animal catches one by one. He throws them in series of fives, and, before the commencement of any series, he tells the seal to miss the first, the second, the third, the fourth, or the fifth, as the on-lookers may dictate: the seal thereupon makes no attempt to catch the member of the series thus verbally indicated. It is only a day or two ago, however, that I witnessed this performance, and as yet I am not satisfied that the seal really "counts," because it appears to me probable that the keeper may unintentionally throw, with some slight difference in his manner of throwing, the piece of fish which he expects the seal to miss, and that it is really this slight difference in the manner of throwing which the seal perceives and acts upon. Therefore, I intend to get an arrangement fitted up whereby the pieces of fish shall be thrown mechanically. But, whatever the result of this experiment may be, I think there can now no longer be any question that it lies within the capacity of animal intelligence to "count" correctly (in the sense already explained) as far as five, and even to show a well-marked appreciation, although progressively a more and more uncertain one, of numbers lying between five and ten.

The only other direction in which I have thus far subjected the Chimpanzee to psychological experiment has been in that of attempting to teach her the names of colours. It appeared to me that if I could once succeed in getting her thoroughly well to know the names of black, white, red, green, and blue, a possible basis might be laid for many further experiments wherein these five colours could be used as signs of artificially associated ideas. The result, however, of attempting to teach her the names of colours has been so uniformly negative, that I am disposed to think the animal must be colour-blind. It is perhaps desirable to state the facts which have led me to entertain this as their most probable interpretation.

The method adopted in these experiments was to obtain from the importers of Oriental matting a number of brightly and uniformly coloured pieces of straw—each piece being either white, black, red, green, or blue. Taking the straws two by two of different colours, on each occasion the ape was invited to choose the straw of the colour named from the one whose colour was not named, and, of course, on choosing correctly she was rewarded with a piece of fruit. In this way she quickly learnt to distinguish between the white straws and the straws of any other colour; but she never could be taught to go further. Now the distinction between the white straws and the straws of any other colour is a distinction which could have been drawn by an eye that is colour-blind; and from the fact that the ape is always able to perceive this distinction (she will search long and patiently for a straw of any colour when told that it occurs somewhere in the general litter of white straws constituting her bed,

[1] See, for instance, Galton, "Tropical South Africa," p. 213

[1] "Letters, &c." [2] "Fac. Ment. des Anim.," tom. ii. p. 207.

and eventually picks it out), while she cannot be taught to distinguish any of the others, I conclude that her failure in this respect is not due to any want of intelligence, but to some deficiency in her powers of colour-perception.

NOTES.

THE annual meeting for the election of Fellows of the Royal Society was held at the Society's rooms in Burlington House, on June 6, when the following gentlemen were elected:—John Aitken, Dr. Edward Ballard, Alfred Barnard Basset, Horace T. Brown, Latimer Clark, Prof. David Douglas Cunningham, Lazarus Fletcher, William Botting Hemsley, Charles Thomas Hudson, Prof. Thomas McKenny Hughes, Edward B. Poulton, Prof. William Johnson Sollas, Charles Todd, Herbert Tomlinson, Prof. Gerald F. Yeo.

THE statue of Le Verrier is to be unveiled in the court of the Paris Observatory on June 25.

HERR VICTOR APFELBECK, the entomologist, will shortly start, in behalf of the Bosnian Government, on a journey of research in Herzegovina. Last year he discovered in Southern Bosnia five new species of eyeless cave beetles, and his investigations excited much interest among entomologists.

ACCORDING to the *British Medical Journal*, the programme of the Leeds meeting of the British Medical Association in August next "is developing in such manner as to afford the ample promise of a meeting of great scientific as well as social interest, and one which will be worthy of the traditions of this great medical centre."

MR. JOHN FREDERICK LA TROBE BATEMAN, F.R.S., died on Monday morning at Moor Park, Farnham, at the age of seventy-nine, after a severe illness. Mr. Bateman was well known as the engineer who supplied Glasgow with water from Loch Katrine.

THE death of Eugen Ferdinand von Homeyer, the eminent ornithologist, is announced. He had been President of the Ornithological Society at Berlin, was the author of several works, and possessed the largest existing collection of European birds. He was born at Herdin, near Anklam, in 1809, and died at Stolp, in Prussia, on June 1.

INFORMATION has been received in Berlin of the death of Dr. Bernhard Weissenborn, the zoologist to the German Cameroons Expedition, from a fever contracted through the hardships of the work and the bad climate.

GERMAN papers record the death of Dr. C. Jessen, the naturalist, formerly Professor at Greifswald, and lately at the Berlin University. He was sixty-eight years of age.

AT a meeting of the Royal Horticultural Society on Tuesday, a paper on orchids was read by Mr. H. Veitch. In the discussion which followed the reading of this paper, various speakers referred with regret to the death of Prof. Reichenbach, and to the strange provisions of his will, by which botanists of the present generation will be prevented from studying his fine collection of orchids. Mr. Thiselton Dyer invited those interested in the nomenclature of orchids to put themselves in communication with the Kew Herbarium, and it was stated that Messrs. Veitch and Sander could furnish many duplicates of the examples which were to be locked up under the will of Reichenbach. Sir T. Lawrence spoke of an orchid which had been in this country to his knowledge for fifty years.

THE June number of the *Kew Bulletin* opens with an instructive paper on Jamaica cogwood. This is one of the most valuable timber-trees in Jamaica, yet until recently its flowers and fruit had not been received in this country, so that, as the writer points out, the position of the plant in botanical classification had been left in doubt. Good herbarium specimens, including flowers and fruit, have lately been sent to Kew by Mr. W. Fawcett, Director of Public Gardens and Plantations in Jamaica; and from this material Prof. Oliver has determined the cogwood to be a species of *Zizyphus*, a genus not previously recorded from Jamaica. *Zizyphus* is the Jujube or Lotus genus of *Rhamneæ*, and the fruits of several species, such as *Z. vulgaris* and *Z. Jujuba*, have an agreeable flavour, and are commonly eaten. Besides this paper, there are contributions on cocoa-nut coir from Lagos, a wheat pest in Cyprus, patchouli, P'u-êrh tea, and agricultural industries at the Gambia.

WE take the following from *Allen's Indian Mail*:—"The appointment of Mr. A. Hartless from the Royal Gardens, Kew, to fill the vacancy in the staff of the Botanic Gardens at Shippur has given much satisfaction. This gentleman is a first-class botanist, and will no doubt contribute hereafter many original and important observations on the flora of India."

IN addition to the papers announced to be read at the ordinary meeting of the Royal Meteorological Society on June 19, a communication will be made on the recent thunderstorms, and a number of photographs of lightning will be exhibited.

A VIOLENT shock of earthquake, accompanied by local subterranean rumblings, was felt at Brest on June 7 at a quarter past one o'clock, its direction being from north to south. The shock is said to have resembled the vibration caused by the firing of a gun of large calibre. On the same day a shock of earthquake was felt at New Bedford, in Massachusetts.

ON April 13 and 14 a volcanic eruption occurred on Oshima Island, Japan. It is said that upwards of 300 houses were destroyed, and that 170 persons were killed by being buried beneath the ruined buildings.

ACCORDING to the *Japan Weekly Mail*, an earthquake of a most unusual character was recorded at 2h. 7m. 41s. p.m., on Thursday, April 18, in the Seismological Observatory of the Imperial University, Tokio. The peculiarity lies, not in its violence, but in the extreme slowness of its oscillations. The beginning of the shock had all the characteristics of the ordinary earthquake, but gradually the motion augmented, until at a certain stage of the shock it reached 17 millimetres, but the ground swayed so gently that the house did not vibrate visibly, nor were the senses alive to it. It took from four to seven seconds to complete one oscillation—a most unusual phenomenon, and one never before noted in the Observatory. The motion was almost entirely confined to the horizontal plane, and mostly south to north, but there were a few vertical motions of equally slow periods. This state of things lasted for 10 minutes 36 seconds. Prof. West, of the Engineering College, observed the water in a small pond to oscillate gently from north to south. At one time the water-level fell about 2 inches on one side of the pond, and exposed the bank, while, a few seconds later, the water immersed it nearly to the same depth, exposing the opposite bank, and this process continued for a quarter of an hour. "Slow oscillations of this nature have been called earth-pulsations, and these usually take place where there is a destructive earthquake or a submarine disturbance going on at a great distance. Earth-pulsations are known to have caused slow oscillations of the water in lakes. From this fact it may not be unreasonable to conjecture that a terrestrial or submarine agitation of unusual magnitude has taken place somewhere. The authorities of the Science College have sent to the Hydrographical Bureau of the Naval Department, asking for information as to the state of the tide and seas. It may be as well to remark that it is not certain whether the maximum motion of 17 millimetres, as given by the seismograph, is perfectly accurate, as it is very difficult to measure slow oscillation like this with absolute certainty." It is now known as a fact that Vries Island, outside Yokohama Bay, and possibly sixty miles off, was in a state of violent volcanic eruption.

THE Admiralty has published an interesting Report on the bore of the Tsien-Tang Kiang, by Captain W. U. Moore, of H.M.S. *Rambler*, as a fitting termination to a long series of tidal observations made on that vessel in Chinese waters. Scarcely anything was before known about this phenomenon, although it occurs twice a day, seventy miles from Shanghai. The bore was found to originate, not at the mouth of the river, as was expected, but twelve or fifteen miles outside it. Captain Moore states that the bore cannot be accurately described as a wave, there being no undulation, nor any depression after it has passed. It is divided into two branches, which join together four miles from Haining, making a continuous white line two miles in length. It shortly afterwards contracts in width, and increases in speed and height, rising 8 to 11 feet high, and travelling between 12 and 13 knots an hour. The three cutters employed in making the observations were at times in considerable danger, and the Hydrographer pays a high compliment to the skill with which the boats were brought safely out of their dangerous situation.

THE meteorological observations for the year 1888, made at the Rousdon Observatory, Devon, under the superintendence of Mr. Cuthbert E. Peek, have been published. They are a continuation of those issued last year. The instruments continue to perform to Mr. Peek's satisfaction, and have been regularly read by his assistant, Mr. C. Grover. The observatory is a second order station of the Royal Meteorological Society.

MR. THOMAS SCOTT, of the Scientific Department, Scottish Fishery Board, recently fertilized ripe ova of the common gurnard (*Trigla gurnardus*) with milt of the whiting (*Gadus merlangus*). Segmentation soon set in, and development proceeded for about a day and a half; but the ova then gradually sank, showing that death had supervened, this being attributed to an imperfect supply of fresh sea-water. An attempt to fertilize gurnard ova with milt of the common dab (*Pleuronectes limanda*) failed; but ova of the lemon sole (*P. microcephalus*) were successfully fertilized by milt of the same species, and floated buoyantly.

A SHARK 10 feet long and 4 feet in girth was caught on the morning of June 7, about twenty-four miles south-east of Ventnor by the mackerel nets of the smack *Pioneer*, of Brighton. It has three rows of teeth, and is supposed to be three years old.

TRACES of glacial action have been discovered on the Thomasberg, which is over 800 metres high, near St. Margarethen, in the Rosenthal in Carniola.

MESSRS. MACMILLAN AND CO. have issued a new edition of Prof. T. H. Core's "Questions on Stewart's Lessons in Elementary Physics." The late Prof. Balfour Stewart, writing of the first edition of this useful little volume, said that Prof. Core had made his questions "at once simple and suggestive, leading on in some cases to higher results, so as to encourage students to proceed with the subject."

ALL students of ethnology and anthropology will welcome the first number of *Veröffentlichungen* from the Berlin Museum für Völkerkunde. This periodical, which is clearly printed on good paper, takes the place of the *Original-Mittheilungen aus der Ethnologischen Abtheilung der Königlichen Museen*. The first number consists of plates illustrating American antiquities, with full descriptions and explanations. In some instances analogous objects from other parts of the world are represented along with those from America. The text is by Dr. Uhle, and Dr. Bastian contributes a brief prefatory note.

AN interesting paper on Palæolithic man in America, by Mr. W. J. McGee, of the United States Geological Survey, has been reprinted from the *Popular Science Monthly*. Mr. McGee holds that there is definite and cumulative evidence of man's existence in America during the latest ice epoch, with a strong presumption against an earlier origin than the first Quaternary ice-invasion; and that the primitive American "haunted the ice front rather than the fertile plain, and must have been hunter or fisherman."

AMONG the antiquities recently acquired by the Christiania Museum are some from the middle Iron Age, found in two barrows at Larvik. They consist of fragments of a lance, a shield with iron handle, a pair of shears or scissors, and a buckle of silver, besides a number of vessels, among which the most remarkable is a glass beaker, ornamented with threads of glass fused on to the exterior, a wooden bucket caulked with tar, and many urns. Among the latter is a large handsome one with a long neck. The graves in the barrows were made of stones. On a farm in the parish of Tjölling, also on the west coast of the Christiania fjord, a barrow, which had been formerly disturbed, has been excavated. Round it is a ring of raised stones. It dates from the early Iron Age. On the eastern and western side a *Bautasten*, or memorial stone, is raised. The funeral chamber is built of stone. Only three buckles of bronze, with silver ornaments, a plain ring made from an alloy of gold and silver, and the jaw-bone of a man with teeth remaining, were found. The body had not been burned. A yard further to the east a grave with calcined human remains was also found.

THE fourth issue of the *Jahrbuch der Naturwissenschaften* has just made its appearance. It is published by the Herderschen Verlagshandlung at Freiburg im Breisgau, and it remains under the editorship of Dr. Max Wildermann. It contains about 570 octavo pages, with an introduction. The subdivisions are under the control of different competent authorities. The section on physics occupies seventy-six pages, and is under the care of the editor; chemistry, with forty-six pages, and several sub-heads, under that of Dr. Hovestadt; applied mechanics, forty-six pages, under Dr. van Muyden; astronomy, thirty pages, under Dr. Franz; meteorology, under Dr. Pernter, forty-four pages; zoology, under three different editors, thirty-two pages; and similarly with botany, forestry, and agriculture, mineralogy and geology, anthropology, physiology, medicine and sanitary matters, geography, and ethnography. An appendix contains obituaries of eminent scientific men, and a report of the proceedings of the sixty-fourth meeting of the Association of German Naturalists and Physicians.

NAPHTHA is now much used as fuel in Middle Russia. Last year, 880,000 tons of it were sent up the Volga for fuel purposes; and it is expected that the export for the same purpose will this year reach no less than one million tons.

THE province of St. Petersburg is very rich in marshes covered with a thick carpet of vegetation, which conceals water to the depth of several feet—sometimes 25 feet and more. Small lakes and branches of rivers are continually being transformed into such marshes, and M. Tanfilieff, who has studied the way in which the transformation goes on, comes to the following conclusions (*Mémoires* of the St. Petersburg Society of Naturalists, vol. xix.). The pioneers of the transformation of a lake into a marsh invariably are flowering plants, such as *Menyanthes*, *Comarum*, *Cicuta*, *Equisetum*, *Carices*, and the like. Their roots and underground stems make a thickly-woven floating carpet, which soon totally conceals the water. The *Sphagnum* invades this floating carpet, while the water beneath becomes filled with *débris* of decaying plants, transformed later on into peat-bog. In shallow basins the transformation goes on at a much speedier rate, as their bottoms are invaded by plants like *Phragmites* and *Scirpus lacustris* which reach a considerable height, and thus supply, after their decay, a good deal of additional material for the filling up of the basin. A mass of smaller plants, such as *Lemna*, *Hydrocharis*, *Callitriche*, *Utricularia*, *Hypnum fluitans*, and several others, usually grow also amidst the rushes. Of course, the streamlets which flow into the basin contribute also to fill it up by bringing in sand and loam. As soon as the floating carpet has reached a certain thickness, and the *Sphagnum* has still more increased its bulk, various plants, such as *Drosera*, *Vaccinium*, *Eriophorum*, the dwarf birch, and other bushes, begin to grow upon it, although the space beneath still remains filled with water. As the *Sphagnum* does not grow upon ponds containing a chalky water, its place in such ponds is mostly taken by the *Hypnum*, and in these cases a variety of other plants, such as *Typha*, *Stratiotes*, *Butomus*, *Ranunculus divaricatus*, and *Chara fragilis*, make their appearance. As to the *Sphagnum*, it invades wet meadows as well.

AT a recent meeting of the French Academy of Sciences, M. de Malarce, speaking of the extension of the metric system of weights and measures, gave some interesting figures. In 1887 the aggregate population of the countries in which the metric system was compulsory was over 302,000,000, being an increase of 53,000,000 in ten years. In 1887, in countries with a population of close on 97,000,000, the use of the system was optional; and the countries where the metric system is legally admitted in principle and partially applied (as in Russia, Turkey, and British India) had in 1887 a population of 395,000,000, being an increase of 54,000,000 in ten years. The increase is due to the growth of population in the countries which had already adopted the system, and to its adoption by new countries. The systems of China, Japan, and Mexico, are decimal, but not metric. The metric system is thus legally recognized by 794,000,000 of people, and the three last-named countries have a population of about 474,000,000. So that only about 42,000,000 of inhabitants of the civilized world have systems which are neither metric nor decimal.

SIR ARTHUR NICOLSON, the British Consul at Buda-Pesth, in his last Report on Hungary, referring to technical education in that country, says that it will afford an indication of the attention which is being paid to this important question to instance the steps which have been taken in Buda-Pesth in regard to primary technical education. By paragraph 80 of the Trade Law of 1884, every *commune*, where there are fifty or more apprentices, is bound to provide for their education, and to afford special courses of instruction. The apprentice schools in Buda-Pesth contain a preparatory class, provide a course of three years, and are chiefly destined to educate apprentices for the higher trade schools. Each district of the town must have at least one apprentice school. No class is to comprise more than fifty pupils, or at most sixty pupils; and should the number of pupils be larger, parallel classes can be established. A pupil passes at the end of each year into a higher class if he can show proficiency and good progress. Theoretical instruction is given six hours in the week, and drawing and modelling are taught five hours weekly, on Sundays. The first schools were established in 1887, and numbered 12 with 125 teachers. There were 42 classes, or, including the parallel classes, 93, attended by 5173 pupils. In 1888 the number of schools had risen to 16, the number of classes to 127, the staff of teachers 151, and the number of pupils to 6459. In the other towns and counties of Hungary there were 229 apprentice schools, with 1237 teachers, and 38,081 pupils. For all these schools, including those of the capital, the *communes* contribute in florins 214,302; private individuals, 1387; Chambers, 680; counties, 9080; State, 35,806; fees and fines, 129,488; making a total of 390,843 florins.

THE British Consul at Ancona, in his last Report, refers to a School of Practical Agriculture established in Fabriano in 1882. It is subsidized by the Government, the province of Ancona, the municipality of Fabriano, and the local Chamber of Commerce. The school has a Director, two Professors, and a Teacher of Practical Agriculture. The course of study is spread over three years as follows: first year, Italian, geography, elements of natural history, elementary arithmetic, agronomy, and writing; second year, Italian, geography, elements of natural philosophy and chemistry, agriculture, and rural accounts; third year, horticulture, rural direction and management of a farm, technical agriculture, and arithmetic. The school at present has thirty-six scholars, of whom nineteen are in the first year, nine in the second, and eight in the third. Of these, twelve are agriculturists, ten sons of land stewards, eleven sons of gentlemen, and three sons of tradesmen. The day's work begins at 5.30 a.m. in winter, and is over at 8 p.m. Seven hours are devoted to practical work, five to study, the remainder being allowed for meals and recreation. In summer the students rise at 4.30 a.m.; otherwise, with the exception of an extra hour and a half for recreation, the studies are carried on as in winter.

THE additions to the Zoological Society's Gardens during the past week include two Australian Thicknees (*Œdicnemus grallarius*), an Eyton's Tree Duck (*Dendrocygna eytoni*) from Australia, two Lineated Parrakeets (*Bolborhynchus lineolatus*) from Mexico), two Senegal Touracous (*Corythaix persa*) from West Africa, purchased; two Elliot's Pheasants (*Phasianus ellioti* ♂ ♀) from China, deposited; a Hog Deer (*Cervus porcinus* ♀), two Mule Deer (*Cariacus macrotis* ♀ ♀), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

STONYHURST COLLEGE OBSERVATORY.—The results of the observations made during the year 1888 at this Observatory have recently been published in the ususal form. The bulk of the volume is occupied with the routine magnetic and meteorological observations, and an appendix gives the meteorological results for St. Ignatius College, Malta. The weather in 1888 was less favourable for the daily delineation of the solar surface than in 1887, but 223 full-sized drawings were secured. The daily areas of sun-spots derived from these show very strikingly, especially as given in graphical form, the nearness of our approach to minimum. The chromosphere was completely examined on eighty-four days, and partly on three other dates. The most important event of the year in connection with the Observatory has been the installation of a large grating-spectroscope for the especial purpose of photographing the solar spectrum, and the spectra of sun-spots in particular—a work which, in the present state of solar physics, greatly needed to be undertaken, and carried out with persevering regularity. The grating is a flat one, by Rowland, of 14,438 lines to the inch, and 3½ inches in length. It is to be used in connection with a heliostat and a 5½-inch object-glass by Alvan Clark. The preliminary experiments promise well for its efficiency, and the Director of the Observatory is to be greatly congratulated on so valuable an addition to his equipment.

The Rev. E. Colin, S.J., who spent the last year at Stonyhurst Observatory, has just been appointed Director of the French Government Observatory at Antananarivo.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1889 *JUNE* 16–22.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on June 16

Sun rises, 3h. 44m.; souths, 12h. 0m. 26·5s.; daily increase of southing, 12·8s.; sets, 20h. 17m.: right asc. on meridian, 5h. 40·2m.; decl. 23° 22′ N. Sidereal Time at Sunset, 13h. 58m.

Moon (at Last Quarter on June 20, 8h.) rises, 22h. 31m.*; souths, 2h. 35m.; sets, 6h. 44m.: right asc. on meridian, 20h. 13·2m.; decl. 21° 39′ S.

Planet.	Rises.	Souths.	Sets.	Right asc. and declination on meridian.	
	h. m.	h. m.	h. m.	h. m.	° ′
Mercury..	4 25	12 20	20 15	5 59·8	20 14 N.
Venus ...	1 55	9 4	16 13	2 43·7	12 45 N.
Mars ...	3 41	12 2	20 23	5 42·1	24 4 N.
Jupiter ...	20 47*	0 42	4 37	8 19·6	23 11 S.
Saturn ...	8 5	15 38	23 11	9 18·1	16 55 N.
Uranus...	13 55	19 26	0 57*	13 7·0	6 27 S.
Neptune..	2 37	10 25	18 13	4 4·7	19 11 N.

* Indicates that the rising is that of the preceding evening and the setting that of the following morning.

June.	h.	
18	2	Mars in conjunction with the Sun.
19	11	Mercury in inferior conjunction with the Sun.
21	6	Sun at greatest declination north; longest day in northern latitudes.

GEOGRAPHICAL NOTES.

SIG. GIULIO BORELLI writes from Cairo to the May number of the Italian Geographical *Bollettino*, on the outflow of the River Omo, in connection with Count Teleki's recent discovery of Lake Rudolf (Samburu). Combining the data supplied by this explorer and his comrade, Lieutenant Hoenel, with his own observations further north, he finds that the Omo is a tributary neither of the White Nile nor of the Juba, as hitherto supposed, but almost certainly flows south to Lake Rudolf. But at its confluence with the Gojieb, south of Shoa, the Omo flows at an altitude of 1100 metres, about the same or very little more than that of Victoria Nyanza; and as beyond the confluence it has still a very long and rapid course, it follows that it cannot be a tributary of the great equatorial lake. Lake Rudolf stands at an elevation of about 550 metres, showing a fall of over 500 metres from the Gojieb confluence in a space of four degrees of latitude. Hence this basin, with its Omo feeder, can have no connection with the Nile, and, as asserted by its discoverers, is in fact a flooded depression without any outlet. Thus would appear to be solved one of the last hydrographical problems on the African continent.

AT the last meeting of the Russian Geographical Society it was definitely announced that the Society had decided to take part in the Geographical Congress which is to be held at Paris during the Exhibition. At the same meeting, Colonel Nadaroff communicated some interesting facts about the South Usuri region. It appears that the level of the great Lake Khangka, at the sources of the Usuri, has fallen to a considerable extent since the Russian occupation of the country thirty years ago. Even a hasty glance over the region of the Lower Amur and its tributaries, surrounded by numberless lakes, shows that the river-beds of the region belong to what Peschel described as "young rivers"—that is, rivers which have not yet completed the excavation of definite beds. It is natural, therefore, to suppose that the lakes which surround the Lower Amur must by and by be emptied into the channel of the great river, and thus in the meantime gradually diminish in size. M. Nadaroff's statement tends to confirm this view, and adds new facts in support of the theory of the rapid desiccation of Northern Asia.

AT the meeting of the Physical Section of the Russian Geographical Society on May 10, General Tillo made a communication about his remarkable hypsometrical map of European Russia, for which he has collected all available data obtained by levellings for the building of railways and along Russian rivers, as well as for the draining of marshes, together with data furnished by the trigonometrical survey of Russia and by individual explorers.

THE PRIORITY OF CHINESE INVENTIONS.

A WRITER in the *North China Herald* of Shanghai, referring to the Chinese claims to have originated many modern Western scientific inventions, says that Chinese patriotism has exhibited itself in an ardent desire to claim priority over Europeans in this respect. They are a very ingenious people, and, in past times having invented many valuable implements, it has always seemed to them a fair hypothesis that as every machine is an improvement on something that preceded it, the machinery and telescopes of the West may have originated at first in something Chinese. Yuen-yuen, a former Governor-General of Canton, in his "History of Astronomers," written at the beginning of this century, again prominently brought forward the idea that European mathematics came from China, and many subsequent writers have made the same claim. Not only is this the case in mathematics, but the Chinese say that our telescopes, steam-engines, firearms, and cannons are owing to them. Ever since China first saw steamers, fifty years ago, and since she came to know of the existence of European mathematics three hundred years ago, she has, from time to time, with more or less eagerness shown herself bent on claiming that the knowledge and skill shown in the West began in the first place with China. Mei-wen-ting, a great Chinese scholar, who died at an advanced age in the year 1722, after considering the whole question from the Chinese point of view, came to the conclusion that Europeans had got their mathematics and science from China. Amongst other reasons for this belief he states that in the "Chon-pi," a mathematical work of about B.C. 1100, although not expressly stated, the rotundity of the earth is implied. In the same book are to be found, he says, the properties of a right-angled triangle, as, for instance, that the square of the hypotenuse is equal to the sum of the squares of the other two sides. Since this is a fundamental problem, Mei-wen-ting claims that Western geometrical and trigonometrical knowledge is due to China. He accounts for the spread of Chinese astronomy to us by the scattering of the schools of astronomy in China, which, according to Szu-ma-chien, an historian who wrote a century before the Christian era, took place about B.C. 760. The fugitive astronomers, flying from the tyranny of the early Chow dynasty, diffused Chinese learning amongst the barbarians. Similarly in other matters the Chinese claim that the metaphysics of Indian Buddhism are due to the journey of Lao-tse to the West. The writer concludes his interesting discussion as follows:—"We need not trouble ourselves much respecting the Chinese claim to have originated Western science: they only claim to have started the preliminary ideas. As to the Chinese having always had enlightened views on many scientific and political subjects, we may frankly admit it. They speak 2200 years ago of concave and convex mirrors being able to magnify objects. Four thousand years ago they had instruments for observing the stars. In the year A.D. 1122 they made use of the magnet pointing to the south on board ship to guide the vessel on her course. With the proviso that they may have derived some of their early knowledge in these things and in others, such as the manufacture of fireworks, from foreign countries, these and many like facts we may allow. But we would be glad for them to study the history of Western inventions, and show a willingness to recognize the ingenuity, knowledge, and intellectual power of other nations wherever they are found. Let them also enter on a rivalry in inventions. Let them make new discoveries and advance in the arts in new ways such as may be of benefit in the world. The Western nations will not be slow to acknowledge any efficient aid they may give in science, politics, or the arts."

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Nearly twenty courses of scientific and medical instruction for medical students will be carried on in the Long Vacation, including, besides chemical, botanical, anatomical, and physiological courses, Dr. Anningson and Mr. Robinson on the examination of water, air, and foods, chemically and microscopically, and Prof. Roy and Mr. Adami on pathology, morbid histology, and bacteriology.

The Museums and Lecture Rooms Syndicate have recommended the erection of the buildings required for human anatomy, together with the joint anatomical and physiological lecture-room, at a cost which will fall within the £10,000 reported to be available for the purpose.

The honorary degree of Doctor in Science has been conferred on Prof. Mendeleeff, of St. Petersburg; and the honorary M.A. on Baron A. von Hügel, Curator of the Museum of Archæology here.

The Senior Wrangler, Mr. G. T. Walker, and Messrs. Dyson and Gaul, bracketed Second Wranglers, are all members of Trinity College.

In the second part of the Mathematical Tripos, Messrs. Brunyate, of Trinity, and Orr, of St. John's, have been placed in the first division of Class I., in alphabetical order; and Messrs. Buchanan, of Peterhouse, and Sampson, of St. John's, in the second division of the first class.

The Moral Sciences Tripos seems in a state of rapid progress towards obliteration. This year one first class and one second class represent the men; and this is but natural, for the range of work is such as to task the energy and thoughts of a matured thinker.

SOCIETIES AND ACADEMIES.

LONDON.

Chemical Society, May 16.—Dr. W. J. Russell, F.R.S., President, in the chair.—The following papers were read:—The magnetic rotation of nitrogen compounds, by Dr. W. H. Perkin, F.R.S. In previous communications the author has shown that in the magnetic field the plane of polarization of light is rotated to a greater extent in unsaturated than in saturated carbon compounds, and it is now shown that in the case of nitrogen compounds the magnetic rotation is in like manner correlated with changes in the valency of the nitrogen. From the discussion of his results generally the author concludes that in compounds of unsaturated triad nitrogen, the nitrogen has a greater influence than when it is present in the saturated condition, the difference in the values being about 0·5; this is only about half the difference usually observed on comparing the rotations of carbon compounds differing by two atoms of hydrogen. In the discussion which followed the reading of the paper, Dr. Gladstone, F.R.S., said that the general result of Dr. Perkin's work, establishing a difference in nitrogen according as it is present in the saturated or unsaturated condition, was in accordance with the conclusion which he had arrived at from the study of refractive power; the peculiarities brought out by the study of the magnetic behaviour, however, were chiefly indicated by peculiarities in dispersive power, being less obvious in the refraction equivalents.—The nature of solutions as elucidated by a study of their densities, electric conductivities, heat capacity, and heat of dissolution, by Mr. S. U. Pickering. The solutions examined were those of calcium chloride, calcium nitrate, and sulphuric acid, and the various hydrates which are proved to exist in solution are numerous and complex. The hydrates which calcium chloride forms contain 6, 7, 8, 10, 13, 18, 28, 86, and 1500 H_2O; calcium nitrate gives hydrates with 3, 3·5, 4·5, 5, 6, 10, 17, 51, 265, and 1810 H_2O; while with sulphuric acid hydrates are found containing $\frac{1}{6}$, $\frac{1}{3}$, $\frac{2}{3}$, 1, $\frac{3}{2}$, 2, 4, 5, 9, 13, 24, 52, 135, 510, 1430, and 4950 H_2O. The existence of these is, naturally, more doubtful in some cases than in others, and it is impossible to determine the exact molecular composition when more than about $10H_2O$ is present. In some cases the hydrates of sulphuric acid were established by six independent sets of results obtained from the study of four distinct properties. The excessively large amount of water present in the highest hydrate is a matter of especial interest, and the existence of such compounds explains the influence which mere traces of one substance may have on another substance (*e.g.* impurities in metals). The final conclusion which the author deduces from his work is the absolute rejection of any theory of dissolution other than the hydrate theory.—The expansion of water and other liquids, by the same. The author gives some determinations of the density of water at different temperatures, which indicate sudden changes in the expansion at about 10° and 18°. On examining the results obtained by Pierre, Kopp, Rosetti, Matthiessen, Solly, Despretz, and Hagen, he obtained further evidence of these changes, as well as of another change at 50°–60°. Pierre's results also show marked changes at 0° and 2°·5. Pierre's results with eleven organic liquids were also examined, and in most of them there appeared to be sudden changes of density at certain temperatures, which temperatures were different for different liquids. Nearly all of these results show that the densities of liquids when plotted against temperature form a series of parabolic curves of the second order, not meeting tangentially, and differentiating, therefore, into a series of straight lines which do not meet at the points where the breaks occur.—The formation of phenylindoles by isomeric change, by Dr. W. H. Ince. It is known that the phenylindole $C_6H_4\left\langle\begin{matrix}CPh\\NH\end{matrix}\right\rangle CH$, when heated with zinc chloride at 170°, is converted into the isomeride $C_6H_6\left\langle\begin{matrix}CH\\NH\end{matrix}\right\rangle CPh$ (Fischer and Schmitt, *Ber. der deut. chem. Gesellsch.*, 1887, 1071, 1811). The author finds that the corresponding naphthindole, $C_{10}H_6\left\langle\begin{matrix}CPh\\NH\end{matrix}\right\rangle CH$, and methylphenylindole, $C_6H_4\left\langle\begin{matrix}CPh\\NMe\end{matrix}\right\rangle CH$, undergo a like change under similar conditions, although action takes place neither so easily nor so completely as in the simpler case.—An improved Soxhlet extractor, and vacuum distilling apparatus, by Dr. I. Lewkowitsch.

Institution of Civil Engineers, May 28.—Annual General Meeting.—Sir George B. Bruce, President, in the chair.—After the reading and adoption of the Report, hearty votes of thanks were passed to the President, to the Vice-Presidents, and other Members of the Council, to the Auditors, to the Secretaries and Staff, and to the Scrutineers.—The ballot for the Council resulted in the election of Sir John Coode, K.C.M.G., as President; of Mr. G. Berkley, Mr. H. Hayter, Mr. A. Giles, M.P., and Sir Robert Rawlinson, K.C.B., as Vice-Presidents; and of Mr. W. Anderson, Mr. B. Baker, Mr. J. W. Barry, Mr. E. A. Cowper, Sir James N. Douglass, F.R.S., Sir Douglas Fox, Mr. J. C. Hawkshaw, Mr. C. Hawksley, Sir Bradford Leslie, K.C.I.E., Mr. G. F. Lyster, Mr. J. Mansergh, Mr. W. H. Preece, F.R.S., Sir E. J. Reed, K.C.B., F.R.S., M.P., Mr. W. Shelford, and Mr. F. W. Webb, as other Members of the Council.—The session was then adjourned until the second Tuesday in November, at 8 p.m.—The Council have awarded the following premiums in respect of the original communications submitted during the session 1888–89:—For papers read and discussed at the ordinary meetings: a Telford Medal and a Telford Premium to Gisbert Kapp, for his paper on alternate-current machinery; a Watt Medal and a Telford Premium to William Henry Greenwood, for his paper on the treatment of steel by hydraulic pressure, and the plant employed for the purpose; a George Stephenson Medal and a Telford Premium to Edgar Worthington, for his paper on the compound principle applied to locomotives; a Watt Medal and a Telford Premium to Charles Edward Emery, for his paper on the district distribution of steam in the United States; a Telford Premium to John Audley Frederick Aspinall, for his paper on the friction of locomotive slide-valves; a Telford Premium to John Oliver Arnold, for his paper on the influence of chemical composition on the strength of Bessemer steel tires. For papers printed in the Proceedings without being discussed: a Watt Medal and a

Telford Premium to Robert Runeberg, for his description of steamers for winter navigation and ice-breaking; a Telford Premium to Bryan Donkin, Jun., for his account of experiments with gas-flame jackets; a Telford Premium to Prof. Victor Auguste Ernest Dwelshauvers Dery, for his reduction of experiments on the effect of superheating, steam-jacketing, and gas-flame jackets on cylinder-condensation; a Telford Premium to Robert Henry Smith, for his paper on stress diagrams of solid structures; a Telford Premium to Leveson Francis Vernon-Harcourt, for his paper on Alpine engineering; a Telford Premium to George Lopes, for his account of the reparation of Betchworth Tunnel, Dorking, on the London, Brighton, and South Coast Railway; a Telford Premium to Neil Kennedy, for his paper on the tacheometer and its uses. For papers read at the supplemental meetings of students: a Miller Scholarship to Edward Carstensen de Segundo, for his account of experiments on the strain in the outer layers of cast-iron and steel beams; a Miller Prize to Henry Byrom Ransom, for his paper on the cyclical velocity-variations of steam and other engines; a Miller Prize to William Wade Fitzherbert Pullen, for his account of water-softening and filtering apparatus, for locomotive purposes, at the Taff Vale Railway Company's Penarth Dock Station, near Cardiff; a Miller Prize to James Denis Twinberrow, for his paper on flexible wheel-bases for railway rolling-stock; a Miller Prize to Samuel Joyce, Jun., for his paper on electrical measuring-instruments, their properties and calibration; a Miller Prize to Richard John Durley, for his paper on moulding and casting cylinders for marine engines; a Miller Prize to Julian James King-Salter, for his description of the 26-knot Spanish torpedo-boat *Ariéte;* Miller Prizes to Charles Henry Gale and Vernon Warburton Delves-Broughton, for their joint paper on photography for engineers.

Geological Society, May 22.—Mr. W. T. Blanford, F.R.S., President, in the chair.—The following communications were read:—Note on the hornblende schists and banded crystalline rocks of the Lizard, by Major-General C. A. McMahon. The reading of this paper was followed by a discussion, in which the President, Dr. Geikie, Mr. Teall, Prof. Bonney, Mr. Rutley, and Dr. Hicks took part.—The Upper Jurassic clays of Lincolnshire, by Mr. Thomas Roberts. In Lincolnshire it has generally been considered that the Oxford and Kimeridge clays come in direct sequence, and that the Corallian group of rocks is not represented. The author, however, endeavoured to show that there is between the Oxford and Kimeridge a zone of clay which is of Corallian age. Six palæontological zones were recognized in the Oxford clay. The clays which come between the Oxford and Upper Kimeridge the author divided into the following zones: (1) black selenitiferous clays; (2) dark clays crowded with *Ostrea deltoidea;* (3) clays with *Ammonites alternans;* and (4) clays in which this fossil is absent. The black selenitiferous clays (1) are regarded as Corallian, because: (*a*) they come between the Oxford clay and the basement bed of the Kimeridge; (*b*) out of the twenty-three species of fossils collected from this zone, twenty-two are Corallian; (*c*) *Ostrea deltoidea* and *Gryphæa dilatata* occur together in these clays, and also in the Corallian, but in no other formation. The zones (2), (3), and (4) are of Lower Kimeridge clay age. The lowest zone, (2), is very persistent in character, and is met with in Yorkshire, Cambridgeshire, Oxfordshire, and the south of England. The remaining zones, (3) and (4), are local in their development. Some remarks on this paper were offered by Prof. Blake and Mr. Hudleston.—Origin of movements in the earth's crust, by Mr. James R. Kilroe. Communicated by Mr. A. B. Wynne.

Zoological Society, May 21.—Prof. Flower, F.R.S., President, in the chair.—Mr. Sclater exhibited and made remarks on a mummied Falcon from Egypt; and some photographs of groups of Sea-birds and Seals taken on the shores of Antipodes Island, Antarctic Ocean.—Mr. Sclater also called attention to a specimen of Leaf-insect, living in the Society's Insect House, which had been received from the Seychelles, and presented by Lord Walsingham. It was not quite fully developed, but was believed to be referable to *Phyllium gelonus*, Gray.—Mr. Martin Jacoby read a list of the species of Coleoptera of the families Crioceridæ, Chrysomelidæ, and Galerucidæ, of which specimens had been collected in Venezuela by M. Simon, and gave descriptions of the new species.—A communication was read from Mr. A. G. Butler containing the description of a new extinct genus of Moths belonging to the Geometrid family Euschemidæ, based on a fossil specimen obtained from the Eocene Freshwater Limestone of Gurnet Bay, Isle of Wight. This insect was named *Lithopsyche antiqua*.—Mr. W. F. Kirby read a paper containing descriptions of new genera and species of Dragonflies in the collection of the British Museum, chiefly from Africa.—Dr. Hans Gadow read a paper on the taxonomic value of the intestinal convolutions in birds. After pointing out the different forms assumed by the intestinal convolutions in this class of animals, and suggesting a nomenclature for them, the author proceeded to give the outlines of a classification of birds based solely on this part of their structure, and to show the differences and resemblances of the various groups.

Edinburgh.

Royal Society, June 3.—Sheriff Forbes Irvine, Vice-President, in the chair.—Some photographs of mirage were exhibited.—Prof. T. R. Frazer communicated the remainder of his paper on the natural history, chemistry, and pharmacology, of *Strophanthus hispidus*.—Prof. Tait read a note on the compressibility of mercury.—Dr. E. Sang gave a notice of fundamental tables in trigonometry and astronomy arranged according to the decimal division of the quadrant.—Prof. Tait communicated a note on the inscription, in a sphere, of a closed polygon, each of whose sides shall pass through a given point, and he also discussed the problem of the non-oscillating pendulum.—A paper, by Sir W. Thomson, on the Bravais' uniform distribution of points, was submitted.

Paris.

Academy of Sciences, June 3.—M. Des Cloizeaux, President, in the chair.—Heat of combustion of carbon under its various forms of diamond, graphite, and amorphous carbon, by MM. Berthelot and Petit. By means of the new methods based on the employment of the calorimetric bomb, the authors have determined the molecular heat of combustion of amorphous carbon at 97·65 calories; of crystallized graphite at 94·81; of the diamond at 94·31; and of bort (uncleavable diamond) 94·34. The old values, hitherto accepted, must consequently be considerably increased, and this again involves an increase of the heats of formation for all organic compounds, from their elements upwards, so far as they have yet been calculated.—Note on the spectrum of Uranus, by Mr. J. Norman Lockyer.—On the surface-currents of the North Atlantic, by Prince Albert of Monaco. Of the 1675 floats cast into the sea during the recent explorations of the *Hirondelle*, as many as 146 have already been recovered at various points of the seaboard, apparently demonstrating a circular movement of the surface-waters round a point situated somewhere to the south-west of the Azores. The outer edge of this current sets east-north-east to the neighbourhood of the English Channel, where it is deflected southwards along the coasts of Europe and Africa to the Canaries, thence trending south east to the equatorial current, thus completing the circuit by merging in the Gulf Stream.—On Prof. Charles Sumner Tainter's graphophone, by M. Georges R. Ostheimer. The essential feature of this instrument, which solves the problem of the storage of sound, is the employment of wax, or a pasteboard cylinder coated with wax. The process, devised by Prof. Tainter after the original phonograph had been discarded by Mr. Edison as of no immediate practical utility, has since been so highly approved of by the American inventor that he has adopted it for what he now calls his "improved phonograph."—Observations of the new planet discovered on May 29 at the Observatory of Nice, by M. Charlois. The observations are for the period May 29-31, when the planet appeared to be of the twelfth magnitude.—On the stability of the solar system, by M. D. Eginitis. The authors here study the nature of the slight perturbations usually neglected in planetary theories, and endeavour to determine their more important general analytical forms. The results are given for the earth and Saturn, showing that the long axes of their orbits are subject to extremely slight secular perturbations of the third order. These irregularities are periodical, the periods being excessively long, but of such a nature as to imply that both Saturn and the earth are at present approaching the sun.—Apparatus for determining melting-points under ordinary conditions and variable pressures, by M. B. C. Damien. The apparatus here described will be found useful in determining the melting-points of various mixtures of spermaceti and ether, of gum-lac and alcohol, and in general of solidified solutions of various solids.—The electric conductivity of saline solutions, applied to the problems of chemical mechanics, by M. P.

Chroustchoff. In continuation of his previous paper on this subject the author here gives in tabular form the measurements of the conductivity of neutral saline mixtures capable of double decomposition. In a supplementary paper, MM. Chroustchoff and V. Pachkoff deal with the electric conductivity of saline solutions containing mixtures of neutral salts. The chief object of this research is to confirm by experiment the assumption that a partial formation of double salts in solutions is a general phenomenon. — On some substances derived by polymerization from ethyl cyanide, by MM. M. Hanriot and L. Bouveault. The preparation and properties are described of two bodies of which the formulæ are respectively $C_2H_5 . CO . C(CH_3)_2CN$ and $C_2H_5 . CO . C(C_2H_5)(CH_3)CN$, the former obtained by the action of methyl iodide, the latter by that of ethyl iodide.—On some rocks of the Maures district, by M. A. Le Verrier. Of the old eruptive rocks here described the most interesting is a lherzolite consisting of olivine and hypersthene (labrador schiller spar), the first associated with serpentine, the second with talc.—On the toxic property of meteoric waters, by M. Domingos Freire. An epidemic presenting some hitherto unknown symptoms having broken out at Rio de Janeiro last March, the author, with a view to determining its origin, made some experiments on the character of the aqueous vapour suspended in the atmosphere. The result of these experiments was a strong suspicion, if not certainty, that the disorder was due to a toxic principle diffused in the atmosphere, and belonging perhaps to the cyanic series (hydrocyanic acid ?).—Papers were contributed by M. G. André, on some ammonio-chlorides of mercury; by M. E. Péchard, on the combinations of metatungstic acid with the alkaline bases and the resulting thermic phenomena; by M. Léon Bourgeois, on the preparation of the crystallized orthosilicates of cobalt and nickel; by M. Trouessart, on the marine Acarians of the French seaboard; by M. Flammarion, on the earthquake of May 30; and by M. Th. Moureaux, on the possible connection of magnetic disturbances with the same earthquake.

BERLIN.

Physical Society, May 24.—Prof. du Bois Reymond, President, in the chair.—Prof. Börnstein exhibited a photograph which he had taken during the recent heavy thunder-storms. Two flashes could scarcely be distinguished on the photograph owing to the marked occurrence of sheet lightning; they appeared as simply very sinuous lines without any zig-zags.—Dr. Pringsheim had carried out a series of researches with the phonautograph in order to determine by physical methods upon what the French accent is dependent, whether it is due to the duration, pitch, or intensity of the tones. Several Frenchmen spoke single words and short sentences slowly into the funnel of the instrument so as to impinge upon a membrane, made of the thinnest india-rubber, whose vibrations were recorded on a smoked rotating drum by means of a fibre of glass. The somewhat troublesome analysis of the minute curves brought to light very characteristic waves for the consonants, but these differed considerably according as they were spoken at the beginning or end of a word. The vowels showed a considerable difference from the consonants chiefly in respect of their pitch. The speaker exhibited and explained a number of the curves; but further researches are necessary before any general conclusions can be arrived at, or the question as to the real nature of "accent" can be decided.—Dr. Dieterici gave an account of his researches on the determination of the specific volume of saturated aqueous vapour at 0° C. On account of the difficulties which presented themselves in connection with the measurements necessary in the methods of research hitherto employed, he had devised a new method. He measured the amount of water which must be converted into vapour at 0° C. in order to completely fill a known space with saturated vapour, by means of the heat which becomes latent during its evaporation. The vessel containing the water was immersed in an ice-calorimeter, and was connected with a large space which could be rendered both vacuous and dry. The water, or dilute saline-solution which behaves like water, was then allowed to evaporate until the space was filled with saturated vapour; the amount of heat requisite to produce the observed evaporation was determined from the amount of mercury which was expelled from the calorimeter, and this then gave the amount of water evaporated. From among the experimental details, which the speaker described in full, the only points which may here be mentioned are that a small residual quantity of air in the vacuum has no effect on the total amount of water which evaporates, but only slows the rate of evaporation to a slight extent; on the other hand, the pellicle of water which is condensed on the inner surface of the vacuous space was found to exert a quantitative influence on the evaporation, and necessitated special modifications of the methods of experiment for its exclusion. As one outcome of the experiments may be mentioned that Gay Lussac's law holds good almost up to the temperature of saturation, and that the mass of water which must be evaporated in order to saturate a space of 1 litre capacity at 0° C. is 4·886 mgr.; hence the specific volume of aqueous vapour saturated at 0° C. is 204·7 litres, and its pressure is 4·62 mm. The speaker had deduced a considerable number of other important constants from the results of his experiments; and he further intends to determine the above for other fluids and at other temperatures in a subsequent research.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

An Essay on Asphyxia: G. Johnson (Churchill).—The Working and Management of an English Railway: G. Findlay (Whittaker).—Scientific Memoirs by Medical Officers of the Army of India, Part 4, 1889: edited by Sir B. Simpson (Calcutta).—Método de los Cuadrados Minimos: Libro de Texto por M. Merriman; traducido del Inglés por V. Balbin (Buenos Aires, Biedma).—Blackie's Modern Cyclopedia, vol. ii. (Blackie).—Life Lore, vol. i. (Mawer).—Kant's Critical Philosophy, a new and completed edition, vol. i., the Kritik of Pure Reason Explained and Defended: J. P. Mahaffy and J. H. EVOLUTION ETHICS.

Moral Order and Progress: an Analysis of Ethical Conceptions. By S. Alexander. "English and Foreign Philosophical Library." (London: Trübner, 1889.)

"IT will be found that moral ideals move by a process which, allowing for differences, repeats the law by which natural species develop. . . . The growth of a new ideal is analogous to the growth of a new species in the organic world. According to the generally accepted view, a new species is produced through giving rise to variations which struggle with one another and with the parent species. . . . The good ideal has been created by a struggle of ideals in which it has predominated. Evil is simply that which has been rejected and defeated in the struggle with the good." These sentences contain the key-note of Mr. Alexander's able and valuable work--a work which will be read with interest by students of ethics of whatever school. Based upon a dissertation, for which Mr. Alexander obtained the Green Moral Philosophy Prize at Oxford in 1887, written by one who has carefully studied and grasped the principles set forth by Mr. Herbert Spencer and Mr. Leslie Stephen, this work is in some sense the offspring of the fertile union of the "Prolegomena" and the "Science of Ethics." Or, as he himself expresses it, coming to the ideas borrowed from biology and the theory of evolution, which are prevalent in modern ethics, with a training derived from Aristotle and Hegel, Mr. Alexander has found "not antagonism, but, on the whole, fulfilment."

Morality being a matter of conduct and the outcome of character, the first book of the three into which Mr. Alexander's work is divided deals with conduct and character, which he regards as the same thing facing different ways. Think of a man's conduct in relation to the mental conditions from which it proceeds, and you think of his character: think of his character as it produces results beyond these sentiments themselves, and you have conduct. Following in the footsteps of Prof. Max Müller, who identifies language with thought, Mr. Alexander thus identifies conduct with character. As language is the expression of thought, so is conduct the expression of character. But just as thought is not co-extensive with the psychological field, so is conduct not co-extensive with the field of action. Conduct is willed action: it implies volition. And Mr. Alexander goes so far as to deny to the brutes any share in conduct, any participation with us in volition. Character, too, as identical with conduct, or merely another aspect thereof, implies volition. Non-volitional activities are not the outcome of character; they merely arise out of the disposition or temperament of the agent. Animals have dispositions, but no character.

What, then, is the nature of that volition which distinguishes character and makes morality possible? It is this: that "when a man wills he does not merely perform an act which issues in a certain end, but has before him the idea of the end, or is conscious of his object, or, in homely language, knows what he is doing, though he need not reflect on what he is doing." The presence of the idea then, as such, distinguishes volition (human) from mere impulse (animal). But the presence of the idea also distinguishes desire: whence desire would also seem to be restricted to man. Desire consists in the feeling of tension, which may be described as a sense of disparity between the ideal object and the actual state of the agent. The act of volition is the passage from the actual state to the ideal state: it is the conscious realization of the ideal.

Moral action, then, in Mr. Alexander's system being willed action, we naturally turn to see what his position is with regard to the free-will controversy, and we find him occupying the standpoint of determinism. It would have been well, perhaps, to state this earlier than in the last chapter but one of the work. But, though there is no index, his table of contents contains a full and clear conspectus of the argument, and a little trouble enables the reader to turn to this or other points on which he may desire information in the course of his perusal. The idea of a free will in the sense of an undetermined will is, Mr. Alexander believes, "a sheer delusion." Though invented to save responsibility, free will, he says, renders it inexplicable. A will independent of motives could never be responsible because it would not be called to account. Mr. Alexander connects responsibility and punishment. When we call a bad man responsible, we mean that the good man holds him to be justly punished. "His responsibility lies in a feeling not on his own part, but on the part of the good, just as the badness of his action consists in the good man's disapprobation."

We must leave the upholders of the doctrine of free will to pick serious holes in Mr. Alexander's argument. But accepting with him the determinist position, we think there are certain points which he might have made clearer. He says, in effect, that a man is responsible for such acts as are the outcome of his character (willed acts), but not for such as are the outcome of his disposition (impulsive acts). For these but not for those he is justly punishable. It is idle, he says, to praise a feeling [or action] which cannot be commanded: what is praised is its indulgence or its cultivation. But if both are inexorably determined, why is the one more praiseworthy than the other? Why is it just to punish one set of actions and not the other? We punish the dog for certain of his actions, though in Mr. Alexander's view he cannot be responsible for them. Do we not often punish, and that wisely, men for similar acts for which Mr. Alexander would not hold them responsible? The distinction between willed acts and impulsive acts, as defined by Mr. Alexander, is a valid distinction in psychology. But does not determinism break down this distinction (or at least make it somewhat arbitrary) when we come to responsibility? Does Mr. Alexander mean that it is *practically convenient* to hold men responsible for the (determined) acts of will: or does he consider the psychological distinction a justification for the moral distinction? Undoubtedly, as it seems to us, the latter; for he contends that the sphere of morality is the sphere of willed action. The evil that a man does as the impulsive outcome of his disposition he regards as a subject for pity, but not for moral aversion. His psychological basis is clear; but we think he might have more explicitly reconciled it with his determinism.

We must now pass on to consider that part of the work which deals with the struggle of ideals. Moral order Mr. Alexander regards as an equilibrium. This is seen both in the individual and in society. The good man is described as an equilibrated order of conduct, or an equilibrium of moral sentiments. Good and bad acts and conduct are distinguished by their adjustment or failure of adjustment to the social order. Good conduct falls within the order; bad conduct fails to adjust itself and is condemned. The equilibrium is not a state of rest, but a mobile equilibrium in which all the parts are shifting. The conception of a man's character is represented under the name of an *ideal*—a plan of conduct or way of life upon which he acts. A bad man's way of life is his ideal as much as the good man's, and every one of his acts implies such an ideal. Moral progress results from a conflict of ideals and the elimination of those which are bad. But not only are there, in any given society, a great number of interdependent individuals, each with his moral ideal, but the society itself may be regarded as an individual (the social organism) having relations to other social individuals of the same order. Hence arises the conception of a social ideal.

With regard to this social ideal, what it is, and wherein it lies, Mr. Alexander is not quite explicit—or perhaps the fault is in ourselves; for we have always found the social organism a difficult conception. It is clear that the social ideal cannot in any sense be the mean of the individual ideals of the constituent units of the society. It is presumably not the ideal of the average man. It must be, we take it, the moral ideal of the perfectly "equilibrated" individual —of the man in completely harmonious adjustment with his social surroundings. Such a representative man may not exist in the flesh; but he represents the ideal standard of the social morality of his time. After-times may show that there existed contemporaneously individuals with far loftier ideals than the social standard. But these were not perfectly equilibrated with their social surroundings, and not improbably paid the penalty for their want of equilibrium.

The social ideal is thus the type-form of a species of which the various ideals, as they exist in the minds of good men, are the different individuals. "But," says Mr. Alexander, "the type in the case of man is, owing to his social character, itself an organism of which the individual is an organ. Hence, if we are to use the analogy at all, we must compare the relation of a species to its individuals with that between the social ideal and the individual ideals." A little later on we read that "an ideal is nothing but a person in so far as he acts the ideal." We fail satisfactorily to correlate the idea of the type as organism of which the individual is an organ, with that of he social ideal as species of which the personal ideals are individuals.

Mr. Alexander next proceeds to show: (1) that the social ideal varies; (2) that there is a struggle between the varieties; (3) that the prevalence of good, and successively better ideals constitutes moral progress. "All good men, so far as good, represent ideals which are the individual members of one variety represented by the good ideal: their various degrees of perfection correspond to more or less strong, or swift, or big members of the animal species. All bad men, so far as bad, act upon ideals which form other varieties. There is the variety of thieves, of murderers, and the like. The distinction of good and bad corresponds to the domination of one variety, that of the good, which has come to prevail according to the process described in virtue of its being a social equilibrium."

The differences between the struggle of ideals and the struggle of animals under nature are not slurred over by Mr. Alexander. "In morality," he says, "the struggle is between *ideals*, and persons are concerned only as the bearers of these ideals. Ideals of conduct exist in minds (wills), not in bodies. Hence two important differences. The animal variety predominates by two concurrent methods: it multiplies its offspring, and it exterminates other animals, and these two things are practically the same, for other animals die out before the spread of the more successful. But in man the predominance of the good does not always require, and except in extreme cases never requires, the extinction of the opposing person, but only the extinction of his ideal, or its retirement from his mind or will in favour of the good ideal. In the next place, whereas animals multiply by propagation of new individuals, the moral ideal acquires strength by teaching and example, and it acquires adherents not only among the new generation but among the old. Hence, while if an animal variety were composed of only a few individuals it would perish, the reformer's cause may win though he individually is destroyed. His ideal lives on in the minds of those whom he has influenced, and his influence may grow greater with his death."

Enough has now been said—and as much as our space will permit—to indicate the scope of Mr. Alexander's conception of the nature and methods of moral progress. How he works in such biological ideas as degeneration and mimicry—the bad man simulating the external actions of the good—must be ascertained from the work itself.

And what shall we say of this conception? Fully admitting the value of Mr. Alexander's independent treatment of the subject, it still seems to us that the separation of the moral ideals from the men and women whose product they are is unsatisfactory. All that Mr. Alexander contends for could be as well, nay better, explained as the result of the interaction of moral and immoral human beings under the conditions of social co-operation and the varied play of social life. For the purposes of ethical science they may be divided, according to their ideals of conduct, into moral varieties. And in the course of their individual moral development they may pass through several varietal states. The struggle among men and women differs very considerably from the struggle among animals, from the fact that man is, in virtue of his high mental development, more plastic, that he is to so large an extent a conscious agent in his own evolution, and that his environment is a social environment of similar conscious agents. It is questionable whether the conception of a social organism and a moral organism helps us much. In any case it has to be used with extreme care and with many reservations. And if we can reach as good results with the more prosaic and less imaginative conception of a co-operative society of human individuals, we shall be wiser, and shall act more in accordance with the spirit of science, to adhere to that conception which sticks closest to the facts of organic life. We doubt whether Mr. Alexander's work would have suffered anything by dealing with men and women possessed of moral ideals, instead of ideals floated off in imagination from their bearers; and we think it would have gained considerably in practical directness, and points of application to the facts of social life.

We cannot take leave of Mr. Alexander's work without again expressing our warm appreciation of its earnestness, its ability, and its orderly method. It is a valuable contribution to ethical literature. C. LL. M.

THE ZOOLOGICAL RESULTS OF THE "CHALLENGER" EXPEDITION.

Report on the Scientific Results of the Voyage of H.M.S. "Challenger" during the Years 1873–76, *under the command of Captain George S. Nares, R.N., F.R.S., and the late Captain Frank T. Thomson, R.N.* Prepared under the superintendence of the late Sir C. Wyville Thomson, Knt., F.R.S., &c., Director of the Civilian Staff on board, and now of John Murray, LL.D., Ph.D., &c., one of the Naturalists of the Expedition. Zoology—Vol. XXX. Published by Order of Her Majesty's Government. (London: Printed for Her Majesty's Stationery Office, and sold by Eyre and Spottiswoode, 1889.)

VOLUME XXX. of the zoological series of the *Challenger* Reports contains an account of the Asteroidea by W. Percy Sladen, and is without doubt one of the most important of the whole series.

The Report contains a description not only of the species collected during the cruise of the *Challenger*, but of those collected during the cruises of the *Lightning*, *Porcupine*, *Knight Errant*, and *Triton*. In the *Challenger* collection there were 84 genera, 5 subgenera, 268 species, and 13 varieties. 184 species and 12 varieties are described as new, and several new genera are established; the new species and varieties found during the other expeditions bring up the total of new species to 196, and new varieties to 15.

In the latest summary of the Asteroidea, published by Prof. Perrier in 1878, he enumerates 52 genera, which Mr. Sladen reduces to 49, and of these, representatives of no less than 38 were obtained by the *Challenger;* thus indicating in a striking manner that the collection affords a fair representation of the general character of the Asteroid fauna of the globe.

The large number of deep-sea forms, belonging to previously unknown types, as well as the very peculiar features distinguishing most of these, demanded a quite new classification; and Mr. Sladen has framed one in accordance with morphological characters, which is certainly far in advance of any that have hitherto been made. The usefulness of this Report has been greatly increased, without its bulk being materially added to, by a list given under each genus of all its authentic species, and their geographical distribution.

At the end of the Report there is added a synoptic list of all the known species of recent Asteroidea, with particulars of their geographical distribution, also their distribution in depth and their synonymy. This most carefully compiled list will be of the greatest value to all interested in the study of this group. 137 genera and 810 species are therein enumerated.

The introduction opens with a history of the classification of the Asteroidea, the earliest attempt at which was made by Linck in 1733. This, which was a purely artificial one, was not improved on by Linnæus or Lamarck. In 1840, Müller and Troschel published their well-known classification, chiefly based on the presence or absence of an anal orifice, and on the arrangement of the ambulacral tube-feet; and this formed the basis of all systematic arrangements of the group until 1875, when Prof. Perrier insisted on the importance of the pedicellariæ from a classificatory point of view, in addition to the disposition of the ambulacral feet. A couple of years later Viguier published his elaborate researches on the skeleton of the Asteroidea, and on these also proposed an amended arrangement of the group. In 1854, Prof. Perrier again discussed the question, examining it from Viguier's standpoint, but concluded to retain the pedicellariæ as the basis of his system of classification, which indeed he but slightly modified.

Mr. Sladen briefly gives his reasons for dissenting from the views of Perrier; and passing in review the various morphological features or fundamental points of structure which are common to the whole class, selects the following: (1) the adaptation of the organism to subserve the functions of respiration and excretion; (2) the character of the ambulacral skeleton; (3) the character of the ambital skeleton.

For the first of these he selects the organs called "papulæ" by Stimpson, which penetrate the body-wall in the form of delicate transparent membranous cæca, permitting an exchange of fresh fluid from without by osmosis, thereby introducing oxygen; these "papulæ" may be distributed over the whole body, or may be confined to a limited area, and thence the division into the Stenopneusia, and the Adetopneusia.

The ambulacral skeleton exhibits two modes of growth; in the one the production of parts is accelerated in relation to the growth of the starfish, in the other the production of parts is retarded, or proceeds *pari passu* with the general development of the skeleton. The ambital skeleton is formed by the marginal plates and their supplementaries when present; these the author considers one of the most important systems of plates in the body, as determining form and superficial character.

The introduction concludes with a summary of the classification as far as the genera, and a synopsis of the orders and families is also given.

The description of the species calls for no remark, unless the critical one in passing that according to the usual practice the date of the publication of this volume, not the date when the individual sheets contained therein were passed "for press," must be taken as those for the new families, genera, and species. No less than 109 species and varieties were found at depths from 500 to 2500 fathoms. The volume consists of 935 pages, and is accompanied by an atlas of 118 plates, which well merit our special praise. In most instances the figures of the abactinal and actinal aspects of each species is given on one plate, and then in the plate following we have the magnified details of the mouth-plates, the supradorsal membrane, the adambulacral plates, and other characteristic portions.

The publication of this Report cannot fail to give a fresh stimulus to the study of this hitherto rather neglected group of the Echinoderms, and the best thanks of every student of natural history are due to Mr. Sladen for the thorough and honest manner in which he has accomplished a troublesome and arduous task.

GREEK GEOMETRY FROM THALES TO EUCLID.

Greek Geometry from Thales to Euclid. By Dr. G. J. Allman, F.R.S. (Dublin: Hodges, 1889.)

THE subject-matter of this work has at different times been brought under the notice of the readers of NATURE, for it is very little more than a collected and corrected reproduction of papers which have at varying intervals appeared during the last eleven years in *Hermathena.* In all our previous notices, we believe, we strongly insisted upon the desirability of Dr. Allman's giving a permanent form to his labours, which should render his brilliant achievements the more readily accessible to mathematical and, we may say also, to general readers. Hitherto all the original investigation in this direction has been carried on by German, French, and Danish writers, for Mr. Gow's "Short History of Greek Mathematics," interesting though it is, is confessedly not founded upon independent research, nor does Mr. Heath's "Diophantus," concerned as it is with Greek algebra, form exception to our statement. In the historical domain of mathematics, Montucla held sway until quite recently, and even the latest French work, by M. Marie, the outcome of forty years' travail, holds fast by him, so that Heiberg (quoted by our author) writes: "The author [Marie] has been engaged with his book for forty years: one would have thought rather that the book was written forty years ago." Far different is the case with Dr. Allman: all along the line of his labours he has consulted the original Greek authorities, and fought every inch of the ground with such experts as Heiberg, Bretschneider, Cantor, Tannery, and several other writers we could name, many times adopting their results, but in nearly as many cases putting forward and convincingly maintaining views of his own. In evidence that the views we have all along held of the importance of this contribution to our knowledge of the early Greek geometers was not a singular one, we have now the confirmation of the favourable reception the papers in their original form met with from many competent authorities on the Continent and elsewhere, the outcome of which has been the present handy volume. Dr. Allman states that "it has been, throughout, my aim to state clearly the facts as known to us from the original sources, and to make a distinct separation between them and conjectures, however probable the latter might be." This testimony is, we believe, true: certainly the reader is put in possession of the facts so far as they are at this date obtainable.

We may just call to mind the points discussed. In an introduction the authorities on the early history are named: had Eudemus's history come down to us we should possibly have had a summary of the period treated of here, but now we are dependent upon Proclus. Then the work of Thales, of Pythagoras and his school, of Hippocrates of Chios, of Democritus, and of Archytas, is clearly discussed in Chapters I. to IV. In Chapter V., as we showed in a former notice, ample justice is done to Eudoxus, and his right place in the history of science is duly assigned. "In astrologia judicio doctissimorum hominum facile princeps," writes Cicero; in his "Histoire de l'Astronomie ancienne" Delambre has, "rien ne prouve qu'il fut géomètre"; and even De Morgan writes, "he has more of it [of fame] than can be justified by any account of his astronomical science now in existence." M. Marie is more just; though he devotes only two pages to the account of his work, he remarks, "il n'était pas au reste moins bon géomètre que bon astronome" (cf. Delambre, *supra*). Had Dr. Allman done no more than reinstate in its proper place a name "highly estimated in antiquity," this would have been a *raison d'être* for his work. We must remember, however, with regard to this tardy act of justice, that "it is only within recent years that, owing to the labours of some conscientious and learned men, justice has been done to his memory, and his reputation restored to its original lustre." In the following chapters (VI. to VIII.), we have accounts of the successors of Eudoxus, viz. Menæchmus, Deinostratus, and Aristæus. The concluding chapter takes up the work of Theætetus, and herein we have a discussion of the part which Euclid himself most probably contributed to his well-known "Elements."

All readers of this standard contribution to the early history of geometry, which has placed its author in the first rank of writers on the subject, and thereby brought credit to the whole body of English-speaking mathematicians, must hope that Dr. Allman will not lay his armour down, but that, after a brief respite it may be, he will undertake some such work again on a kindred subject. We would have suggested a careful edition of the text of Euclid had not labour in this direction been anticipated by Dr. Heiberg in his recently completed edition of the "Elements."

A bust of Archytas, from Gronovius, forms the frontispiece, a few notes are appended at the end to bring information as to books and editions up to date of issue, and a full index completes the volume.

One of the notes (p. 218) on "the theorem of the bride" is very interesting to us. On pp. 633, 637, of "Clifford's Mathematical Papers," we have given footnotes on the term "the figure of the bride's chair," which Clifford evidently used for a particular figure of Euclid i. 47. We had an idea at the time of writing the notes that the term ought to occur in Arabic, and so made application to Mr. Spottiswoode (a fair Arabic scholar himself), and through him to Oxford authorities, but no one could identify the expression. Dr. Allman notes: "M. Paul Tannery ('La Géométrie Grecque,' p. 105) has found in G. Pachymeres ('MSS. de la Bibl. nationale') the expression τὸ θεώρημα τῆς νύμφης to designate the 'theorem of Pythagoras.'" This seems to point to the old Egyptian idea as handed down by Plutarch (cf. Allman, pp. 29–32).

R. T.

OUR BOOK SHELF.

Die Meteorologie, ihrem neuesten Standpunkte gemäss, und mit besonderer Berücksichtigung geographischer Fragen dargestellt. Von Dr. Siegmund Günther. With 71 Illustrations. 304 pp. (Munich: Ackermann.)

DR. SIEGMUND GÜNTHER is already known by his "Lehrbuch der Geophysik," in two volumes, which appeared in 1884 and 1885, and runs up to nearly 1200 pages. The title of the present work is ambitious, and the endeavour to produce a text-book of the whole of meteorology in the space of 300 pages is a bold one. The work is a digest of existing text-books, such as Van Bebber's "Handbuch der ausübenden Witterungskunde," and Sprung's "Lehrbuch der Meteorologie." It is therefore excessively condensed, and to such an extent that it can only be used as a sort of index, for on all the subjects discussed, the reader is referred to other sources of information. The conception of the treatise is good enough, and the subdivisions are: (1) the general properties of the atmosphere, and observations thereon; (2) the movements of the atmosphere; (3) general climatology; and (4) the special climatology of the different zones. These are followed by two appendixes which might well have formed separate chapters; their subjects are, respectively, practical weather knowledge, and optical meteorology.

As might be expected, the sources of Dr. Günther's information are almost exclusively German, so that his *résumé* is slightly one-sided. This is especially the case when he is dealing with marine meteorology, as he almost ignores all work and all methods except those of the Deutsche Seewarte. In his notice of the marine barometer (p. 45), he entirely omits any mention of the principle by which the necessity for a capacity correction is dispensed with by the employment of a modified scale of inches. In speaking of the origin of weather telegraphy, Dr. Günther does scant justice to FitzRoy, who is merely casually mentioned as a former head of the English office. At p. 39 he gives the reader to understand that Kew, Pawlowsk, and Zikawei are the only stations in the world employing photographic self-recording instruments. A more serious slip, for a German, is at p. 243, where he speaks of two international Congresses at Leipzig and Rome, forgetting that the private meeting at Leipzig in 1872 was only preliminary to the Congress of Vienna in the following year. The correction of the press has not been carefully done: not only are letters dropped out in the printing of Latin and English words, but even in the German we have noticed several slips.

However, Dr. Günther's work is undoubtedly useful as indicating to geographers the main outlines of existing knowledge in the most important branches of science with which they come in contact at every turn, and also the lines in which further investigation is desirable.

Haunts of Nature. By H. W. S. Worsley-Benison. (London: Elliot Stock, 1889.)

SOME time ago we had the pleasure of recommending an excellent little book by Mr. Worsley-Benison, called "Nature's Fairy-land," consisting of a series of simple, pleasantly-written papers on some of those aspects of Nature which are most likely to excite the interest of children. The present volume has been planned on exactly the same lines, and is in every way worthy of its predecessor. In the opening essay the author describes the proceedings of two house-martins who did him the honour to select as the site for their nest a small wooden projection under the eaves of his roof. This paper has all the freshness and charm that spring from direct observation, and young people will read it with genuine pleasure. Among the subjects dealt with in other papers are wild roses, water scavengers, the dragon-fly's haunt, protective mimicry in insects, "fast asleep for months," and the ministry of leaves.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Structure and Distribution of Coral Reefs.

I AM somewhat disappointed that my criticism of Prof. Bonney's appendix in the last edition of Mr. Darwin's work on "Coral Reefs" has resulted only in an affair of outposts on the part of my opponents, since the main body of my arguments remains to be assailed. It would have been interesting, for instance, to obtain some further information concerning the evidence establishing the existence of the "90-fathom" reef of Rodriguez; and I should have welcomed the opinion of some zoologist as to the degree of our acquaintance with the fauna of the greater depths, say between 30 and 100 fathoms, around the shores of tropical islands in the Indian and Pacific Oceans. If this acquaintance is as scanty as I contend it is, then it is premature to fix the absolute limit of depth of the reef-coral zone.

At present, however, I shall be content with the establishment of the fact that corals occasionally grow in greater depths than 20 or 30 fathoms; and it was with this intention that I purposely singled out Commander Moore's observation in his Report on the Tizard and Macclesfield Banks. It is just this occasional greater depth of reef-coral growth that is the *crux* of the whole matter as far as the necessity for a theory of subsidence is concerned. Prof. Bonney admits in his last letter that "reef-building corals occasionally grow at depths considerably greater than 25 fathoms," and thus practically abandons the scanty foundation on which the surviving portion of the theory of subsidence now rests. My critic in this manner dispenses with the necessity of a movement of subsidence to explain the circumstance that lagoons are occasionally deeper than the usual limit of depth of the reef-coral zone, and to account for the occasional considerable thickness of upraised coral reefs. The supporters of Mr. Murray's anti-subsidence views will welcome this admission. It removes, in the first case, one of the chief points in favour of subsidence brought into prominence by Agassiz and Geikie in their hostile criticisms of the theory of Mr. Darwin—I refer to the abnormal depths of some atolls. In the second case, it shows that some of the evidence ranged in Prof. Bonney's appendix on the side of Darwin—I allude to that concerning the thickness of the upraised reefs of Cuba and the depth of limestone penetrated by the artesian borings at Oahu—should at least be placed in a neutral position. This is especially necessary in the instance of the artesian borings at Oahu, since Prof. Agassiz in his recent extensive memoir on the Hawaiian reefs,[1] which has not hitherto been quoted in this discussion, regards the borings from a point of view very different from the standpoint of Prof. Dana.

In this and in my previous letters I have shown to the best of my ability that nearly all the evidence ranged by Prof. Bonney on the side of Darwin should be placed at least in a neutral position. It almost all hinges on inferences that have not been established, or else on assumptions that cannot yet be proved. Surely the "90-fathom" reef of Rodriguez, if there has been no mistake in the matter, can be explained without subsidence by those who admit that "reef-building corals occasionally grow at depths considerably greater than 25 fathoms." The upraised reefs of Cuba must be placed on neutral ground. Masamarhu Island I have claimed for Mr. Murray. Lastly, there remain the artesian borings at Oahu; and, accepting Prof. Agassiz as our authority, we do not at present receive them as in favour of subsidence.

H. B. GUPPY.

June 11.

P.S.—After writing the above, I received a letter from Mr. John Murray, relating to the "90-fathom" reef of Rodriguez; he has kindly allowed me to quote from it the following remarks:—"I have examined all the charts and other available information, and have consulted some of the surveyors of the island. The result is that I don't think Prof. Balfour had sufficient grounds for stating with regard to Rodriguez that 'an older reef exists now quite submerged in some places to a depth of over 90 fathoms. Upon it the present reef rests, and it extends westward nearly fifteen miles from the present coast, while on the east it stretches

[1] Bulletin of the Museum of Comparative Zoology at Harvard College, vol. xvii., No. 3, April 1889.

about six miles' (Phil. Trans. R.S., vol. clxviii. p. 289; quoted on p. 308 of Darwin's 'Coral Reefs,' third edition). Here he evidently refers to the shallow water extending on all sides to the 100-fathom line, where there is about that depth a sudden fall. The fact is, such a character belongs to a large number of oceanic islands, whether surrounded by fringing reefs or no reefs whatever, and is due to quite other causes than reef-building."

June 14. H. B. G.

The Fireball of May 29, 1889.

THE fireball which I mentioned in NATURE of June 13 (p. 150) as having been seen at Leeds on May 29, was also observed at Belfast by Mr. I. W. Ward, who recorded the latter part of its course as from Vega to α Cygni.

Comparing this path with that assigned by Mr. D. Booth at Leeds, I find the radiant point at $214\frac{1}{2}^\circ - 7^\circ$, which was in azimuth 11° (west of south), and altitude $28\frac{1}{2}^\circ$ at the time (10h. 45m.) of observation.

When first seen at Leeds the fireball was situated over a point in the Irish Sea, in lat. 53° 58′ N., long. 5° 22′ W., and its height was sixty-one miles. At its disappearance it was six miles west-south-west of Stranraer on the coast of Wigtown, Scotland, at a height of twenty-five miles. The earth point was ten miles west of Troon, Ayrshire. The real length of path traversed was seventy-five miles, and the velocity eight and a third miles per second deduced from the estimated time of flight (nine seconds) at Leeds.

The radiant point at $214\frac{1}{2}^\circ - 7^\circ$ in Libra is situated near the earth's anti-apex, and the motion of the fireball would therefore be extremely slow, as it must have overtaken the earth in her orbit. It is curious that several doubly-observed meteors which have made their apparitions in the spring months have given the same radiant point. Thus the large fireball of May 12, 1878, seen in Scotland and the north of England had a radiant at 214° − 7° (Prof. A. S. Herschel). The conspicuous meteor of April 21, 1889, observed by Prof. Herschel at Croydon and the writer at Bristol, had a radiant at 218° − 5°. The vernal months appear to furnish us with a long-enduring shower from this special region of the zodiac. W. F. DENNING.

Bristol, June 15.

Meteor.

ABOUT 11.30 p.m. on the night of June 13, the sky being partially covered with fleecy clouds slowly drifting from the south-west, so that the full moon was frequently obscured, a shooting-star appeared in the north, at an elevation of about 50° to 60°, and descended obliquely towards the east. It was as bright as a star of the first magnitude, and was visible during a slightly zigzag flight of some 30°, leaving no trail. But the remarkable thing was that the sky in that quarter was pretty closely covered with the slowly-moving fleecy clouds, so that no fixed stars were visible. The meteor, therefore, must have been below the clouds, at least in the latter part of its course.

Birstal Hill, Leicester. F. T. MOTT.

Stationary Dust-Whirl.

YESTERDAY morning, at 9.30, I was fortunate in witnessing a stationary dust-whirl, about a hundred yards from where I stood, on a dust-covered highway lying due east and west. The morning was warm, 67°·5 in the shade, barometer at 30·06, and the sky clear, excepting a few isolated cumulus patches. The air was still, the wind-vane indicating north-west. The appearance of the whirl presented a resemblance to a fountain of water playing, only the base was broader than the upper part, which was perfectly columnar. It remained, for nearly five minutes, absolutely stationary, then suddenly ceased, recommencing for a few seconds, on a much smaller scale, some ten yards westwards. Its height, when at its best, would be about 25 feet, and its diameter, midway, 2 feet. I could not correctly ascertain the spiral motions of the whirl, but judged the outer spiral to move from west to east, and upwards. The wind jumped round into the north-east shortly afterwards, with clear sky, and the barometer steadily rising. No others were seen during the day. J. LOVEL.

Driffield, June 17.

Bunsen's Photometer.

IF we place the "grease-spot" screen between two sources of light, situated at A and B, whose intensities are I and I′ respectively, and if C be the position of the screen for which the spot disappears when viewed from the side towards A, and C′ the corresponding position when viewed from the other side, it is usual to say: Take the mean of AC and AC′, and the mean of BC and BC′; the squares of the means will be approximately proportional to the intensities.

The relation

$$\frac{I}{I'} = \frac{AC \,.\, AC'}{BC \,.\, BC'}$$

is more exact, as may be shown by the following:—

Let a be the fraction of the light falling on unit area of the spot from A which reaches the eye, and b the corresponding fraction for the dry part; and let c and d be the respective fractions of the light falling on the other side of the paper, which, after passing through, reach the eye. Then, since the spot and the dry part in the position C are equally bright when viewed from the side towards A, we have, equating the light per unit area from the two parts—

$$\frac{I}{AC^2}a + \frac{I'}{BC^2}c = \frac{I}{AC^2}b + \frac{I'}{BC^2}d,$$

or

$$\frac{I}{AC^2}(a - b) = \frac{I'}{BC^2}(d - c) \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

If C′ be the position of the screen for which the parts appear equally bright, as seen from the other side, we have—

$$\frac{I}{AC'^2}c + \frac{I'}{BC'^2}a = \frac{I}{AC'^2}d + \frac{I'}{BC'^2}b,$$

or

$$\frac{I'}{BC'^2}(a - b) = \frac{I}{AC'^2}(d - c) \quad . \quad . \quad . \quad . \quad . \quad (2)$$

From (1) and (2)—

$$\frac{I}{I'} = \frac{AC \,.\, AC'}{BC \,.\, BC'}.$$

If $a + c = b + d$, we see that C and C′ must coincide. This condition implies that the light lost is the same for the spot and for its surroundings.

In the method of using the photometer, in which the two lights to be compared are balanced successively against a third light, and the spot in both cases is viewed from the same side, the inequality of the portions of light lost by the two parts does not disturb the result. D. M. LEWIS.

University College, Bangor, June 6.

THE TUTICORIN PEARL FISHERY.

AFTER an interval of more than twenty-seven years, the pearl-oyster (*Avicula fucata*, Gould) has produced pearls off the Madras coast of the Gulf of Manaar, in sufficient quantities to be worth the expense of fishing. The last fishery of the Tuticorin banks took place in the years 1860-62, and resulted in a net profit to Government of Rs. 3,79,297 (£37,929 at par). In olden times, when Tuticorin was in the possession of the Portuguese and Dutch, the fishery used to be carried on much more frequently than it is at the present day, and a difficult problem, which remains to be solved, is, What are the causes of the decline of the pearl fishery, and how can the Tuticorin banks be made to yield a more frequent harvest? Whether the baneful influence of the Mollusca known locally as *sooram* and *killikoy* (Modiota sp., and Avicula sp.), the ravages of the file-fishes (Balistes) and Rays (Trygon, &c.), poaching, or currents, are responsible for the non-production of an abundant crop of adult pearl-producing oysters during more than a quarter of a century, it would be impossible to decide until our knowledge of the conditions under which the pearl-oysters breed, develop, and live, is more precise than it is at present.

Superstition, as of old, still clings to the native divers; and I read, in a recent issue of the *Times of Ceylon*, that "at present there are said to be 150 boats, with their full complement of men, all waiting at Kilakarai in readiness to proceed to Dutch Bay, but they will not leave until after some festivities which occur on the 15th instant, when it is customary for them to pray for protection from sharks, &c., while engaged in diving." I can find no record of a diver being killed, in recent years, by a shark. But a case is cited, in which a native died at Tuticorin from the poisonous stings of a jelly-fish. At certain seasons of the year, jelly-fish are very abundant in the Tuticorin harbour, and a resident merchant tells me that, so great is the dread of them among the natives, that he has known coolies, engaged in carrying loads of palmyra jaggery through the shallow water to the cargo-boats, refuse to enter the water till a track free from jelly-fish was cleared for them by two canoes dragging a net between them.

The pearl-bank which is being fished at the present time, is known as the "Tholayiram Par," which covers an area of about five square miles, and lies more than ten miles east of Tuticorin, in from 8 to 10½ fathoms. The following record, by the Superintendent of the Pearl Banks, shows the condition of this bank as regards oyster-supply from the year 1860 to 1884, the oysters which are now being obtained having been first noticed at an early stage of growth in the latter year:—

April 1860.—Plenty of oysters three and a half years old.
November 1861.—Oysters scarce; nearly all gone.
April 1863.—*Sooram* and *killikoy* with some young oysters.
November 1865 to April 1869.—Blank.
March 1871.—Five oysters with a quantity of *sooram*.
February 1872.—Five oysters of three years old found.
May 1873.—Three oysters found.
January 1875.—Three oysters of two years old found.
March 1876.—North part blank.
April 1877.—South part blank.
April 1878.—Thickly stocked with oysters one year old.
May 1879.—Blank.
May 1880.—Blank.
May 1881.—Some oysters mixed with *killikoy*.
May 1882.—No oysters; dead shells and *sooram*.
April 1883.—Three oysters found.
March 1884.—Plenty of oysters one year old; clean and healthy.

This record shows very clearly how capricious is the life of the pearl-oyster, how easily the hopes of a productive bank may be banished (witness the total disappearance of the oysters in 1879), and points to the evil influence of *sooram*, which, spreading in dense masses along the rocky bottom, crowds out the young pearl-oysters.

Since 1884, the "Tholayiram Par" has been carefully watched, and the growth of the oyster, from the young to the adult stage, has steadily advanced.

In November last, 15,000 oysters were taken from the bank for the purpose of valuation by pearl-merchants, and the product was valued at Rs. 13,12,8 per 1000 oysters.

The shells of the oysters which are now being brought in daily are incrusted with various marine animals (Sponges, Polyzoa, &c.), and enveloped in masses of delicate Algæ; but, among very many thousands which I have examined, I have met with no *sooram*, and only very few specimens of *killikoy*. The oysters are living either on sand, by which they are partially buried, or on coral rocky ground (Turbinaria, Montipora, Porites, &c.), and are often brought up attached by their byssus to dead branches of Madrepores, or *Melobesian nodules*. Large specimens of the big *anai mullu shanku* (Murex sp.) are frequently brought up by the divers, and the tough animal, when removed from the shell, is served up for the evening meal.

The improvised camp, from which the fishery is conducted, is situated on the coast about two miles north of Tuticorin, and, on the way thither across a long stretch of sand, the kilns in which coral and shells are converted into *chunam* are passed, and the chank godowns, in which the chanks (*Turbinella rapa*), whose shells afford an annual source of revenue to Government, are stored, the animal matter being got rid of by the combined influence of insects and bacteria. The camp, which is built of bamboo and palmyra, is made up of residential huts, tents, and bungalows, offices (treasury, dispensary, &c.), sheds called *kottoos*, in which the oysters are counted and submitted to the unsavoury washing process, and the native *bazár*, gaily decorated with flags, in which the product of the oysters is exposed for sale.

As soon after midnight as the land wind sets in, the signal gun is fired on the shore by the native beach master, and, amid a good deal of shouting, all sail is set, and the fleet, which is unfortunately composed of less than fifty boats, with its complement of divers, makes for the bank, which should be reached by daylight. The hoisting of a flag on the schooner which is stationed on the bank is the signal for the day's fishery to commence. The limits of the entire bank are marked out by buoys, and the divers are supposed only to work, on any given day, over an area which is also indicated by buoys; but, owing to adverse winds and other causes, it is sometimes found impossible to keep the boats within the prescribed area. A stone, to which a rope is attached, is put over the boat's side, and a basket or net fastened in a similar way. These ropes the diver takes in one hand, and, placing one foot on the stone, he draws in a deep breath, closing his nostrils with his other hand; or the nose is inserted into a clip, which tightly compresses the nostrils. At a given signal the ropes are let go, and the diver descends to the bottom. The slacking of the ropes shows that this is reached. The diver then lets go the stone, which is drawn up to the surface, and, after filling the basket or net with oysters, he ascends to the surface to regain his breath. The divers work in couples, two to each stone, and the oysters brought up are kept carefully separated from those of other divers. The other day 237,000 oysters were brought up by 454 divers, in about 5½ hours, giving an average of 524 oysters to each diver. A European diver is engaged experimentally on the bank, but his greatest haul in a day has been only 1500 oysters.

The diving operations cease for the day about 1.30 p.m., and the boats start for the land, the signal gun being fired and the Union Jack run up on the flagstaff as soon as they are sighted. On reaching the shore the boats are secured, the oysters carried to the shed, rapidly counted, and divided into three heaps. The superintendent of the fishery, or some other responsible officer, touches with his stick one of these heaps, which becomes the property of the divers, who receive a pass and carry their hard-gained earnings outside the shed, where a swarming crowd of natives is waiting, eager to try their luck by purchasing a few oysters at a rate varying from about fifteen to forty for a rupee. Until long after dark crowds of natives may be seen squatting in circles on the sand, opening their oysters and carefully examining the flesh with a knife in search of even the smallest pearls. The utmost good temper prevails, and the possessor of only a few seed pearls is, apparently, perfectly happy. The two heaps which are left by the divers constitute the Government share, and are carefully counted by Government coolies. The beating of the *tom-tom* then announces that the Government auction is about to commence. The oysters are put up for sale in lots of 1000, and the purchaser has the option of taking a certain number of thousands at the same rate. As soon as the purchase money has been paid, the oysters are handed over to the purchaser, who sends them off by train, or deposits them in the *kottoo* at the northern end of the camp, where various natural agents bring about the requisite process of dissolution of the animal matter. After some days the residue is carefully washed, the prevailing maggots skimmed off, and a careful search made for the pearls.

Pearl Camp. EDGAR THURSTON.

CALIFORNIAN FORESTRY.

IT is matter for great satisfaction to learn that the "people of the State of California represented in Senate and Assembly" have created a Board of Forestry for the purpose of collecting and diffusing information with regard to forestry, tree-culture, and tree-preservation. The readers of NATURE will not fail to appreciate the economic significance of wisely administered forest laws so far as those laws are based upon scientific knowledge, and there are special reasons why they should feel an interest in the forests of the Pacific slope. They will consequently be glad to learn from the second biennial Report of the State Board of Forestry now before us that whereas, "under the old conditions, waste, destruction, and violation of law were rife, . . . the activity of the Board in attempting a reform, and the consequent investigations of the Government, have had a most gratifying result." Fires have been reduced in frequency and extent, watersheds and springs have been protected, slopes saved from further denudation, and replanting effected. It seems strange that, with so great a wealth of native trees, replanting should have become necessary, and still more that the Eucalypts of Australia should be preferred for this purpose to the pines of the Sierras. Nevertheless there are many sites where drought-resisting trees are specially required, and in which some of the Eucalypts, such as *viminalis* and *corynocalyx*, do better than the pines. Experimental stations have been established under different conditions of soil and climate, survey-maps have been constructed, while in the Report now before us a beginning has been made of a scientific and popular description of the forest trees of California. The preparation of this catalogue has been intrusted to Mr. J. G. Lemmon; its illustration will be undertaken by Mrs. Lemmon, and by photographs. For botanical purposes the writings of Engelmann, Sargent, Watson, Parry, and others in recent times, of Sir W. Hooker and Dr. Arnott at a more remote period, will supply what is needed.

Mr. Lemmon waxes enthusiastic, as well he may, over the forests of California. Pre-eminent over all forestal regions of the earth are the dense and extensive tree-growths clothing the slopes of that most diversified and wonderful of mountain-ranges—the Sierra Nevada of Western America—a range distinguished by the abruptness of its majestic uprise from the plain, the splintered and rough-hewn forms of its thousand peaks, the high elevation of their pinnacles ever bearing their crowns of snow, but most of all pre-eminent for its bounteous and beautiful "enrobing forest, . . . the noblest in North America, perforated along its raised centre-line by a thousand peaks rising through the mantle into perpetual winter; while both slopes, east and west, are rent by a million valleys, depressed through the robe (of forest) into the middle region of changing seasons, and the fringe of the garment trails out over the domain of almost perpertual summer." In a similar strain Mr. Lemmon proceeds at considerable length and in a style we are not accustomed to meet with in "Blue-books." The Sierra forests, so far as environment is concerned, occupy a middle position between torrid and frigid conditions. They are composed mainly of evergreen trees, not one of which is specifically identical with the trees on the Atlantic side of the Continent, though often so curiously alike that each genus has its "representative species" on either side. The "big trees," *Sequoia gigantea*, or *Wellingtonia*, have been written about so often that most people are familiar with them. "Far excelling them in loveliness" are the four species of *Abies—nobilis, grandis, magnifica*, and *concolor*. These are all, with many others, cultivated in our parks and gardens, where they thrive better as a rule than in the Eastern States of America. Already they justify in a measure Mr. Lemmon's ecstasies; though it is probable that their beauty will not be enhanced as they grow old, for many of these trees which are pictures of grace and beauty when young become "scraggy" and unlovely when old. Fortunately the standard of age is different in trees and men, and some generations of men may pass before the trees lose their charm. Of their value as timber trees in this country we need not speak here; indeed, little definite is yet known; but, at any rate, there are well-founded hopes in the case of the Douglas fir, the Nootka Sound cypress, *Thuya borealis*, the *Thuja gigantea*, and some others which seem destined to play an important part in the forestry of the future.

After some generalities Mr. Lemmon proceeds to give a classification of the true pines (*Pinus*), of the Pacific slope, a classification intended for popular purposes, and therefore one in which the histological characters of the leaves are passed over. The main divisions are into smooth-coned pines and rough-coned pines, corresponding to the sections *Strobus* and *Pinaster* respectively. In the one the scales of the cone end in thick, prominent, often spiny bosses, in the other the ends of the scale are nearly flat or project but little. Then comes a subdivision according to the length of the cone, surely a most untrustworthy criterion; for instance, Lambert's pine, the gigantic sugar pine, bears cones varying from 10 to 22 inches in length according to Mr. Lemmon's own showing. Further subdivisions are founded on the position of the young cone near the terminal leaf-bud or at some distance from it, on the length of time the cones remain on the tree, the way in which the scales eventually separate, and so forth. Having characterized the various species of *Pinus*, the author proceeds to give detailed information about each. This is the most valuable portion of Mr. Lemmon's report for European botanists. We would fain make many quotations, but our space allows us only to mention two species. The magnificent sugar-pine (*Lambertiana*), was first made known by Douglas. It sends up a magnificent shaft two hundred feet high, and sometimes much more. The value of this tree for "lumber" purposes is as great as its stateliness is imposing, hence thousands of noble trees have been shamefully destroyed. "Lawless vagabonds penetrate the Sierra forests with only the equipment of an axe and a long saw, and, levelling these monstrous trees, they saw out a cut, examine it, and perchance move on to the destruction of others, leaving to rot on the ground trees that would yield to the careful lumberman twenty thousand to fifty thousand feet of clear lumber, worth hundreds of dollars." *Pinus Torreyana*, the lone pine, also deserves special notice here as a species of much structural interest, and as one which, it appears, is on the high road to extinction, unless that process can be obviated by forest ordinances or by the care of the cultivator. On the coast of Southern California, on the bluffs at Del Mar, San Diego County, within a range of four miles only, and nowhere else so far as known, are a few small trees, buffeted and often prostrated by ocean winds, clinging to the face of crumbling yellow sandstone. On the sheltered inner side of the hills and on the spurs of the cañons, bathed with frequent sea-fog, the trees have indeed a better chance, and they accordingly there form a trunk some thirty or even fifty feet in height, capped with a spreading crown. The leaves are in fives, as in many of the Mexican pines, and the cones have thick scales, each terminated by a short strong prickle. "In many respects this species of pine stands alone among Californian Conifers. No other species is found within fifty miles of it; none other survives such buffetings by the sea winds, and no other bears such large flowers, hard nuts, and such strong leaves. . . . In the few localities young trees of all ages are found, but always less in number than the older trees, from which it is inferred that the species is slowly succumbing to its environment, and must if not protected soon become extinct." Such a tree, apart from its interesting structure and history, would be a valuable introduction as a sea-coast pine, wherever the climatal conditions are otherwise favourable.

The Report from which we have taken these particulars is illustrated by photographs, which, if not in all cases very clear, at least show fairly well the general habit of the trees. For details of structure they are not so well suited, and we trust that in future Reports some other means may be taken to give adequate representation of such details. We look forward with eagerness to the continuation of the history of the Californian trees, the silver firs, the Douglas firs, and others that yield in no respect to the pines.

THE EXTINCT STARLING OF RÉUNION (FREGILUPUS VARIUS).

TIME alone can prove whether we are right in calling the *Fregilupus* an extinct species, for many people have imagined that the bird still exists in the interior forests of the Island of Réunion; but as year after year passes by and no specimens are discovered, we fear that we must class the starling of Réunion, along with the Dodo and other birds of the Mascarene Islands, as having been exterminated by the hand of man.

The earliest mention of the *Fregilupus* is believed to be that of Flacourt, who, in an account of a voyage to Madagascar, speaks of a bird called the "Tivouch," found in Madagascar, Bourbon, and the Cape, and described as being "black and grey, with a fine crest." The species was for a long time supposed to inhabit the Cape, and Montbeillard calls it the "Huppe noire et blanche du Cap de Bonne Espérance." Its crested head and curved bill were evidently the cause of the bird being called a Hoopoe, as was done by most of the older writers, until Levaillant in 1806 put it down as a *Merops* or Bee-eater. The latter author knew of eight specimens at least, two in the Paris Museum, one in the possession of each of the following persons, MM. Gigot Dorey, Mauduit, l'Abbé Aubry, M. Poissonier, one in the collection of M. Raye, at Amsterdam, and one in Levaillant's own collection. The fate of most of these specimens is unknown at the present day; they have doubtless decayed or been destroyed, as the mode of preservation of animals at the beginning of the century was by no means perfect.

In 1833 a very fine specimen was sent by Mr. Nivoy to the Paris Museum, where we saw it a few days ago, along with a more ancient individual, doubtless one of the two known to Levaillant. The same Museum also possesses two specimens in spirit. The only representative of the genus *Fregilupus* in this country has hitherto been a skeleton in Prof. Newton's possession. This individual was shot in 1833 by the late Jules Verreaux, who gave it to Prof. Newton. We are happy to announce, however, that the Trustees of the British Museum have recently acquired a very fine example of this extinct starling, one too which, curiously enough, was not known to Dr. Hartlaub when he gave in 1877 the list of specimens supposed to exist in Museums. The bird now in the Natural History Museum has been acquired from the well-known Riocour collection at Vitry-la-Ville. This famous collection, the work of three generations of the Counts De Riocour, consisted of a series of excellently mounted specimens, forming a choice little Museum which it would be hard to excel. The grandfather of the present Count was the founder of the collection, and was an intimate friend of Vieillot and the old French naturalists at the beginning of the century. Nearly all the specimens of that age are named by Vieillot, several of whose types are in the Riocour collection; and Dr. Günther has been successful in securing these also for the cabinets of the British Museum. A more interesting link with the past than this collection of the Counts De Riocour can scarcely be imagined, and we are glad to know that in the hands of Mr. Boucard, who is now the owner of the collection, it will receive the kindly consideration which such a famous Museum deserves.

Writing in 1877, Dr. Hartlaub, in his "Vögel von Madagascar's," gives a list of the specimens of *Fregilupus* known to him, as follows:—Four in the Paris Museum (two stuffed and two in spirits); one in the Caen Museum; one at Leyden (old and bad); one in the Stockholm Museum; one in the Museum at Florence; one in the Pisa Museum; one in the Genoa Museum; one in the Turin Museum; and one in the collection of Baron de Selys-Longchamps.

Sir Edward Newton likewise knew of two specimens in the Museum at Port Louis in Mauritius, and there is also the skeleton in Prof. Newton's possession; so that, with the one recently added to the British Museum, there are probably sixteen specimens in existence. The Italian Museums received their specimens from the same source, viz. from Prof. Savi at Pisa; and some of those in other Museums are from the same source. Count Salvadori has published a very interesting article on the *Fregilupus*, in which he informs us that Savi received several specimens from a Corsican priest named Lombardi, and that these specimens were given away by Savi in the most generous spirit, as he appears to have retained only a single specimen for the Pisa Museum.

Like other insular forms, the *Fregilupus* seems to have courted extermination by its very tameness and ignorance of danger. The late Mr. Pollen stated in 1868 that the species had become so rare in Réunion that when he visited the island not one had been heard of for ten years, though it was still believed to survive in the forests of the interior. The old people who remembered when the birds were still common told him that they were so stupid and fearless that they could easily be knocked down with sticks.

The extinct *Necropsar rodericanus*, Slater, was the representative of *Fregilupus* in Rodriguez (cf. Günther and E. Newton, Phil. Trans., vol. clxviii. p. 427), and its nearest living ally of the *Fregilupus* is probably *Falculia* of Madagascar, but there is also considerable affinity to *Basileornis* of Celebes and Ceram. An excellent account of the osteology of the genus was given by Dr. Murie in the Proceedings of the Zoological Society for 1873.

R. BOWDLER SHARPE.

A MANSION HOUSE MEETING IN AID OF THE PASTEUR INSTITUTE.

THE Lord Mayor has fixed July 1, at 3 p.m., at the Mansion House, for a public meeting to hear the statements of scientific and medical men with regard to the prevention and cure of hydrophobia. Sir James Paget has promised to address the meeting, and it is expected that Sir Henry Roscoe, Dr. Lauder Brunton, Sir Joseph Lister, Prof. Ray Lankester, Sir Joseph Fayrer, Mr. Victor Horsley, Mr. Everett Millais, and others will take part in the proceedings. All scientific men interested in M. Pasteur's discoveries are earnestly requested to attend and support the Lord Mayor. The following resolutions will be moved:—

1. "That this meeting desires to express the gratitude of the people of Great Britain and Ireland to M. Pasteur and the staff of the Institut Pasteur for the generous aid afforded by them to over 200 of our fellow-countrymen suffering from the bite of rabid dogs."

2. "That this meeting, having heard the statement of Sir James Paget and others, records its conviction that the efficacy of the anti-rabic treatment discovered by M. Pasteur is demonstrated, and requests the Lord Mayor to establish a fund for the double purpose of making a suitable donation to the Institut Pasteur, and of providing for the expenses of British subjects unable to pay the cost of a journey to Paris when bitten by rabid animals."

3. "That this meeting, whilst recognizing the value of M. Pasteur's treatment, and taking steps to provide for its accessibility to Englishmen who may hereafter be bitten by rabid animals, is of opinion that rabies can easily be stamped out in these islands, and calls upon the Government to introduce at once a Bill for the simultaneous muzzling of all dogs throughout the British Islands, as provided in the measure drafted by the Society for the Prevention of Hydrophobia."

NOTES.

THE King of Sweden has invited Prof. Max Müller, the representative of Oxford, to be his guest at the Royal palace in Stockholm during the forthcoming Congress of Orientalists. Some 500 foreign members will attend the Congress. During the visit to Christiania, King Oscar will give a banquet to the members of the Congress at his villa at Bygdö, and the city has voted the necessary funds for a civic entertainment.

PROF. A. C. HADDON, whose movements in the Torres Straits we have from time to time recorded, is now on his way home. Contrary to the expectations of his friends and well-wishers, illness has overtaken him; but, as he writes from Brisbane, hope for the best would appear justifiable. He has worked indefatigably during his sojourn in the tropics, and has accumulated a vast collection, the greater part of which is now safely delivered.

MR. HENRY WILLIAM BRISTOW, F.R.S., died on Friday last at the age of seventy-two. In 1842 he was appointed a member of the staff of the Geological Survey of the United Kingdom. Mr. Bristow published various works on mineralogy and geology, and was the author of the mineralogical articles in Brande's "Dictionary of Science, Literature, and Art," and of articles on minerals and rocks in Ure's "Dictionary of Arts, Manufactures, and Mines." He became a Fellow of the Geological Society in 1843, and of the Royal Society in 1862, and an honorary Fellow of King's College, London, in 1863. He received the diploma of the Imperial Geological Institute of Vienna, and from the King of Italy the diploma and insignia of an officer of the Order of SS. Maurice and Lazarus.

SIR JOHN LAWES entertained the members of the Lawes Agricultural Trust Committee at Rothamsted on Friday last. In the afternoon the Committee inspected the experimental farm and the laboratories connected with it.

THE Geologists' Association propose to organize a geological excursion to the volcanic regions of Italy—Naples, Sicily, and the Lipari Islands, or to some of these places if not to all of them—during the month of October next. This excursion, in which ladies may take part, is not confined to members of the Association, and at the meeting of the Geological Society on June 5, Prof. Judd announced that the authorities of the Geologists' Association particularly invite the attendance of Fellows of the Geological Society.

A ROSE CONFERENCE will be held in connection with the Royal Horticultural Society at Chiswick on July 2 and 3. According to the official programme, the objects of the Conference are "to get together as large and as representative a collection of roses of all descriptions as possible; to form an Exhibition of all subjects pertaining to the rose, whether in its botanical, its horticultural, its literary, or its artistic aspects; and to bring together for the purposes of reciprocal information and fellowship all those interested in the rose and its culture." The Royal Horticultural Society appeal to lovers of the rose to help them to attain these ends.

ON Wednesday, July 10, the annual meeting of the Society of Chemical Industry will take place in the theatre of the Royal Institution at 11 a.m. In the evening the President will hold a reception and *conversazione* in the Grosvenor Gallery. On the two following days there will be various visits and excursions, and on the evening of July 11 the annual dinner of the Society will be held.

IN connection with the bequest of the late Dr. Swiney, Prof. W. R. McNab, of the Dublin College of Science, will begin a course of twelve lectures on fossil plants at the Natural History Museum, Cromwell Road, on Monday, the 24th inst. The subject will be continued from the course of last year, and will include the Ferns and Gymnosperms of the Palæozoic and Mesozoic epochs, and the dawn of the Angiospermous flora. The lectures will be given on Mondays, Wednesdays, and Fridays at half-past four o'clock, and will be free to all visitors to the Museum.

THE Indian Government has purchased the coins collected by the Afghan Boundary Commission. They are over 4600 in number, and are to be catalogued by Mr. C. J. Rogers, of Amritsar.

THE Russian Academy of Sciences offers a prize of 5000 roubles (£500) for the best inquiry into the nature and effects of the poison which develops in cured fish. The objects of competitors must be: "(1) To determine, by means of exact experiments, the physical and chemical nature of the poison which develops in fish; (2) to study, by experiments on animals, its action upon the heart, the circulation of the blood, the organs of digestion, and the nervous system; (3) to determine the rapidity of its absorption by the digestive organs; and (4) to study and describe the characteristics which may serve to distinguish contaminated fish from such as are not contaminated." The fifth and sixth questions, with which it may be impossible for any one to deal satisfactorily, relate to the means of preserving fish from the development of the poison, and to the question of counter-poisons and the medical treatment of poisoned persons. The competition is open to all. The memoirs must be sent in, either in manuscript or printed, before January 1, 1893, and may be written in any one of the following languages: Russian, Latin, French, English, German. If none of the papers is deemed worthy of the full prize, the accumulated interest upon the above-named sum may be handed over to the author who presents the best solution of some part of the problem.

A RECENT issue of the French *Journal Officiel* contains the Report of the Consultative Committee for Sea Fisheries in France on the subject of poisoning through the eating of mussels. The Committee, in the first place, recognize that the oysters which cause poisoning are those which have become stale, or have been kept in water rendered foul by decomposed organic matter, and question whether the same may not be the case with regard to mussels. Various explanations of mussel poisoning were made to the Committee. By some it was attributed to a parasite crab (*Pinnotheres pisum*). This explanation, however, was unsatisfactory, for in the United States this *Pinnotheres* is sought after as food. By others, the presence of the poison was attributed to the spawn of star-fish, and also to copper absorbed from wrecks. Both these suggestions were, however, disproved. The theory of Orfila, also, that the poisonous action of the mussels in the stomach is the result of imagination, does not find acceptance at the hands of the Committee. An authority on the subject has found that the mussels lose their poisonous property if cooked for a period of ten minutes with carbonate of soda. The Committee conclude that the poisonous nature of the mussels is due to the presence in them, especially in the liver, of a volatile organic alkaloid (*mytilotoxine de Brieger*), developed under the influence of a particular microbe, which is only found in mussels living in stagnant and polluted waters. Finally, they advocate the removal of all restrictions on mussels in artificial beds, and recommend the sale at all times, at fish markets, of mussels coming from such beds, which are usually situated in favourable localities, a sale which is at present prohibited in France during May and June.

MR. TUPPER, the Canadian Minister of Marine and Fisheries, is reported to be now arranging for the establishment at Halifax of an Intelligence Department, for the purpose of supplying fishermen on the Atlantic coasts with information as to the movement of the various food and bait fishes. Bulletins will be issued frequently upon the subject, and will be widely circulated, and in addition fishermen will always be able to obtain, by means of a telegram or letter, any reasonable information they may require regarding their industry.

THE Cornell University has found in Mr. Henry W. Sage, of Ithaca, a friend whose good-will reveals itself in a very practical manner. A suit is now going on, involving $1,500,000, bequeathed to the library of Cornell. In the event of the suit being lost, Mr. Sage proposes to pay for the library building—to cost over $200,000—on which work has begun; and also to give the library an endowment of $300,000. Should the suit be won, as is confidently expected, Mr. Sage's half a million will probably go to the University for other purposes. *Science* says that the giving of this sum will make Mr. Sage's benefactions to the University amount to about $1,000,000 in cash. The institution also owes much to him for counsel and services.

ON June 12, Dr. A. B. Meyer, of the Zoological and Ethnographical Museum at Dresden, received from Prince Ferdinand of Bulgaria a telegram announcing that immense numbers of the bird called *Pastor roseus*, L., had arrived some days before at Knjajevo, near Sofia, and were still there. The usual haunts of *Pastor roseus* are in the valleys of the Danube, in South Russia, and in the neighbouring districts of Asia; but this year it seems to have extended its range, and Dr. Meyer announces that he will be glad to receive any information that may be sent to him as to its appearance in new neighbourhoods. Between 1774 and 1875 the bird is said to have been seen in Germany thirty-one times, in Switzerland sixteen times. In June 1884 it was seen in Bavaria, and in the autumn of the same year in Würtemberg. It appeared again in Bavaria in May 1886. Until the other day it has not visited Bulgaria since 1876.

A LARGE meteoric stone which recently fell in Scania has been acquired by Baron Nordenskiöld for a sum of £84 for the National Museum.

ON May 31, about 11 p.m., a brilliant meteor was seen at Ljungby, near the Sound. It went in a direction east to north, emitting a bright red colour, and was accompanied by a distinctly audible hissing.

IN reference to the destructive volcanic eruption on the Island of Oshima (better known to the Western world as Vries Island), of which information has been telegraphed from San Francisco, it seems that the first news of it was brought to Yokohama by the master of a passing steamer, who described the mountain Miharaizan as being in fiercely active eruption on the morning of April 13. The eruption was of such a nature that it attracted attention on board the steamer at a great distance. Afterwards it was ascertained that the outbreak was at the western base of the mountain. From this it would appear that a new crater has been formed, as the old crater is at the top of the mountain, though there is a place to the south-west whence smoke is always issuing from the sands. The *Japan Weekly Mail*, from which this information is taken, gives the following historical account of this remarkable volcanic island. Miharaizan, according to the oldest Japanese historical records, was an active volcano so far back as 684 A.D., but the earliest authentic notice of its activity appears to have been taken in 1421, when the sea boiled, and the fish died in shoals. In 1684 an eruption commenced which lasted seven years, and in 1703 there was a great earthquake and tidal-wave, and part of the island broke down and formed the present harbour. In 1777 the mountain was in active eruption, and the island was covered several inches deep with ashes, such phenomena being almost constantly repeated from that date till 1792. It was then quiet till 1837, and more or less in action for the following twenty years. Another lull then took place, when, in 1868, it again broke out, and continued in action four days. The next eruption occurred in 1876, and lasted nearly two months. The most destructive eruptions of Miharaizan were probably those of 1781 and 1789, as, during the latter, the village of Shimotaka was entirely destroyed, and the people and their houses were completely buried in ashes. There are at present six villages on the island, containing a population of 5000 persons, mostly fishermen.

REPORTS from New Zealand describe a recurrence of volcanic activity in Mount Ruapehu. On April 29 an enormous cloud of steam was seen ascending from the summit. There is said to be every indication that considerable thermal activity is going on in the hot lake on the summit, as the outburst was of the nature of a colossal geyser ascending rapidly and subsiding in a few minutes. Since the terrible eruption at Tarawera in 1886, any new outburst, of however trifling a character, naturally gives cause for much alarm all along the belt of volcanic country from Rotorua to Tongariro and Ruapehu.

THE Pilot Chart of the North Atlantic Ocean, published by the Hydrographer of the United States, shows that the month of May was characterized by generally fair weather, and, with the exception of one day, by the absence of storms of great violence. Much fog was encountered during the month, and seriously interfered with commerce in the vicinity of New Jersey and New York. Icebergs were met with in large quantities between longitude 40° and 51°, north of latitude 46°. The approach of the hurricane season in the West Indies was marked by two well-defined depressions on the 4th and 17th respectively.

IT appears that the somewhat eccentric weather of Western Europe during the present year finds a parallel both in China and Japan, where people complain bitterly of the sudden changes of temperature, the premature heat followed by cold "snatches," the storms in quick succession and of great intensity. Thus, the *Chinese Times* of Tientsin, one of the most northern parts of China, says that since foreigners have had any connection with the place there has not been known such an inclement spring. A warm week in February broke up the ice on the Peiho River prematurely, but afterwards cold set in with great severity, and March was characterized by a succession of gales, lasting sometimes a week without intermission, and as late as the 24th the ground was covered with snow. As a rule, the country people never can have enough of snow, which they consider has a most benignant effect on the soil, but the snowfall this spring was so unusual that at last the farmers cried out that they had had too much of it.

THE *Glasgow Herald* states that last year, while some workmen were engaged in drainage operations at Lochavullin for the purpose of forming a public park, they discovered what was believed to be an old "crannog" or lake-dwelling, and several experts who visited it were of opinion that it was a very good specimen of an ancient lake-dwelling. Arrangements were made by the Town Council for its being properly investigated and preserved as far as possible, but the weather has rendered operations impracticable till within the last few days. Workmen are now engaged in excavating round the place, and recently it was visited by Mr. Cochran-Patrick, Under-Secretary for Scotland, and other gentlemen interested. Among the articles turned up by the workmen during the examination were a stone bullet, such as would have been used in the slings of the period to which the dwelling is supposed to have belonged, and portions of the wattle used in the construction of the dwelling. Prof. Hedley, of St. Andrews, took some photographs of the place.

MR. H. B. CRESSON, of Philadelphia, has been studying certain stakes or piles, which were first pointed out to him nearly twenty years ago, by a fisherman, in the mud at the mouth of Naaman's Creek, a small tributary of the Delaware River. These piles are the first indication of anything in North America resembling the remains of lake-dwellings in Europe. Prof. F. W. Putnam, in his twenty-second Annual Report relating to the work of the Peabody Museum, says that Mr. Cresson's recent investigations led to the discovery of three distinct localities, near each other, which he designated Stations A, B, and C. Around these stations were found a very important and instructive collection of stone implements, a few points and fragments of bone, and a human tooth. At one station a number of fragments of rude pottery were found, and at this were obtained several pile-ends which are now in the Museum. This collection Mr. Cresson has given to the Museum, and he proposes soon to prepare a full account of his discoveries for publication. The Museum is also indebted to Mr. A. B. Huey, of Philadelphia, for a number of specimens which he obtained while with Mr. Cresson during the examination of Station B, and to Mr. W. R. Thompson, of Philadelphia, for several potsherds, and a large stone maul with a hole drilled through it, from the same station.

MR. A. E. BROWN, Superintendent of the Philadelphia Zoological Garden, says in his last Report that among the most valued additions to the collection of reptiles, during the past year, were five iguanas from the Isle of Pines, West Indies. These were at once seen to be different from any previously in the collection, and were subsequently identified by Prof. E. D. Cope as *Cyclura nubila*, Gray. The habit noticeable among the iguanas, of remaining fixed in one position when the attention is excited, or of "striking attitudes," is specially marked in these animals, and, several of them being of large size, they have attracted considerable attention. They are of an aggressive disposition, and cannot be readily handled, as they strike blows of astonishing force with their long tails, and bite with great tenacity any object with which they are disturbed. As with the better-known iguanas, their most suitable food in captivity appears to be bananas, hens' eggs, and milk.

IN the same Report, Mr. Brown says that the Philadelphia Zoological Society lately received, from the proprietor of a menagerie, a splendid male elephant called "Bolivar." The animal came originally from Ceylon, is now about thirty years old, stands nearly 10 feet in height at the shoulder, and weighs nearly 10,000 pounds. "It may well be doubted," says Mr. Brown, "if a finer specimen of his race has ever been included in a zoological collection."

MESSRS. BLACKIE AND SON have issued the second volume of their excellent "Modern Cyclopædia of Universal Information," edited by Dr. Charles Annandale. The present volume, if we may judge from the articles we have examined, is in all respects equal to the first, which we have already noticed.

WE have received from Tashkent an interesting Russian work, by A. Wilkins, on the culture of the American cotton-tree in Russian Turkestan. It appears that, though the first attempts at cultivating the *Gossypium hirsutum* in Central Asia proved unsuccessful, a new attempt, made since 1884, under the leadership of the Tashkent model farm, and with seeds taken from the continental States of America, has proved to be a real success. In 1887, there were no less than 38,700 acres under that crop in Turkestan, and in the following year the area was trebled. The crop of 1887 was estimated at 68,000 cwts. of raw cotton. Besides giving practical advice for the culture of the American cotton-tree, M. Wilkins's book contains valuable information about the climate of Turkestan, analyses of the soil and so on, from which it appears that, although the American species can be cultivated about Tashkent, where from 214 to 237 days every year are without frost, its real domain will be on the banks of the Zerafshan and the lower Amu-Daria, and in the Transcaspian region. It is also worthy of note that a new interesting variety of *Gossypium hirsutum*, differentiated by the fact that its flowers grow in groups of two, three, and four on a common stalk, has been obtained at the Tashkent model farm.

THE additions to the Zoological Society's Gardens during the past week include two Prairie Wolves (*Canis latrans* ♂ ♀) from the Rocky Mountains, presented by Mr. Charles Martin; two Long-fronted Gerbilles (*Gerbillus longifrons*) from Western Asia, presented by Lieut.-General Sir Harry B. Lumsden, K.C.S.I.; a Chattering Lory (*Lorius garrulus*) from Moluccas, presented by Mr. Thomas Taylor; two Slender-billed Cockatoos (*Licmetis tenuirostris*) from South Australia, two Goffin's Cockatoos (*Cacatua goffini*), habitat uncertain, presented by Dr. Seton; two Razorbills (*Alca torda*), British, presented by Dr. B. Hewetson; two Viperine Snakes (*Tropidonotus viperinus*), three Green Lizards (*Lacerta viridis*), two Marbled Newts (*Molge marmorata*), two Spotted Salamanders (*Salamandra maculosa*), two Edible Frogs (*Rana esculenta*), three Green Tree-Frogs (*Hyla arborea*) from Southern France, presented by the Rev. F. H. Holmes; a Smooth Snake (*Coronella lævis*) from Southern France, presented by Miss Agnes Flemyng; a Cocos-nut Crab (*Birgus latro* ♂) from India, presented by Commander Alfred Carpenter, R.N.; two Nicobar Pigeons (*Calœnas nicobarica* ♂ ♀) from the Indian Archipelago, a Collared Peccary (*Dicotyles tajaçu*) from South America, three Australian Waxbills (*Estrelda temporalis*) from Australia, purchased; three New Zealand Parakeets (*Cyanorhamphus novæ-zealandiæ*) from New Zealand, received in exchange; a Black Lemur (*Lemur macaco*), an Axis Deer (*Cervus axis* ♀), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

TWO REMARKABLE CONJUNCTIONS.—Mr. Marth called the attention of the Royal Astronomical Society at its last meeting, on June 14, to two remarkable conjunctions which will occur in the autumn of the present year, and which should be most carefully watched by astronomers the world over. The first is the conjunction of Mars and Saturn on September 20, at 20h. G.M.T., the closest conjunction of the two planets on record, the geocentric distance being only 54″, so that to the naked eye the two stars would probably appear to coalesce. The conjunction is rendered the more interesting from its occurring in the near neighbourhood of Regulus, which will be distant only 4′ of arc; whilst Venus passes over the same region of the sky three days later, passing within 12′ of Regulus. The conjunction of Mars with the Saturnian system on September 20 will be so close that it will have a very narrow escape of occulting Iapetus, the two being 12″ apart at 22h.

The second remarkable conjunction will be that of Iapetus, the outermost satellite of Saturn, with Titan. This will occur on November 1 at 8h., and the two satellites, moving in different directions, will pass within 3″ of each other. Shortly after this close approach Iapetus will enter the shadow of the ring system, and as Saturn is then near quadrature, the entire passage of the satellite through the shadow will be clear of the planet as seen from the earth. The satellite's path traverses the shadow of the rings on both sides of the planet, and the clear space between the planet and ring on one side, but probably not on both. It will be a matter of the greatest interest and importance to note if the satellite shines out when crossing the projection of the Cassinian division, and if it is at all visible when in the shadow of the dusky ring or crape veil. The Australian astronomers will have the opportunity, if weather serves, of observing this most rare and interesting occurrence, whilst those of America will be best able to observe the first-named conjunction, viz. that of Saturn and Mars.

The General Relations of the Phenomena of Variable Stars.—Under this title Mr. S. C. Chandler, who has in such an especial manner made the subject of variable stars his own, contributes to *Gould's Astronomical Journal*, No. 193, the results of his discussion of the facts as yet ascertained with relation to these objects. Making abstraction of the stars of the Algol time, it appears that variables may legitimately be divided into two great classes, those of short and those of long period; the former including the stars of less than 90 days' period, the latter those of more than 120 days. The first characteristic related to the length of period is that of colour—"the redder the tint, the longer the period." The range of variability is another feature. This also appears to depend upon the period—the greater the range, the longer the period—but the relation is not one of simple proportionality. The form of the light-curve is a third point. For the short-period variables the time of increase averages about two-thirds the time of decrease, but for the long-period stars the rate varies in a curious manner. Increase and decrease take about the same time for stars, between 100 and 200 days; then the ratio lessens, until for stars of about a year's period the time of increase is only about half that of increase; the ratio then increases again, and for the stars of longest period decline and recovery proceed with about equal speed. It is also noteworthy that though it would appear that stars with a period of a year or nearly a year are less likely to be readily discovered than those of a longer or shorter variation, yet as a matter of fact they form distinctly the most numerous class of the long-period stars. Both these curious facts stand as yet without explanation.

A point of difference between the long-period and short-period stars appears to be indicated in the irregularities to which their periods are severally subject; the irregularities in the first case being, broadly speaking, periodic in their nature, but in the second case secular, or at all events requiring very many cycles of the star for their development. These irregularities are common for the first class, but quite exceptional for the second. For these reasons, and considering the absence of stars of between 90 and 120 days, the difference in colour in average range of variation, and in form of light curve between the two classes, Mr. Chandler is led to believe that the cause of variation is probably different for the two classes of stars, as it is probably different again for the third class we call after Algol. With regard to the distribution of variables, Mr. Chandler shows that our present knowledge is insufficient to justify any very substantial inferences. A certain aggregation of short-period variables near the plane of the Milky Way does, however, seem to be indicated with some distinctness.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1889 *JUNE* 23–29.

(For the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on June 23

Sun rises, 3h. 45m.; souths, 12h. 1m. 57·1s.; daily increase of southing, 12·9s.; sets, 20h. 19m.: right asc. on meridian, 6h. 9·3m.; decl. 23° 26′ N. Sidereal Time at Sunset, 14h. 28m.

Moon (New on June 28, 9h.) rises, 1h. 29m.; souths, 8h. 19m.; sets, 15h. 23m.: right asc. on meridian, 2h. 25·3m.; decl. 9° 21′ N.

Planet.	Rises. h. m.	Souths. h. m.	Sets. h. m.	Right asc. on meridian. h. m.	Declination on meridian. ° ′

GEOGRAPHICAL NOTES.

The recent telegrams relative to Mr. Stanley's movements cannot be regarded as satisfactory. There can be no doubt that he has reached the east coast of the Victoria Nyanza, but that he could do so in eighty-seven days from Yambuya, on the Aruwimi, is incredible. Therefore the date, December 2, as that on which Mr. Stanley was at Ururi, on the south-east of Victoria Nyanza, must be wrong. Moreover a message would not take six months to reach Zanzibar from there; the journey in normal times can be done in one month. It is to be feared that Mr. Stanley has had to leave the problems connected with the Mwuta Nzigé unsolved. It would seem as if he had come round by the country to the north of Uganda, and so reached the Nyoro country on the north-east of Victoria Nyanza. After Emin received all the stores which Stanley took back with him (from Mslala on the south of Victoria Nyanza), the probability is that the Pasha would return to Wadelai. However, it is expected that a letter from Mr. Stanley will arrive in a few days.

Dr. Frithjof Nansen arrives in London to-morrow, and during his stay will be the guest of Prof. Flower.

The June number of the *Scottish Geographical Magazine* is a particularly good one. Mr. H. B. Guppy contributes the first part of the results of his observations on the Cocos-Keeling Islands, which promise to be an important addition to the already abundant literature on the formation of coral islands. Mr. Guppy also sends an interesting short paper on Tridacna pearls. Mr. W. B. Tripp's notes on South American rainfall south of the tropics are useful. Dr. H. R. Mill contributes a highly suggestive paper on scientific earth-knowledge as an aid to commerce. Dr. Mill really indicates the lines on which the scientific bases of commercial geography should be laid; and his paper, combined with what is being done elsewhere, leads us to hope that that hitherto ill-used and profitless subject may yet be worthy of a high place in technical education. In the same magazine is the report of an address by M. Kropotkin on the study of geography, which we commend to all interested in this important subject.

At the recent German Geographentag, Dr. Eschenhagen, of the Imperial Marine Observatory, described the results of his magnetic survey of the Harz Mountains, begun last autumn, and comprising about 3000 measurements. He has shown that no connection can be proved to exist between the ancient geological line of fracture of the Harz and the distribution of terrestrial magnetism, such as Naumann demonstrated in the case of Japan. Dr. Eschenhagen has extended his explorations in terrestrial magnetism over the whole of the north-west of Germany, so that, inasmuch as a similar survey of Austria-Hungary will be completed about 1892, our knowledge of the distribution of terrestrial magnetism in Central Europe has made a great advance.

Dr. O. Krummel contributes to the current number of *Petermann's Mitteilungen* an important paper on erosion through the agency of tidal currents, in which, by a careful examination of several specific instances, he endeavours to come to some conclusion as to the laws which govern the erosive work performed by the tides. There is paper of some practical importance on the suitability of Central Asia for Russian colonization, by General Annenkof.

The number of the *Boletino* of the Lisbon Geographical Society is entirely occupied by a long paper in French, by M. A. Marques, giving a detailed account of the Samoan Islands in all their aspects. As a summary of our knowledge of these islands, the paper will be found useful.

In the current number (4) of the *Mittheilungen* of the Vienna Geographical Society will be found the first part of a paper, by Herr Jankó, on the development and topography of the Rosetta mouth of the Nile.

Dr. Schweinfurth writes with great satisfaction of his journey in Hodeida, in Southern Arabia, in the early part of the present year. Among the places he visited were Khalife, at the foot of the Jebel Bura, Wolleje, the Jebel Melhān, Bajil, Hojela, Wossil, and Jebel Harrassa. The climate he found quite European, the nights bitterly cold, though it was hot enough for an hour or two in the middle of the day. Dr. Schweinfurth's botanical collections exceeded all his expectations; the mountain-slopes are covered with vegetation. He sent home some 600 species (1800 specimens), besides seeds and living plants.

In a very able memoir published by the Danish Society of Northern Antiquaries (in English), Prof. Gustav Storm rediscusses the vexed question of the Vinland voyages of the Norse colonists of Greenland, for the purpose of determining as accurately as the data will permit the various lands mentioned in the old Sagas. "Helluland," Prof. Storm is inclined to think, must be Labrador; Markland corresponds to Newfoundland, and Vinland to Cape Breton Island and Nova Scotia.

Mr. J. Y. Buchanan has been appointed Lecturer in Geography at the University of Cambridge.

It is reported from Sydney that the New South Wales branch of the Royal Geographical Society is sending an explorer, Mr. Arthur J. Vogan, to gather information relative to the far interior. Mr. Vogan will travel northwards from Fort Bourke to Pitchiri Creek, on the Upper Mulligan (lat. 21° S.), and after exploring the country from that point to the Herbert River, will either make his way to the Gulf of Carpentaria or to Hughenden. Mr. Vogan intended leaving Sydney during May.

ALUMINIUM.[1]

Chemists of many lands have contributed to our knowledge of the metal aluminium. Davy, in 1807, tried in vain to reduce alumina by means of the electric current. Oerstedt, the Dane, in 1824 pointed out that the metal could be obtained by treating the chloride with an alkali metal; this was accomplished in Germany by Wöhler in 1827, and more completely in 1845, whilst in 1854, Bunsen showed how the metal can be obtained by electrolysis. But it is to France, by the hands of Henri St. Claire Deville, in the same year, that the honour belongs of having first prepared aluminium in a state of purity, and of obtaining it on a scale which enabled its valuable properties to be recognized and made available, and the bar of "silver-white metal from clay," was one of the chemical wonders in the first Paris Exhibition of 1855. Now England and America step in, and I have this evening to relate the important changes which further investigation has effected in the metallurgy of aluminium. The process suggested by Oerstedt, carried out by Wöhler, and modified by Deville, remains in principle unchanged. The metal is prepared, as before, by a reduction of the double chloride of aluminium and sodium, by means of metallic sodium in presence of cryolite; and it is therefore not so much a description of a new reaction as of improvements of old ones of which I have to speak.

I may perhaps be allowed to remind my hearers that more than thirty-three years ago, Mr. Barlow, then secretary to the Institution, delivered a discourse, in the presence of M. Deville, on the properties and mode of preparation of aluminium, then a novelty. He stated that the metal was then sold at the rate of £3 per ounce, and the exhibition of a small ingot, cast in the laboratory by M. Deville, was considered remarkable. As indicating the progress since made, I may remark that the metal is now sold at 20*s*. per pound, and manufactured by the ton, by the Aluminium Company, at their works at Oldbury, near Birmingham. The improvements which have been made in this manufacture by the zeal and energy of Mr. Castner, an American metallurgist, are of so important a character, that the process may properly be termed the Deville-Castner process.

The production of aluminium previous to 1887, probably did not exceed 10,000 pounds per annum, whilst the price at that time was very high. To attain even this production required that at least 100,000 pounds of double chloride, and 40,000 of sodium should be manufactured annually. From these figures an idea of the magnitude of the undertaking assumed by the Aluminium Company may be estimated, when we learn that they erected works having an annually producing capacity of 100,000 pounds of aluminium. To accomplish this, required not only that at least 400,000 pounds of sodium, 800,000 of chlorine, and 1,000,000 of double chloride, should be annually manufactured, but in addition that each of these materials should be produced at a very low cost, in order to enable the metal to be sold at 20*s*. per pound.

The works, which now cover a space of nearly five acres, are divided into five separate departments, viz. (1) sodium; (2) chlorine; (3) chloride; (4) aluminium; and (5) foundry, rolling, wire mills, &c.

In each department an accurate account is kept of the production each day, the amount of material used, the different furnaces and apparatus in operation, &c. In this manner it has been found possible to ascertain each day exactly how the different processes are progressing, and what effect any modification has, either on cost, quantity, or quality of product. By this means a complicated chemical process is reduced to a series of very simple operations, so that whilst the processes are apparently complicated and difficult to carry out successfully, this is not the case now that the details connected with the manufacture have been perfected, and each operation carried on quite independently until the final materials are brought together for the production of the aluminium.

Manufacture of Sodium.

The first improvement occurs in the manufacture of sodium by what is known as the "Castner process." The successful working of this process marks an era in the production of sodium, as it not only has greatly cheapened the metal, but has enabled the manufacture to be carried out upon a very large scale with little or no danger. Practically, the process consists in heating fused caustic soda in contact with carbon whilst the former substance is in a perfectly liquid condition. By the process in vogue before the introduction of this method, it was always deemed necessary that special means should be taken to guard against actual fusion of the mixed charges, which, if it were to take place, would to a large extent allow the alkali and reducing material to separate. Thus, having an infusible charge to heat, requiring the employment of a very high temperature for its decomposition, the iron vessels must be of small circumference to allow the penetration of the heat to the centre of the charge without actually melting the vessel in which the materials are heated. By the new pro-

[1] The Friday evening discourse delivered by Sir Henry Roscoe, M.P., D.C.L., LL.D., V.P.R.S., at the Royal Institution of Great Britain, on May 3, 1889.

cess, owing to the alkali being in a fused or perfectly liquid condition in contact directly with carbon, the necessity of this is avoided, and consequently, the reduction can be carried on in large vessels at a comparatively low temperature. The reaction taking place may be expressed as follows:—

$$3NaHO + C = Na_2CO_3 + 3H + Na.$$

The vessels in which the charges of alkali and reducing material are heated are of egg-shaped pattern, about 18 inches in width at their widest part, and about 3 feet high, and are made in two portions, the lower one being actually in the form of a crucible, while the upper one is provided with an upright stem and a protruding hollow arm. This part of the apparatus is known as the cover. In commencing the operation, these covers are raised in the heated furnace through apertures provided in the floor of the heated chamber, and are then fastened in their place by an attachment adjusted to the stem; the hollow arm extends outside the furnace. Directly below each aperture in the bottom of the furnace are situated the hydraulic lifts, attached to the top of which are the platforms upon which are placed the crucibles to be raised into the furnace. Attached to the hydraulic lifts are the usual reversing valves for lowering or raising, and the platform is of such a size as, when raised, completely to fill the bottom aperture of the furnace. The charged crucible, being placed upon the platform, is raised into its position, the edges meeting those of the cover, forming an air-tight joint which prevents the escape of gas and vapour from the vessel during reduction, except by the hollow arm provided for this purpose. The natural expansion of the iron vessels is accommodated by the water-pressure in the hydraulic lifts, so that the joint of the cover and crucible are not disturbed until it is intended to lower the lift for the purpose of removing the crucible.

The length of time required for the first operation of reduction and distillation is about two hours. At the end of this time the crucibles are lowered, taken from the platforms by a large pair of tongs on wheels, carried to a dumping pit, and thrown on their side. The residue is cleaned out, and the hot pot, being again gripped by the tongs, is taken back to the furnace. On its way, the charge of alkali and reducing material is thrown in. It is again placed on the lift and raised in position against the edges of the cover. The time consumed in making the change is a minute and a half, and it only requires about seven minutes to draw, empty, recharge, and replace the five crucibles in each furnace. In this manner the crucibles retain the greater amount of their heat, so that the operation of reduction and distillation now only requires one hour and ten minutes. Each of the four furnaces, of five crucibles each, when in operation, are drawn alternately, so that the process is carried on night and day.

Attached to the protruding hollow arm from the cover are the condensers, which are of a peculiar pattern specially adapted to this process, being quite different from those formerly used. They are about 5 inches in diameter and nearly 3 feet long, and have a small opening in the bottom about 20 inches from the nozzle. The bottom of these condensers is so inclined that the metal condensed from the vapour issuing from the crucible during reduction, flows down and out into a small pot placed directly below this opening. The uncondensed gases escape from the condenser at the further end, and burn with the characteristic sodium flame. The condensers are also provided with a small hinged door at the further end, by means of which the workmen from time to time may look in to observe how the distillation is progressing. Previous to drawing the crucibles from the furnace for the purpose of emptying and recharging, the small pots each containing the distilled metal are removed, and empty ones substituted. Those removed each contain, on an average, about 6 pounds of metal, and are taken directly to the sodium casting shop, when it is melted and cast, either into large bars ready to be used for making aluminium, or in smaller sticks to be used.

Special care is taken to keep the temperature of the furnaces at about 1000° C., and the gas- and air-valves are carefully regulated, so as to maintain as even a temperature as possible. The covers remain in the furnace from Sunday night to Saturday afternoon, and the crucibles are kept in use until they are worn out, when new ones are substituted without interrupting the general running of the furnace. A furnace in operation requires 250 pounds of caustic soda every one hour and ten minutes, and yields, in the same time, 30 pounds of sodium and about 240 pounds of crude carbonate of soda. With the four furnaces at work, 120 pounds of sodium can be made every seventy minutes, or over a ton in the twenty-four hours. The residual carbonate, on treatment with lime in the usual manner, yields two-thirds of the original amount of caustic operated upon. The sodium, after being cast, is saturated with kerosene oil, and stored in large tanks holding several tons, placed in rooms specially designed both for security against either fire or water.

Chlorine Manufacture.

This part of the works is connected with the adjacent works of Messrs. Chance Bros. by a large gutta-percha pipe, by means of which, from time to time, hydrochloric acid is supplied direct into the large storage cisterns, from which it is used as desired for making the chlorine. For the preparation of the chlorine gas needed in making the chloride, the usual method is employed; that is, hydrochloric acid and manganese dioxide are heated together, when chlorine gas is evolved with effervescence, and is led away by earthenware and lead pipes to large lead-lined gasometers, where it is stored.

The materials for the generation of the chlorine are brought together in large tanks or stills, built up out of great sandstone slabs, having rubber joints, and the heating is effected by the injection of steam. The evolution of gas, at first rapid, becomes gradually slower, and at last stops; the hydrochloric acid and manganese dioxide being converted into chlorine and manganous chloride. This last compound remains dissolved in the "spent still liquor" and is reconverted into manganese dioxide, to be used over again, by Weldon's manganese recovery process. Owing to the difficulty of keeping up a regular supply of chlorine under a constant pressure directly from the stills, in order that the quantity passed into the sixty different retorts in which the double chloride is made can be regulated and fed as desired, four large gasometers were erected. Each of these is capable of holding 1000 cubic feet of gas, and is completely lined with lead, as are all the connecting mains, &c., this being the only available metal which withstands the corrosive action of chlorine. The gasometers are filled in turn from the stills, the chlorine consumed being taken direct from a gasometer under a regular pressure until it is exhausted; the valves being changed, the supply is taken from another holder, the emptied one being refilled from the still.

Manufacture of the Double Chloride.

Twelve large regenerative gas furnaces are used for heating, and in each of these are fixed five horizontal fire-clay retorts about 10 feet in length, into which the mixture for making the double chloride is placed. These furnaces have been built in two rows, six on a side, the clear passage-way down the centre of the building, which is about 250 feet long, being 50 feet in width. Above this central passage is the staging, carrying the large lead-mains for the supply of the chlorine coming from the gasometers. Opposite each retort, and attached to the main, are situated the regulating valves, connected with lead and earthenware pipes, for the regulation and passage of the chlorine to each retort. The valves are of peculiar design, and have been so constructed that the chlorine is made to pass through a certain depth of liquid, which not only, by opposing a certain pressure, allows a known quantity of gas to pass in a given time, but also prevents any return from the retort into the main, should an increase of pressure be suddenly developed in the retorts.

The mixture with which the retorts are charged is made by grinding together hydrate of alumina, salt, and charcoal. This mixture is then moistened with water, which partially dissolves the salt, and thrown into a pug mill of the usual type for making drain pipes, excepting that the mass is forced out into solid cylindrical lengths upon a platform alongside of which a workman is stationed with a large knife, by means of which the material is cut into lengths of about 3 inches each. These are then piled on top of the large furnaces to dry. In a few hours they have sufficiently hardened to allow of their being handled. They are then transferred to large waggons, and are ready to be used in charging the retorts.

The success of this process is in a great measure dependent—(1) on the proportionate mixture of materials; (2) on the temperature of the furnace; (3) on the quantity of chlorine introduced in a given time; and (4) on the actual construction of the retorts. I am, however, not at liberty to discuss the details of this part of the process, which have only a commercial interest. In carrying on the operation, the furnaces or retorts, when at the proper temperature, are charged by throwing in the balls until they are quite full, the fronts are then sealed up, and the charge allowed to remain undisturbed for about four hours, during which time the water of the alumina hydrate is completely expelled. At the end of this time the valves on the chlorine main are opened, and the gas is allowed to pass into the charged retorts. In the rear of each retort, and connected therewith by means of an earthenware pipe, are the condenser boxes, which are built in brick. These boxes are provided with openings or doors, and also with earthenware pipes, connected with a small flue for carrying off the uncondensed vapours to the large chimney. At first the chlorine passed into each retort is all absorbed by the charge, and only carbonic oxide escapes into the open boxes, where it burns. After a certain time, however, dense fumes are evolved, and the boxes are then closed, while the connecting pipe between the box and the small flue serves to carry off the uncondensed vapours to the chimney.

The reaction which takes place is as follows:—

$$Al_2O_3 + 2NaCl + 3C + 6Cl = 2AlCl_3NaCl + 3CO.$$

The chlorine is passed in for about seventy-two hours in varying quantity, the boxes at the back being opened from time to time by the workmen to ascertain the progress of the distillation. At the end of the time mentioned the chlorine valves are closed, and the boxes at the back of the furnace are all thrown open. The crude double chloride as distilled from the retorts, condenses in the connecting pipe and trickles down into the boxes, where it solidifies in large irregular masses. The yield from a bench of five retorts will average from 1600 to 1800 pounds, which is not far from the theoretical quantity. After the removal of the crude chloride from the condenser boxes the retorts are opened at their charging end, and the residue, which consists of a small quantity of alumina, charcoal, and salt, is raked out and remixed in certain proportions with fresh material, to be used over again. The furnace is immediately re-charged and the same operations repeated, so that from each furnace upwards of 3500 pounds of chloride are obtained weekly. With ten of the twelve furnaces always at work the plant is easily capable of producing 30,000 pounds of chloride per week, or 1,500,000 pounds per annum.

Owing to the presence of iron, both in the materials used (viz. charcoal, alumina, &c.) and in the fire-clay composing the retorts, the distilled chloride always contains a varying proportion of this metal in the form of ferrous and ferric chloride. When it is remembered that it requires 10 pounds of this chloride to produce 1 pound of aluminium by reduction, it will be quite apparent how materially a very small percentage of iron in the chloride will influence the quality of the resulting metal. I may say that, exercising the utmost care as to the purity of the alumina and the charcoal used, and after having the retorts made of special fire-clay containing only a very small percentage of iron, it was found almost impossible to produce upon a large scale a chloride containing less than 0·3 per cent of iron.

This crude double chloride, as it is now called at the works, is highly deliquescent, and varies in colour from a light yellow to a dark red. The variation in colour is not so much due to the varying percentage of iron contained as to the relative proportion of ferric or ferrous chlorides present, and although a sample may be either very dark or quite light, it may still contain only a small percentage of iron if it be present as ferric salt, or a very large percentage if it is in the ferrous condition. Even when exercising all possible precautions, the average analysis of the crude double chloride shows about 0·4 per cent. of iron. The metal subsequently made from this chloride therefore never contained much less than about 5 per cent. of iron, and, as this quantity great injures the capacity of aluminium for drawing into wire, rolling, &c., the metal thus obtained required to be refined. This was successfully accomplished by Mr. Castner and his able assistant, Mr. Cullen, and for some time all the metal made was refined, the iron being lowered to about 2 per cent.

The process, however, was difficult to carry out, and required careful manipulation, but as it then seemed the only remedy for effectively removing the iron, it was adopted and carried on for some time quite successfully, until another invention of Mr. Castner rendered it totally unnecessary. This consisted in purifying the double chloride before reduction. I cannot now explain this process, but I am able to show some of the product. This purified chloride, or pure double chloride, is, as you see, quite white, and is far less deliquescent than the crude, so that it is quite reasonable to infer that this most undesirable property is greatly due to the former presence of iron chlorides. I have seen large quantities containing upwards of 1½ per cent. of iron, or 150 pounds to 10,000 of the chloride, completely purified from iron in a few minutes, so that, whilst the substance before treatment was wholly unfit for the preparation of aluminium, owing to the presence of iron, the result was, like the sample exhibited, a mass containing only 1 pound of iron in 10,000, or 0·01 per cent. The process is extremely simple, and adds little or no appreciable cost to the final product. After treatment, this pure chloride is melted in large iron pots and run into drums similar to those used for storing caustic soda. As far as I am aware, it was generally believed to be an impossibility to remove the iron from anhydrous double chloride of aluminium and sodium, and few, if any, chemists have ever seen a pure white double chloride.

Aluminium Manufacture.

I now come to the final stage of the process, viz. the reduction of the pure double chloride by sodium. This is effected, not in a tube of Bohemian glass, as shown in Mr. Barlow's lecture in 1856, but in a large reverberatory furnace, having an inclined hearth about 6 feet square, the inclination being towards the front of the furnace, through which are several openings at different heights. The pure chloride is ground together with cryolite in about the proportions of two to one, and is then carried to a staging erected above the reducing furnace. The sodium, in large slabs or blocks, is run through a machine similar to an ordinary tobacco-cutting machine, where it is cut into small thin slices; it is then also transferred to the staging above the reducing furnace.

Both materials are now thrown into a large revolving drum, when they become thoroughly mixed. The drum being opened and partially turned, the contents drop out into a car on a tramway directly below. The furnace having been raised to the desired temperature, the dampers of the furnace are all closed to prevent the access of air, the heating gas also being shut off. The car is then moved out on the roof of the furnace until it stands directly over the centre of the hearth. The furnace roof is provided with large hoppers, and through these openings the charge is introduced as quickly as possible. The reaction takes place almost immediately, and the whole charge quickly liquefies. At the end of a certain time the heating gas is again introduced and the charge kept at a moderate temperature for about two hours. At the end of this period the furnace is tapped by driving a bar through the lower opening, which has previously been stopped with a fire-clay plug, and the liquid metal run out in a silver stream into moulds placed below the opening. When the metal has all been drawn off, the slag is allowed to run out into small iron waggons and removed. The openings being again plugged up, the furnace is ready for another charge. From each charge, composed of about 1200 pounds of pure chloride, 600 pounds of cryolite, and 350 pounds of sodium, about 115 to 120 pounds of aluminium are obtained.

The purity of the metal entirely depends upon the purity of the chloride used, and without exercising more than ordinary care the metal tests usually indicate a purity of metal above 99 per cent. On the table is the metal run from a single charge, its weight is 116 pounds, and its composition, as shown by analysis, is 99·2 aluminium, 0·3 silicon, and 0·5 iron. This I believe to be the largest and the purest mass of metal ever made in one operation.

The result of eight or nine charges are laid on one side, and then melted down in the furnace to make a uniform quality, the liquid metal, after a good stirring, being drawn off into moulds. These large ingots, weighing about 60 pounds each, are sent to the casting shop, there to be melted and cast into the ordinary pigs, or other shapes, as may be required for the making of tubes, sheets, or wire, or else used directly for making alloys of either copper or iron.

The following table shows approximately the quantity of each material used in the production of one ton of aluminium:—

Metallic sodium	6,300 pounds
Double chloride	22,400 ,,
Cryolite...	8,000 ,,
Coal	8 tons.

To produce 6,300 pounds of sodium is required:—

Caustic soda	44,000 pounds
Carbide, made from pitch, 12,000 pounds, and iron turnings, 1,000 pounds	7,000 ,,
Crucible castings	2½ tons
Coal	75

For the production of 22,400 pounds double chloride is required :—

Common salt	8,000 pounds
Alumina hydrate	11,000 ,,
Chlorine gas	15,000 ,,
Coal	180 tons.

For the production of 15,000 pounds of chlorine gas is required :—

Hydrochloric acid	180,000 pounds
Limestone dust...	45,000 ,,
Lime	30,000 ,,
Loss of manganese	1,000 ,,

[These figures were rendered more evident by the aid of small blocks, each cut a given size, so as to represent the relative weights of the different materials used to produce one unit of aluminium.]

It might seem, on looking over the above numbers, as if an extraordinary amount of waste occurred, and as if the production is far below that which ought to be obtained, but a study of the figures will show that this is not the case. I would wish to call attention to one item in particular, viz. fuel, it having been remarked that the consumption of coal must prevent cheap production. I think, when it is remembered that coal, such as is used at the works, costs only 4*s*. per ton, while the product is worth £2240 per ton, the cost of coal is not an item of consequence in the cost of production. The total cost of the coal to produce one ton of metal being £50, the actual cost for fuel is less than 6*d*. for every pound of aluminium produced. The ratio of cost of fuel to value of product is indeed less than is the case in making either iron or steel. In concluding my remarks as to the method of manufacture and the process in general, I do not think it is too much to expect, in view of the rapid strides already made, that, in the future, further improvements and modifications will enable aluminium to be produced and sold even at a lower price than appears at present possible.

Properties of Aluminium.

In its physical properties, aluminium widely differs from all the other metals. Its colour is a beautiful white, with a slight blue tint. The intensity of this colour becomes more apparent when the metal has been worked, or when it contains silicon or iron. The surface may be made to take a very high polish, when the blue tint of the metal becomes manifest, or it may be treated with caustic soda and then nitric acid, which will leave the metal quite white. The extensibility or malleability of aluminium is very high, ranking with gold and silver if the metal be of good quality. It may be beaten out into thin leaf quite as easily as either gold or silver, although it requires more careful annealing.

It is extremely ductile, and may be easily drawn, especial care only being required in the annealing.

The excessive sonorousness of aluminium is best shown by example [large suspended bar being struck]. Faraday has remarked, after experiments conducted in his laboratory, that the sound produced by an ingot of aluminium is not simple, and one may distinguish the two sounds by turning the vibrating ingot.

After being cast, it has about the hardness of pure silver, but may be sensibly hardened by hammering.

Its tensile strength varies between 12 and 14 tons to the inch [test sample which was shown having been broken at 13 tons or 27,000 pounds], ordinary cast iron being about 8 tons. Comparing the strength of aluminium in relation to its weight, it is equal to steel of 38 tons tensile strength. The specific gravity of cast aluminium is 2·58, but, after rolling or hammering, this figure is increased to about 2·68.

The specific gravity of aluminium being 1, copper is 3·6, nickel 3·5, silver 4, lead 4·8, gold 7·7.

The fusibility of aluminium has been variously stated as being between that of zinc and silver, or between 600° and 1000° C.

As no reliable information has ever been made public on this subject, my friend Prof. Carnelley undertook to determine it. I was aware, from information gained at the works at Oldbury, that a small increase in the percentage of contained iron materially raised its point of fusion, and it has been undoubtedly due to this cause that such wide limits are given for the melting-point. Under these circumstances two samples were forwarded for testing, of which No. 1, containing $\frac{1}{2}$ per cent. of iron, had a melting-point of 700° C. No. 2, containing 5 per cent. of iron, does not melt at 700°, and only softens somewhat above that temperature, but undergoes incipient fusion at 730°.

According to Faraday, aluminium ranks very high among metallic conductors of heat and electricity, and he found that it conducted heat better than either silver or copper. The specific heat is also very high, which accounts for length of time required for an ingot of the metal to either melt or get cold after being cast.

Chemically, its properties are well worthy of study.

Air, either wet or dry, has absolutely no effect on aluminium at the ordinary temperature, but this property is only possessed by a very pure quality of metal, and the pure metal in mass undergoes only slight oxidation even at the melting-point of platinum.

Thin leaf, however, when heated in a current of oxygen, burns with a brilliant, bluish-white light. [Experiment shown.] If the metal be pure, water has no effect on it whatever, even at a red-heat. Sulphur and its compounds also are without action on it, while, under the same circumstances, nearly all metals would be discoloured with great rapidity. [Experiment shown using silver and aluminium under the same conditions.]

Dilute sulphuric acid and nitric acid, both diluted and concentrated, have no effect on it, although it may be dissolved in either hydrochloric acid or caustic alkali. Heating in an atmosphere of chlorine it burns with a vivid light, producing aluminium chloride. [Experiment shown.] In connection with the subject it may be of interest to state the true melting-point of the double chloride of aluminium and sodium, which has always been given at 170° to 180° C., but which Mr. Baker, the chemist to the works, finds lies between 125° and 130° C.

Uses of Aluminium.

Its uses, unalloyed, have heretofore been greatly restricted. This is, I believe, alone owing to its former high price, for no metal possessing the properties of aluminium could help coming into larger use if its cost were moderate. Much has been said as to the impossibility of soldering it being against its popular use, but I believe that this difficulty will now soon be overcome. The following are a few of the purposes to which it is at present put: telescope tubes, marine glasses, eye-glasses and sextants, especially on account of its lightness; fine wire for the making of lace, embroidery, &c; leaf in the place of silver leaf, sabre sheaths, sword handles, &c., statuettes and works of art, jewellery and delicate physical apparatus, culinary utensils, harness fittings, metallic parts of soldiers' uniforms, dental purposes, surgical instruments, reflectors (it not being tarnished by the products of combustion), photographic apparatus, aëronautical and engineering purposes, and especially for the making of alloys.

Alloys of Aluminium.

The most important alloys of aluminium are those made with copper. These alloys were first prepared by Dr. Percy, in England, and now give promise of being largely used. The alloy produced by the addition of 10 per cent. of aluminium to copper, the maximum amount that can be used to produce a satisfactory alloy, is known as aluminium bronze. Bronzes, however, are made which contain smaller amounts of aluminium, possessing in a degree the valuable properties of the 10 per cent. bronze. According to the percentage of aluminium up to 10 per cent., the colour varies from red gold to pale yellow. The 10 per cent. alloy takes a fine polish, and has the colour of jeweller's gold. The 5 per cent. alloy is not quite so hard, the colour being very similar to that of pure gold. I am indebted to Prof. Roberts Austen for a mould in which the gold at the mint is usually cast, and in this I have had prepared ingots of the 10 and 5 per cent. alloy, so that a comparison may be made of the colour of these with a gold ingot cast in the same mould, for the loan of which I have to thank Messrs. Johnson, Matthey, and Co., all of which are before you.

I have also ingots of the same size, of pure aluminium, from which an idea of the relative weights of gold and aluminium may be obtained.

To arrive at perfection in the making of these alloys, not only is it required that the aluminium used should be of good quality, but also that the copper must be of the very best obtainable. For this purpose only the best brands of Lake Superior copper should be used. Inferior brands of copper or any impurities in the alloy give poor results. The alloys all possess a good colour, polish well, keep their colour far better than all other copper alloys, are extremely malleable and ductile, can be worked either hot or cold, easily engraved, the higher grades have an elasticity exceeding steel, are easily cast into complicated objects, do not lose in remelting, and are possessed of great strength, dependent, of course, on the purity and percentage of contained aluminium. The 10 per cent. alloy, when cast, has a tensile strength of between 70,000 and 80,000 pounds per square inch, but when hammered or worked, the test exceeds 100,000 pounds. [A sample shown broke at 105,000 pounds.]

An attempt to enumerate either the present uses or the possible future commercial value of these alloys is beyond my present purpose. I may, however, remark that they are not only adapted to take the place of bronze, brass, and steel, but they so far surpass all of those metals, both physically and chemically, as to make their extended use assured. [Sheets, rods, tubes, wire, and ingots shown.]

But even a more important use of aluminium seems to be its employment in the iron industry, of which it promises shortly to become an important factor, owing to certain effects which it produces when present, even in the most minute proportions. Experiments are now being carried on at numerous iron and steel works, in England, on the Continent, and in America. The results so far attained are greatly at variance, for whilst in the majority of cases the improvements made have encouraged the continuance of the trials, in others the result has not been satisfactory. On this point I would wish to say to those who may contemplate making use of aluminium in this direction, that it would be advisable before trying their experiments to ascertain whether the aluminium alloy they may purchase actually contains any aluminium at all, for some of the so-called aluminium alloys contain little or no aluminium, and this may doubtless account for the negative results obtained. Again, others contain such varying proportions of carbon, silicon, and other impurities, as to render their use highly objectionable.

It seems to be a prevailing idea with some people, that, because aluminium is so light compared with iron, they cannot be directly alloyed, and, furthermore, that, for the same reason, alloys made by the direct melting together of the two metals would not be equal to an alloy where both metals are reduced together. Now, of course, this is not the case, and the statement has been put forward by those who were only able to make the alloys in one way.

Aluminium added to molten iron and steel lowers their melting-points, consequently increases the fluidity of the metal, and causes it to run easily into moulds and set there, without entrapping air and other gases, which serve to form blow-holes and similar imperfections. It is already used by a large number of steel founders, and seems to render the production of sound steel castings more certain and easy than is otherwise possible.

One of the most remarkable applications of the property which aluminium possesses of lowering the melting-point of iron has been made use of by Mr. Nordenfeldt in the production of castings of wrought iron.

Aluminium forms alloys with most other metals, and although each possesses peculiar properties which in the future may be utilized, at present they are but little used.

In conclusion, I beg to call your attention to the wood models on the table, one being representative of aluminium, the other aluminium bronze. The originals of these models are now in the Paris Exhibition, each weighing 1000 pounds. With regard to aluminium bronze, I cannot speak positively, but the block of pure aluminium is undoubtedly the largest casting ever made in this most wonderful metal. I have to thank the Directors of the Aluminium Company, and especially Mr. Castner, for furnishing me with the interesting series of specimens of raw and manufactured metal for illustrating my discourse.

THE PALÆONTOLOGY OF STURGEONS.[1]

THE palæontological history of the Acipenseroid fishes is at present very imperfectly known. In the existing fauna, only two families are recognizable—that of the Acipenseridæ, with series of bony dermal scutes upon the trunk, and that of Polyodontidæ, destitute of any such armour; both these occupy so low a position in the scale of organization, that considerable evidence of numerous extinct allies might naturally be expected to occur among the fossils of the older rocks. Such evidence, however, can as yet be only slightly recognized. Remains of typical members of the two existing families seem to occur as low in the Tertiary series as the Eocene formation. Pectoral spines and dermal scutes, indistinguishable from those of the living *Acipenser*, are met with in the Upper Eocene of the Hampshire Basin, and the London Clay (Lower Eocene) of the Isle of Sheppey; and Prof. E. D. Cope has described a fish (*Crossopholis*) from the Eocene Green River Shales of Wyoming, U.S.A., differing only from the typical Polyodontidæ in the possession of rudimentary scales upon the sides of the trunk.

The only Cretaceous fossils yet known, which are at all comparable with characteristic parts of the Acipenseroid skeleton, are two specimens from the English Chalk. The remains of a tail from Gravesend, in the British Museum, are most satisfactorily interpreted as belonging to a fish of this type; and the extremity of a snout from Sussex, in the Willett Collection, Brighton, seems to be more nearly paralleled by the snout of *Acipenser* than by that of any other known fish. Other fragmentary evidence of Acipenseroids in Upper Jurassic rocks will probably soon be recognized, thanks especially to the investigations of Mr. Alfred N. Leeds in the Oxford Clay of Peterborough; but the most complete and unmistakable fossils occur in the English Lower Jurassic—both in the Upper Lias of Whitby and the Lower Lias of Lyme Regis.

The gigantic Acipenseroid of Whitby was first noticed by Agassiz, under the name of *Gyrosteus mirabilis*, but it has not hitherto been scientifically investigated and described. The head seems to have been enveloped in few membrane bones, none externally ornamented or covered with ganoine; the chondrocranium is scarcely ossified; and the jaws are toothless. The opercular apparatus is incomplete, without branchiostegal rays; and the membrane bones of the pectoral arch are unornamented. There is evidence of a persistent notochord, and a few ossified ribs occur anteriorly. The upper lobe of the tail exhibits the characteristic series of large fulcra, and the trunk seems to have been naked.

Gyrosteus thus conforms to the normal Acipenseroid type as represented at the present day; but the genus of the Lower Lias, *Chondrosteus*, displays many striking differences. As pointed out especially by Dr. R. H. Traquair, these differences tend to place the fish half-way between the modern Sturgeons and the typically Palæozoic group of Palæoniscidæ. The roof of the skull exhibits definite frontal, parietal, squamosal, and supra-temporal membrane bones; in addition to the operculum and sub-operculum there are distinct branchiostegal rays; and in minor features there are several interesting resemblances to points of Palæoniscid osteology. Dr. Traquair, indeed, places the Palæoniscidæ in the "Acipenseroidei"; and it may be that, as no typical Acipenseroids of corresponding antiquity are known, the Sturgeons and Polyodons are the somewhat degenerate descendants of Palæozoic fishes upon this biological level. At the same time, it must be remembered that the Palæoniscidæ pass by several known gradations into the characteristic bony Ganoids of Mesozoic age; and if the ascertained facts of palæichthyology are already a sufficient basis for phylogenetic speculation, it thus appears that two diverging series arise from this primitive stock. In his latest classification (*American Naturalist*, 1887, p. 1018), Prof. Cope admits the origin of the later Ganoids from fishes of a Palæoniscid type; but, on the assumption that the basal cartilages (baseosts) of the pelvic fin in Palæoniscidæ were minute or absent, the Sturgeons are placed lower in the series than the latter. Under any circumstances, the relative development of a single structural feature is a slight point for the distinction of two "superorders"; and if "Podopterygia" and "Actinopterygia" are to hold separate rank, the Palæoniscidæ (so far as all positive evidence is concerned) may be as justly placed in the former as in the latter.

[1] Abstract of a Paper, by A. Smith Woodward, read before the Geologists' Association on January 4.

NITRATE OF SODA, AND THE NITRATE COUNTRY.

I.

TILL lately, nitrate of soda has only been known to the few who dealt in manures, or who were engaged in chemical manufactures; but within the last two years the British public have invested vast sums of money in the shares of Nitrate Companies, while the presence in society of live millionaires who have made their money in Tarapaca, and the strong personality of a "Nitrate King," have made "nitrates" a household word.

Deposits of nitrate of soda are known along the west coast of South America for a distance of 500 miles at least, from a little south of Taltal up to the River Camerones; and it is reported that beds have been discovered 150 miles further north, in the province of Arequipa (see Fig. 1).

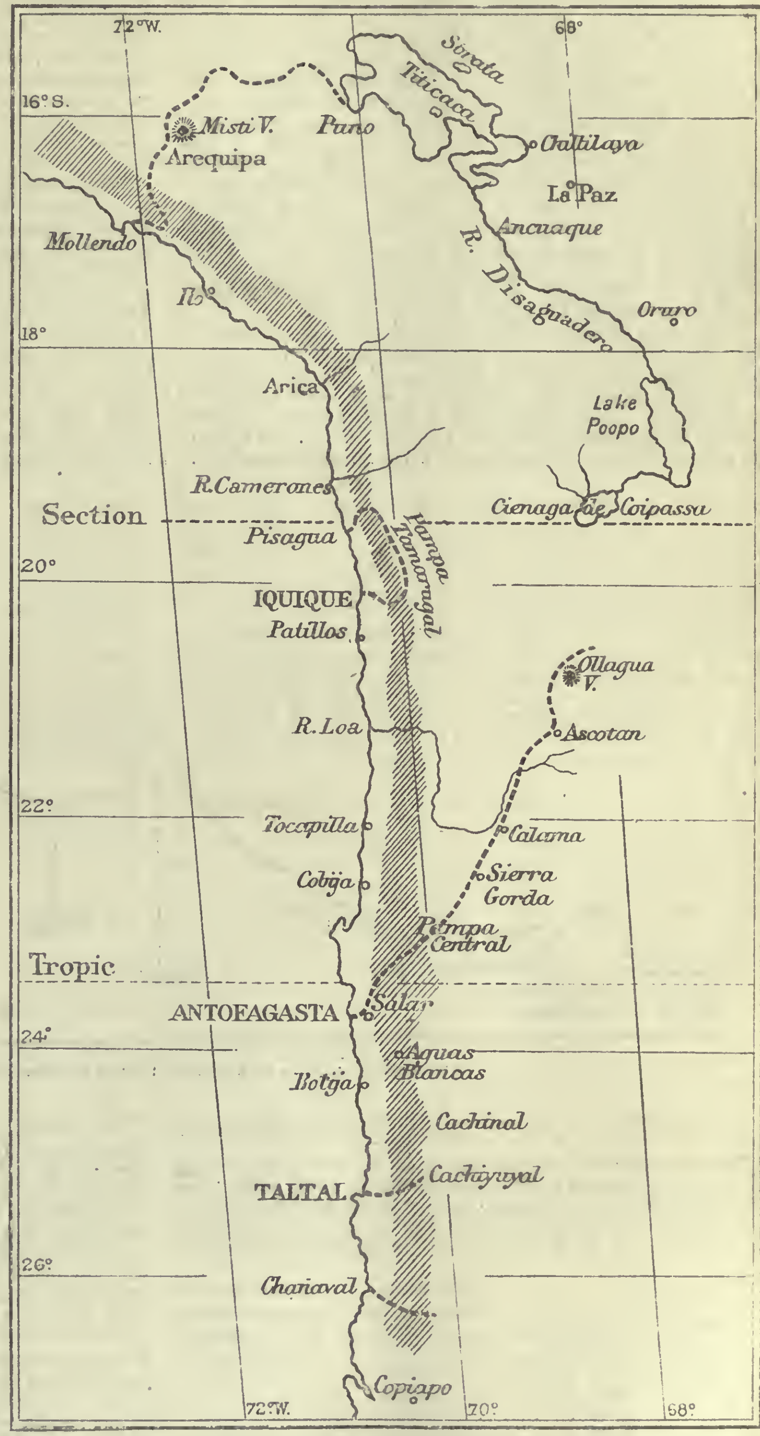

Fig. 1.—Map of the nitrate districts of South America. The shaded parts are nitrate grounds; but those north of the River Camerones are uncertain.

The physical structure of the coast is identical throughout all that great length. Everywhere an arid range of hills 4000–6000 feet high rises abruptly out of the sea; while, behind them, a flat, waterless desert Pampa slopes gradually up for 50–100 miles to the foot of the snowy Cordillera. Nitrates are only found on this desert Pampa, but under somewhat variable conditions. On the Tamarugal Pampa—where all the great English companies have their factories—the nitrate is found exclusively on the western or seaward edge of the Pampa, on the first slopes of the coast-range; in the Noria district, on the lowest portion of a district surrounded by hills; and above Antofagasta on the sides of a dry river-bed.

The aspect of the Pampa is always essentially of the desert type. Above Iquique, the plain is sparsely covered with Tamarugal bushes; and the bold features of the Cordillera above Tarapaca form a sufficiently pleasing landscape. Inside from Antofagasta, on the desert of Atacama, there is no view of the mountains, and nothing greets the eye but a sloping plain of brown earthy sand, whose distant outlines can scarcely be distinguished through the quivering air. No cloud on the sky tempers the rays of a nearly vertical sun, blue mirage lakes tantalize the thirsty traveller, the hand can scarcely touch the scorching sand at 130°, the parched air may indicate 90°, and a light south-west wind raises whirlwinds of dust in every direction. Not a bird, nor a beast, nor a plant of the lowest type can live on these barren wastes; and yet the hidden wealth below has led to the erection of villages which contain more than 500 people, whose every necessary of life has to be brought from a great distance.

The absence of water has always been a great difficulty in the way of carrying on any industry in these deserts. Fifteen years ago, water sold on the Atacama desert for $20 the *arroba*—say 10*s*. a gallon—and a drink for a mule cost 15*s*. At Carmen Alto, in the same district, a sun condenser, with 50,000 square feet of glass, was employed to distil fresh from salt water; and though this was afterwards wrecked by a whirlwind, a smaller apparatus, on the same principle, is now working at a profit at Sierra Gorda, though the water is sold at only 30 cents. the *arroba*, or about $1\frac{1}{2}$*d*. a gallon.

Fresh water is now supplied to most of the towns on the coast, and to the factories inland, by means of condensed steam. Some of the condensers can produce no less than 25 tons of good water for every ton of coal burnt in the boilers; and some are even reported to have attained an efficiency of 30 tons of water for the same amount of fuel.

More recently, schemes have been started for the water supply of the towns on the coast by pipes from springs at the foot of the mountains beyond the Pampa; and Mollendo, Iquique, Antofagasta, and Taltal are either actually supplied with drinking-water by this means, or works are in progress for the same purpose.

Very few Indians can have lived on the Pampa before the arrival of Europeans. A few Changos still survive along the seaward face of the coast range, who live by fishing, and who till recently had no knowledge of metals. The Aymara language is still spoken in Tarapaca, and all the place-names on the Tamarugal Pampa—such as Paccha, Jaz Pampa, Puntunchara, &c.—belong to that idiom. In the Antofagasta and Taltal districts, on the contrary, though further to the south, the place-names, such as Cachinal, &c., are Quichua, and any Indians of the Cordillera speak in that tongue. A good many of the *peons*, or labourers, who work in the *maquinas*, are Bolivians from Cochabamba, who talk Quichua, and some of the words used in the factories, such as *cancha*, &c., are derived from that language. These men chew *coca*, and though not so strong, are more laborious than the Chillenos from the south.

Passing from these generalities, we will now examine in more detail the structure and climate of the Tamarugal Pampa, between Iquique and Pisagua, in which most English people are interested. Fig. 2 is a diagrammatic section from the sea across the Cordillera, through the nitrate beds of Tarapaca. To the left we see the barren coast range rising from the sea and falling again to the level of the Tamarugal Pampa. The nitrate beds are marked in their proper place at the first spring of the hill; then comes the level Pampa, sloping gently not only from the Cordillera, but also slightly in a south-west direction. This slope is of course enormously exaggerated in the diagram.

Next the counterforts of the Sierra of Huatacondo rise abruptly above the plain. Here and there the barren slopes of these mountains are intersected by narrow valleys or *quebradas*, each of which carries down a small stream of water that is eventually lost in the sand of the Pampa. Artificial irrigation at the side of each affords sustenance for a very scanty population, and only one village is of sufficient importance to form anything approaching to a small town. This is the town of Tarapaca, in a valley of the same name, which gives its name to the province in which Iquique and the nitrate beds are situated.

A high cold upland, or Puna, some 20 miles across, separates the crests of the outer Sierra of Huatacondo from the rather higher range of the Cordillera Silillica, and then the mountains slope steeply down to the plateau of Bolivia, some 12,000 feet above the sea. None of the crests of the outer Sierra retain any snow on their summits during the summer months, but a few of the crests of the inner Cordillera are white throughout the year.

Allusion has been already made to the Tamarugal bushes which are found in places on the Pampa. These owe their existence to the floods, or *avenidas* as they are called locally, which every few years rush down from the Sierra, and run over the plain almost to the edge of the nitrate grounds. The soil of the Pampa is just what might have been expected under such circumstances, for the surface is not sharp sand, but really dry earth with a certain proportion of sandy particles, and only irrigation is required to turn the desert Pampa into a fertile plain. Below ground, numerous sections which have been made in sinking wells, show alternating layers of gravel, sand, mud, and as each series of layers represents the sequence of a single flood, it follows that the Pampa has been subject to periodical inundations for a very long period.

The labours of Signor Don Guillermo Billinghurst have made us acquainted both with the *régime* of underground waters on the Pampa, and with their chemical constitution. From his researches it appears that water is found almost anywhere under the Pampa, at depths varying from about 50 to 150 feet, but that nowhere are the conditions necessary for artesian wells fulfilled. The well water from the centre of the Pampa contains too great a proportion of salts to be considered drinkable; and that from the western margin of the plain, but not in the nitrate beds, belongs to the calcareo-magnesian class, which is totally unfit for domestic or culinary purposes. The following examples will make this very clear, and also the remarkable fact that *the underground waters of the Pampa do not contain the slightest trace either of nitrate of soda, or of iodine*, though they contain a greater proportion of mineral salts the further westward they run.

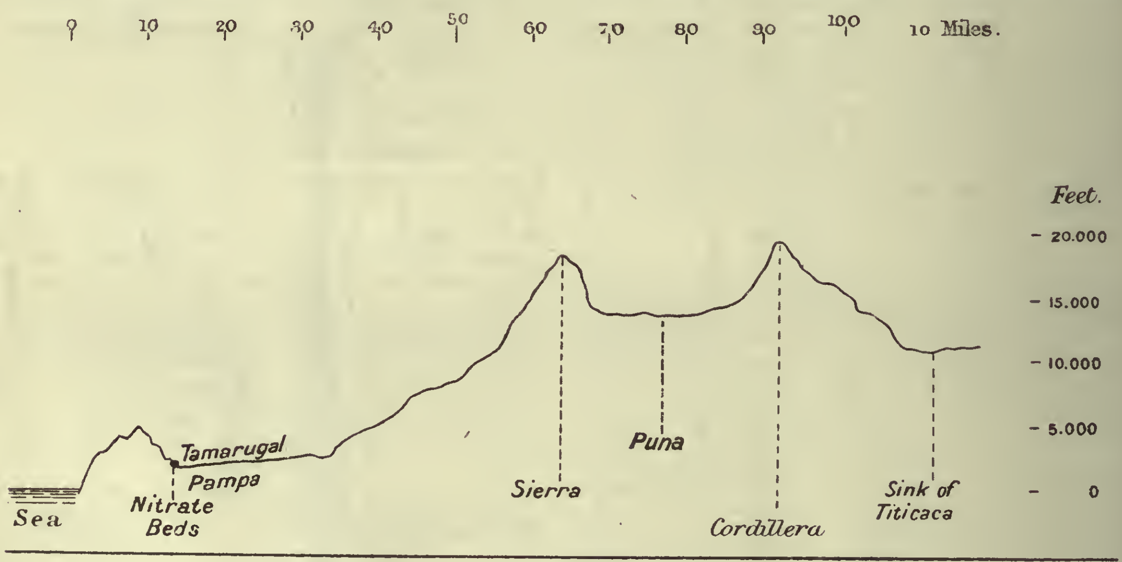

FIG. 2.—Section across the Cordillera, through the nitrate beds of Tarapaca.

The two subjoined analyses are those (1) of well water from Cerro Gordo, situated 7 miles from the nitrate beds, on the open plain of the Tamarugal Pampa; and (2) of the Pozo de Almonte, quite close to the nitrate beds, and from which a large proportion of the water used by the Nitrate Railway Company is derived—

	Cerro Gordo. Grammes per litre.	Pozo de Almonte. Grammes per litre.
Carbonate of lime	0·01500 ...	0·2499
,, magnesia ...	0·00300 ...	0·0323
Sulphate of lime	0·12920 ...	0·9843
,, magnesia	0·08166 ...	—
,, potash	0·00860 ...	—
,, soda	0·18062 ...	0·0735
Chloride of sodium	0·62261 ...	1·5799
,, magnesium	— ...	0·1737
Oxide of iron and alumina ...	0·01000 ...	—
Silica, and insolubles	0·00500 ...	0·0200
	1·05569	3·1136

In connection with underground waters we may as well dispel for ever the fiction so commonly believed that some of the overflow from Lake Titicaca filters under the Cordillera and reappears on the Tamarugal Pampa. This idea was started in a pre-scientific age, more than 300 years ago, in 1550, by the celebrated historian Cieza de Leon ("La Cronica del Peru," p. 445); but unfortunately for such a supposition the facts of the case are as follows. The only outlet of Lake Titicaca is the River Disaguadero (Span. drain), and the water at starting contains about 1 gramme of salts in every litre. By the time the river has reached the shallow lake of Poopo or Aullagas (see map, Fig. 1), the water is so salt as to be undrinkable, and then the river runs out for a short distance till it is finally lost in the salt mud marsh, or Ciénaga de Coipasa. No doubt this marsh is due east of the Pampa near Pisagua, and is marked "Sink of Titicaca" in Fig. 1; but still it is impossible to believe that salt water can come out fresh on the other side of the Cordillera. The water of the Tamarugal Pampa must be derived from the rainfall on the slopes of the Sierra, immediately above the plain.

RALPH ABERCROMBY.

(*To be continued.*)

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Oxford.—The Savilian Professor of Geometry, J. J. Sylvester, will deliver, early next term, a public lecture on the sufficiency of Barbier's principle to furnish a universal and geometrical solution of a celebrated problem of chances originated by Buffon, but whose solution of it, and also that of Laplace, was limited to the two simplest cases, and involved the use of the integral calculus. The lecture will be divested as far as possible of technical terms, so as to be made intelligible to a general audience. Time and place will be stated in a subsequent notice.

Cambridge.—In the Natural Sciences Tripos, Part I., lately issued, the following men are placed in Class I.:—Beddard, Trinity; Blackman, St. John's; Bottomley, Caius; Cole, Christ's; de Havilland, Peterhouse; L. G. Glover, St. John's; Hewitt, St. John's; Lehfeldt, St. John's; Luce, Christ's; Peters, Caius; Reynolds, Trinity; Rolleston, King's; Spivey, Trinity; Thomas, Sidney; Wood, Caius; Woods, St. John's. The following women also obtained a first class:—A. I. M. Elliot, Newnham; L. Martin-Leake, Girton; M. O. Mitchell, Newnham.

In the Natural Sciences Tripos, Part II. (advanced), eleven candidates are placed in Class I. Of these no fewer than six are scholars of St. John's College, including Mr. Horton-Smith, who receives the coveted mark of distinction in Physiology. No mark of distinction has been granted since 1883. The following are the names, in alphabetical order:—Baily, St. John's (Physics); d'Albuquerque, St. John's (Chemistry); Ds Daniel, Trinity (Human Anatomy with Physiology); S. F. Dufton, Trinity (Chemistry); Elliott, Christ's (Chemistry); Groom, St. John's (Geology); Hankin, St. John's (Physiology); Horton-Smith, St. John's (Physiology and Human Anatomy with Physiology); Locke, St. John's (Physiology); Ds Tennant, Caius (Chemistry); Whetham, Trinity (Physics). No women obtained a first class in this part.

Dr. W. H. Gaskell, F.R.S., has been elected Fellow and Prælector in Natural Science of Trinity Hall. This long-deferred recognition of Dr. Gaskell's eminent services to the teaching of physiology at Cambridge, and also of his many valuable original researches, will be welcomed by all scientific men.

The General Board of Studies recommends that the stipend of Dr. Gaskell, as University Lecturer in Physiology, be raised from £50 to £150 per annum, and that of Mr. Walter Gardiner, University Lecturer in Botany, from £50 to £100. Both these gentlemen hold College Fellowships in addition.

Mr. E. G. Gallop, late Fellow of Trinity College, and Senior Wrangler, has been elected to a Fellowship at Gonville and Caius College.

At the annual election at St. John's College on June 17 the following awards were made in Mathematics and Natural Science:—

Hutchinson Studentship (for research in Physiology): Horton-Smith.

Foundation Scholarships (continued or increased): Mathematics—Flux, R. A. Sampson, Rudd, Lawrenson, Cooke, Monro, Burstall, G. T. Bennett, Dobbs, Reeves, Gedye. Natural Science—Groom, d'Albuquerque, Locke, Hankin, Baily, Horton-Smith, Hewitt.

Foundation Scholarships (awarded): Mathematics—W. Brown, Alexander, Finn. Natural Science—Lehfeldt, Woods.

Exhibitions: Mathematics—Bennett, Finn, Reeves, Ayers, Blomfield, Maw, O. W. Owen, Schmitz, Speight, Wills. Natural Science—Baily, Lehfeldt, Locke, Blackman, Cuff, L. G. Glover, MacBride.

Proper Sizarships: Mathematics—Ayers, Maw, Pickford, C. Robertson.

Wright's Prizes: Mathematics—Bennett. Natural Science—Horton-Smith, Hewitt, MacBride.

Hockin Prize (for Physics): Baily.

Herschel Prize (for Astronomy): Monro, *proxime accessit* Bruton.

Hughes Prize (for best student of third year): Natural Science—Horton-Smith.

SCIENTIFIC SERIALS.

American Journal of Science, June.—Topographical development of the Triassic formation of the Connecticut Valley, by William Morris Davis. In this paper are embodied the results of two visits paid to the region about Meriden with the Harvard Summer School of Geology in 1887 and 1888. After describing the topographical development of the Triassic belt, the author shows that the whole region was base-leveled in late Cretaceous times, and the present valleys worn in the Cretaceous base-level plain after its elevation. The Connecticut River was originally consequent on the monoclinal faulting, and still persists near the course then taken, but has entered a second cycle of life as a result of the elevation of the lowland that was produced in its first cycle.—Analyses of three descloizites from new localities, by W. F. Hillebrand. The specimens, of which full analyses are here given, came from the mines of Beaverhead County, Montana; Grant County, New Mexico; and Cochise County, Arizona. It is suggested that, in view of the well-defined character of all these highly cupriferous varieties, they might be appropriately designated by some common distinctive name, such as Rammelsberg's cupro-descloizite, as indicating the relationship to descloizite.—A new meteorite from Mexico, by J. Edward Whitfield. This specimen of meteoric iron, weighing 33 kilos, came originally from the Sierra de San Francisco in the State of Durango, date of discovery and name of finder being unknown. Analysis shows iron 91·48, nickel 7·92, cobalt 0·22, with traces of sulphur and carbon. Slices when etched show rather coarse Widmanstättian figures with dark diagonal bands of triolite.—Contributions to the petrography of the Sandwich Islands, by Edward S. Dana. The eruptive rocks here described were partly obtained in 1887 by Prof. J. D. Dana, and partly in 1888 by the Rev. E. P. Baker, of Hilo. They include about thirty specimens from Kilauea, a dozen from the island of Maui, and a like number from the island of Oahu. The chief points brought out by their study are the characters of the clinkstone-like basalt with its novel forms of feather-augite, and also of the heavy chrysolitic basalt, both from the summit crater. The lavas from Maui and Oahu belong mostly to the basaltic type, though often resembling andesite in appearance.—The determination of water and carbonic acid in natural and artificial salts, by Thomas M. Chatard. An apparatus is described, which has been successfully used for the analysis of a large number of natural and artificial alkaline carbonates, giving results satisfactory both for accuracy and the ease and rapidity with which they were obtained. The method is in every way superior to the distillation process, and promises to be of value for technical purposes.—Preliminary note on the absorption spectra of mixed liquids, by Arthur E. Bostwick. The experiments here described were undertaken to determine the true character of the absorption spectra of mixed liquids, which, according to Prof. Melde, are not formed by simple addition of the component spectra, but by the shifting of the bands, a large band of one liquid seeming to attract a small band of the other, and more strongly as the proportion of the former in the mixture is increased. On the other hand, Dr. Shuster held that where a small band falls on the slope of a large one the effect of optical addition is to shift the apparent maximum of absorption. But Mr. Bostwick's experiments apppear to prove that, while a small part may be due to the cause alleged by Dr. Shuster, the bands are shifted principally by a true action of one liquid on the other.—Notes on metallic spectra, by C. C. Hutchins. An attempt is here made to determine the wave-length of several metallic lines with something of the precision with which wave-lengths of solar lines are known and tabulated.—On allotropic forms of silver, by M. Carey Lea. By means of a new reaction (the reduction of silver citrate by ferrous citrate) the author has obtained three remarkable forms of allotropic silver, the properties and physical condition of which are here described in detail.

In the *American Meteorological Journal* for April, Prof. Abbe contributes an article on the red sunsets of 1884–85, which is of interest from the fact of its having been written before the publication of the Krakatão Report of the Royal Society Committee relating to the glows of the previous year. The author considers that in the production of the glows, vapour haze is more important than dust haze, and that the Krakatão eruption sufficed to throw enough moisture into the atmosphere to explain the diffraction phenomena of 1883–84, without the hypothesis of the accumulation of the vapour of meteoric dust.—Lieut. Finley gives a chart and list of the tornadoes in the State of Missouri during the 75 years ending 1888. The total number of storms was 169, the month of greatest frequency was May, and none occurred in January.—Prof. Marvin contributes an interesting article on the measurement of wind velocity, and the results of recent anemometrical experiments by the Signal Service. He points out that if the equation of an anemometer, whose constants have been determined by a whirling machine, be used to reduce observations made in the open air, the computed wind velocities will be too high, by an amount which will depend upon the moment of inertia of the cups and revolving parts. Some of the experiments described were of a delicate nature, the cups being made of paper fastened to pieces of fine knitting-needles, which served as arms.—The concluding article is by Prof. R. Owen, on magnetic phenomena in the southern hemisphere, the object being to give some particulars regarding the experiments made in that hemisphere, as compared with results obtained in the northern half of the globe.

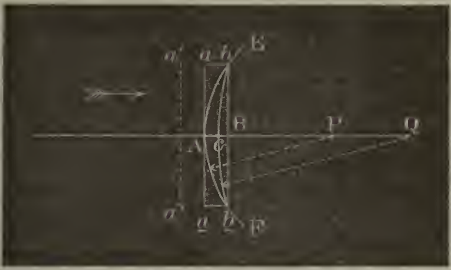
SOCIETIES AND ACADEMIES.

London.

Royal Society, June 6.—"Report on the Effects of Contact Metamorphism exhibited by the Silurian Rocks near the Town of New Galloway, in the Southern Uplands of Scotland." By S. Allport and Prof. Bonney, F.R.S.

In the neighbourhood of New Galloway a mass of granite cuts across and sends veins into a series of Silurian rocks, which are considerably altered near the junction. These, originally, were a variable series of more or less sandy rocks, such as older authors would call greywacke. The minerals resulting from the "contact-metamorphism" were enumerated: these were quartz brown mica (which, as was pointed out, must be much richer in iron than in magnesia), white mica, and iron oxides, with some hornblende, augite, garnet, and perhaps epidote. Chiastolite is absent; andalusite very inconspicuous; tourmaline very rare The point to which special attention was directed was that in several of the slides, the larger fragments which had been present in the original greywacke could still be recognized, such as clastic quartz, feldspar (often more or less converted into white mica and quartz), bits of argillite or earthy sandstone (represented by mixtures of brown mica and quartz in varying proportions). The bearing of the results of the investigation on general questions of metamorphism was indicated: (1) that heat, in presence of water, and probably under considerable pressure, had produced rocks which bore some resemblance to, but could be distinguished from, crystalline schists, such as those of known Archæan age; (2) that, while these agents of metamorphism have produced a crystalline rock from a clastic one, they have not obliterated the original structure, when this was somewhat coarse. Hence that it is safe to conclude that, at any rate in the less highly crystalline schists, the alternation of mineral constituents which so closely simulates bedding is due to an original stratification of clastic constituents.

Physical Society, June 8.—Prof. Ayrton, F.R.S., Vice-President, in the chair.—The following communications were made:—A photograph of lightning flashes was exhibited and described by Dr. Hoffert. The photograph was obtained during the storm on the 6th inst., whilst the camera was being waved about in the hand, and shows three similar and parallel flashes, thus proving that successive sparks in multiple flashes may traverse the same path and may be separated by appreciable intervals of time. The supposed primary spark is intersected by numerous tributary ones spread out on both sides, the second spark shows one tributary, and the third none. Faint bands of light pass across the plate parallel to the direction of motion, and these prove that some residual illumination exists during the intervals between the successive flashes. Evidence of a dark flash is also presented by the plate. Prof. Herschel, who had taken photographs during the same storm, referred to the fluttering appearance of the flashes, and on their long duration; in many cases the time was sufficient to allow him to direct the camera towards the flash, and make a successful exposure. He had also observed multiple flashes with the unaided eye, and on waving his hand about he had sometimes noticed about a dozen distinct images of it during one discharge. Mr. Gregory said that he watched the storm along with two others, and they could seldom agree as to the shape of the flashes, or on their simple or multiple character. The want of agreement as to multiplicity he thought might be caused by their eyes being directed towards different parts of the sky when a multiple flash occurred; the one who happened to be looking towards the flash might be conscious of only one impression, whereas the others in directing their eyes would receive the flashes on different parts of the retina. In some cases as many as three distinct flashes (occurring at intervals of about ten seconds) traversed the same path, and a number of the discharges presented a beaded or striated appearance. The beads seemed to remain after the main flash had faded, and this might account for the bands shown in Dr. Hoffert's photograph. Mr. C. V. Boys, in referring to multiple flashes, said that although his statements made in the discussion of Mr. Whipple's paper on April 13 were not readily accepted, yet no one who watched the recent storm could doubt their existence. Prof. S. P. Thompson thought the order of the flashes on the photograph may have been the reverse of that supposed, for he observed that the band of light extended on both sides of the (so called) primary flash, whereas the outside of the third flash was quite dark. Mr. E. W. Smith noticed many cases of "sympathetic discharge," in which a flash in the north seemed to precipitate another in the north-west within a few seconds, and in this he was corroborated by Mr. Gregory, who viewed the storm from a different locality. Mr. C. V. Burton thought the heating of the air by the first spark might give rise to the tributary sparks in subsequent ones. Mr. A. W. Ward mentioned a long flash observed at Cambridge which passed from the zenith, and struck some farm-buildings at a distance, and he was particularly impressed by the considerable time occupied in its progress.—On the methods of suppressing sparking in electro-magnets, by Prof. S. P. Thompson. The object of this paper is to classify the methods which have been suggested, and to draw attention to a novel method of some importance. The classification is as follows: (1) *Mechanical devices:* (*a*) simple snap switch; (*b*) break in magnetic field; (*c*) break under liquid; (*d*) wiping break (asbestos, &c., brushes); (*e*) blow out. *Electrical devices:* (A) use of condensers, (*a*) placed across gap, and (*b*) across terminals of magnet; (B) mutual induction protectors, (*a*) copper sheath around core, and (*b*) layers of foil between windings; (C) short-circuit working; (D) differential winding; (E) high-resistance shunt (non-inductive); (F) voltameter or liquid resistance across gap; (G) multiple wire arrangement of Mr. Langdon Davies; (H) electro-magnet with two bobbins in series or parallel. The merits and demerits of the different methods are indicated. The multiple-wire arrangement used by Mr. Langdon Davies in his harmonic telegraph consists in winding each layer separately and uniting all in parallel. The effect of this is to make the time constants of the layers different, and on breaking the circuit the energy is spent in mutual discharges.—A shunt transformer, by Mr. E. W. Smith. Two conductors, A and B, of equal impedance, are placed in series between alternate current mains, and the same mains are connected through two incandescent lamps in series. The conductor A has great resistance, and B has large self-induction, and when their junction is joined to that of the two lamps, both lamps become brighter, and the main current is reduced. These phenomena were shown before the Society. Since A may consist of lamps and B may be a choking coil, the arrangement will serve to increase the P.D. between the terminals of the lamps without wasting much energy. Experiments of a similar nature have been made on a Mordey transformer wound with three equal coils. One coil was used as primary, and the other two as separate secondaries, their respective circuits consisting of lamps and an alternate current motor. Under these conditions the arithmetical run of the mean secondary currents exceeded the primary current by about 14 per cent.; the secondary volts were 8 per cent. less than the primary. All these experiments strikingly illustrate the effects of acceleration and lag in alternate current circuits, and (as was pointed out by the author) show that meters registering "ampere hours" merely, may give readings differing greatly from the numbers representing the energy used.—Notes on geometrical optics: (1) on the deduction of the elementary theory of mirrors and lenses from wave principles; (2) on a diopteric spherometer; (3) on the formula of the lenticular mirror, by Prof. S. P. Thompson. Instead of deducing the formulæ for lenses and mirrors by means of "rays," and the relations between angles of incidence, reflection, and refraction, the author considers it better to derive them from the curvatures impressed on waves at the bounding surfaces of the different media. Indices of refraction are replaced by their reciprocals, which express the relative velocities of light, and curvature is measured by the camber at the middle of chords of equal, but small, lengths. An example will assist in making the method of treatment clear. Suppose a',a', a,a two successive positions of a plane wave-front in air, which impinges on a curved surface, EAF, at A, and let the curvature at A be R, and the velocity constant of the substance h. Then, whilst the part a travels in air to h, the part in the denser medium reaches C, where $AC = h \cdot ab$, and a curvature, F, represented by BC, is impressed on the wave, which thus converges to a point Q. Since $AC = h \cdot ab = h \cdot AB$, and $\frac{BC}{AB} = \frac{AB - AC}{AB}$, $\therefore \frac{BC}{AB} = 1 - h$, and the relation between the impressed curvature and that of the surface becomes $F = R(1 - h)$. By successive application of the above method, all the ordinary lens problems may be treated,



and the resulting expressions are simplified by being expressed in curvatures. The ordinary mirror formula, $f = R$, becomes $F = 2R$, and that for the lenticular mirror, $F' = 2R + F$. The method readily lends itself to the determination of the changes in the shape of wave-fronts entering or emerging from surfaces of irregular outline. The diopteric spherometer has its outer feet situated on a circle of 44·71 millimetres radius, and is provided with a screw of 1 millimetre pitch. The instrument so constructed reads off directly in "diopteries," *i.e.* curvatures expressed on a scale in which that of a sphere of 1 metre radius is taken as unity.—On the use of the biquartz, by Mr. A. W. Ward. This is a mathematical investigation into the causes of the varying degrees of accuracy obtained by different observers who have used the biquartz in rotation measurements. Assuming that elliptically polarized light passes through the biquartz, the equation which must be satisfied to give equality of tint on the two halves is shown to be: $\cos 2\gamma \cdot \sin 2\phi \cdot \sin \overline{2\omega - \theta} = 0$, where $\tan \gamma$ = ratio of axes of ellipse, ϕ = rotation produced by quartz for wave-length λ, θ = angle between plane of vibrations of analyzer and that of xz, the axis of z being parallel to the direction of transmission, and ω = angle between one axis of the ellipse and that of x. The equation is satisfied by either $\cos 2\gamma = 0$, or $\sin 2\phi = 0$, or $\sin \overline{2\omega - \theta} = 0$. The first solution relates to circularly polarized light, and need not be considered; the second can only hold for one particular wave-length depending on the thickness of the quartz; and, in interpreting the third solution, it is shown that a satisfactory result is only obtained when the light is plane-polarized. The deductions are in accordance with experiment, for the biquartz has been used with considerable accuracy when experimenting on isotropic media; but with doubly refracting substances, where the light is liable to become elliptically polarized, the results are very discordant.

Errata.—Page 143, lines 27 and 29, for "volumes" read "densities."

Mathematical Society, June 13.—Mr. J. J. Walker, F.R.S., President, in the chair.—The President opened the proceedings of this the last meeting of the session with commenting on the losses the mathematical world had recently sustained by the deaths of Prof. Genocchi, of Turin, Prof. Du Bois-Reymond, Berlin, and M. Halphen, of Paris.—The following communications were made:—The square of Euler's series, by Dr. Glaisher, F.R.S.; a theorem in the calculus of linear partial differential operations, by Major Macmahon, R.A.; on crystalline reflection and refraction, by A. B. Basset, F.R.S.; on some rings of circles connected with a triangle and the circles (Schoute's system) that cut them at equal angles, by W. W. Taylor; the figures of the Pippian and Quippian of a class of cubic curves, by the President (Sir J. Cockle, F.R.S., in the chair); and a generalization of Buffon's problem, by Prof. Sylvester, F.R.S., (communicated by J. Hammond).—The following papers, on the small wave-motions of a heterogeneous fluid under gravity, by Prof. W. Burnside, and on the uniform deformation in two dimensions of a cylindrical shell of finite thickness, with applications to the general theory of deformation of thin shells, by Lord Rayleigh, Sec. R.S., were taken as read.

Zoological Society, June 4.—Mr. Osbert Salvin, F.R.S., Vice-President, in the chair.—The Secretary read a report on the additions that had been made to the Society's Menagerie during the month of May 1889.—Mr. H. E. Dresser exhibited and made remarks on some eggs of the Adriatic Black-headed Gull (*Larus melanocephalus*) and of the Slender-billed Gull (*Larus gelastes*), which had lately been obtained at their nesting-places in the marshes of Andalusia by Colonel Hanbury Barclay and himself.—Dr. G. J. Romanes, F.R.S., read a paper on the intelligence of the Chimpanzee, as shown in the course of experiments made with the female Chimpanzee called "Sally," which has been living several years in the Society's Menagerie.—A communication was read from Signor Fr. Sav. Monticelli. containing notes on some Entozoa in the collection of the British Museum.—Mr. Sclater read a list of the birds collected by Mr. George A. Ramage (the collector employed by the joint Committee of the Royal Society and the British Association for the exploration of the Lesser Antilles) in Dominica, West Indies, and made remarks upon some of the species.

Entomological Society, June 5.—The Right Hon. Lord Walsingham, F.R.S., President, in the chair.—Mr. S. Stevens exhibited a specimen of *Acrolepia assectella*, Zeller, included in a lot of *Tineidæ*, purchased by him at the sale of the late Mr. A. F. Sheppard's collection. He also exhibited, for comparison, a specimen of *A. betuletella*.—Mr. J. J. Walker, R.N., exhibited a collection of Lepidoptera made in 1887 and 1888 in the immediate vicinity of the Straits of Gibraltar. The collection included sixty-eight species of butterflies, of which thirty-six were obtained on the Rock of Gibraltar itself, and the remainder on the European side of the Straits; and about 160 species of moths.—Dr. P. B. Mason exhibited a number of specimens of a South European species of ant—*Crematogaster scutellaris*, Oliv. He said that the specimens were all taken in the fernery of Mr. Baxter, of Burton-on-Trent, and had probably been imported with cork.—Mr. O. E. Janson exhibited a pair of *Neptunides stanleyi*, a species of *Cetoniidæ*, recently received from Central Africa, and described by him in the February number of the *Entomologist*; also some varieties of *N. polychrous*, Thoms., from the Zanzibar district.—Dr. N. Manders exhibited a number of Lepidoptera collected by himself in the Shan States, Burmah; also a collection of Lepidoptera made by Captain Raikes in Kárenni.—Mr. McLachlan exhibited over 400 specimens of Neuroptera, being a portion of the collection formed in Japan by Mr. H. J. S. Pryer. They represented nearly all groups (excepting *Odonata*, now in the hands of Baron De Selys). Some of the *Ascalaphidæ*, *Panorpidæ*, and *Trichoptera*, were of great beauty.—Dr. Sharp exhibited the peculiar cocoons of an Indian moth, *Rhodia newara*, Moore; these were the cocoons possessing a drain at the bottom in order to allow water to escape, already described in the Proceedings of the Zoological Society for 1888, p. 120, where, however, their great resemblance to the pods of a plant had not been alluded to.—Mr. Enock exhibited, and made remarks on, specimens of *Cecidomyia destructor*, bred from American wheat.—Mr. W. Warren exhibited a bred specimen of *Retinia posticana*, Zett., from Newmarket; also specimens of *Eupithecia jasioneata* and *Gelechia confinis*, bred by Mr. Gardner.—Mr. C. O. Waterhouse exhibited and explained a number of diagrams illustrative of the external characters of the eyes of insects.—Mr. A. G. Butler communicated a paper entitled "Descriptions of some new Lepidoptera-Heterocera in the collection of the Hon. Walter de Rothschild." He also contributed a second paper entitled "Synonymic Notes on Moths of the earlier genera of Noctuites."—Dr. Sharp read a paper entitled "An Account of Prof. Plateau's Experiments on the Vision of Insects." Lord Walsingham, Mr. Jacoby, Mr. White, and Mr. Waterhouse took part in the discussion which ensued.

PARIS.

Academy of Sciences, June 11.—M. Des Cloizeaux, President, in the chair.—On the exceptional deviations of some tropical cyclones, by M. H. Faye. As far as 35° of latitude tropical cyclones present a remarkable regularity, with the exception that the geometrical figure described by their trajectory is deflected towards the north between 20° and 30° according to the seasons, as has been clearly determined by le Père Viñez, of the Havana Observatory. But although the laws laid down by this meteorologist appeared to be absolute, they were certainly deviated from by the tornado of September 3–4, 1888, in the West Indies, as well as by that of June 1885, in the Gulf of Aden. The disturbing cause in the first instance was attributed by Viñez to a second cyclone exercising a strong repellent action on the other, and driving it with disastrous consequences across the island of Cuba. But Mr. E. Hayden, of the United States Meteorological Bureau, rejects this explanation, and traces the disturbance to the influence that zones of high pressure appear to exercise on low pressures and especially on cyclones. M. Faye seems inclined to accept this view, if it could be shown that the action of high-pressure zones is felt in the higher atmospheric regions far above the crests of the loftiest mountain ranges.—On the value of a finite continuous and purely periodical fraction, by Prof. Sylvester. The positive root of the equation

$$[{}^{\backprime}t]x^2 - ([t] - [{}^{\backprime}t'])x - [t'] = 0$$

gives the value of the purely periodical infinite fraction (t^{∞}), where t is a type—that is, a succession—of any elements whatever. By means of a formula given in a previous communication the author here offers an easy solution for the problem: To find the value of the analogous periodical but finite continuous fraction (t_n).—Researches on the elasticity of solids, by M. E. H. Amagat. The method applied by the author to crystal, as described in a former note (*Comptes rendus*, October 15, 1888), is here employed for other substances, such as glass, steel, copper, brass, and lead, which are also treated by the Wertheim process. The tabulated results, obtained at a mean temperature of 12° C., seem to show that for metals the value of Poisson's coefficient μ increases with the coefficient of compressibility, and for the other substances with the facility with which they undergo permanent deformation. The value of μ, theoretically equal to 0·50 for fluids, would appear to increase in the scale of bodies, passing through all the intermediate states (pasty, viscous, &c., and consequently for the same body passing through these various states), and approaching 0·25 according as the bodies become more and more refractory to permanent deformations—that is, more perfectly elastic. Glass approaches nearest to this theoretic condition, the next in order being steel, copper, and lead, while caoutchouc occupies the opposite extremity of the scale. Hence the perfect solid, for which the value of μ would be 0·25, should realize the double condition of being at once perfectly elastic and perfectly isotropic.—On the solubility of saccharose in distilled water, by M. Léon Périer. After the disastrous vintages of 1888 in the Gironde district, various growers attempted to substitute for the ordinary wines a drink prepared from grape-cake and sugar refermented. M. Périer here describes the results of the examination he has made of numerous specimens of these liquids submitted to his inspection.—Erosions due to wind action, by M. Contejean. During a recent visit to Corinth the author observed a remarkable instance of this phenomenon on the neighbouring plateau, where an old amphitheatre some fifteen metres from the edge of the escarpment communicates with the beach through a cavern with wide opening at both ends, and above which the limestone rock forms a natural bridge. The walls of this cavern, which is formed in the sandstone stratum at the foot of the cliff, are extremely rugged and irregularly corroded, nowhere showing traces of human workmanship. The tunnel could not possibly have been excavated either by the rains or the running waters, and its existence can be explained only by the action of the sands playing on a point of least resistance under the influence of the fierce northern gales prevalent in this region.—On the rectification of alcohol, by M. E. Sorel. In continuation of his previous communication on this subject (*Comptes rendus*, May 27, 1889), the author here shows how the theoretical data may be verified, and indicates the practical conclusions that may be drawn from them.—Some documents were submitted to the Academy by le Père Denza, on the recent earthquakes in the north-west of France, slight vibrations of which were also felt in Genoa, Sinigaglia, Sienna, and other parts of Italy. At the Observatory of Moncalieri the seismic instruments showed some indications of the underground disturbances.

BERLIN.

Physiological Society, May 31.—Prof. du Bois-Reymond, President, in the chair.—Dr. Nitze described and demonstrated his apparatus for observing and examining the interior of the urinary bladder. The apparatus, called a cystoscope, consists of a small incandescent electrical lamp, a prism, and a small ocular and objective, the whole arranged in the form of a catheter. Before making an observation the bladder is washed out with water, the instrument is then introduced, and the terminals of the electric lamp are connected with a battery. While intended in the first instance to facilitate the ocular inspection of pathological conditions of the bladder, this instrument also makes it possible to observe various physiological functions, such as the periodic extrusion of small quantities of urine from the mouths of the ureters, and the peristaltic movements of the ureters themselves. The applicability of the method was demonstrated on two patients.—Starting with the observed fact that canaries fed with cayenne pepper acquire a ruddy plumage, Dr. Sauermann has based upon it a scientific investigation of canaries, fowls, pigeons, and other birds. From these he has obtained the following results. Feeding with pepper only produces an effect when given to young birds before they moult; the colour of the feathers of older birds cannot be affected. Moisture facilitates the change of colour to a ruddy hue, which is again discharged under the influence of sunlight and cold. A portion of the constituents of cayenne pepper is quite inactive, as for instance piperin and several extractives: similarly the red colouring-matter alone of the pepper has no effect on the colour of the feathers. It is rather the triolein, which occurs in the pepper in large quantities, together with the characteristic pigment, which brings about the change of colour by holding the red pigment of the pepper in solution. Glycerin may be used instead of triolein to bring about the same result. The same statement holds good with regard to the feeding of birds with aniline colours. The red pigment of the pepper is also stored up in the egg-yolk as well as in the feathers. The first appearance of the pigment in the yolk may be observed as a coloured ring four days after the commencement of feeding with the pigment dissolved in fat; after a further two days' feeding the whole yolk is coloured. Dr. Sauermann is still engaged in carrying on his researches.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

The Flora of Switzerland for the Use of Tourists and Field Botanists: A. Gremli; translated by S. W. Paitson (Nutt).—Commercial Organic Analysis, vol. iii. Part 1, 2nd edition: A. H. Allen (Churchill).—Morocco: H. M. P. De la Martinière (Whittaker).—Woolwich Mathematical Papers for the Years 1880-88, edited by E. J. Brooksmith (Macmillan).—Physiological Diagrams for Use in Schools; also Index: G. Davies (W. and A. K. Johnston).—Days with Industrials: A. H. Japp (Trübner).—New Verse in Old Vesture: J. C. Grant (E. W. Allen).—Catalogue of the Fossil Reptilia and Amphibia in the British Museum (Natural History), Part 2: R. Lydekker (London).—Climatology of New Jersey (Trenton, N.J.).—Bulletin of the United States National Museum, No. 33: T. Egleston (Washington).

SCIENTIFIC WORTHIES.

XXVI.—Dmitri Ivanowitsh Mendeleeff.

DMITRI IVANOWITSH MENDELEEFF was born on February 7 (N.S.), 1834, at Tobolsk, in Siberia. He was the seventeenth and youngest child of Ivan Paolowitsh Mendeleeff, Director of the Gymnasium at that place. Soon after the birth of Dmitri his father became blind, and was obliged to resign his position, and the family became practically dependent upon the mother, Maria Dmitrievna Mendeleeva—a woman of great energy and remarkable force of character. She established a glass-works at Tobolsk, the management of which for many years devolved entirely upon her, and on the profits of which she brought up and educated her large family. The story of Mendeleeff's youth is given in the preface to his great work "On Solutions," which he dedicated to the memory of his mother in a passage of singular beauty and power. Having passed through the Gymnasium at Tobolsk, Mendeleeff, at the age of sixteen, was sent to St. Petersburg, with the intention that he should study chemistry at the University, under Zinin. He was, however, transferred to the Pedagogical Institute, the aim of which was to train teachers for the District or Governmental Gymnasiums throughout the Empire. The Institute (which was abolished in 1858) was established in the same building as the University, and was divided into two Faculties—Historico-philological and Physico-mathematical. Mendeleeff attached himself to the natural sciences, and thus came under the influence of Woskresenky in chemistry, of Emil Lenz in physics, of Ostrogradsky in mathematics, of Ruprecht in botany, of F. Brandt in zoology, of Kutorga in mineralogy, and of Sawitsh in astronomy, most of whom were Professors of the same sciences in the University. Whilst at the Institute he wrote his first paper on "Isomorphism," and on the termination of his course of instruction he was appointed to the Gymnasium at Simferopol, in the Crimea. During the Crimean war he was transferred to one of the Gymnasiums at Odessa, and in 1856 he was admitted to the degree of *Magister Chemiæ* of the Physico-mathematical Faculty of the University of St. Petersburg, and was made *Privat-Docent* in the University. Even at this early period of his career we find Mendeleeff speculating on the great problems with which his name is inseparably connected. The relations between the specific gravities of substances and their molecular weights had begun to attract increased attention. Kopp had just published the first instalment of that long and laborious series of experimental observations which constitutes the real foundation of all our knowledge concerning the specific volumes of liquids, when the young Siberian philosopher laid a number of theses on problems relating to specific volumes before the Physico-mathematical Faculty of the University. He pointed out that magnetic elements have smaller specific volumes than diamagnetic elements. He also showed that Avogadro's supposition, that electro-positive elements have larger specific volumes than electro-negative elements, was in accordance with the greater number of well-established facts. When we remember how slowly, in spite of the powerful advocacy of Williamson, the ideas of Laurent and Gerhardt and what came to be known as the modern French school, found favour in this country, it is remarkable, as indicating the radical and progressive character of his mind, and the keenness of his mental vision, to find Mendeleeff, as far back as 1856, insisting that to Gerhardt was due the best mode of determining the chemical molecule; that the molecule of oxygen was expressed by the symbol O_2; those of arsenic and phosphorus by As_4 and P_4 respectively; that of alcohol by $\left.\begin{matrix} C_2H_5 \\ H \end{matrix}\right\} O$; and that of ether by $\left.\begin{matrix} C_2H_5 \\ C_2H_5 \end{matrix}\right\} O$.

Mendeleeff's researches on specific volumes were begun in 1855, and were continued, with intermissions, down to 1870; but part only of the work has been published. In 1859, Mendeleeff obtained permission from the Minister of Public Instruction to travel, and repaired to Heidelberg, where he established a small private laboratory, and occupied himself with the determination of the physical constants of chemical compounds. He returned home in 1861, and in 1863 was named Professor of Chemistry at the Technological Institute of St. Petersburg. In 1866 he became Professor of Chemistry at the University, and was made Doctor of Chemistry after a public defence of his dissertation "On the Combinations of Water with Alcohol." He is now Emeritus Professor, and delivers annually a course of lectures on general chemistry.

Mendeleeff is so prolific a writer that it is impossible within the limits of an article of this kind to do justice to his work. There is, in fact, no section of chemical science which he has not enriched by his contributions. Some of his earliest work related to questions of mineralogy and chemical geology; and at times, as in his papers on Œnanthol-Sulphurous Acid, on Fermentation Propyl Alcohol, and on the Nitriles, he cultivated the rapidly extending domain of organic chemistry. But his reputation mainly rests upon his contributions to physical chemistry and to chemical philosophy. In his papers on Specific Volumes he extends Kopp's generalizations, and traces the specific volumes of substances through various phases of chemical change. He shows that in the thermal expansion of homologous liquids the expansion-coefficient diminishes in a regular manner as the series is ascended, and he indicates the intimate connection which exists in the case of liquids between expansion and cohesion, and the *rôle* played by molecular cohesion in the determination of chemical activity. His paper on the thermal expansion of liquids above their boiling-points is noteworthy as demonstrating that the empirical expressions given by Kopp, Pierre, and others, for the expansion of liquids up to their boiling-points, are equally applicable to far higher temperatures, and that the expansion-coefficient gradually increases with the diminution in molecular cohesion of the liquid, until, in the case of certain liquids, *e.g.* ether at 133°, it becomes even greater than that of the gas. The expansion-coefficient of ether increases to 0·0054 at the temperature of its *absolute boiling-point*—that is, at about 190°. The absolute boiling-point is defined by Mendeleeff as that temperature at which the cohesion and latent heat of vaporization are *nil*, and at which the liquid becomes gaseous independently of pressure and volume. It is, in fact, that temperature which the researches of Andrews have made us familiar with as the "critical-point." In this paper Mendeleeff presents us for the first time with a number of determinations of the critical-temperatures of various substances, founded partly on his own determinations, and partly on those of Cagniard de la Tour, Wolff, and Drion.

Other papers on physical chemistry relate to Contact Action, to Fractional Distillation, and to the Heat of Combustion of Organic Substances. In 1883 Mendeleeff was made an honorary member of our Chemical Society, and in the following year he contributed a remarkable paper to the Journal of the Society (Transactions of the Chemical Society, xlv. 126), in which he developed an extremely simple general expression for the expansion of liquids under constant pressure between 0° and their boiling-points. This expression may be written $1/V_t = 1 - kt$, in which V_t is the volume at $t°$ (that at 0° being unity), and k is a quantity which varies with different substances, but which may for any one substance be considered invariable between 0° C. and the neighbourhood of the boiling-point. This formula is analogous to that which expresses Gay Lussac's law of the uniformity of expansion of gases. But just as Gay Lussac's formula, $V = 1 + kt$, applies only to a so-called ideal gas, Mendeleeff's expression is in like manner to be regarded only as a first approximation—that is, as applicable only to ideal liquids. The deviations are not large in either case; they are, as might be expected, especially remarkable near temperatures at which the states of the bodies change. In the case of actual liquids the deviations from the ideal form of expansion increase not only as the liquid approaches the point at which its state of aggregation is changed, but also with diminishing density, increasing cohesion, and diminishing molecular weight. This last cause is especially noteworthy since Mendeleeff showed, more than a dozen years ago (*vide supra*), that the deviations from Gay Lussac's law were related to the molecular weights of the gases. The well-known irregularities in the expansion of water are, according to Mendeleeff, connected with its small molecular weight, its high capillary constant (which expresses its cohesion), and the comparatively small temperature-interval within which its state of aggregation is unchanged. Subsequent observers, by applying Van der Waal's theory of the general relation between the pressure, volume, and temperature of bodies to Mendeleeff's expression for the thermal expansion of an ideal liquid, have shown that the reciprocal of the constant k is the number obtained by subtracting 273 from the product of the critical temperature into a quantity which should be the same for all substances. The value of this quantity is approximately 2, and since the range of its variation is apparently very small, the development of Mendeleeff's formula affords a simple and ready method of calculating the critical temperature of bodies from observations of their expansions as liquids.

Mendeleeff's skill in physical measurement is well illustrated by his determinations of the Specific Gravities of Aqueous Solutions of Alcohol. Such determinations have been frequently made the subject of the most rigorous experiment in this and other countries, inasmuch as they constitute the basis of the methods of assessing the duty on spirits, which is so important a factor in the national income of many States. Mendeleeff's work has served to confirm and extend that of Drinkwater, Fownes, and Squibb, and has been utilized by certain Continental Governments (*e.g.* that of Holland) for the purposes of revenue. But it was not the utilitarian aspect of this subject which alone attracted Mendeleeff. In a paper communicated a couple of years ago to our Chemical Society (Trans. Chem. Soc., li. 778), these determinations are applied towards the elucidation of a theory of solution in which it is sought to reconcile Dalton's doctrine of the atomic constitution of matter with modern views respecting dissociation and the dynamical equilibrium of molecules. According to Mendeleeff, solutions are to be regarded as strictly definite atomic chemical combinations at temperatures higher than their dissociation temperature, and just as definite chemical substances may be either formed or decomposed at temperatures which are higher than those at which dissociation commences, so we may have the same phenomenon in solutions; at ordinary temperatures they can be either formed or decomposed. In addition, the equilibrium between the quantity of the definite compound and of its products of dissociation is defined by the laws of chemical equilibrium, which require a relation between equal volumes, and their dependence on the mass of the active component parts (*loc. cit.* p. 779). It follows from this hypothesis that the specific gravities of solutions depend on the extent to which active substances are produced, or that the expression for the specific gravity, s, as a function of the percentage composition, p, may be represented by the general equation—

$$s = C + Ap + Bp^2.$$

Between two definite compounds which exist in solution, the differential coefficient $\frac{ds}{dp}$ is a linear function of p—

$$\frac{ds}{dp} = A + 2Bp.$$

By the application of this method to the case of aqueous solutions of ethyl alcohol, Mendeleeff infers the existence of three definite hydrates, viz. $EtHO.12H_2O$, $EtHO.3H_2O$, and $3EtHO.H_2O$, the first two of which he has isolated by subjecting the mixture to low temperatures. The hypothesis respecting the linear character of the differential coefficient $\frac{ds}{dp}$ has been proved to be correct for solutions of many salts, of acids, and of ammonia.

We have the consummation of this work on solution in the monograph published by Mendeleeff last year. This volume, the fruit of many years of labour, is unquestionably the most important contribution to the theory of solution yet given to science.

Much of Mendeleeff's scientific activity since 1871 has been absorbed in an extended work on the elasticity of the gases, which he has executed in conjunction with his pupils, Kirpitshoff, Hemilian, Bogusky, and Kajander. Part only of the results have as yet appeared. The first volume, published in Russian in 1875, contains details of the modes of measurement, which involved many forms of apparatus new to physical science. A summary of the principal results obtained was published in the form of a pamphlet in 1881. Regnault found that the product

$p . v =$ const.—*i.e.* Boyle's law—was true for ideal gases only. Between one atmosphere and thirty atmospheres the deviations were positive in the case of hydrogen, and negative in those of all other gases. Mendeleeff pointed out that the deviations must become positive for all gases at sufficiently high pressures, and the fact has since been confirmed by the observations of Amagat and Cailletet. Mendeleeff, more particularly, made observations at low pressures, *i.e.* below one atmosphere; and here the deviations were again found to be positive and relatively very large. It was found, in fact, that, at the limit of condensation, the gases seemed to behave like solid bodies—*i.e.* the molecules were incapable of being stretched or brought nearer together to any appreciable extent by varying pressure. Mendeleeff has further determined the *real* coefficients of thermal expansion of gases. This, for air between 0° and 100° under a standard atmosphere, was found to be 0·0036829. Determinations made in the case of other gases have shown that the coefficients of expansion increase with increasing molecular weight, gases of the same molecular weight giving the same coefficient.

	Molecular weight.	Coefficient of expansion.
Hydrogen	2	0·00367
Nitrogen / Carbon monoxide	28	0·00373
Nitrous oxide / Carbon dioxide	44	0·00373
Sulphur dioxide	64	0·00385
Hydrogen bromide	81	0·00386

The coefficient of expansion is found to decrease with increasing pressure in the case of hydrogen. Thus at

200 mm.	0·00369
760 ,,	0·00367
8 atmos.	0·00366

But with the so-called coercible gases the reverse is found to take place. Thus, in the case of carbon dioxide,

120 mm. pressure	0·00372
220 ,, ,,	0·00370
760 ,, ,,	0·00373
3 atmos. ,,	0·00389
8 ,, ,,	0·00413

The decrease of the coefficient of expansion with increasing pressure is a normal phenomenon of gases, the positive deviation observed in the case of hydrogen being found to hold equally good for all gases at very high and very low pressures. Hence the laws of Boyle and Charles are only valid at points of the curve when the deviation changes from positive to negative or *vice versâ*.

These experiments have also borne fruit in various meteorological papers on the physical nature of the highly rarefied air existing in the upper strata of the atmosphere. In this connection it may be stated that Mendeleeff has attempted to organize meteorological observations in the upper regions of the atmosphere by means of balloons, and hence he has been led to study aëronautics. His practical acquaintance with the subject induced him to make an ascent from Klin during the total solar eclipse of August 19, 1887, for the purpose of observing the extension and structure of the corona when seen through highly rarefied air.

Russia is indebted to Mendeleeff for the training of two generations of her chemists. His writings have largely modified the mode of teaching chemical science in that country. His treatise on Organic Chemistry was the standard work of its time, and exercised great influence in spreading abroad the conceptions which are associated with the development of modern chemistry. His "Principles of Chemistry," published in 1869, and repeatedly reprinted, is a veritable treasure-house of ideas, from which investigators have constantly borrowed suggestions of new lines of research. This book is one of the classics of chemistry; its place in the history of science is as well assured as the ever-memorable work of Dalton. Mendeleeff, indeed, might with equal fitness have styled his book a "New System of Chemical Philosophy." In it he has developed the great generalization which is known under the name of the "Periodic Law"—a generalization which is exerting a profound influence on the development of chemical science in all countries in which its study is actively prosecuted. Mendeleeff first drew attention to the principles upon which the Periodic Law is based in a paper read to the Russian Chemical Society in 1869, in the following series of propositions:—

(1) The elements, if arranged according to their atomic weights, exhibit an evident *periodicity* of properties.

(2) Elements which are similar as regards their chemical properties have atomic weights which are either of nearly the same value (*e.g.* platinum, iridium, osmium), or which increase regularly (*e.g.* potassium, rubidium, cæsium).

(3) The arrangement of the elements, or of groups of elements in the order of their atomic weights, corresponds to their so-called *valencies*, as well as, to some extent, to their distinctive chemical properties; as is apparent among other series in that of lithium, beryllium, barium, carbon, nitrogen, oxygen, and iron.

(4) The elements which are the most widely diffused have *small* atomic weights.

(5) The *magnitude* of the atomic weight determines the character of the element, just as the magnitude of the molecule determines the character of a compound body.

(6) We must expect the discovery of many yet *unknown* elements—for example, elements analogous to aluminium and silicon—whose atomic weight would be between 65 and 75.

(7) The atomic weight of an element may sometimes be amended by a knowledge of those of its contiguous elements. Thus the atomic weight of tellurium must lie between 123 and 126, and cannot be 128.

(8) Certain characteristic properties of elements can be foretold from their atomic weights.

In the Faraday Lecture recently delivered to the Chemical Society, and from which these words are taken, Mendeleeff has indicated for us the lines upon which the evolution of his theory proceeded. In the first place, it is to be noted that it is based wholly on experiment: it is as much the embodiment of fact as are the laws of chemical combination formulated by Dalton. Without the knowledge of certain data it could not possibly have been discovered; with this knowledge its appearance, says Mendeleeff, is natural and intelligible. Three series of data were necessary to pave the way for its enunciation:—

(1) The adoption of the definite numerical values of the atomic weights founded on the conceptions of Avogadro and Gerhardt, as insisted upon by Cannizzaro.

(2) The recognition that the relations between the atomic weights of analogous elements were governed by some general law. Many chemists, and more especially Dumas, Gladstone, and Strecker, had drawn attention to the numerical relationship existing between correlated groups of elements, but no one before Newlands in England, and De Chancourtois in France, had sought to generalize this conception, and to extend it to all the elements by considering their properties as functions of their atomic weights. (3) A more accurate knowledge of the relations and analogies of the rarer elements, such, for example, as that given to us by Roscoe in the case of vanadium, and by Marignac in that of niobium. The law of periodicity was the systematized expression of these data; it was, to use Mendeleeff's language, "the direct outcome of the stock of generalizations of established facts which had accumulated by the end of the decade 1860–70."

We can only very rapidly allude to some of the more striking services which Mendeleeff's generalization has rendered to science during the twenty years of its existence. By a more systematic arrangement and co-ordination of the known chemical elements, it has not only indicated the existence of new forms of elementary matter, but it has pointed out the probable sources of the undiscovered substances, and has enabled us to know their properties even before we have knowledge of their existence. It was this power of divination inherent in the law which, perhaps more than any other feature, first attracted attention to it, and quickened the interest with which its development was regarded by men of science. There are now three instances of elements of which the existence and properties were foretold by the periodic law: (1) that of *gallium*, discovered by Boisbaudran, which was found to correspond with the *eka-aluminium* of Mendeleeff; (2) that of *scandium*, corresponding to *eka-boron*, discovered by Nilson; and (3) that of *germanium*, which turns out to be *eka-silicium*, by Winckler. No one who was present on the occasion of the delivery of the Faraday Lecture will forget the enthusiasm which followed the reading of these words of Mendeleeff's: "When, in 1871, I described to the Russian Chemical Society the properties, clearly defined by the periodic law, which such elements ought to possess, I never hoped that I should live to mention their discovery to the Chemical Society of Great Britain as a confirmation of the exactitude and the generality of the periodic law."

Up to the time of the formulation of the law, the determination of the atomic value or valency of an element was a purely empirical matter, with no apparent necessary relation to the atomic value of other elements. But to-day this value is as much a matter of *a priori* knowledge as is the very existence of the element or any one of its properties. Striking examples of the aid which the law affords in determining the substituting value of an element are presented by the cases of *indium*, *cerium*, *yttrium*, *beryllium*, *scandium*, and *thorium*. In certain of these cases, the particular value demanded by the law, and the change in representation of the molecular composition of the compounds of these elements, have been confirmed by all those experimental criteria on which chemists are accustomed to depend. One of the most interesting instances of the kind is seen in the example of *uranium*, the atomic weight of which was formerly regarded as 120, then as 180, but which, on the authority of the periodic law, is now established as 240, a value completely confirmed by the independent experiments of Zimmermann and Rammelsberg. Uranium has a special interest in being the last term in the series: no element of higher atomic weight is at present known.

As examples of the value of the law in enabling us to correct the atomic weights of elements whose valencies and true position were well known, we may cite the cases of *gold*, *tellurium*, and *titanium*, the values of which were apparently higher than those demanded by it. In each of these cases a redetermination of the atomic weight has resulted in a value which is in conformity with the previsions of the periodic law.

The law has, moreover, enabled many of the physical properties of the elements to be referred to the same principle of periodicity. At the Moscow Congress of Russian physicists in August 1869, Mendeleeff pointed out the relations which existed between the density and the atomic weights of the elements; these were subsequently more fully examined by Lothar Meyer, and are embodied in the well-known curve in his "Modern Theories of Chemistry." Similar relations have been discovered in certain other properties, such as ductility, fusibility, hardness, volatility, crystalline form and thermal expansion; in the refraction equivalents of the elements, and in their conductivities for heat and electricity; in their magnetic properties and electro-chemical behaviour; in the heats of formation of their haloid compounds; and even in such properties as their elasticity, breaking stress, &c.

In the Faraday Lecture, Mendeleeff indicated the bearing of the law of periodicity upon the doctrine of constant valency, and especially on the conception of a primordial matter. The mind almost instinctively clings to the notion that the law can only find its rational interpretation in the idea of unity in the formative material, and it is not surprising that the promulgation of the law has been heralded by some as the most convincing proof of the validity of the Pythagorean conception that experiment has yet been able to adduce. But the author of the periodic law will not admit that his generalization has either sprung from this conception or has any relations towards it. "The periodic law, based as it is on the solid and wholesome ground of experimental research, has been evolved independently of any conception as to the nature of the elements; it does not in the least originate in the idea of an unique matter; and it has no historical connection with that relic of the torments of classical thought; and therefore it affords no more indication of the unity of matter or of the compound nature of the elements than do the laws of Avogadro and Gerhardt, or the law of specific heats, or even the conclusions of spectrum analysis. None of the advocates of an unique matter has ever tried to explain the law from the standpoint of ideas taken from a remote antiquity, when it was found convenient to admit the existence of many gods—and of an unique matter."

No record of Mendeleeff's intellectual activity would be complete without some reference to his influence on the development of the industrial resources of Russia. In 1863 he brought out the first encyclopædia of chemical technology of any magnitude which the literature of that country possessed, and he has been frequently commissioned to report on the progress of chemical industry as manifested at the various International Exhibitions. But it was on the petroleum industry of Baku, on the Caspian, that this influence has been most widely felt. Fifteen years ago the production of petroleum in Russia was a monopoly, and was accompanied by all the evils which usually spring from monopolies: the trade was exceedingly limited, and apparently incapable of development. Thanks largely to his action, both on the platform and in the press, the opening up of the boundless supplies of the peninsula of Apsheron was thrown open to the world, with the result that petroleum threatens to effect an industrial revolution in Eastern Europe and in Asia. Indeed, it is not too much to say that the oil industry of Baku is rapidly becoming, directly and indirectly, one of the most powerful factors in the Central Asian problem. Mendeleeff's interest in the development of the Baku industry has led to his being sent to the Caucasus and to Pennsylvania, to report upon the best modes of working the wells, and of separating and utilizing the products. Last year, during the coal crisis in Southern Russia, he was commissioned to study the economic condition of the industry in the rich coal-basin of Donetz.

No man in Russia has exercised a greater or more lasting influence on the development of physical science than Mendeleeff. His mode of work and of thought is so absolutely his own, the manner of his teaching and lecturing is so entirely original, and the success of the great generalization with which his name and fame are bound up is so strikingly complete, that to the outer world of Europe and America he has become to Russia what Berzelius was to Sweden, or Liebig to Germany, or Dumas to France. Nowhere has Mendeleeff's pre-eminence been more quickly or more fully recognized than in this country. English men of science and of learning have delighted to do him honour. In 1882 the Royal Society gave him the Davy Medal; and now, the Chemical Society, which is proud to number him among its Honorary Fellows, has conferred upon him the highest distinction in its power, by the award of the Faraday Medal. To the great regret of the large gathering of British chemists which had assembled to welcome him and to listen to the memorable address on the subject which he of all others is best fitted to expound, Mendeleeff was unable to receive the gift in person; but the circumstances of his absence awakened a deep feeling of commiseration and sympathy, and served to intensify the sentiment of respect and admiration with which he is regarded by all English men of science.[1]

T. E. THORPE.

THE PREVENTION OF HYDROPHOBIA.

AS was foretold three years ago, by those experienced in its behaviour, rabies is again making itself felt in this country by becoming epidemic. No disease probably has been more misunderstood in the past, none is more clearly known to-day. We are not therefore, as in 1885, caught napping. Since M. Pasteur showed us the whole story of rabies, we have acknowledged the brilliancy of his researches and the most gratifying discovery he made of the way in which the disease may be prevented from developing in any individual unfortunately bitten by a rabid dog. The manner too in which he gradually unfolded one secret of Nature after another, by his extraordinary insight into the phenomena of infectious disease, has been demonstrated with beautiful clearness in the recent Croonian Lecture delivered by Dr. Roux before the Royal Society.

The gradual evolution of the science of preventive inoculations by M. Pasteur has taught us how to obviate the appearance of rabies or hydrophobia when the virus has been introduced into the system; how, in fact, the virus may be hindered from exerting its frightful effects on the nervous centres of those unfortunately exposed to the danger. Consequently he enjoys the supreme pleasure of having saved hundreds, not only from a most painful and miserable death, but from what is actually far more painfully important—the most dreadful of apprehensions.

But this last point, the apprehension or dread of the disease, which is so appalling a feature of this malady, owing to the extraordinary length of its incubation period, has forced upon everyone save the anti-vivisectionists, the fact that it is far more necessary, in this of all troubles, to prevent the chances of the mischief occurring, than to try and shut the door after the evil has found admission. We have persistently urged that in islands like Great Britain the mere existence of rabies is a matter of the greatest reproach; that preventive legislation is to a very unusual degree able to cope with it and destroy it utterly. A brief repetition of the grounds of this belief will not be out of place. Of all acute specific diseases, rabies is evidently the one in which the virus survives removal from living tissues with the greatest difficulty. As retention of virulence and viability by the viruses of different acute specific diseases is a subject of the highest interest, as well to the practical hygienist as to the pathologist, we fortunately know enough from the work of recent years to speak with confidence on the point. Bacteriological experience has shown that the difficulty of artificially cultivating a zymotic virus in dead material, *e.g.* gelatine, increases, roughly speaking, in proportion to the length of the incubation period. In proof of our contention we may quote the extreme cases of tuberculosis and anthrax. In the former disease the virus is a slow-growing bacillus, growing in artificial cultures with the utmost difficulty, and destroying life only at the end of many weeks. In anthrax, on the contrary, we have a bacillus which develops with the utmost activity on artificial nutrient soils, and which kills in a few hours.

Duration of incubation period, however, is not necessarily an index to the viability of a bacillus. But while it was clear from what has just been said that we were *a priori* fully justified in prophesying that the rabic virus would probably not develop in the absence of a living pabulum, *i.e.* living tissue, we have actual evidence to show that fortunately this most terrible virus in all probability is not possessed of powers of active resistance to those injurious influences which act upon it

[1] I have to express my grateful acknowledgments to Prof. Menshutkin and M. Gorboff, of St. Petersburg, and to Dr. B. Brauner, of the University of Prague, for much of the information on which this article is based.—T. E. T.

when exposed to the air, &c. This evidence is simply the fact that no case bears investigation in which the poison was asserted to have been found infecting the ground, woodwork, &c., of places habited by rabid animals—that, in short, the rabic virus cannot survive the drying, changes of temperature, &c., it necessarily undergoes when scattered over the ground, as we often see happen by the slobbering of a rabid animal.

This is the first and a most important point, upon which our opinion was based. We pass now to the second, which is to a certain extent the corollary of the first. It is, that the disease is communicated only by one animal biting another. There is really no evidence to show that accidental inoculation with the blood, &c., has ever occurred, and we are now in possession of direct experimental evidence to show that the poison cannot be absorbed, by being combined with food, through the mucous membrane of the alimentary canal. The only practicable mode of transmission of the disease, therefore, is by one animal biting and lacerating another's tissues, or by licking a wound and so introducing the virus.

This point, coupled with the first, establishes irrefragably the proposition that, for the permanent extinction of rabies from a country into which its reintroduction can reasonably be prevented, it is only necessary to prevent rabid animals from biting healthy ones. In other words, it is only necessary to apply the muzzle. Usually the public does not listen to scientific men, unless the matter happens to be one where their own experience, favourable or unfavourable, serves to help them to a conclusion. On the present question the experience of London in 1885 and 1886 is sufficient; and from the recent memorial of the County Council addressed to the Privy Council, the knowledge gained by the last epidemic has been speedily utilized. But, with particular wisdom the County Council have asked for the general adoption of the muzzle all over the country, so that we may have not merely a temporary extinction of the disease in one locality, but a riddance of it from the whole country. It might well be asked, Why have not the Privy Council, who hold in their hands the machinery of prophylactic legislation, brought this consummation to a perfect conclusion without waiting to be urged by the public outcry which it was well known would certainly be raised sooner or later, according as rabies rapidly or slowly increased? The answer is simple, being nothing more than the well-known cowardice of authorities to interfere with what they believe to be a popular interest, sentiment, or feeling, on any point, however contrary to reason or fact that sentiment may be. The Select Committee of the House of Lords, whose Report we reviewed two years ago, did yeoman service to the cause by collecting an immense amount of valuable evidence; but unfortunately, misled by the interests falsely stated to be interfered with, reported adversely to a general adoption of muzzling regulations all over the country, and advised leaving the whole matter in the hands of the local authorities.

Even those members of the Upper House who were most interested in the subject, both from philanthropic and agricultural reasons, hesitated to support any measure which might involve some trouble in application. We allude of course to the muzzling of sporting dogs more especially, and to the exemption of sheep and other dogs actually engaged in work. All these points were considered fully two years ago by the Society for the Prevention of Hydrophobia, a Society composed of dog owners and scientific men, and were treated by them in the provisional draft of a Bill which provided for each of the cases referred to. Fortunately this Bill will be introduced into the Lower House by Sir Henry Roscoe, so that the question will now be brought to a very definite head.

Nothing, however, in the way of philanthropic reform is said ever to succeed unless it is violently opposed. Violent opposition to the present proposals has assuredly not been wanting, nor will apparently be wanting. At the time of the last epidemic, and ever since, the anti-vivisectionists, turning from vilifying M. Pasteur's charitable efforts, maligned the police, and, to parody the celebrated dictum of Spinoza, first asserted that there was no such thing as rabies; secondly, that it was contrary to religion (of humanity); and thirdly (this only recently), that the disease was well known, but did not require preventing.

The diatribes of these people may be amusingly ridiculous, but naturally they are also mischievous. It is scarcely conceivable, in this present century of intelligence, that none of their subscribers should have seen that they are really opposing the only known means of counteracting rabies, and that their money is consequently being spent to perpetuate this terrible infliction among us. However, the infallible test of time is fortunately dispersing the mists of falsehood which have been so carefully spread around the subject.

M. Pasteur's splendid achievements have, as all scientific truth must, contributed greatly to the success of the movement for obliterating the curse from this country. For, attracted by the value of the work of the Pasteur Institute, and its single-mindedness, the Prince of Wales and the Lord Mayor of London have recently visited it, have seen the immense importance of the researches carried on in the laboratory there, and they are in consequence greatly desirous of providing similar blessings for this country. The Lord Mayor, in order to give effect to the opinions he has so strongly formed, has summoned a meeting at the Mansion House for July 1, at 3 p.m., and the Prince of Wales will write a letter in support of the same. At the last meeting of the Royal Society for the present session, held on Thursday, the 20th instant, the Society adopted a letter which had been drawn up by the President and Council, expressing sympathy with the Lord Mayor's attempt to obtain some public recognition in this country of the services rendered by M. Pasteur to science and humanity, and appointing the officers with Sir James Paget, Sir Joseph Lister, Sir Henry Roscoe, and Prof. Lankester, as their representatives at the meeting called by the Lord Mayor.

The whole business of the meeting will be devoted to, first, the providing of a sum of money to be paid to the funds of the Pasteur Institute as a slight acknowledgment of the great benefits which the Institute has gratuitously extended to over 200 of our fellow-countrymen threatened with rabies; secondly, the formation of a fund to cover the expenses of poor people travelling to Paris for inoculation and unable to support themselves; and thirdly, a strong resolution calling upon the Privy Council to instantly inaugurate such muzzling and other restrictive measures as shall definitely and finally exterminate rabies. The anti-vivisection agitators, whose object it is apparently to keep alive rabies in this country, have opposed the meeting, which we hope will be crowded by genuine lovers of men and animals. The form their opposition has taken is amusing to the last degree, since it consists of a petition, advertised in the daily papers, made of four or five headings, each of which may be called in question. In the very first paragraph it is stated that the Manager of the Dogs' Home in Battersea has passed a large number of dogs through his hands, and that he never saw a case of rabies among them. If this means that there has never been a case of rabies at the dogs' home, we believe evidence can be produced to the contrary.

The innate falsity of this agitation is always making itself felt, and it is nothing more than Nemesis that the statements made by agitators in the hope of deceiving the public, should be detected and exposed again and again. Such a statement as that asserted to have been made by the Manager, even if he did make it, has no value in view of the incontrovertible facts of the police records of the existence—nay, more, of the increase — of rabies in London. The Mansion House meeting will do much to blow away this miserable opposition, which attacks biological science alone, knowing full well that no false sentiment can be hashed up against physical science and its benefits to mankind. The object of the meeting is to honestly acknowledge our great indebtedness to M. Pasteur, to provide for our poorer fellow-countrymen gaining the benefits of the Pasteur Institute, and, finally, to stamp out rabies.

No scientific man who really has the interests—in fact, the honour—of his country at heart will refuse his support on this important occasion; and we may well hope that many will be found able to attend the meeting personally, to render the occasion worthy of the great chemist whose work has so essentially led to the successful performance of the hygienic measures now about to be executed.

STELLAR EVOLUTION.

Stellar Evolution and its Relation to Geological Time. By James Croll, LL.D., F.R.S. (London: Edward Stanford, 1889.)

DR. CROLL'S book, though chiefly dealing with the question of stellar evolution from the astronomer's point of view, calls in the evidence afforded by geology in favour of the theory which is set forth in its pages. The particulars of the theory are clearly stated, and the new facts which have been gathered since the theory was first published are fully considered.

Dr. Croll accepts the nebular hypothesis of Kant and Laplace, and deals mainly with the question of the pre-nebular condition. According to his theory, large cool dark bodies, moving with enormous velocities, were either created or were eternal; and these colliding with each other here and there, the evolution of the celestial bodies was accomplished. With regard to the origin of these bodies endowed with motion, Dr. Croll states:—"We are perfectly at liberty to begin by assuming the existence of stellar masses in motion; for we are not called upon to explain how the masses obtained their motion, any more than we have to explain how they came into existence. If the masses were created, they may as likely have been created in motion as at rest; and if they were eternal, they may as likely have been eternally in motion as eternally at rest" (p. 3). It is argued that the heat energy which would have been derived from gravitation alone could not possibly have been equal to that which the solar system originally possessed. But there is absolutely no limit to the amount of available energy from Dr. Croll's point of view. The most important argument against the gravitational theory is undoubtedly the geological and biological one. The whole question of geological time rests on an estimation of the time during which the sun has been radiating its heat, and on this point Dr. Croll remarks: "If gravitation be the only source from which the sun has derived its heat, then life on the globe cannot possibly date farther back than 20,000,000 years, for under no possible form could gravitation have afforded, at the present rate of radiation, sufficient heat for a longer period" (p. 35). The adoption of Langley's value (1·7 times that of Pouillet) for the rate of solar radiation reduces Helmholtz's estimate of 20,000,000 years to 12,000,000 years, and even this would not be available for plant and animal life, as millions of years must have undoubtedly elapsed before the earth was prepared for them. Prof. Tait ("Recent Advances in Physical Science," p. 175) has shown that, from the physical point of view, "10,000,000 years is about the utmost that can be allowed for all the changes that have taken place on the earth's surface since vegetable life of the lowest known form was capable of existing there." Sir William Thomson states his conclusions on this point thus: "In the circumstances, and taking fully into account all possibilities of greater density in the sun's interior, and of greater or less activity of radiation in past ages, it would, I think, be exceedingly rash to assume as probable anything more than 20,000,000 years of the sun's light in the past history of the earth, or to reckon on more than five or six million years of sunlight for time to come" ("Popular Lectures and Addresses," p. 390).

It is not necessary here to enter into details of the various methods by which geologists and biologists have attempted to estimate the length of time which must have elapsed since the earth first received the heat of the sun. On this point Dr. Croll says: "The grounds upon which the geologists and biologists found the conclusion that it is now more than twenty or thirty millions of years since life began on the earth are far more certain and reliable than the grounds upon which the physicist concludes that the period must be less" (p. 68). Here again, it may be well to quote Sir William Thomson, who says:—"What then are we to think of such geological estimates as 300,000,000 years for the 'denudation of the Weald'? Whether is it more probable that the physical conditions of the sun's matter differ 1000 times more than dynamics compel us to suppose they differ from those of matter in our laboratories; or that a stormy sea, with possibly channel tides of extreme violence, should encroach on a chalk cliff 1000 times more rapidly than Mr. Darwin's estimate of one inch per century?"[1]

But granted that the geological evidence is against the gravitation theory, it remains for us to see how Dr. Croll's theory bears the strain put upon it when the details of the evolutionary processes are inquired into.

According to the impact theory of Dr. Croll, "meteorites are but the fragments of sidereal masses which have been shattered by collision" (p. 12). The result of such a collision would be mainly to produce a gaseous mass, but some of the exterior fragments would have velocities sufficient to carry them beyond the influence of the central mass. This view is obviously in direct contradiction to the opinion held by Mr. Lockyer, who looks upon meteorites as the parents, and not the children, of sidereal systems. The explanation of the thumb-marks and the heterogeneous structure of meteorites which has been given by Mr. Lockyer (Proc. Roy. Soc., vol. xliii. p. 151) would apply equally to Dr. Croll's view.

Comets, according to the impact theory, have a similar origin to meteorites, Dr. Croll apparently agreeing that they are nothing more than swarms of meteorites. Those with elliptic orbits probably had their origin in the collision which produced the nebula out of which the solar system has been evolved, whilst those with parabolic and hyperbolic orbits are probably the outcasts of other systems.

The first condition of a nebula, according to Dr. Croll, is that in which it consists of broken fragments scattered through a gaseous mass of excessively high temperature. Mr. Lockyer's recent researches are consistent with this view, as far as meteorites and interspaces are concerned, but they point to the opposite conclusion with regard to temperature. Mr. Lockyer's spectroscopic work has shown that the highest temperature is in all probability only reached by a nebulous mass after the complete volatilization of all the meteorites composing it, and he has shown that the intermediate stages which should occur on this supposition are actually represented amongst the stars, the stars of Group II. being amongst these. This therefore furnishes a strong argument against the high-temperature theory of nebulæ.

According to the impact theory of Dr. Croll, the meteorites scattered through the gaseous mass have nothing whatever to do with the luminosity; whereas, from Mr. Locker's point of view, the luminosity is in great part, if not entirely, due to collisions between the meteorites. Dr. Croll objects to this latter view because it "does not appear to afford any rational explanation of this banging about of the stones to and fro in all directions; for, according to it, the only force available is gravitation, and this can only produce merely a motion of the materials towards the centre of the mass" (p. 20). Dr. Croll has evidently given but little thought to this theory, originally advanced by Prof. Tait, for it is obvious that all the meteorites would not lose all their momentum by collisions during their first movements towards the common centre of gravity. Those which escaped collision would move on beyond the centre of gravity with considerable velocities, and would continue to oscillate to and fro until all their momentum was converted into heat by collisions. The banging about might therefore go on for a very long time, and the observations made by Dunér, and classified by Mr. Lockyer, show that this is probably the case. The increase of temperature would accordingly take place gradually, and not suddenly, as Dr. Croll supposes; and further, the highest temperature would be associated with a certain class of stars, and not with the nebulæ themselves.

The subject of new stars is dismissed with very few words. The general view adopted by Dr. Croll seems to be that in such a case as Nova Cygni the outburst was due to the collision of a star with a swarm of meteorites. The spectroscopic evidence in favour of Mr. Lockyer's view, that such an outburst is due to the collision between *two* swarms of meteorites, is not even referred to. The case of Nova Cygni, indeed, has an important bearing on theories of cosmogony. Its spectrum, as observed by Copeland when it was just fading from our view, was that of a planetary nebula. If, therefore, a nebula is at a higher temperature than a star, Nova Cygni must have got hotter as it got dimmer!

Dr. Croll shows that his theory explains other details of the structure of our universe, including the proper motions of stars and the origin of binary systems, but these need not be more than mentioned.

Assuming that Dr. Croll has established that gravitation alone would have been incompetent to produce the heat originally possessed by the solar nebula, it is only necessary to reconcile this with the low-temperature theory of nebulæ, as the high-temperature theory has been shown to be inconsistent with the facts.

It may be suggested that instead of the dark stellar masses endowed with motion which Dr. Croll supposes to have been the pre-nebular condition, meteorites at great distances apart were endowed with similar velocities. In the first groupings, the collisions would only occur very rarely, and there would be more grazes than anything else, so that the average temperature might still be low in the earlier stages. Prof. G. H. Darwin[1] has recently shown that the conception of fluid pressure which is demanded by Laplace's nebular hypothesis is not difficult to reconcile with the meteoritic hypothesis. If we substitute meteorites in collision for the molecules of a gas impinging against each other, there would be a quasi-fluid pressure as the average result of the impacts of the meteorites, and the separation of the planets from the meteor-swarm would take place exactly as in a gaseous mass.

THE TELEPHONE.

The Telephone. By William Henry Preece, F.R.S., and Julius Maier, Ph.D. Pp. i-xvi., and 1-498. (London: Whittaker and Co., 1889.)

THIS book is one of the "Specialists' Series" of technical manuals now being issued by Messrs. Whittaker and Co. Its aim is to give as full an account as possible of telephony as a practical art, and the authors have certainly succeeded in inclosing within the compass of a handy octavo volume a vast amount of well-arranged information on a subject hitherto unrepresented in English by any systematic treatise. After two chapters, comprising about twenty pages, on sound and speech, and on such parts of electrical theory as are more immediately connected with the action of the telephone, the authors proceed to deal with the construction of the telephone, and treat in detail the subject of transmitters and receivers of all kinds. This part of the book is very interesting, giving as it does an account of the principal forms of telephone receivers and transmitters which were the outcome of the marvellous activity of telephonic research aroused by the publication of the inventions of Bell, Edison, and Hughes. In chapter x. come telephone lines and cables, and modes of installing them; then chapters on auxiliary apparatus, and on terminal and intermediate stations, lead up to the important subject of telephone exchanges, and appliances connected with their working, to which chapters xiv. to xx. are devoted. Long-distance telephony is introduced in chapter xxi., and systems of translation between the terminal networks, and the return wire or other induction avoiding circuit between the two places, are fully described. Various problems of practical telephony are then discussed, such as multiplex telephony, and the numerous devices for enabling several subscribers to work in one circuit. Chapters on the telephone as applied to the telegraph service, its military uses in camp and in the field, and finally some miscellaneous although important scientific applications of the instrument, conclude the work.

Of the main body of the work the contents of which are briefly analyzed above, we have no remark to make that is not commendatory. As has been already indicated, the work is full of most valuable practical details of actual working systems of telephony. The descriptions of complicated apparatus and appliances are full and clear, and bear everywhere the stamp of the work of men accustomed to exposition, and professionally acquainted with the subjects of which they treat.

In our examination of the work, we have noted a few points in which perhaps improvement might be effected in a second edition. Most of these occur in the preliminary chapters on the theory of the telephone, a part of the subject in some ways much more difficult to treat successfully than that which follows. For example, such a phrase as that on p. 14—that in a current following the simple harmonic law of variation with the time the electricity flowing is, "so to speak, thrown into undulatory motion"—is very apt to create an erroneous impression on the mind of a learner, and in no way describes what actually takes place. What is thrown into undulatory motion is not the electricity conveyed but the medium which forms its vehicle.

On p. 16 the phenomena of induction of currents are hardly "described with due precision." It is stated that "if there be a magnetic field, and a conductor in that field, any change in that field will produce the conditions that determine a current in that conductor." No doubt it is stated immediately afterwards that, "if a conductor forming part of a closed circuit be moved *across* a magnetic field in a direction at right angles to the lines of force in that field, a current will be induced whose strength is proportional to the strength of the field and to the rate at which the conductor cuts across the lines of force," but it nowhere appears that a change of the magnetic induction through the circuit is the one determining condition of an induced current. The authors, indeed, as if to sum the matter up, conclude this passage with the unqualified statement, which, as it stands, is not true except under certain conditions which are not stated: "In fact, currents are produced in a closed circuit placed in a magnetic field, whenever any change whatever occurs in the intensity of that field." If the circuit be so placed in the field that there is zero magnetic induction through it, the field may be absolutely annulled without producing any current whatever.

Again, on p. 18 it is stated that "the energy of the current in a coil at any moment is expressed by the product of the electromotive force (E) at the terminals of the coil producing the current, and the current itself (C), that is, W = E C." Now, what is here called the "energy of the current" is in reality the *activity* or time-rate of working of the current. The energy of the current at any instant is the energy which would be evolved in the form of a spark, or otherwise, if the current in the circuit were at that instant annulled. It is just this kind of misuse of the word energy that has led to the popular confusion (very common among the so-called "practical" (!) men who have applauded the Quixotic crusade against theory and "theoreticians") between work and rate of working, and to the astounding proposition, not yet exploded in all quarters, that the efficiency of a motor is a maximum when half the whole energy spent is wasted.

There are various other points and some omissions in the introductory and theoretical portions which we had noted. The remarks on self-induction might be improved, and it would have been well to point out here that conductors carrying rapidly-alternating currents (and telephone wires certainly do this) have, as Lord Rayleigh has shown, a virtually increased resistance due to the concentration of the current in the outer part of the wire. Another point is the apparently unguarded application, made at pp. 123, 124, of the results of the theory of a slowly worked submarine cable to the transmission of the rapidly alternating currents of telephones. The state of the case is much less simple than the authors here make it appear. Also, it is not possible, with any approach to accuracy, to regard copper wires, in this connection, as "virtually free from electro-magnetic inertia." But we have said enough as to these blemishes. They can be removed by careful extension and rewriting of the introduction. After all, it ought to be recognized that it is impossible to give in a book on a branch of electrotechnics any statement of theory which can supersede that full and detailed treatment which is indispensable, and which must be sought in systematic treatises on electrodynamics.

As to the more purely technical portion of the work, we have only to repeat that it is full and trustworthy, and, moreover, remarkably well illustrated. There are several statements made by the authors which might be questioned, but as these are in many cases matters of opinion rather than of actual fact, we need not enter into them.

In conclusion, we have to say that this book is a striking testimony to the rapid development of telephony. Thirteen years ago the first rude model of a telephone was brought from America by Sir William Thomson. One year later, Graham Bell himself brought to Scotland and exhibited first in Glasgow, and Mr. Preece brought to England, the telephone receiver (then also used as transmitter), almost exactly as it is now constructed. But a vast amount of practical work of a most important kind remained to be done before telephony could be made a commercial success. Without, however, waiting for this to be accomplished, a telephone line was immediately installed by Sir William Thomson between his house at the University and his laboratory, and between both and the workshop of his instrument-maker, Mr. White, in Sauchiehall Street, and this (now merged in the Telephone Exchange) has been in daily use ever since. From this very appropriate first practical beginning has developed the present immense and continually extending system, whose wires form a network above all our great cities, which plays so great a part in the transaction of business, and even of ordinary domestic affairs, and which now enables men in different cities at great distances apart to converse with one another by the living voice. All this has taken place in little more than ten years. Who knows what scientific wonders we may not see before A.D. 1900? But it is mournful to reflect that, as the applications of a scientific principle or invention become more and more wonderful, the thing itself excites so little interest among the people at large who continually use it. This is, no doubt, in part due to our curiosity- and admiration-stifling systems of education, and in part to other causes, about which it is useless to speculate. But true it is, "Familiarity breeds contempt," and, by the ordinary member of the British public, the telephone will soon be as much used, quite as little understood, and regarded with just as little curiosity, as the wonderful machine which he carries in his pocket from his boyhood to the end of his life.

A. GRAY.

OUR BOOK SHELF.

Morocco. By H. M. P. de la Martinière, F.R.G.S. (London: Whittaker and Co., 1889.)

IN this book, which has been translated directly from the author's manuscript, M. de la Martinière records the impressions produced upon him during journeys in the kingdom of Fez, and to the Court of Mulai Hassan. He had exceptional opportunities of making himself acquainted with the facts of social life in Morocco; and in a simple, graphic, and clever narrative he describes exactly what he saw, and the inferences that may be reasonably drawn from his observations. Upon the whole, his account of the condition of the people is most unfavourable, and everyone who studies the evidence he brings forward will admit that the regeneration of Morocco, by whomsoever or in whatever way it may be undertaken, will be no easy task. One of the few bright spots in the author's picture is a passage in which he praises what he calls the refined taste of the Arabs of Morocco. This reveals itself in the industrial products of the country, in the decoration of the pavements and ceilings of their houses, and in the skill with which they match colours in dress. They by no means display the same aptitude for science, which is generally regarded, from a religious point of view, as a forbidden subject. On the other hand, alchemy flourishes, and M. de la Martinière says there are many rogues who trade upon the credulity of the public. Some good route-maps and plans illustrate the text, and a preface is contributed by Colonel Trotter.

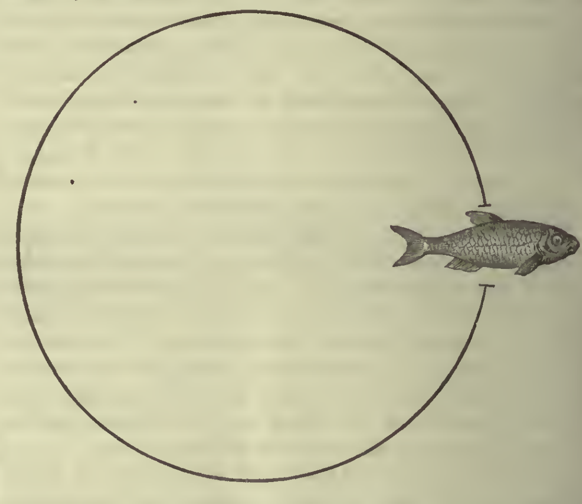
LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The "Hatchery" of the Sun-fish.

I HAVE thought that an example of the intelligence (instinct?) of a class of fish which has come under my observation during my excursions into the Adirondack region of New York State, might possibly be of interest to your readers, especially as I am not aware that anyone except myself has noticed it, or, at least, has given it publicity.

The female sun-fish (called, I believe, in England, the roach or bream) makes a "hatchery" for her eggs in this wise. Selecting a spot near the banks of the numerous lakes in which this region abounds, and where the water is about 4 inches deep, and still, she builds, with her tail and snout, a circular embankment 3 inches in height and 2 thick. The circle, which is as perfect a one as could be formed with mathematical instruments, is usually a foot and a half in diameter; and at one side of this circular wall an opening is left by the fish of just sufficient width to admit her body, thus:—



The mother sun-fish, having now built or provided her "hatchery," deposits her spawn within the circular inclosure, and mounts guard at the entrance until the fry are hatched out and are sufficiently large to take charge of themselves. As the embankment, moreover, is built up to the surface of the water, no enemy can very easily obtain an entrance within the inclosure from the top; while there being only one entrance, the fish is able, with comparative ease, to keep out all intruders.

I have, as I say, noticed this beautiful instinct of the sun-fish for the perpetuity of her species more particularly in the lakes of this region; but doubtless the same habit is common to these fish in other waters.

Black Rain.

ON Friday, April 12 last, the rain is stated to have come down black during a thunderstorm at places distributed over a considerable area in the County of Galway, King's County, and County of Tipperary.

I was in England at the time, and after my return to Ireland, on hearing of the rain-water being black in the tanks at a friend's house, I was at first sceptical as to its origin, as a heavy shower after a spell of tolerably dry weather might have brought down much dirt from the roofs, and hence I missed several opportunities of obtaining samples at once.

Finding, however, that other neighbours had noticed the same thing, and that at Golden Grove, near Roscrea, the workmen had observed that not only the water in the barrels was black, and was even next morning "like ink," but also that there was a decided blackness and scum in the pools on the carriage drive, at some distance from any chimney, I was convinced that the blackness had come from the thunder-cloud.

At so great a distance (about 200 miles) from any large smoke-producing town this was somewhat remarkable.

I was able to procure from one place, from near Eyrecourt, Co. Galway, through the kindness of the Rev. C. Lawrence, of Lisreaghan, Eyrecourt, a sample of the water. It is stated to have been of a dark blue colour, but when it reached my hands it had become pale reddish brown, with a considerable amount of solid matter in suspension.

Dr. W. J. Russell, F.R S., has been good enough to examine the sample, which appears to behave in all respects much as London rain water, except in being free from acid reaction (this may be due to previous impurity in the collecting vessel). The amount of sulphates is represented by 0·074 gramme of H_2SO_4, and of chlorides by 0·066 gramme of HCl, in a litre. The solid matter is devoid of structure or of crystalline form, and appears to be soot. The specimen is, however, the less satisfactory from having been taken from near a house where coal has been burnt.

I understand that the rain was black near Shinrone, King's County, and that a few blackish drops were noticed at Dundrum, near Cashel. From Ballymore Castle, near Eyrecourt, where the sample was obtained, to Golden Grove, the distance is about 23 statute miles, and Shinrone is between them. From Eyrecourt to Dundrum is about 48 miles. Mr. Lawrence tells me that the blackness of the rain was noticed by several of his neighbours, and that a laundress kept the water three weeks in the barrels, and had then to reject it, as it was still too much discoloured.

Possibly it may be worth noting that two days before (April 10) there was an intense blackness like that of a moonless night in London, between 12.30 and 1.30 p.m., but I have at present no evidence to connect it with the phenomenon above described.

Athenæum Club, S.W., June 18. ROSSE.

On the Theory of Hail.

IN last week's NATURE (p. 151) Prof. Robinson gives an account of a hailstone that fell at Liverpool on the 2nd instant, consisting of an opaque nucleus, surrounded by almost clear ice, and this by opaque ice.

Hailstones formed of concentric layers, like the coats of an onion, are by no means uncommon. The number of layers has been known to amount to as many as thirteen (*American Journal of Science*, l., 403); but the statement that such a structure is formed, as Prof. Robinson supposes, "during electric oscillation from cloud to cloud," belongs to a theory that has often been disproved. Nor would it probably have excited much attention, but that it originated with no less a man than Volta, who, seeing how pith balls and other light objects oscillated between two metal plates in opposite electrical states, imagined that the hailstone acquired its successive coatings by oscillating between two clouds in opposite states, until its weight became too great for the electric force to sustain it against the gravitating force.

The two most distinguished writers who have examined this theory, and have shown its futility are Kämtz (*Lehrbuch der Meteorologie*, ii. 525) and Becquerel ("Traité de l'Electricité," iv. 151).

The theory of hail which scientific meteorologists now accept, originated with Prof. Olmsted, of Yale College (I have not the reference at hand to the *American Journal of Science*, but see *Edin. New Phil. Journ.*, ix. 244). This theory has received its finishing touches in the papers of the United States Coasts Survey ("Meteorological Researches for the use of the Coast Pilot," Part ii., p. 85, Washington, 1880). The writer is Mr. William Ferrel.

Limiting our notice to such compound hailstones as the one described by Prof. Robinson, which from their size and velocity are the most destructive, and are produced during a tornado or a violent thunderstorm, the following is in few words the theory of their formation. When the wind gyrates rapidly round an axis, more or less inclined to the earth, the space at and about the axis is rarefied. When air charged with vapour is drawn into this rarefied space, it may be condensed into cloud or rain, but at a greater elevation into snow. Now, supposing the rain formed in the lower region to be drawn up by the ascending current into the snowy region, and so held for a short space, the drops will be frozen, and then if propelled beyond the gyrations it will fall to the ground as a shower of ordinary hail. But if in the descent they are again drawn in by the inflowing current, they will be again carried up into the cold region, and so acquire another coating of snow, or, if wetted in the previous descent, the water will freeze into a coat of transparent ice. In this way the globule may make a number of ascents and descents, and acquire a fresh coating each time.

From the date of Franklin's experiments even to our own day, the formation of hail has been attributed to electricity. Even so good an observer as Peltier ("Météorologie," p. 116), while rejecting Volta's theory, offers an electrical theory of his own, with the complacent remark that "Volta a placé des suppositions où je place des faits;" but De la Rive, in noticing Olmsted's theory, very properly remarks that although electricity always accompanies the formation and fall of hail, these two phenomena are not connected as cause and effect.

Highgate, N., June 20. C. TOMLINSON.

Curious Effects of Lightning on a Tree.

DURING the recent thunderstorms a large elm-tree was struck by lightning in a private park at Dulwich, but the only visible effects were linear interrupted grooves about ¾ inch deep, extending down one side of the tree to the ground, where two or three depressions some 3 inches deep were found. The bark is scooped out as clearly as if done with a gouge, and the intervals are from 1 to 2 feet in length, while the grooves themselves are from 1 to 3 feet in length. The grooves are now filled with mildew, which, I take it, indicates the death of the adjacent bark. I have often seen trees which have been struck by lightning, but none in which the effects have at all resembled those I have described. ALFRED S. GUBB.

Gower Street, W.C.

The Formation of Cumuli.

A VERY perfect illustration of the method of formation of cumuli was noted by the writer recently. A perpendicular column of smoke was seen capped at a vast height by a rounded mass of cumulus cloud having a flattened under surface. The ascending warm current being traceable by the smoke, and the cloud-cap very distinct and persistent, the appearance was very striking, the sky in the vicinity being intensely blue and otherwise cloudless. M. A. VEEDER.

Lyons, N.Y., June 10.

Coral Reefs.

THE business of the surveyor abroad is not with theories. It is to collect facts; to apply the resources under his command to the delineation of the earth's surface; and to examine the bottom of the ocean. When he begins to theorize, he may be suspected with some reason of bias, and of insensibly colouring his reports with preconceived notions of what he expected to find, instead of carefully storing up evidence. He is, however, at liberty to study the writings of our great naturalists, and to him Darwin is, at present, the great authority: not so much the young naturalist of the *Beagle*, as the matured thinker who, after forty years of deep research into various problems of Nature, published that edition of "Coral Reefs" which has been before the world for the last fifteen years.

With your permission, I desire to ask two or three questions of those gentlemen who are unable to reconcile their views with Mr. Darwin's theory of subsidence.

The Fiji Islands present the most complete collection of coral reefs in the world. We have there the fringe reef, the barrier, and the atoll; islands which have a barrier all around them, others where it is sunken on one side; the island, such as Lakemba, where there is a fringe on one side and a barrier on the other; as Thithia, which is surrounded by fringe only. There are extinct craters, such as Fulanga, and islands with exterior rim and depression in the centre, the formation of which is apparently not due to the volcanic action; islets on the edge of atolls like Ngele Levu which are wholly coral, others of coral in the centre of lagoons. In the same locality may be found islands which have a fringe to windward and barrier to leeward, and those which have a fringe to leeward and a barrier to windward. One island which is about the size of Jamaica, has a fringe on one side and an extensive barrier on the other. Shells and coral have been found at great heights, and there are many evidences of upheaval. One small island, called Vatu Leile, appears to be raised on one side and depressed on the other; the raised coast is lined with a fringe-reef, the submerged by a barrier.

In the Lau group, there are two fine barrier reefs—those of the Exploring Isles and the Bukatatanoa. Inside the lagoons of these and other reefs, there are an infinity of coral banks with various depths of water over them, many being mushroom-headed.

The prevailing wind throughout the Fiji group is east-south-east. Unquestionably the coral is in most vigorous growth where there is the most violent surf; and no matter what the current, it is in least vigorous growth on the lee or north-west side.

I believe that it is not inconsistent with the theory put forward by Mr. Darwin that, in the same group, some islands should be rising and some falling at the same time; nor that an island should have fallen to a certain level and have then undergone a movement of upheaval. If this be so, there is nothing, as far as one can see, in the Fiji group which disproves subsidence as the origin of barrier reefs. The questions which I desire to ask are these:—

How does Dr. Guppy account for the remarkable similarity in many instances in this group, between the shape of the barrier reef and that of the coast of the island within it? As examples, I would point to the islands of Nairai and Ngau, and to the correspondence in form between the north-east horn of the barrier of the Exploring Isles and the nearest cape of Vanua Mbalavu with its off-lying islets.

In the case of the Bukatatanoa reefs, how does he account for this great rim being all much on the same level, except by the supposition that it commenced its growth on the same contour? or for the cleanly-cut ship channels which occur on the *weather* side of some of the barriers, except by the supposition that the growth was originally checked by the streams from the land?

It is, I believe, universally admitted that there are large areas of elevation—such, for instance, as the New Hebrides—and corresponding areas of depression. What form, does Dr. Guppy suppose, is assumed by the growing coral on the coasts of the descending islands?

Let me draw attention to Kandavu. To the north of this island there is a barrier reef inclosing a chain of islands of volcanic origin, and gradually decreasing height. The most northerly islet, which is a mere rock (now surmounted by a lighthouse), stands in the centre of a circular barrier of great symmetry. The highest part of Kandavu is over the western end, and here there is comparatively little coral. Has not this group every appearance of a range of mountains, the northern half of which is sinking beneath the ocean? There are many strings of islands in Fiji and eleswhere the position and coral surroundings of which seem to be accounted for only by the theory of subsidence.

Mr. Darwin did not visit Fiji; but it is worthy of note that Mr. Dana spent five months there, and enjoyed peculiar advantages of examination, and that he left it convinced of the general truth of Mr. Darwin's theory.

8 Ashburton Road, Southsea. W. USBORNE MOORE.

Hydrophobia.

I THINK it cannot fail to interest some of the readers of NATURE to know what is written "in the Talmud of old—in the legends the Rabbins have told" about this baneful malady. I have therefore translated a fragment preserved in this ancient work, which, read through the mist of ages and wrapped in the garb of expressions and ideas of a long-ago past, may be of value to the antiquarian, and perhaps not wholly uninteresting to the man of science. A. D.

June 11.

"It is not permissible to give to a person bitten by a mad dog from the lobe of the mad dog's liver, but Rabbi Matya, the son of Hheresh, considers it permissible"[1] ("Mishna," "Tractate Yoma," p. 83).

[1] The subject of hydrophobia is introduced quite incidentally, the question in dispute between the "Mishna" and R. Matya being whether the patient might eat of the mad dog's liver upon the fast of the Day of Atonement, and the difference of opinion is in consequence of the prescribed remedy being held to be only imaginary on the one side, and a real one on the part of R. Matya.

"He who is bitten by a mad dog, &c." The Rabannan have learnt that there are five indications of rabies, viz. open mouth, dripping saliva, elongation of ears, tail resting on buttocks, and wandering along the sides of the streets. There are some who add barking without sound. How does this come about? Rav says that witches have practised their sorceries upon them, and Samuel says an evil spirit has rested upon them.

What deduction may be made from this difference of opinion? That the mad dog should be killed by means of a weapon hurled from a distance, for in accordance with the view held by Samuel we learn that the dog, when killed, should be despatched from a distance. He who has come into contact with a mad dog by the animal brushing against him is in danger, and he who has been bitten by a mad dog is in peril of his life.

"He who has come into contact, &c." What precaution should he take? He should divest himself of his robes and *run*. Rav Huna, the son of Rav Joshua, came into collision with a mad dog in the street. He threw off his robes and ran, exclaiming, "I illustrate in my own person the Scriptural verse, 'And wisdom is a source of life to those who possess her.'"

"He who is bitten, &c." What precaution should he adopt? Abaya says he should obtain the skin of a male ape and write thereon, "I, so and so, the son of so and so, write upon thee, 'Kanti, Kanti, Kiloroth,'"[1] and those present should respond "Kandi, Kandi, Kiloroth,[1] the Lord, the Lord, the Lord of Hosts, Amen, Amen, Selah." He should then throw off his clothes and bury them in the burial-place for twelve months, after which he should recover them and burn them in a furnace, scattering the ashes across the roads.

During these twelve months, if he should drink water he should do so only through a copper tube, otherwise he might see the reflection of the demon in the water held in the vessel, and suffer dangerous consequences.

It is said of Aba, the son of Matya (he is Aba, the son of Menimah), that his mother made for him a tube of gold ("Gemara," "Tractate Yoma," p. 84).

SIR LYON PLAYFAIR ON UNIVERSITIES.

WE congratulate Sir Lyon Playfair on the admirable speech he delivered last week in the House of Commons on the Scottish University Bill. It was a powerful and luminous exposition of the true functions of Universities, and of the duty of the State with regard to the highest departments of education.

Speaking of the fact that the adaptation of degrees in Scotland had not followed the steady improvement in the education of the people, Sir Lyon Playfair said:—

"Degrees remained much as they were two or three centuries ago. The University was not a technical school, but a school to introduce culture into the professions. Unless that culture were introduced there was no justification for professional schools in the Universities. The *via antiqua* ought to be replaced by a *via moderna*. The Commission of 1878 proposed to open five gateways of knowledge—the gateways of literature and philology, of philosophy, of law and history, of mathematical sciences, and of the natural sciences. Now there was a great difference between the Universities of rich and of poor countries. The Universities of poor countries must rest on the professions. The rich men of Scotland went to Oxford and Cambridge, whereas those who attended the Scotch Universities had to earn their bread by a profession. Unhappily those professions were now being taught without culture; that was, with the exception of theology, the men went through the technical part of their education without taking a degree in arts, though there was a sort of matriculation examination, which did not represent a very high degree of culture. In that way the great medical schools were technical schools which gave length but not breadth of education. One of the greatest reforms to be attained was to carry out the recommendations of 1878 so that, by proper courses in arts, culture might be restored to the professions."

Sir Lyon Playfair spoke as follows about the provision

[1] The meaning of these words is lost.

Nature June 27th 1889

Engraved by G. J. Stodart from a Photograph by Warwick Brookes

London, Macmillan & C.

made in the Bill for an increase in the vote for the Scottish Universities:—

"The increase of £13,000 in the vote was no striking example of Parliamentary generosity when measured by the efforts of other countries. Reference had been made to what had been done in Holland, a country with a revenue of nine millions, and a population about the same as that of Scotland. Holland gave £136,000 to her Universities. The case of France was equally striking. The French Institute discussed for a whole week why it was that the great crisis in her history produced no men of ability in France. The decision they came to was that the reason was to be found in the decay of the provincial Universities. Since that time the French Government had spent £3,280,000 on the provincial Universities, and voted half a million a year for their support. Then Germany had spent £711,000 in order to build and equip the University of Strasburg, which they endowed with £46,000 a year. This country must be prepared to spend more money on higher education not only in Scotland, but in England. Modest, however, as was the proposal of the Government, he was rejoiced at the disappearance of the abominable finality clause. There was no finality in knowledge or the progress of science. Notwithstanding the stern aspect of the Chancellor of the Exchequer, we could not help ourselves. We must be prepared to adequately support our Universities, and to make sufficient provision for higher teaching in all our great towns. Though he thought the provision inadequate for what the Bill proposed, he had perfect confidence in the generosity of Parliament that, having begun the reform of the Scotch Universities, they would take care that the reform was thoroughgoing. In the Scotch Universities, while the number of students was very large relatively to the number of teachers as compared with, say, the German Universities, they had one Professor for one single subject. For the Chair of Chemistry in Edinburgh, for example—a chair which he had had the honour to hold—there was but one Professor, whereas in any moderate-sized German University there were four or five. They must add largely to the teaching staff of the Universities in Scotland if they expected them to become prosperous. . . . The teaching Universities in England had one student to 3500 of the population; in Ireland there was one student to 2040 of the population; while in Scotland there was one University student to 580 of the population. Therefore, the roots of University education had gone seven times wider and broader among the people of Scotland than they had done either in England or in Ireland. The object had always been to try and evolve brain power from all capable citizens, and it was this which had made Scotland what it was. Nevertheless, it was his deliberate opinion that Scotland was decidedly behind England in education. The English Universities had been adapting themselves to the changing conditions of the world very largely, and the Scottish Universities had been remaining behind in modern wants altogether. The lion rampant in Scotland had been standing on its hind legs pawing the air, while the lion passant with its fore-feet on the ground had been going ahead; and it was because of that consideration that he was extremely anxious to see this Bill pass into law."

THE OXFORD UNIVERSITY OBSERVATORY.

THE Savilian Professor of Astronomy, in his Annual Report, read on June 5, thus refers to the work done:—

In addition to the statutable lectures, four others were given on the recent speculations concerning the construction of the sidereal universe, in relation to possible meteoric collisions.

The renovation of the macro-micrometer, mentioned in the last Report, has been completed by Mr. Simms, who originally constructed it; and it has since been in constant use. The mounting of the De la Rue instrument has been provided with a slow motion in right ascension, of a peculiar and delicate construction, and set in motion by electro-magnets; the driving-clock also has been thoroughly renovated in the parts which exhibited the effects of wear. The object of all these extensive improvements is to make it possible to expose photographic plates during those lengthened periods of several hours, rendered necessary for the purposes of the recent modifications of astronomical inquiries. These improvements have been so recently effected, and the twilight is at present so protracted, that it has not yet been possible to fully test their practical efficiency on the skies.

The mounting of the Grubb equatorial has been completed. It is now furnished with automatic driving apparatus of the most modern and efficient construction, well worthy of the high reputation of its eminent constructor. The visual object-glass has been refigured, and is now in a greatly improved condition. The tube of the photographic telescope is *in situ*, but the object-glass of 13 inches' aperture, meeting the conditions required by the International Congress, has not yet been supplied by the maker. Two experimental object-glasses have, however, been already examined, but their performance did not prove satisfactory. Prof. Pritchard is now expecting the speedy arrival of a third, which, he is assured by Sir Howard Grubb, will relieve him from further anxiety, and place him in a position to prosecute the essential preliminary operations necessary for the International scheme.

All these important renovations and additions, so necessary to practical astronomy in its present phase, have been provided by the unsolicited generosity of the late Dr. De la Rue. Prof. Pritchard expresses deep regret —which he has no doubt is shared by the Board of Visitors—that their lamented and munificent friend did not live, as he had hoped, to see the fulfilment of his anticipations in connection with this judicious expenditure.

The first extensive series of the observations connected with the new application of the photographic method to stellar parallax, as applied to stars of the second magnitude in the northern hemisphere, has been brought to a conclusion, and is now, through the liberality of the Delegates of the University Press, in course of printing. The volume, it is hoped, will be distributed among astronomers in the course of a few weeks. It comprises no less than thirty distinct determinations of stellar parallax: these are applied to eight stars, referred in most cases to four faint stars of comparison. Progress also has been made in the continuation of the like observations to other stars connected with the general scheme. Prof. Pritchard has had the gratification of finding that this method of parallactic determination, which was originally devised at Oxford, is in process of adoption at other well-known Observatories.

At the request of Dr. Gill, he proposes to assist in a scheme of photographic observation of the minor planet Victoria, for the determination of solar parallax during the present summer; efficient assistance, however, can be rendered in this direction only on the condition of the arrival of a satisfactory object-glass from Dublin.

He has been engaged in the examination of a Wedge photometer for the Observatory of Pulkova at the instance of its eminent Director. It is not without some satisfaction that he finds that this method of photometry is likely to be employed in other Observatories.

The Director states that the various operations mentioned above could not have been thus efficiently completed without the continuous and intelligent co-operation of the two able assistants, Mr. W. E. Plummer and Mr. C. A. Jenkins. It has been a source of great gratification to him that Mr. Plummer's ability has been recognized by the Royal Astronomical Society in their selection of him for a seat on their Council.

JOHN PERCY, M.D., F.R.S.

BY the death of Dr. Percy, on the 19th inst, this country has lost a distinguished man, who has greatly influenced its metallurgical progress.

He was born in 1817, and at an early age entered the Medical School of the University of Edinburgh, where, at twenty-one, he took the degree of M.D. He subsequently became Physician to the Queen's Hospital at Birmingham, and the few papers he published on medical subjects show that he would probably have risen to eminence in medicine had it not been for the fact that in the great metallurgical centre of the Midlands his studies were soon diverted to the particular line of work to which his life was ultimately devoted. This is not perhaps surprising when it is remembered that the connection between therapeutics and metallurgy has been traditional since the days of Paracelsus and Agricola.

When we look back at Dr. Percy's career, the remarkable fact stands out that notwithstanding the great importance of metallurgy to this country, with its vast industrial interests, there was no metallurgical treatise worthy of the name until he wrote one; and, what is stranger still, up to the time when he accepted the chair in the Royal School of Mines, in 1851, there was no systematic teaching of metallurgy. Dr. Percy found it practised mainly as an empirical art. Sir Henry de la Beche indicated the direction the teaching had to take, and in his inaugural discourse as Director of the School of Mines, he said, "We still too frequently hear of practical knowledge as if, in a certain sense, it were opposed to a scientific method of accounting for it, and as if experience without scientific knowledge were more trustworthy than the like experience with it." Reference to the pages of the Journal of the Iron and Steel Institute will show that this, the most practical body of men in the world, not only thoroughly recognizes that mere empiricism would be fatal to industrial success, but constantly appeals to science for guidance. This is in great measure owing to Dr. Percy's teaching, and is not the least important of its results.

Ten years after he began to teach, he published the first volume of his treatise on "Metallurgy," which he dedicated with "sincere respect and affectionate regard" to Faraday. This work, which he calls the "task of his life," has developed into a series of volumes containing 3500 octavo pages. One remarkable feature of these books is that almost every woodcut may be regarded as an accurate, though small, mechanical drawing, and it is only measurable drawings of this kind which are of real utility in practice. Treatises such as his naturally embody descriptions of processes furnished by those actually engaged in conducting the operations—aid which was always most fully acknowledged. The thoroughness of his own research is well shown by the careful digests of monographs, which were gathered from all kinds of sources; and it is evident that immense pains were bestowed upon the work. Some years ago a foreign friend, himself a laborious and conscientious author, forcibly expressed to the writer his appreciation of Dr. Percy's labours, looking up from one of the volumes and exclaiming, "*C'est énorme ce qu'il a compilé.*"

It may perhaps be admitted that his intolerance of inaccuracy at times led him to magnify points which now seem to be somewhat trivial, and he sometimes withholds the expression of his own opinion when the reader has fairly a right to expect it, and would be grateful for the support of his authority.

With the notable exception of a process for the extraction of silver from argentiferous ores and residues, he can hardly be said to have originated any important metallurgical process; but his works teem with suggestions, and many improvements in metallurgical practice can be directly traced to his teaching. Such is the case with the practical application of the basic process for eliminating phosphorus in the Bessemer converter—a process of truly national importance, and one which has been widely adopted in other countries. It may fairly be claimed that during the thirty years he held his chair he trained a body of scientific workers in whose hands the immediate future of metallurgy to a great extent rests.

Remarkable evidence as to the strength of his individuality is afforded by the fact that those who were admitted to his friendship, and even his students who only saw him in the lecture-room or laboratory, were all singularly attracted to him, notwithstanding the occasional ruggedness of his manner. The purity of his style and the quaintness of his illustration recall the writings of another doctor, Sir Thomas Browne, making, of course, due allowance for the difference of the periods at which they wrote. The subjects he dealt with were very diverse, and it would be interesting to collect his trenchant letters, which appeared in the *Times*, usually over the signature Y. One especially occurs to the writer. Dr. Percy was charged with the superintendence of the ventilation of the Houses of Parliament, and amusingly describes his difficulties in meeting the varied and often contradictory requirements of the members, as to the temperature best suited to their work. He was an honorary member of the Institution of Civil Engineers, and held the office of President of the Iron and Steel Institute in 1885, having received the Bessemer Medal of that Institute in 1877. His artistic skill was considerable, and he possessed a fine collection of water-colour drawings.

Two days before his death the Prince of Wales awarded him, on the nomination of the Council, the Albert Medal of the Society of Arts. Dr. Percy was still able to appreciate the honour which had been done him, and received the intimation with the characteristic words, almost his last, "My work is done."

W. C. ROBERTS-AUSTEN.

HENRY WILLIAM BRISTOW, F.R.S.

MR. BRISTOW'S death, which we briefly chronicled last week, requires a fuller notice. With him passes away one of the gentlest and most courteous of English geologists—one whose associations connected him with the magnates of geology in the early decades of this century, and whose death breaks another of the links that unite us personally with that heroic time. Born in 1817, he was the only son of Major-General H. Bristow, a distinguished officer, who devoted himself to the cause of Spain, where he died, and received the honours of a public funeral. Mr. Bristow suffered from an inveterate deafness. An old school-fellow, speaking of his boyish days not long ago, remarked that he was as deaf then as he was even late in life. This ailment was undoubtedly a life-long hindrance to him, for it kept him from mingling as freely among his associates, and taking so public a part, as his tastes and abilities would have prompted and fitted him to do.

When twenty-five years of age, he joined the Geological Survey under Sir Henry De la Beche, and he remained in that department of the public service for the long space of forty-six years. Most of his scientific work was done for the Survey, and is to be found in the official maps, sections, and memoirs. It is thus, perhaps, less generally known than that of some of his colleagues who have published communications in the more widely circulated scientific journals. To those, however, who can appreciate accurate and artistic mapping, the work which he did, more particularly among the Secondary rocks of

Dorsetshire and the Isle of Wight, will always possess a special value and charm. It was among the earliest work of its kind, and to this day may be taken as a model of admirable geological cartography. His memoirs, too, are remarkable for their lucidity of statement and clear presentation of fact; also for a certain literary and antiquarian flavour thoroughly characteristic of the author.

In the last fifteen or twenty years of his official life Mr. Bristow's time and thought were mainly given to the duties of administration required by the high appointments to which he was promoted. Under Sir Roderick Murchison he became one of the two district-surveyors charged with the immediate supervision of the field-work in England and Wales, and on the death of that chief and the promotion of Sir Andrew C. Ramsay to succeed him, Mr. Bristow was appointed Senior Director, an office which he held until his retirement last summer.

Yet in spite of the pressure of his official duties, which grew greater as years advanced, Mr. Bristow contrived to find leisure for various pieces of literary work. Perhaps the best known and most useful of them was his "Glossary of Mineralogy,"—a volume which has long been out of print, and in the preparation of a new edition of which he looked forward to employ himself during the present year. He also edited translations of Figuier's "La Terre avant le Déluge" and Simonin's "La Vie souterraine," besides furnishing mineralogical and geological articles to Brande's "Dictionary of Science, Literature, and Art," to Ure's "Dictionary of Arts, Manufactures, and Mines," and to the geological journals. But it is on his contributions to the Geological Survey that his scientific reputation will mainly rest. His last work was the revision of the proof-sheets of a new edition of his classic memoir on the "Geology of the Isle of Wight"—a volume which is now in the press. He did not live to see its publication, and to receive the congratulations of his friends on its appearance as the crowning work of his scientific career. Mr. Bristow has carried with him to the grave the affectionate regrets of his colleagues and of all who ever came in contact with his genial kindly nature.

NOTES.

DR. ARCHIBALD GEIKIE has been elected a corresponding member of the Physical and Mathematical Section of the Royal Academy of Science, Berlin.

ON Thursday last, the 20th inst., a dinner was given in Paris to Prof. Francis Darwin, by the members of Scientia, a group of French men of science, who are accustomed to meet once a month at a friendly dinner, and to invite a distinguished guest of scientific renown. This dinner was the fourteenth since the foundation of the Society, and among the guests have been MM. Pasteur, de Lesseps, Eiffel, Renan, Janssen, Berthelot, and Chevreul. Mr. F. Darwin was the first foreign guest of the Society. The dinner was attended by many eminent scientific men, among whom were MM. Marey, the physiologist, acting President, Eiffel, de Brazza, Richet, de Lesseps, Giard, and some fifty others. Prof. Marey, in very appropriate terms, recalled the great achievements of Charles Darwin, and spoke enthusiastically of the doctrine of evolution—a fact worthy of note, when it is remembered that Prof. Marey is a member of the Institute. Mr. Darwin expressed cordial thanks for the honour conferred upon him, but, in the opinion of most of the members, adopted too modest a tone. His "Life and Correspondence of Charles Darwin" has won for him high rank in the esteem of the French scientific public.

THIS year the summer meeting of the Institution of Mechanical Engineers will be held in Paris. It will begin on Tuesday, July 2. The following papers have been offered for reading and discussion:—Description of the lifts in the Eiffel Tower, by M. A. Ansaloni, of Paris (this paper will be supplemented by results of working to date, communicated verbally by M. Gustave Eiffel, President of the Société des Ingénieurs Civils); the rationalization of Regnault's experiments on steam, by Mr. J. Macfarlane Gray, of London; on warp weaving and knitting without weft, by Mr. Arthur Paget, Vice-President, of Loughborough; on gas-engines, with description of the Simplex engine, by M. Edouard Delamare-Deboutteville, of Rouen; on the compounding of locomotives burning petroleum refuse in Russia, by Mr. Thomas Urquhart, Locomotive Superintendent, Grazi and Tsaritsin Railway, South-East Russia; description of a machine for making paper bags, by Mr. Job Duerden, of Burnley, communicated through Mr. Henry Chapman, honorary local secretary.

WITH reference to the proposed visit of geologists to the volcanic regions of Italy next October—a scheme to which we referred last week—Dr. J. Foulerton, Secretary of the Geologists' Association, writes to us that the excursion will be under the direction of Dr. H. J. Johnston-Lavis, of Naples, assisted by eminent Italian geologists. Anyone desiring further information on this subject should communicate as early as possible with Dr. Foulerton, at 44 Pembridge Villas, Bayswater, W., sending a stamped and addressed envelope for reply.

AT a meeting on Friday last of the Council of the University College of North Wales, it was decided to open an Agricultural Department at the College in October, and steps were taken with a view to the appointment of a Lecturer in Agriculture. It was stated that the proposal for the formation of dairy schools in connection with the College had met with much support.

FROM the Annual Report of the Principal of the Owens College, Manchester, read on Friday last, at the meeting for the distribution of honours and prizes, it appears that the total number of students has increased during the year from 1269 to 1297, and of these no fewer than 380 are in the Medical School. The number of associates elected during the year was 33: the associates, of whom there are now more than 300 on the roll, are *alumni* of the College, and are only elected after taking a degree at a University. It appears also that during the last year 104 Owens College students passed in arts, science, and law, and 57 in medicine, at the Victoria University. In the London University 51 Owens College students passed in arts, science, and law, and 24 in medicine. Reference was naturally made to the liberal gifts to the College by Sir Joseph Whitworth's legatees. A considerable portion of the most recent extension of the College buildings is devoted to the housing of the old Manchester Natural History and Geological Museums, and the additions made to them since they were handed over to the College. In addition to the sum of £3000 previously given, the Whitworth legatees extended their gift by the further benefactions of £25,000 to the Museum Building Fund, and of £10,000 in augmentation of the Museum Trust Fund.

PRIZES will be distributed at the Medical School, St. Thomas's Hospital, on Tuesday, July 2, at 4 o'clock in the afternoon, by Sir Henry Doulton, almoner of the hospital.

A MEETING of the National Health Society is to be held on Saturday, June 29, in the Town Hall, Westminster, when the Society's certificates gained during the year for proficiency in "domestic hygiene," "sick nursing," and "first aid to the injured," will be presented to the candidates by the Duchess of Westminster.

THE large herbarium of Fungi, transferred by Dr. M. C. Cooke to the Herbarium of the Royal Gardens, Kew, is now for the most part incorporated with the previous collection. The total number of specimens reaches to 46,000, being nearly double that of the Berkeley Herbarium; and these, approximately, represent—

Hymenomycetes	11,000
Gasteromycetes and Myxogastres	2,000
Ustilagines and Uredines	6,000
Discomycetes	6,000
Pyrenomycetes	12,000
Incompletæ...	9,000

The number of species has not been calculated. A large number of these are types, and others as important as types; such, for instance, are the individual specimens used in the illustration of "Mycographia." The entire collection is a most valuable addition to the national collection at Kew, containing as it does contributions from most of the mycologists of the past forty years—Berkeley, Broome, Bloxam, Cesati, Currey, Curtis, De Notaris, Duby, Ellis, Fries, Kalchbrenner, Leveillé, Montagne, Peck, Ravenal, Rabenhorst, Westendorp, Winter, &c., &c.

In a British official Report on Brazil, which has just been laid before Parliament, reference is made to the Pasteur Institute founded at Rio de Janeiro on February 9, 1888. Out of 106 persons treated between then and January 8, 1889, only one died, viz. a child who only attended ten times out of twenty-three attendances ordered. In sixty-two instances the dog biting the people treated at Rio was recognized as undoubtedly mad. Besides the 106 cases, 130 other persons were sent away as having nothing the matter with them.

The National Association for the Promotion of Technical Education has reprinted the excellent series of "Opinions of Practical Men" on the industrial value of technical training, which lately appeared in the *Contemporary Review*. A prefatory note is contributed by Lord Hartington.

We regret to announce the death of Signor G. Cacciatore, Director of the Palermo Observatory. He died on June 16, in his seventy-sixth year.

Prof. Oscar Howard Mitchell, of Marietta College, U.S.A., died at Marietta on March 29, in his thirty-eighth year. Prof. Mitchell did some mathematical work which excited the warm admiration of Prof. Sylvester, whose pupil he had been. Of two papers by him in the *American Journal of Mathematics*, Prof. Sylvester wrote: "I should have been very glad, not to say proud, to have been the author of them."

Early on Saturday morning an earthquake occurred at Watts Town, in the valley of the Little Rhondda. A shock, which was accompanied by a rumbling noise, shook the walls of houses, and caused the inhabitants to run into the streets in alarm. Crockery was broken, and in one instance children were thrown from their beds. At Pontygwaith the shock was severely felt. Mr. Davis, of Penrhys Cottage, says he was alarmed by the noise, and thought it a more than usually violent explosion in one of the collieries which abound in the valley. The walls of his house shook so that he thought the place was coming down, and he ran into the street. The scene in Llewellyn Street was one of the wildest confusion, women and children partly undressed running hither and thither, the greater number of them being of Mr. Davis's opinion that an explosion had occurred. A considerable time elapsed before the people were induced to go back to bed. The weather had been exceedingly sultry for some days.

We learn from the *American Meteorological Journal* that the Chief Signal Officer, Washington, has issued the following instructions relating to weather predictions for two or three days:—"In view of the great importance of long-time weather predictions to the business interests of the country, it is hereby directed that, on and after May 1, 1889, the Indications Official shall make, whenever practicable, a general prediction, showing the condition of the weather two or three days in advance. This class of long-time predictions will be confined to such occasions and such sections of the country as from peculiar and persistent meteorological conditions seem to urge successful forecasts. These predictions will not be too much in detail, but will clearly set forth the section of the country for which they are intended, and the days of the week which they will cover. . . . In making these long-time forecasts, the language should be varied according to the necessities of the occasion, but should always be in such form as to convey clearly to the general public the opinions of the Indications Official, and also the degree of positiveness that attaches to his opinions."

Krüss and Schmidt's statement that both nickel and cobalt contain a small percentage of a hitherto unknown element—gnomium—amounting in the case of one specimen of nickel to as much as 2 per cent. (*Ber. der deut. chem. Gesellsch.*, xxii. 11; Nature, vol. xxxix. p. 325), has not been permitted to pass unchallenged, and quite recently two papers have appeared which tend to show that the supposed new element is non-existent. At the time when they were led to recognize the presence of this common impurity, Krüss and Schmidt were engaged in repeating Winkler's old determination of the atomic weights of nickel and cobalt, in which the ratio Au : Ni or Au : Co was arrived at from the amount of gold precipitated by these metals from neutral solutions of gold chloride. Winkler, in the meantime, has repeated this work with carefully purified materials (*Ber. der deut. chem. Gesellsch.*, xxii. 890), and has not only failed to obtain any evidence of the existence of gnomium, but moreover calls in question the purity of the metallic specimens employed by Krüss and Schmidt. A communication from Dr. Fleitmann to the *Chemiker Zeitung* (xiii. 757) lends considerable support to this view. Adopting the method patented by Krüss and Schmidt for separating this common impurity from nickel and cobalt by extracting the hydroxides of these metals with sodium hydroxide, Fleitmann has examined a number of specimens of commercially pure nickel and cobalt, and, so far from obtaining 2 per cent. of gnomium oxide, has failed to isolate from 50 grammes of material a weighable amount of any impurity which would serve to justify the view that a hitherto unknown element was associated with these metals. Fleitmann points out that when the hydroxides of commercially pure nickel and cobalt are treated with large quantities of sodium hydroxide, impurities go into solution which vary in composition and amount with the source and degree of purity of the metals; these impurities consist of small quantities of the oxides of lead, zinc, arsenic, manganese, molybdenum, silicium, aluminium, cerium, chromium, &c., together with an amount of nickel or cobalt oxide not exceeding 1/20 per cent. of the hydroxide extracted, and when separated from the alkaline solution by the addition of an acid and subsequent precipitation with ammonium carbonate give rise to a highly complex mixture of oxides and acids which can only be separated and identified with considerable difficulty. It is not improbable, therefore, that Krüss and Schmidt have been dealing with some of the constituents of this mixture, and that on further examination gnomium oxide will prove to be a mixture of the oxides of elements already known.

We learn from the *Daily Inter-Ocean*, of Chicago, that Lieutenant Schwatka has reported the discovery of a large tribe of cave-dwellers in the unexplored regions of Northern Mexico. Their abodes are exactly like the old, abandoned cliff-dwellings of Arizona and New Mexico. So wild and timid were the inmates that it was hardly possible to get near them. Upon the approach of white people they usually fly to their caves or cliffs by means of notched sticks placed against the face of the cliffs. They can also ascend perpendicular cliffs without the use of these sticks if there are the slightest crevices for their fingers and toes. A number of children, playing in a deep cañon, were interrupted, and immediately fled to the low brush and rocks and could not be found, hiding as completely as young quail. These cliff-dwellers are usually tall, lean, and well formed, their skin being very blackish-red, much nearer the colour of the negro than the copper-coloured Indian of the United States. They are said to be sun-worshippers.

In response to demand, a new edition of Prof. A. Gray's small work on "Absolute Measurements in Electricity and Magnetism" will be issued immediately by Messrs. Macmillan and Co. The whole work has been very carefully revised, and several alterations and additions made, which it is hoped will bring it into accordance with the present state of practical electricity, and render it still more useful to students and electrical engineers. The preparation of the second volume of the same author's larger treatise on the same subject is being pushed on at the same time as quickly as possible.

Part VI. of the "Catalogue of the Moths of India," by Colonel Swinhoe and Mr. E. C. Cotes, has just been issued. It deals with *Crambites* and *Tortrices*, and there is also a list of "addenda."

The Elizabeth Thompson Science Fund, established by Mrs. Elizabeth Thompson, of Stamford, Connecticut, "for the advancement and prosecution of scientific research in its broadest sense," now amounts to $25,000. The trustees of the Fund have issued a circular, stating that, as accumulated income is again available, they desire to receive applications for "appropriations" in aid of scientific work. This endowment is not for the benefit of any one department of science, but it is the intention of the trustees to give the preference to those investigations which cannot otherwise be provided for, which have for their object the advancement of human knowledge or the benefit of mankind in general, rather than to researches directed to the solution of questions of merely local importance. Applications for assistance from the Fund, in order to receive consideration, must be accompanied by full information, especially in regard to the following points: (1) precise amount required; (2) exact nature of the investigation proposed; (3) conditions under which the research is to be prosecuted; (4) manner in which the appropriation asked for is to be expended. All applications should be forwarded to the Secretary of the Board of Trustees, Dr. C. S. Minot, Harvard Medical School, Boston, Mass., U.S.A. It is intended to make new grants at the end of 1889. The trustees are disinclined, for the present, to make any grant exceeding $500; preference will be given to applications for smaller amounts. The following is a list of the grants hitherto made:—(1) $200 to the New England Meteorological Society, for the investigation of cyclonic movements in New England (results published in the *American Meteorological Journal* for 1887 and May 1888); (2) $150 to Mr. Samuel Rideal, of University College, London, England, for investigations on the absorption of heat by odorous gases; (3) $75 to Mr. H. M. Howe, of Boston, Mass., for the investigation of fusible slags of copper and lead smelting; (4) $500 to Prof. J. Rosenthal, of Erlangen, Germany, for investigations on animal heat in health and disease (results published in the *Sitzungsber. k. Akad. Wiss.*, 1888, 1309–19; 1889, 245–254; *Arch. Anat. u. Physiol. Suppl.*, 1888, 1–53); (5) $50 to Mr. Joseph Jastrow, of the Johns Hopkins University, Baltimore, Md., for investigations on the laws of psycho-physics; (6) $200 to the Natural History Society of Montreal, for the investigation of underground temperatures; (7) $210 to Messrs. T. Elster and H. Geitel, of Wolfenbüttel, Germany, for researches on the electrization of gases by glowing bodies (results published in the *Sitzungsber. k. Akad. Wiss. Wien.*, xcvii., Abth. 2, 1175–1264, 1889); (8) $500 to Prof. E. D. Cope, of Philadelphia, Penn., to assist in the preparation of his monograph on American fossil Vertebrates; (10) $125 to Mr. Edw. E. Prince, of St. Andrews, Scotland, for researches on the development and morphology of the limbs of Teleosts; (11) $250 to Mr. Herbert Tomlinson, of University College, England, for researches on the effects of stress and strain on the physical properties of matter; (12) $200 to Prof. Luigi Palmieri, of Naples, Italy, for the construction of an apparatus to be used in researches on atmospheric electricity; (13) $200 to Mr. Wm. H. Edwards, of Coalburg, W. Va., to assist the publication of his work on the butterflies of North America (results published in the "Butterflies of North America," third series, Part 5); (14) $150 to the New England Meteorological Society, for the investigation of cyclonic phenomena in New England; (15) $25 to Prof. A. F. Marion, for researches on the fauna of brackish waters; (16) $300 to Prof. Carl Ludwig, for researches on muscular contraction, to be carried on under his direction by Dr. Paul Starke; (17) $200 to Dr. Paul C. Freer, for the investigation of the chemical constitution of graphitic acid; (18) $300 to Dr. G. Müller, for experiments on the resorption of light by the earth's atmosphere; (19) $300 to Prof. Gerhard Krüss, for the investigation of the elementary constitution of erbium and didymium; (20) $50 to Dr. F. L. Hoorweg, for the investigation of the manner and velocity with which magnetism is propagated along an iron bar; (21) $150 to Mr. W. H. Edwards, to assist the publication of his work on North American butterflies.

The additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Captain M. S. Riach, 79th Highlanders; a Macaque Monkey (*Macacus cynomolgus*) from the Nicobar Islands, presented by Mr. W. J. McCausland; a —— Wild Dog (*Canis* ——) from Bangay, Bornean Group, presented by Mr. C. T. Kettlewell; a Grey Parrot (*Psittacus erithacus*) from West Africa, presented by Miss L. Davy; a Redwing (*Turdus illacus*), British, a Red-legged Partridge (*Caccabis rufa*), European, presented by Mr. J. C. Clayton; a Purple-crested Touracou (*Corythaix porphyreolophus*) from East Africa, presented by Miss Dolly Kirk; two Canary Finches (*Serinus canarius*), three Teneriffe Chaffinches (*Fringilla tintillon*) from Teneriffe, presented by Mr. E. G. Meade Waldo; a Solitary Thrush (*Monticola cyanus*) from Italy, presented by the Rev. H. A. Macpherson; a Common Trumpeter (*Psophia crepitans*) from Demerara, presented by Mr. C. T. Tudway; four Violaceous Night Herons (*Nycticorax violaceus*) from the West Indies, presented by Dr. A. Boon, C.M.Z.S.; an Alexandrine Parrakeet (*Palæornis alexandri*) from India, presented by Miss J. Wilson; two Bolle's Pigeons (*Columba bollii*) from Teneriffe, a Pallas's Sand Grouse (*Syrrhaptes paradoxus*) from Scotland, deposited; a Specious Pigeon (*Columba speciosa*) from Brazil, a Black Francolin (*Francolinus vulgaris*) from India, a Hawk's-billed Turtle (*Chelone imbricata*) from the West Indies, purchased; two Burrhel Wild Sheep (*Ovis burrhel*), a Yak (*Poephagus grunniens*) a Bolle's Pigeon (*Columba bollii*), a Triangular-spotted Pigeon (*Columba guinea*), a Herring Gull (*Larus argentatus*), a Yellow-legged Herring Gull (*Larus cachinnans*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

Recent Determinations of the Amount of Lunar Radiation.—Prof. C. C. Hutchins, formerly of the Johns Hopkins University, now at Bowdoin College, Brunswick, Maine, has recently made some researches in the same field in which Prof. Langley has already worked, viz. the subject of lunar radiation. Prof. Hutchins's first step was the construction of a new form of thermograph, in which a single thermal junction was employed instead of many, the heat rays being condensed upon this one by means of a concave mirror. This combination proved in his hands very successful, though his galvanometer was not the most sensitive possible, since it was a matter of importance that the needle should quickly come to rest. As actually adjusted, the galvanometer gave a deflection of one scale division for 0·00000007 ampere, the period being 10 seconds.

The two principal points to which attention was directed were the comparative intensity of radiation of the sun and moon and the coefficient of transmission of our atmosphere for lunar radiations. The first point was determined by two methods: in one, but a very small fraction of the sun's rays were suffered to fall on the thermograph; whilst in the second method a resistance was interposed in the galvanometer. The two methods gave very fairly accordant results, the mean giving the solar radiation as 184,560 times the lunar. The experiments on the transmission of the lunar rays through our atmosphere gave a remarkably high value: for the deduced result showed that 89¼ per cent. of the rays of the moon when vertical are transmitted by the air at standard pressure.

Observations on the lunar eclipse of January 28, 1888, agreed with those of Langley and Lord Rosse in their testimony as to the suddenness with which the heat received from the moon is cut off at totality.

As to the quality of the lunar rays, it was found that but 31 per cent. were transmitted through a plate of quartz which allowed 93 per cent. of the sun's rays to pass. The radiations from a platinum coil placed in a Bunsen flame turned down as low as possible, suffered to about the same extent as the rays from the moon. From experiments upon the radiating powers of different rocks, a table of which has been formed, Prof. Hutchins concludes that a very considerable portion, about half indeed, of the incident rays are absorbed. The surface of the moon should therefore become strongly heated, but the evidence afforded by total lunar eclipses appears to show that scarcely any of this surface heat succeeds in passing through our atmosphere.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1889 *JUNE* 30—*JULY* 6.

(For the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on June 30

Sun rises, 3h. 49m.; souths, 12h. 3m. 24·6s.; daily increase of southing, 11·8s.; sets, 20h. 18m.: right asc. on meridian, 6h. 38·4m.; decl. 23° 10′ N. Sidereal Time at Sunset, 14h. 54m.

Moon (at First Quarter on July 6, 6h.) rises, 5h. 35m.; souths, 13h. 48m.; sets, 21h. 54m.: right asc. on meridian, 8h. 22·9m.; decl. 21° 21′ N.

GEOGRAPHICAL NOTES.

To an unusually crowded meeting of the Royal Geographical Society on Monday night Dr. Frithjof Nansen told in detail the story of his journey across Greenland last summer. We have already given the main incidents of this remarkable journey, and need only refer here to some of the scientific results. These cannot be fully given as yet, as the meteorological and other data collected by Dr. Nansen have not been fully worked out. It should be borne in mind that the main purpose of Dr. Nansen's expedition was to prove that it is quite possible to cross Greenland: in this respect the expedition has been completely successful. Dr. Nansen repudiates as untenable the idea that somewhere in the interior of Greenland an oasis of greenery must exist. The conditions there are quite different from those of Grinnell Land, where the winter's snow is annually melted away over a certain extent of the surface. Greenland, on the contrary, Dr. Nansen maintains, is so thickly covered with the ice-accumulations of ages, that no part of the interior is ever laid bare. He surmises that there is a sort of wind-pole about the high centre of the interior, from which, as a rule, the cold winds radiate in all directions to the warmer coasts. The cold experienced by the expedition reached as low as 90° F. below freezing, and as Dr. Nansen's thermometers were not adapted for a lower temperature he believes that the temperature was at times much under that. He compares the configuration of the inland ice to a shield, curving upwards from the edges to a sort of plateau, reaching in parts at least 10,000 feet above sea-level. As to the configuration of the ground underneath, Dr. Nansen maintains that it must be similar to Norway and Scotland, with the same rugged mountain masses, high ridges, valleys, and fjords; and that the shape of the ice-covering has nothing to do with the shape of the land underneath. The immense accumulation of snow has levelled up everything; in places the ice must be 6000 feet deep, and even the tops of the mountains must be covered with hundreds of feet of glacier. He believes the wind has much to do with maintaining the ice-level, and does not believe that the quantity of snow varies much from year to year. The enormous pressure exercised by this vast mass of ice causes it to send off icebergs, and, in Dr. Nansen's opinion, running water helps to maintain the uniform level. Even in winter, he maintains, there are running streams underneath, due to the action of this pressure, and which help to prevent the growth of the mass. From a meteorological point of view the scientific exploration of Greenland is in Dr. Nansen's estimation of immense importance. He therefore means to return to the country, probably in the autumn of next year. He will land on the east coast, much further north than his last year's starting-point. He will endeavour to explore the east and north coasts, and will attempt to cross the continent at its broadest part.

In illustration of Dr. Nansen's paper a large collection of oil paintings of Greenland scenery was exhibited, by a Danish artist, Mr. Carstensen, who spent two summers and autumns travelling up and down the west coast. They show, better than any photographs, the wonderful colour of the Greenland landscapes, the extent and nature of the ice, and the beauty and richness of the vegetation during the short summer of this ice-bound land.

THE LADIES' CONVERSAZIONE OF THE ROYAL SOCIETY.

The Ladies' *Conversazione* of the Royal Society, given on June 19, was a great success. The following were among the objects exhibited:—

Exhibited by Miss Constance F. Gordon Cumming:—Sketches near the active volcano of Mauna Loa, on the Island of Hawaii, and the extinct crater of Haleakala, on Isle Maui, described in "Fire Fountains of Hawaii."

Exhibited by Prof. Silvanus P. Thompson:—(1) Acoustic apparatus illustrating polarization of light. (2) Magnetic rotation of plane of polarization shown by projecting a polarized beam through a bar of heavy glass, and analyzing by a 24-ray disk of mica, or by a fish-lens. (3) Expansion and contraction, by transverse electrification, of the rings seen in quartz by convergent polarized light. (4) Objects electro-plated with the metal cobalt (new process).

Exhibited by the Hon. Ralph Abercromby:—Photographs and specimen, and map, illustrative of the nitrate of soda industry, and of the nitrate country.—Sun distilling apparatus, on the Atacama desert. This apparatus is situated at Sierra Gorda, near Caracoles, and is the property of Signor Oliveira. It consists of 1875 square feet of glass, something like a row of cucumber frames. A thin layer of salt water is led under the glass, when the heat of the sun vaporizes some of the water, which condenses as a sweat on the under surface of the glass top. The drops gradually coalesce, trickle down into the narrow groove on which the panes of glass rest, and are then led by pipes into a reservoir of fresh water. The bars along the outside of the glass are to save the apparatus from being wrecked by whirlwinds. Rather more water distils by night than by day, owing to the better condensation when the outer air is cool. At the time of my visit the outer air was 97°, the air inside the frames 120°, and that of the salt water inside only 117°, while that of the glass frame itself could not be determined. The apparatus is extremely inefficient, owing to the absence of a proper condenser, and the details are bad; still, from 150 to 175 litres of fresh water are distilled every day, which is sold at a profit for 1½*d.* a gallon. Twenty years ago a similar apparatus, with 50,000 square feet of glass, was erected at Carmen Alto on the same desert, and worked very profitably, as 10*s.* a gallon could then be obtained for fresh water. This apparatus was afterwards wrecked by a whirlwind, and is now replaced by a steam condenser.

Exhibited by Mr. Streeter:—Rubies from the Burmah Mines, English cut and mounted, and in the rough as found.

Exhibited and invented by Mr. Ludwig Mond and Dr. Carl Langer:—New form of gas battery. This battery is an improvement on the well-known gas battery invented by Grove fifty years ago, which produces electricity from hydrogen and oxygen gas by the intervention of platinum. The distinguishing feature of the new battery, which has been designed to obtain large currents of electricity by means of these gases, is that the electrolyte is not employed as a mobile liquid, but in a quasi-solid form, and it is therefore named "dry gas battery." Each element of the battery consists of a porous diaphragm of a non-conducting material—for instance, plaster of Paris—which is impregnated with dilute sulphuric acid. Both sides of this diaphragm are covered with very fine platinum leaf, perforated with very numerous small holes, and over this with a thin film of platinum black. Both these coatings are in contact with frame-works of lead and antimony, insulated one from the other, which conduct the electricity to the poles of each element. A number of these elements are placed side by side, or one above the other, with non-conducting frames intervening, so as to form chambers through which hydrogen gas is passed along one side of the element, and air along the other. One element, with a total effective surface of 774 square centimetres = 120 square inches, which is covered by 1 gramme of platinum black and 0·35 gramme of platinum leaf, shows an electromotive force of very nearly 1 volt when open, and produces a current of 2 amperes and 0·7 volt or 1·4 watt, when the outer resistance is properly adjusted. This current is equal to nearly 50 per cent. of the total energy obtainable from the hydrogen absorbed in the battery. The electromotive force decreases, however, slowly, in consequence of the transport of the sulphuric acid from one side of the diaphragm to the other. In order to counteract this disturbing influence the gases are from time to time interchanged. The battery works equally well with gases containing 30 to 40 per cent. of hydrogen, such as can be obtained by the action of steam or steam and air on coal or coke, if the gases have been sufficiently purified from carbonic oxide and hydrocarbons. The water produced in the battery by the combination of hydrogen and oxygen is carried off by the unconsumed nitrogen and an excess of air carried through it for this purpose.

Exhibited by Messrs. Woodhouse and Rawson, Ltd.:—Samples of copper produced by the Elmore depositing process. Sketches of the appearance under the microscope of ordinary deposited copper, and copper made by the Elmore process. By the Rev. F. Howlett, F.R.A.S.

Exhibited by Prof. J. A. Fleming, D.Sc.:—Edison-Swan incandescence lamps, showing the "Edison effect." If a carbon incandescence lamp has a platinum plate, carried on a wire sealed through the glass, placed between the loop or horse-shoe, it is found that when the lamp is in action a galvanometer connected between the middle plate and the *positive* side of the carbon loop shows a current passing. If the galvanometer is placed between the middle plate and the *negative* side of the loop no current is found. The lamps exhibited show this effect very well. It was first pointed out by Mr. Edison, in 1884. It has been found that shielding the negative leg by a glass or metal tube entirely stops the production of the effect.

Exhibited by the Director of the Royal Gardens, Kew:—Photographs of Ceylon vegetation.

Exhibited by Mr. J. Young:—(1) A cluster of nests of a species of swift (Collocalia) taken in one of the Society Islands. (2) A specimen of *Pluvianellus sociabilis*, a plover obtained in South America, of which only two specimens (obtained fifty years ago) were previously known in Europe. (3) The tail of a Japanese barndoor cock, 11 feet long. (4) Bearded-tits' nest, built in Pampas grass heads, stuck in a flower-pot in an aviary.

Exhibited by Mr. P. L. Sclater, F.R.S.:—(1) Head of Thomson's gazelle (*Gazella thomsoni*), from a specimen shot by Mr. H. C. V. Hunter, in Masai Land, Eastern Africa. This gazelle was discovered by Mr. Joseph Thomson during his expedition through Masai Land in 1883–84, and named after its discoverer by Dr. Günther (*Ann. Nat. Hist.*, ser. 5, vol. xiv. p. 427). (2) Head of Grant's gazelle (*Gazella granti*), from a specimen shot by Mr. Frederick Holmwood, C.B., in the Kilimanjaro district of Eastern Africa. This gazelle was discovered by Colonel Grant, C.B., F.R.S., in Ugogo, in 1860, and named after him by Sir Victor Brooke (P.Z.S., 1872, p. 601). (3) Mummy of a small falcon (probably the kestrel, *Tinnunculus alaudarius*) from the tombs at Thebes in Egypt, obtained from the natives by Mr. A. G. Scott. (4) Tray of birdskins, from St. Lucia, West Indies, collected by Mr. Ramage, the naturalist employed by the joint Committee of the Royal Society and British Association for the exploration of the Lesser Antilles.

Exhibited by Profs. Liveing and Dewar, F.R.S.:—Absorption spectrum of oxygen. The oxygen, compressed to 150 atmospheres, is contained in a steel tube fitted with quartz ends. In the red part of the spectrum are seen the absorptions corresponding to the Fraunhofer groups A and B. Less sharply defined absorption bands are seen in the orange, citron, and blue, and faint bands in the green and indigo. These band absorptions have a totally different character from the great line absorptions of A and B. Beyond the visible spectrum, photographs show some absorptions in the ultra-violet, and the extreme ultra-violet rays are wholly absorbed. This complete absorption extends nearly to the limit of the solar spectrum. This proves that the earth's atmosphere limits the rays which can reach us from the outside. Ozone has even a more powerful absorptive action, and oxygen, ozonized and unozonized, put a limit to our observations of stellar spectra. Profs. Liveing and Dewar have experimented with a steel tube 60 feet in length, and easily capable of holding a mass of oxygen equal to that contained in a vertical column of the earth's atmosphere of equal section.

Exhibited by Mr. Francis Galton, F.R.S:—Reaction-time instrument (working model). The time is measured by a half-second pendulum. The signal is the sharp sound made by a small hammer (noiselessly set free) on its striking a detent, and thereby releasing the pendulum. The response is made by touching a key that releases an arrangement (worked very quickly by a spring) whereby an elastic thread, which is secured above and below to the pendulum, parallel to its rod, but not touching it, is nipped and held fast against a horizontal bar. The bar is graduated to hundredths of a second, so that the graduation opposite to the thread shows the elapsed time between the signal and the response. The pendulum receives no jar, and continues to vibrate.

Exhibited by the Hon. A. Holland-Hibbert:—(1) Old telescope, with parchment tubes. (2) Old microscope, of stamped leather. Both formerly the property of King Charles I.

Exhibited by Mr. Fred. Enock:—Microscopical preparations illustrating the life-history of the Hessian fly (*Cecidomyia destructor*, Say).

Exhibited by Mr. Percy E. Newberry, by kind permission of the Director of the Royal Gardens, Kew:—A series of ancient funeral wreaths and plant remains, discovered last year by Mr. W. M. Flinders Petrie, in the cemetery of Hawara, Egypt. (I.) The wreaths, which are of Egyptian and Greek manufacture, were all made in the first century B.C., and were found in wooden coffins, either resting on the heads or surrounding the bodies of the mummies. Among them the following are of special interest:—(1) A very perfect wreath composed of the flowerheads of a species of Immortelle (*Gnaphatium luteo-album*, L.), called by the ancients "helichrysos," and much used by them in making garlands. Helichrysos wreaths are mentioned by Pliny ("Hist. Nat.," xxi. 96) as having been used in Egypt in Ptolemaic times, also by Theophrastus, Athenæus, Cratinus, &c. (2) Portion of a curious garland made of cones of papyrus pith, lychnis and rose flowers, rose petals, and scarlet berries of the woody nightshade. These latter are mentioned by Pliny as having been employed in garland-making by the Egyptians. (3) Portion of a wreath (of Greek manufacture) made of flowers of the Polyanthus Narcissus (*N. Tazetta*, L.). Wreaths made of this flower, the "clustered Narcissus" of the ancients, are often mentioned by early Greek poets. Sophocles thus alludes to them:—

θάλλει δ' οὐρανίας ὑπ' ἄχνας
ὁ καλλίβοτρος κατ' ἦμαρ ἀεὶ
νάρκισσος, μεγάλαιν θεαῖν
ἀρχαῖον στεφάνωμα.—*Œdipus Coloneus.*

(4) Portion of a wreath made of the flowers of a species of rose (*Rosa sancta*, Richards). (5) A perfect wreath composed of rose petals threaded by a needle on to strips of twine. "Recently," writes Pliny in his history of garlands, "the rose chaplet has been adopted, and luxury has now arisen to such a pitch that rose garlands are held in no esteem at all if they do not consist entirely of petals sewn together with the needle" ("Hist. Nat.," xxi. 8). There are also exhibited: (6) a portion of a wreath composed of twigs of sweet marjoram (*Origanum Majorana*, L.), lychnis flowers, coils of papyrus pith, and pieces of copper tinsel; (7) a portion of a wreath composed of chrysanthemum flowers and leaves, purple cornflowers, and petals of the flower of a species of *Hibiscus*; (8) a portion of a wreath made of flowers of *Matthiola Librator*, L., flowers of the polyanthus, narcissus, and *Hibiscus* petals; (9) portions of two necklaces made of flowers of the date palm threaded on strips of twine; and (10) a fragment of a necklace made of fruits of the date palm. (II.) Among the plant remains are peach stones, dates, and date stones, walnut shells, currants, pomegranates, plums, figs, chick peas, common garden beans and peas, lentils, wheat, barley, and oats. These are probably the remains of the ancient funeral feasts which were held in the Hawara Cemetery by the relatives of the deceased people who were buried there. The whole collection (of which the series here exhibited is only the third part) is fully described by Mr. Percy E. Newberry in Mr. Flinders Petrie's "Hawara, Biahmu, and Arsinoe."

Exhibited by Dr. H. H. Hoffert:—Photograph of lightning flashes taken at Ealing, on June 6, 1889.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The Harkness Scholarship, for Geology and Palæontology, has been awarded to T. T. Groom, Scholar of St. John's College.

Mr. J. T. Nicolson, B.Sc. of Edinburgh University, has been appointed Demonstrator in Mechanism and Applied Mechanics.

The Mechanical Workshops Syndicate reports that the practical instruction in engineering and mechanism is producing excellent results in the training of engineers, but that the subject suffers by the lack of a higher technical examination analogous to a tripos, while the workshops do not get all the work they might do, owing to the withdrawal of the University Museums' work.

An examination for Scholarships in mathematics and in chemistry and physics will be held at Peterhouse on October 15. A syllabus of subjects may be obtained from the tutor.

The local lectures in science have been largely attended during the past year; the largest audiences being at Kettering, where astronomy was the subject, and Mr. J. D. McClure the lecturer, and at Lancaster, where Mr. E. A. Parkyn lectured on human physiology.

The Students' Associations have made good progress in many localities, and in Surrey a student, Mr. Broderick, of Guildford, was found sufficiently qualified to repeat the courses in several villages with much success.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 6.—"Notes on the Absorption-Spectra of Oxygen and some of its Compounds." By Profs. Liveing and Dewar.

The authors give a diagram representing the absorption, both in the visible and in the ultra-violet parts of the spectrum, of 18 metres of ordinary oxygen gas at a pressure of about 97 atmospheres—that is, of a mass of oxygen rather greater than is contained in a vertical column of equal section of the earth's atmosphere. Under the circumstances of the experiment the absorptions A and B are very black, and the lines of which they are composed appear much broader than in the ordinary solar spectrum. The other bands are all diffuse at their edges, and, so far as observed, unresolvable into lines. The complete absorption of the ultra-violet rays does not extend quite so far down as the limit of the solar spectrum, though it approaches that limit. There is a diffuse edge of gradually diminishing absorption succeeding the complete absorption, and this fact, together with the rapid diminution of the extent of the complete absorption with decrease of pressure, lead the authors to class this absorption of the extreme rays with the diffuse bands, which, according to Janssen, increase in intensity as the square of the density of the gas. If that be so, it is unlikely that the limit of the solar spectrum is due to the absorption of ordinary oxygen. For though we may suppose interplanetary space to be pervaded by materials similar to our atmosphere, yet they must be in such a state of tenuity that, although they may to some extent reinforce A and B, they will not add sensibly to the strength of the diffuse bands. Moreover, these bands, though identical in position, so far as the blue and less refrangible part of the spectrum is concerned, with bands observed by Brewster and others in the solar spectrum, are seen much more strongly through tubes of compressed oxygen than they appear in the solar spectrum with a low sun. The ultra-violet bands, of which the one near N appears in photographs nearly as strong as the band just above F, and that in the indigo, have not, so far as the authors are aware, been noticed in the solar spectrum. Probably they would appear if photographs were taken with small dispersion when the sun was low.

As the pressure in the tube diminished, the bands rapidly faded; that in the indigo, with an oscillation-frequency or wave number about 2240, was the first to disappear, then those near L and O and that near E. At the same time the limit of the transmitted ultra-violet light advanced from an oscillation-frequency of about 3575 at 97 atmospheres, to 3710 at 50 atmospheres and 3848 at 23 atmospheres. At 20 atmospheres the three bands above C, D, and F, respectively, were still visible, though faint. B remained visible until the pressure was reduced to 2 atmospheres, and A could still be seen, but with difficulty, when the pressure of the 18 metres of oxygen was reduced to 1 atmosphere.

When atmospheric air was substituted for oxygen the authors found that 7 atmospheres was the limit of pressure at which they could certainly distinguish A, and 18 atmospheres the limit at which they could see B. It is a difficult matter to say exactly when an absorption becomes invisible, but the observations on air were made under the same circumstances as those on oxygen, and the two sets of observations were fairly comparable. With air at 75 atmospheres the three bands above C, D, and F, respectively, could all be seen, but that near C only with difficulty. The mass of oxygen and its *partial* pressure in the tube was in this case less by about one-quarter than that which was required to bring out the bands when oxygen alone was used. The cause of this may be that the development of the diffuse bands depends in some degree on the total pressure of the air, and not only on the partial pressure of the oxygen in it.

The mass of oxygen which when unmixed with nitrogen made A visible would correspond to that in the tube filled with air at 5 atmospheres, and that which made B visible would correspond to air at 10 atmospheres. The differences between these pressures and those which are actually needed to render A and B visible seem too great to be ascribed to errors of observation, and seem to indicate that the addition of the nitrogen has some effect on the absorptive action of the oxygen. On the other hand, Egoroff found that he could still distinguish A when the thickness of air at ordinary pressure was reduced to 80 metres (*Compt. Rend.*, vol. ci. p. 1144). This amount of air corresponds to rather less oxygen than the 18-metre tube would hold at a pressure of 1 atmosphere. Differences in the sources of light, in the spectroscope, and the observers, would, however, count for a good deal in observations of this kind.

In order to try the influence of temperature on the absorption, the shorter of the experimental tubes, 165 cm. long, was surrounded by a jacket filled with a mixture of solid carbonic anhydride and ether, which was rapidly evaporated by means of a large air-pump. By this means the temperature would be reduced to – 100°. The absorption of oxygen at several different pressures up to 104 atmospheres was observed through the cooled tube. The authors were not, however, able to detect any increase of intensity, or other change, in the absorptions which could be ascribed to the cooling. To try the effect of an increase of temperature, the 18-metre tube was surrounded by a jacket and heated up to 100° by steam. Heating appeared to render the diffuse bands rather more diffuse and less distinct. On the whole the influence of a change of temperature of 100° either way is slight.

The authors have observed repeatedly the absorption of liquid oxygen in thicknesses of 8 and 12 mm. Their observations confirm those of Olszewski. 8 mm. of liquid oxygen gives plainly the three diffuse bands above C, D, and F, respectively. With a thickness of 12 mm. the authors were not able to detect any more.

The authors observed the absorption produced by liquid oxygen on the one hand when it was cooled by its own evaporation until the tension of its vapour was only equal to that of the atmosphere—that is, to a temperature of – 181°, according to Olszewski—and also when the temperature of the liquid was allowed to rise under pressure up to nearly the critical temperature. There appeared to be no appreciable difference in the absorption under these different circumstances when the oxygen was completely liquid, when it was near its critical temperature, and when it was completely gaseous; so far at least as concerns the three principal bands, which were all that could be seen in the light transmitted by the liquid in a thickness of 12 mm.

It will be observed that taking the density of oxygen at – 181°·4 to be 1·124, as given by Olszewski, 12 mm. of the liquid would be equivalent to 9·37 metres of the gas at atmospheric pressure—hardly more than half the thickness required to make A visible. The experiments, therefore, point to the conclusion that gaseous and liquid oxygen have the same absorption-spectrum. This is a very noteworthy conclusion. For, considering that no compound of oxygen, so far as is known, gives the absorptions of oxygen, the persistency of the absorptions of oxygen through the stages of condensation to the state of complete liquidity implies a persistency of molecular constitution which we should hardly have expected.

In order to compare the absorption of ozone with that of oxygen, the authors employed a tube 12 feet long, made of tinplate fitted with glass ends and coated with paraffin on the inside. Ozonized oxygen was passed into the tin tube for some time, while the ozonizer and the tube itself were cooled with ice and salt. The lime-light, viewed through the tube, looked very blue, and also the spot of light thrown from the tube on to a sheet of white paper was equally blue, indicating a considerable absorption of the less refrangible part of the spectrum. The absorption, so far as the visible rays are concerned, appeared to be of a general character, for the spectroscope revealed only four extremely faint absorption-bands. The centres of these bands were at about the wave-numbers 1662, 1752, 1880, and 1990, and their positions with reference to the bands of oxygen are indicated in the diagram. They were so faint as to be seen only with difficulty. When the hot carbon of an arc lamp was substituted for the lime-light they were rather more distinct, but the positions of the edges were undefinable. The light of a gas-lamp was insufficient to show them, and they were no better seen with a single-prism spectroscope of low dispersive power than with the spectroscope employed for observing the oxygen. Only one of these bands is nearly coincident with an oxygen-band—namely, that near E, the faintest of the oxygen-bands. That at wave-number 1752 overlaps the strongest oxygen-band, but not at its strongest part, and has none of the peculiar character of its shading, abruptly increasing on the less refrangible side and slowly decreasing on the other side. Photographs of the spectrum (taken through a tube with quartz ends) showed that the ozone absorbed all the rays above the wave-number 3086—a point between Q and R—while partial absorption extended below Q. It may be said, therefore, that no identity can be traced between the absorptions of ozone and those of ordinary oxygen. There is no mere displacement of the bands, such as sometimes occurs when a coloured substance is dissolved in different menstrua, nor any such resemblance as subsists between the absorption-bands of the different cobaltous salts derived from different acids.

The four bands which are seen to be produced by ozonized oxygen correspond fairly with the second, third, fifth, and sixth of the bands described by Chappuis as due to ozone (*Annales de l'Ecole Normale*, 2nd ser., vol. xi., May 1882). These four bands, he says, are the first to be seen. The authors have failed to perceive any others with the 3·66 m. tube, though the oxygen was highly ozonized, and maintained at a low temperature. None of the bands were of sufficient intensity to make themselves visible on photographic plates.

It will be noted that the absorption by ozone extends far below the limit of the solar spectrum. By diminishing the proportion of ozone to oxygen in the tube the limit of the transmitted light was continually advanced, as already described by Hartley. The limit of the solar spectrum may, therefore, very well be determined by the average amount of ozone in the atmosphere, as Hartley supposes. The known variations in the limit of the solar spectrum may be taken as confirmatory of this hypothesis, although the comparatively small amount of those variations is certainly less than we should have expected if they measure the changes in the proportion of ozone in the atmosphere.

The absorptions of the class to which A and B belong must be those which are most easily assumed by the diatomic molecules (O_2) of ordinary oxygen. Whether oxygen in more complex molecules, as in ozone (O_3), may be capable of taking up the corresponding vibrations cannot easily be determined, because we cannot isolate ozone; but since none of the compounds of oxygen with nitrogen, hydrogen, or carbon, or, so far as known, with any other element, exhibit these absorptions, it is very probable that they are peculiar to the molecule O_2. From this point of view it will be interesting to determine whether liquefied oxygen, which we suppose to have more complex molecules, produces these absorptions The corresponding spectrum of emission has not as yet been observed, probably because the agency employed to render the gas luminous breaks up the molecules into single atoms of oxygen.

As for the other class of absorption, the diffuse bands, since they appear to have intensities proportional to the square of the density of the gas, they must depend on a change produced by compression. This may either be the formation of more complex molecules, as for example O_4, corresponding to the deviation from Boyle's law exhibited by oxygen gas, or it may be the constraint to which the molecules are subject during their encounters with one another. Increase of temperature would affect the former, tending to diminish the number of complex molecules formed at a given pressure, but would have no effect on the latter, for though the number of encounters of the molecules in a given interval of time would be greater the higher the temperature, yet so long as the volume was unaltered the ratio of the duration of an encounter to that of free motion would be sensibly unaltered. So far as any change due to temperature has been observed, it is that a rise of temperature slightly weakens the diffuse absorptions.

Reverting to the compounds of oxygen, none of them show the absorptions of oxygen, not even the general absorption of the ultra-violet rays. Some of them, such as water and carbon dioxide, appear quite transparent to ultra-violet rays, while in others, such as nitrous oxide, which show a general absorption of the ultra-violet rays, the limit of transparency is different from that of oxygen. In other respects we may say that there is no resemblance between the absorptions of the compounds of oxygen and those due to oxygen itself. Some of the former have very definite and characteristic absorptions, such as the well-known spectra of the peroxides of nitrogen and chlorine, and we must regard these as indicating the rates of vibration which the molecules NO_2 and ClO_2 respectively are capable of easily taking up. The absence of the absorptions due to oxygen from all compounds of oxygen seems to indicate either that chemical combination is not, as has been supposed by some chemists, a temporary relation in which the molecular groupings are continually breaking up, to be formed anew with ever-changing elementary atoms; or, that the periods of dissociation are very small compared with the periods of association. For otherwise we should expect that such compounds of oxygen as CO_2 and NO_2 must always have amongst their molecules some molecules identical with those of oxygen and capable of taking up vibrations of the same period. At least we must conclude that little, if any, of the oxygen of these and other compounds is ever out of the influence of the other components.

The authors have re-examined the absorption-spectrum of N_2O_4 at various temperatures, and agree with the conclusions of Bell (*Amer. Chem. Journ.*, vol. vii. p. 32), that N_2O_4, whether liquid or gaseous, effects only a general absorption at either end of the spectrum, and that the selective absorptions observed with it are due to the presence of NO_2.

In order to obtain pure N_2O_4, the tube in which the liquid was sealed was placed in a freezing mixture, and a large part of the liquid frozen; the remaining liquid was then drained as completely as possible into the other end of the tube, and sealed off.

It should be observed that the crystals of N_2O_4 appear colourless, and that when they are melted the liquid and superincumbent vapour are of a very pale yellow colour. As the temperature rises, both liquid and vapour become, as is well known, of a deep orange, and finally of a dark, reddish-brown colour. The authors examined the spectra produced by two thicknesses of liquid and vapour—(1) by that contained in a narrow tube about 1 mm. in diameter, and (2) by that in a tube about 1 cm. in diameter. At 15° to 20° the vapour in the narrow as well as in the wider tube showed the well-known absorption-spectrum of fine, dark lines; no absorption by the liquid in the narrow tube could be detected, and the liquid in the wide tube showed no fine lines, but several faint, very diffuse bands, unresolvable into lines with a spectroscope of three prisms. These bands had their maxima in places where the fine lines of the vapour were most intense and most closely set, so that it might be inferred that they were due to similar molecules in both cases, but that in the liquid the vibrations of these molecules were no longer sharply defined, but modified by the constraint arising from the liquid state. Some parts, however, of the spectrum of the vapour, where the lines were closely set, did not appear to be represented by any definite bands in the liquid. The liquid absorbed a good deal of blue light in a continuous manner, while the vapour only absorbed it selectively. At the red end the limit of the visible spectrum was lower for the liquid than for the gas—that is, there was more absorption of red light by the vapour than by the liquid, so much so that below a certain point the absorption by the vapour appeared continuous.

The narrow tube was next immersed in a wider tube full of glycerine, which was gradually heated. As the temperature rose, the colour of both liquid and vapour deepened, the absorptions of the vapour were stronger, and the liquid gave the same bands as had been before observed with the greater thickness. At still higher temperature the absorption of blue light, both by liquid and vapour, diminished sensibly, until at 85° the groups of lines in the blue had pretty well disappeared from the spectrum of the vapour. In fact, at 85° there was no sensible difference between the actions of liquid and vapour on blue light, it seemed only some continuous absorption. At the red end the difference between the liquid and vapour remained quite as strongly marked as at lower temperatures—if anything, more so; and the absorptions in the orange, yellow, and green were unaltered. At 90° the lines of the vapour in the green began to fade, and at 100° they were very faint; but those in the orange, as well as the corresponding diffuse bands in the liquid, were as strong as before. There was still considerably more absorption of red light by the vapour than by the liquid, as if there were a strong absorption-band in the red of the vapour which was absent in the liquid.

As the temperature rose to 110° all the lines in the vapour had become faint, and at 115° they were no longer discernible, and there was no difference between the spectra of liquid and vapour except in the red, and even here the difference was less marked than at lower temperatures. At 130° no distinction was observable between the spectra of liquid and vapour; there were no lines or bands in either, but a good deal of general absorption. Liquid and vapour were dark, and appeared much of a colour, but the meniscus at the junction was quite evident. The tube was further heated to 155°, but no further change was noticed in the spectrum. On gradually cooling the tube, at 112° the least refrangible band in the orange was seen coming in both in vapour and liquid, diffuse in both. At 100° the usual lines were well seen in the orange, yellow, and citron of the vapour, faint lines in the green, and none in the blue; and subsequently the appearances presented on heating followed in the reverse order.

A solution of N_2O_4 in carbon bisulphide gave, in a thickness of 7 or 8 cm., diffuse absorption-bands in the green and citron, ill-defined as in liquid N_2O_4 and in corresponding positions. In a thickness of 1 cm. these bands were no longer visible.

These observations bear out the supposition that pure N_2O_4 is without selective absorption of the visible rays, and that the absorption observed is due to NO_2, both in the vapour and liquid, this absorption being modified in the liquid by the state of solution in which the molecules have much less freedom. As the temperature rises, the proportion of NO_2 increases, and at the same time the density of the vapour increases and the freedom of motion of the molecules is diminished, they are less able to assume the more rapid vibrations, and those which they do assume become less sharply defined, so that the lines fade into bands and ultimately into a general absorption.

Chemical Society, June 4.—Dr. W. J. Russell, F.R.S., President, in the chair.—Prof. Mendeleeff's Faraday Lecture on the periodic law of the chemical elements, was read by the Secretary, owing to the enforced absence of the lecturer. At the conclusion of the lecture, a vote of thanks to Prof. Mendeleeff was moved by Prof. Frankland, and seconded by Sir F. A. Abel. The Faraday Medal and a purse were then presented by the President to Mr. Anderson, by whom it was received on behalf of Prof. Mendeleeff.

June 6.—Dr. W. J. Russell, President, in the chair.—The following papers were read:—Experimental researches on the periodic law, Part I., by Dr. B. Brauner. The author gives a detailed account of his attempts to determine the atomic weight of tellurium by as many different methods as possible; in all, eleven were adopted, but each gave a different result, varying from 125–140. He eventually succeeded, but with great difficulty, in preparing what appeared to be pure tellurium tetrabromide, and on most carefully analyzing this, obtained the value Te = 127·64 (O = 16). This number, however, is incompatible with the position of tellurium in the periodic system, and having satisfied himself that there were no experimental errors which could account for the discrepancy, the author was forced to conclude that what had hitherto been regarded as pure tellurium contained foreign elements. By submitting tellurium solutions to a systematic fractional precipitation, he has, in fact, succeeded in obtaining a variety of substances, some of which are undoubtedly novel elements. One of these it is proposed to call *Austriacum* (*Austrium*). In all probability this is the *Dvi-tellurium* (212), the probable existence of which was pointed out for the first time by Mendeleeff in his recent Faraday Lecture. From analyses made with material the uniformity of which is not yet quite established, the author is satisfied that the atomic weight of the element in question approaches very closely to that indicated by Mendeleeff. In addition, there is at least one other novel constituent, and this appears to be more or less closely allied to arsenic and antimony. It follows that true tellurium has yet to be discovered, and that its atomic weight and properties remain to be determined.—The amylo-dextrin of W. Nägeli, and its relation to soluble starch, by Mr. H. T. Brown and Dr. G. H. Morris. Amylo-dextrin, described by W. Nägeli in 1874, is prepared by the long-continued action of cold dilute acids on intact starch granules; when purified by dissolution in water and precipitation with alcohol, it forms crystalline spherules, closely resembling those of inulin. The authors consider amylo-dextrin to be analogous in composition to the malto-dextrin previously described by them (Chem. Soc. Trans., 1885, 528), and assign to it the formula $C_{12}H_{22}O_{11} + (C_{12}H_{20}O_{10})_6$; *i.e.* it may be regarded as constituted of one amylon or maltose group in combination with six amylin or dextrin groups. Soluble starch, with which amylo-dextrin has frequently been confused, is converted into a mixture of maltose and dextrin on treatment with diastase, whilst amylo-dextrin yields maltose exclusively; moreover it is shown that soluble starch is the first product of the action of cold dilute acids on starch, and that this is slowly hydrolyzed to amylo-dextrin, a portion of the starch substance at the same time going into solution as dextrose.—The determination of the molecular weights of the carbohydrates Part II., by the same. As determined by Raoult's method, galactose and malto-dextrin are found to have molecular weights corresponding with the formulæ $C_6H_{12}O_6$ and $C_{12}H_{22}O_{11} \cdot (C_{12}H_{20}O_{10})_2$ respectively. For inulin the formula $2(C_{36}H_{62}O_{31})$ is deduced, and in view of the great similarity in physical properties between inulin and amylo-dextrin the authors are inclined to regard the two substances as closely analogous in composition, representing inulin by the formula $(C_{12}H_{22}O_{11})_2 +$

$(C_{12}H_{20}O_{10})_4$, although the amylon and amylin groups in each possess very different optical and other properties, and the products of the hydrolysis with dilute acid are very different. It was found impossible to apply Raoult's method to starch-paste; solutions of soluble starch produced so slight a depression that no reliable results can be obtained; a number of fairly concordant results, however, pointed to a molecular weight of 20,000 to 30,000. In order to ascertain whether the failure in this case was due to a high molecular weight, and not to the fact that the method was inapplicable to colloid substances, an arabinic acid, having a rotatory power $[\alpha]_j = + 61^{\circ} \cdot 16$, was examined; this gave a molecular weight of 717, thus rendering it probable that the small influence exercised by soluble starch was due to its high molecular weight. Indirect evidence was then sought for by an examination of the dextrins. The authors have previously shown that when starch is broken down by diastase, a resting stage in the reaction is reached when the amount of dextrin produced corresponds with one-fifth by weight of the starch taken, and that the molecule of this stable dextrin is one-fifth of the size of the starch-molecule from which it has been derived. Determinations of the molecular weight of this low dextrin pointed to the formula $20C_{12}H_{20}O_{11}$, and consequently the formula of soluble starch would be $5(C_{12}H_{20}O_{10})_{20}$, and its molecular weight 32,400. The endeavour was also made to apply Raoult's method to the determination of the question whether the dextrins are a series of polymers or whether they are simply metameric. For this purpose a number of the higher dextrins were prepared from starch-transformations which had been stopped at an early stage of hydrolysis. All the numbers obtained show that the freezing method affords no evidence of there being any difference in molecular weight between the high and low dextrins, the numbers being, in fact, almost identical. From a consideration of the results obtained with soluble starch, and with dextrins of varying position in the series, the authors conclude that the evidence points to the conclusion that the dextrins are metameric and not polymeric compounds. They therefore abandon their former working hypothesis of the hydrolysis of starch, and now suppose the starch-molecule to consist of four complex amylin-groups, arranged round a fifth similar group constituting a molecular nucleus. When hydrolysis takes place this complex is broken up, four amylin-groups being liberated, which in turn are capable of undergoing complete hydrolysis into malto-dextrins, and ultimately into maltose, whilst the fifth amylin-group which constituted the nucleus of the original molecule resists the action of hydrolyzing agents, and forms the stable dextrin of the No. 8 equation of the authors' previous papers (Chem. Soc. Trans., 1879, 634; 1885, 539). Each amylin group of the five has the formula $(C_{12}H_{20}O_{10})_{20}$, corresponding with a molecular weight of 6480; the molecule of soluble starch being represented by $5(C_{12}H_{20}O_{10})_{20}$, corresponding with a molecular weight of 32,400.—Researches on silicon compounds, Part V., by Prof. J. E. Reynolds.—The isomerism of the alkyl-derivatives of mixed diazoamido-compounds, by Prof. R. Meldola and Mr. F. W. Streatfield. A critical study of the mixed diazo-amide, , has served to confirm the conclusion arrived at by the authors in their previous communications (Chem. Soc. Trans., 1886, 624; 1887, 102, 434; 1888, 664), that this compound and its alkyl-derivatives are perfectly definite, and that they cannot be formed by crystallizing together mixtures of the corresponding symmetrical di-meta- and di-para compounds. The authors restate their original proposition, viz. that every pair of amines, $X.NH_2$ and $Y.NH_2$, can give rise to three isomeric alkyl-derivatives—(1) by the action of diazotized $X.NH_2$ on $Y.NHR'$; (2) by the action of diazotized $Y.NH_2$ on $X.NHR'$; (3) by the direct alkylation of $X.N_3H.Y$. In support of the general truth of this proposition a large number of triplets have been prepared, all of which conform to the rule laid down. The isomerism of these triplets is shown not only by their melting points, but also by their products of decomposition by cold hydrochloric acid. These products have in all cases been examined quantitatively, and the general results are shown by the equations—(1) $X.N_2.NR'.Y + HCl = X.N_2.Cl + Y.NHR'$; (2) $Y.N_2.NR'X + HCl = Y.N_2.Cl + X.NHR'$; (3) $2X.N_3R'.Y + 2HCl = X.N_2Cl + Y.N_2.Cl + X.NHR' + Y.NH.R'$. From this it appears that the alkyl-derivatives of the mixed diazo-amides always split up like the unalkylated products into a mixture of the two diazo-chlorides and two alkylamines. The most feasible interpretation of these facts is that the mixed diazoamides have double the molecular weight usually assigned to them, and in support of this conclusion the authors have discovered that the mixed alkyl-diazoamides can be synthesized by simply boiling the alcoholic solutions of the other two isomerides of the triplet, thus—$X.N_2.NR'.Y + Y.N_2.NR'.X = (X.N_3R'.Y)_2$.—The atomic weight of zinc, by Dr. J. H. Gladstone and Mr. W. Hibbert. The authors have observed that when amalgamated zinc is used as anode in a zinc sulphate voltameter, the metal dissolved appears to be free from impurity. Results obtained in different voltameters with the same current showed a very close agreement, and the authors therefore determined the atomic weight of zinc by applying Faraday's law of electrolysis. For this purpose a series of copper, silver, and zinc voltameters were arranged in a simple circuit, and the quantity of zinc dissolved was compared with the weights of deposited silver and copper. The silver and copper voltameters were arranged according to the conditions shown to be best by Lord Rayleigh, Gray, and others. The zinc voltameters were almost of the same form as the silver voltameter of Lord Rayleigh. The anode was a sheet of amalgamated zinc supported so as to rest horizontally on the surface of the zinc sulphate solution, which had a specific gravity varying from 1·18 to 1·21. The mean ratio of the equivalents of silver and zinc is 3·298 ± 0·0008. Taking the atomic weight of silver as 107·93, this ratio gives 65·44 as the atomic weight of zinc. If silver is taken as 107·66, zinc = 65·29. The copper sulphate voltameter is not so accurate as the silver one, owing to the solvent action of the solution on the copper, and the ratio Zn : Cu given by the experiments (1·0322) is probably rather too high. Adopting Shaw's value for the atomic weight of copper (63·33), this ratio gives 65·37 as the atomic weight of zinc.—The amount of nitric acid in the rain-water at Rothamsted, with notes on the analysis of rain water, by Mr. R. Warrington. The rain of twenty months, analyzed by the copper-zinc method, contained an average of 0·138 of nitrogen as nitric acid per million of water; this is a little higher than that found by Way in 1855–56—namely, 0·12 per million—but is almost identical with that found by Frankland as a mean of his analyses of Rothamsted rain in 1869–70. In a whole year, 1888–89, with a rainfall of 29·27 inches, the quantity of nitric nitrogen in the rain was 0·917 lb. per acre, and the nitrogen as ammonia 2·823 lbs., or a total of 3·74 lbs.—The product of the action of sulphur on resin, by Dr. G. H. Morris.—The vapour-pressures and specific volumes of similar compounds of elements in relation to the position of those elements in the periodic system, by Prof. S. Young. Determinations have been made of the vapour-pressures and specific volumes of the four haloid derivatives of benzene and also of benzene itself, within very wide limits of temperature; benzene, fluobenzene, and chlorobenzene having been heated to their critical points, 288°·5 and 286°·55 and 360°·8 respectively. It is shown that if the four haloid derivatives are compared at such temperatures that their vapour-pressures are equal, the (absolute) temperatures and also the specific volumes bear a constant ratio to each other, whatever the common pressure. But on comparing benzene with one of its haloid derivatives it is found that these simple relations do not hold. The ratios of the absolute temperatures of benzene and fluobenzene corresponding to equal pressures are very exactly expressed by the equation $R' = R + ct$, where R' is the ratio at a pressure for which the corresponding Centigrade temperature of fluobenzene is t, $R = 0{\cdot}0838$, and $c = 0{\cdot}0000313$.—The vapour-pressures of uqinoline, by the same.

Anthropological Institute, May 28.—Mr. F. Galton, F.R.S., Vice-President, in the chair.—Lieut.-General Pitt-Rivers, F.R.S., exhibited some crania found during some recent excavations at Hunsbury Camp, and the Roman villa at Llantwit.—The Rev. H. G. Tomkins read a paper on the Hyksôs, or Shepherd-Kings, of Egypt.—In a paper on the proprietorship of trees on the ground of others, Mr. Hyde Clarke (Vice-President), showed that this was the case in Asia Minor, Melanesia, Borneo (honey-trees), India, Choto Nagpore (moura), and was supposed to be so in parts of China. He proposed the ownership of trees as a more probable origin in jurisprudence of the rights of property than ownership of land, which has no primitive value.

Paris.

Academy of Sciences, June 17.—M. Des Cloizeaux, President, in the chair.—Numerical results obtained in the study of the vitreous and metallic reflection of the visible and ultra-violet rays, by M. A. Cornu. The tables here communicated contain the values of the following elements: the wave-length, λ, of the reflected radiation; the principal incidence, $\Im$, which corresponds to a difference of phase, ϕ, equal to $\frac{1}{4}$ between the two reflected vibratory components; the coefficient H, calculated on the empirical relation between ϕ and i—

$$H = \sin(\Im - i) \cot 2\pi (\phi - \tfrac{1}{4}),$$

in the neighbourhood of the principal incidence; the coefficient k; Cauchy's coefficient of ellipticity, ϵ, calculated by the formula $H = \epsilon \sin^3 \Im$; the product $2k \cos \Im$, which should be equal to ϵ when ϵ is very small before unity. The substances studied are selenium, realgar (sulphide of arsenic), senarmontite (crystallized antimony oxide), blende, diamond, fluor-spar, and silver. In general, these numerical data confirm the conclusions already announced, especially as regards the constant increase of the positive and negative coefficient of ellipticity with the refrangibility of the reflected radiations.—On the heats of combustion and formation of the nitriles, by MM. Berthelot and Petit. The nitriles of monobasic acids (acetonitrile, propionitrile, benzonitrile, orthotolunitrile, benzyl cyanide), and those of bibasic acids (oxalic, malonic, succinic, and glutaric nitriles) have been investigated.—A short summary of the thermo-chemical method in its principles and results, as applied to anatomical studies, by M. Sappey. Attention is called to a new method of research, which has for its object the study of the intimate structure of the tissues and organs. The advantages, importance, and absolute necessity of this thermo-chemical method are insisted upon, not as superseding, but as supplementing, older processes. M. Sappey has practised it since 1860, but has hitherto refrained from publishing anything on the subject through his desire to thoroughly verify all the facts before proclaiming the new doctrine. The method itself is based on the fundamental principle of the association of calorific with chemical action in the animal organism; and in its application to the study of the tissues, cuticle, secreting glands, the stomach, ovary, &c., yields highly satisfactory, and in some instances quite startling, results, which cannot fail to challenge the attention of all physiologists.—On the prophylactic method as applied to patients after being bitten, by M. L. Pasteur. In his brief report for the year ending May 1, 1889, the Director of the Pasteur Institute announces the treatment of 1673 subjects, of whom 6 were seized with rabies during, and 4 within a fortnight after, the process. But 3 only succumbed after the treatment had been completely carried out, making one death in 554, or, including all the cases, one in 128.—On the photographic spectrum of Uranus, by Dr. W. Huggins.—Improvements in the graphophone, by Prof. C. V. Riley. Several defects inherent in Mr. Tainter's instrument are stated to have been at last completely removed by Mr. John H. White, of Washington, who has greatly improved the graphophone by employing certain appliances which have been constructed by Prof. Riley on acoustic principles.—Observations of the planet Eucharis (181), made at the west equatorial in the garden of the Paris Observatory, by M. D. Eginitis. The observations are for February 7 and 9, 1889.—On the enlargement of the spectral rays of metals, by M. Gouy. These investigations show that the so-called *narrow* metallic rays present two distinct structures. Some are widened in a uniform manner on both sides (symmetric rays), while others are enlarged almost exclusively on one side (dissymmetric rays). The difference is very marked, and the author has failed to detect any intermediate phase. Nearly all the metallic rays are symmetric, the only exceptions hitherto observed by him being those of sodium and potassium, which belong to the dissymmetric group.—On the limit between polarization and electrolysis, by M. H. Pellat. These researches lead to the establishment of a general law thus announced: Electrolysis begins the moment the double electric layer has been neutralized by polarization.—On actino-electric phenomena, by M. A. Stoletow. Owing to some improvements in the conditions of the investigation, the author has succeeded in determining more accurately the laws of the actino-electric currents in the atmosphere at ordinary pressure. He now thinks that the hypothesis attributing the actino-electric phenomena to the condensed gaseous layers which cover the metallic surfaces, must be rejected.—On the duration of lightning, by M. E. L. Trouvelot. Aided in his observations by photography, the author infers that the flash is not instantaneous, as is generally supposed, but has a perceptible duration beyond the thousandth part of a second, denied to it by Wheatstone.—Researches on the phenomenon of dispersion in organic compounds, by MM. P. Barbier and L. Roux. The first results of the researches undertaken by the authors on the dispersive power of fluid organic compounds are here communicated. The present note is confined to the monosubstituted derivatives of benzine.—M. G. A. Le Roy describes a new method of preparing nitrites of the alkaline metals; and M. Alphonse Combes contributes a paper on the action of the diamines on the diketones.

AMSTERDAM.

Royal Academy of Sciences, May 25.—Dr. H. G. van de Sande Bakhuysen in the chair.—M. Lorentz read a paper on the molecular motion of dissolved substances. The values of the osmotic pressure, which M. van't Hoff has deduced from various data, seem to indicate that this pressure is due to the molecular motion of the dissolved body, the mean kinetic energy of a molecule being equal to that of the molecule of a gas at the same temperature. These views were tested by a discussion of molecular equilibrium in a solution under the influence of external forces.—M. van de Sande Bakhuysen exhibited an instrument for determining, by means of rectangular co-ordinates, the right ascensions and declinations of stars on photographs, and the results obtained by measuring, after this method, a photograph by M. Henry. The probable error of each co-ordinate is ± 0″·043. He pointed to the great interest of photographs in the determination of the sun's parallax, and stated that during the coming opposition of Victoria, M. Henry at Paris will make photographs which are to be measured at Leyden.—M. Bierens de Haan announced that the second volume of Huyghens's correspondence will soon be published.—M. Forster treated of the influence of our common salt on the life of pathogenetic bacteria, and stated that, from many and various experiments, he had come to the conviction that, whereas cholera bacilli are very sensible to that salt, and when brought into contact with it very soon die, the typhoid and pyogenetic bacteria, the bacilli of tuberculosis, and the cattle-distemper bacilli may remain for months buried in common salt without losing their powers of growth and reproduction. The salting of butchers' meat may, therefore, in some cases prove ineffectual. M. Forster further exhibited some preparations, obtained in the hygienic laboratory, which went to prove that neither the bacilli of tuberculosis nor cholera bacilli can develop under the influence of iodoform vapour.

CRYPTOGAMIC BOTANY.

A Hand-book of Cryptogamic Botany. By Alfred W. Bennett, M.A., B.Sc., F.L.S., and George Murray, F.L.S. With 378 Illustrations. (London: Longmans, Green, and Co., 1889.)

THE utility of a book presenting in clear outline the present state of our knowledge of the morphology of flowerless plants cannot be doubted. The division of plants into Cryptogams and Phanerogams is, it is true, a non-natural one. As the authors of this hand-book themselves point out, the Vascular Cryptogams are "more nearly allied in many respects to the Phanerogams than to the lower Cryptogams." This fact, however, is not a serious objection to the limitation here adopted. If it is found desirable, for teaching purposes, to treat the vegetable kingdom in two divisions, the line may be as conveniently drawn between the Pteridophyta and the Gymnosperms as anywhere else. The idea of a work dealing with the families of Cryptogamic plants has been familiar to English readers since the publication of Berkeley's famous "Introduction to Cryptogamic Botany" in 1857. Since that date the literature of the subject has accumulated to an incalculable extent. A work of similar scope, written at the present day, demands enormously increased labour in compilation, and offers, perhaps, less room for originality. In the authors' view, the object of the writer of a hand-book is "to gather up and to collate material already existing, winnowing, to the best of his judgment, the wheat from the chaff." The indebtedness of the authors to their predecessors is amply acknowledged, and it may fairly be claimed for the hand-book that the arrangement of the material is to a great extent its own.

The descending order is followed throughout, the Cryptogams being divided into seven groups: Vascular Cryptogams, Muscineæ, Characeæ, Algæ, Fungi, Mycetozoa, and Protophyta. The reappearance of the Characeæ as a main group will be a surprise to those who have become accustomed (and in our opinion rightly) to regard them as green Algæ. The Mycetozoa should probably have been excluded altogether, and the Protophyta, as here limited, form a very heterogeneous collection. On the other hand, we regard the breaking up of the old sub-kingdom, Thallophyta, as a distinct gain. The character on which it was founded is of absolutely no systematic value, and the Algæ and Fungi, at any rate, are groups of sufficient extent and independence to stand by themselves.

The authors have introduced several changes in terminology. The most conspicuous, though not the most important, of these is the adoption of Anglicized terminations for Latin and Greek technical words. This is a matter in which it is hard to draw the line aright; thus we have already become used to "ovule" and "pistil" instead of "ovulum" and "pistillum." But still, as a matter of taste, we think the authors have gone much too far in this direction. They complain of the "awkward and uncouth foreign forms of these words": we should have thought this reproach applied much more strongly to "cœnobe," "sclerote," "nemathece," and "columel." It need hardly be said that the authors themselves have not succeeded in attaining consistency in this matter. Happily, we are still allowed to say "prothallus" and "nucleus," though "nucleolus" has become "nucleole," and "gleba," "glebe."

A more important point is the use of the word *spore*. The authors define a spore as "any cell produced by ordinary processes of vegetation, and not directly by a union of sexual elements, which becomes detached for the purpose of direct vegetative propagation." Thus the word is used in a narrower sense than that of de Bary in his "Fungi," or of Vines in his "Physiology of Plants." The authors' use of the word seems in itself unobjectionable, and is certainly preferable to Sachs's definition; but we do not see that anything is gained by the limitation they propose.

The substitution of "megaspore" for "macrospore" we regard as an improvement, and only hope it may be generally adopted.

For sexual products the authors make use of the termination "sperm" in the place of "spore," thus speaking of zygosperms and oosperms. For the sake of consistency they avoid using words compounded with "sperm" for male cells; thus "antherozoid" is once more substituted for "spermatozoid," while "spermatium" is replaced by "pollinoid." We cannot regard this last name as a happy one, for it suggests a false comparison with pollen-grains. As regards "spermatozoid" and "antherozoid," the reasons on both sides seem very equally balanced, though the former has the great advantage that it emphasizes the homology with the male element in the animal kingdom. The term "spermogonium" is abolished on the additional ground that the "spermogone is a true antherid," a statement which, at least in this general form, is really unwarranted by the facts. The word "reproduction" is limited to "the production of a new individual—that is, to a process of impregnation." This definition seems to us to involve far too much metaphysical hypothesis.

The section on the Vascular Cryptogams is preceded by some useful introductory remarks, in which the homologies with the Phanerogams, and the general course of development, are explained. The statement that in apogamy and apospory "either the oophyte or the sporophyte may be entirely suppressed" is, however, inaccurate; as, in the cases referred to, only the reproductive organs are (wholly or partially) suppressed, and not the generation which bears them.

The Vascular Cryptogams are divided, as in the earlier editions of Sachs's text-book, into a heterosporous and an isosporous series. This arrangement is admittedly provisional, but the difficulty in finding a truly natural arrangement does not seem to us a sufficient reason for adopting one which is manifestly artificial.

The Rhizocarps are the class first described. The only criticism of importance which suggests itself here is that the clear relation of these plants to the isosporous Ferns is insufficiently brought out. The other heterosporous class is the widely different group Selaginellaceæ, including Selaginella and Isoëtes. The following sentence (occurring in the account of the latter genus) is very misleading: "The mode of development of the megaspores presents perhaps the closest analogy to that of the secondary embryo-sacs of Gymnosperms that occurs in any order of Vascular Cryptogams; and the same remark applies to the formation of the microsporanges and pollen-sacs." The structures compared in the latter part of this sentence are homologous; the "secondary embryo-sacs" and megaspores are certainly not so, nor do we see in what sense there is even any "analogy" between them.

The isosporous series is divided into Lycopodiaceæ, Filices, Ophioglossaceæ, and Equisetaceæ. We are glad to see that some account of Treub's classical observations on the sexual generation of Lycopodium is given. In Psilotum the sporangia are described as "plurilocular," and are then said to be "collected into groups of three or four." These two views of the morphology cannot both be true.

The class Filices, as here limited, includes the Marattiaceæ but not the Ophioglossaceæ, an arrangement which we do not think an improvement. At p. 71, the *stem* of Lygodium is wrongly said to be scandent, in contradiction to the correct account given a few pages later on. Slips of this kind are rather frequent in the book, and should be looked to in a future edition.

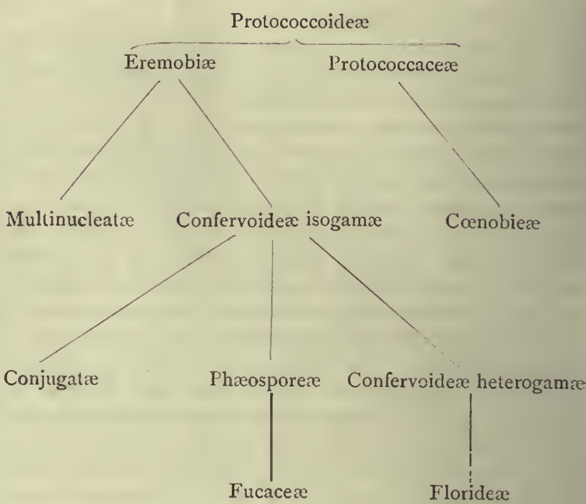
The sections on the Ophioglossaceæ and Equisetaceæ call for no special remark, except that we find Sachs's original description of the division of the spore mother-cells in Equisetum reproduced. The process is a perfectly typical case of cell-division (not "free cell-formation"), and called for no special description here; while Sachs's account, however interesting historically, is now fifteen years out of date.

An interesting notice of fossil Vascular Cryptogams concludes this subdivision. Attention may especially be called to the excellent figure of the stem of Psaronius, which, by the way, is referred to Cyatheaceæ—not, as by Solms-Laubach, to Marattiaceæ. This chapter will be very welcome to English students.

The second subdivision, Muscineæ, is divided as usual into Musci and Hepaticæ. The treatment of these classes, though not very full, is otherwise satisfactory. By an unfortunate mistake, the protonema of the Mosses is twice over described as colourless (pp. 134 and 140). We think that it is undesirable to speak of the archegonia as in any sense "corresponding to the pistil in flowering plants" (p. 141). Expressions of this kind are very likely to mislead the beginner, and the same objection applies to the term "stigmatic cells" for the cells at the apex of the archegonium.

As mentioned above, the Characeæ are separated from the Algæ as a distinct subdivision. The reasons given for this separation do not appear sufficient. Much higher morphological differentiation of the vegetative organs is found among undoubted Algæ, while the great number of Algal characters presented by the Characeæ seem to us to outweigh the points of peculiarity in their reproductive organs. However, the true position of this group is likely long to remain a *vexata quæstio*.

The Algæ themselves are treated at considerable length (120 pages), and the account given is the fullest in any general English work. The authors may be congratulated on being the first in this country to attempt an adequate summary of our knowledge of these plants: as might be expected, however, there are many points which invite criticism. The Algæ are ranged in eight classes: Florideæ, Confervoideæ heterogamæ, Fucaceæ, Phæosporeæ, Conjugatæ, Confervoideæ isogamæ, Multinucleatæ, and Cœnobieæ. The authors' opinion as to the phylogeny of these classes may perhaps be best represented in a tabular form. All Algæ are derived by them from the Protococcoideæ, the latter group being placed among the Protophyta.



On the whole, this arrangement seems to us as good as any which has been proposed, though it is necessarily provisional. We cannot agree that the Dictyotaceæ connect the Fucaceæ with the Phæosporeæ through the Cutleriaceæ. The resemblance between the latter and Dictyotaceæ is a very superficial one. Nor are we satisfied that Coleochæte really marks the transition from oosporous Confervoideæ to Florideæ. Falkenberg has already shown how slender the grounds are for this supposition. We should be disposed to seek the origin of the red seaweeds much lower down in the scale, but in the present state of knowledge it is quite impossible to decide this point.

The Porphyraceæ and Ulvaceæ are included among the Florideæ as degraded forms. The Ulvaceæ, however, have no Floridean characters whatever, and show clear relationships to such Palmelloid forms as Tetraspora, a fact which the authors themselves recognize (p. 418). If, as is possible, Porphyraceæ and Ulvaceæ are really related, the former group will have to be separated again from the Florideæ, with which it has been somewhat too hastily associated on the ground of Berthold's observations.

It is impossible to consider all the authors' classes in detail. As regards the brown Algæ, we do not think it is correct to say that the differentiation of *tissues* in the Laminariaceæ is less strongly developed than in the Fucaceæ, and we entirely decline to believe that the unilocular sporangia of Cladostephus are due to the attacks of parasitic Chytridiaceæ! (p. 250). The Conjugatæ are fully described, but there is some confusion in the use of the words "zygosperm" and "hypnospore" in the order Mesocarpeæ. The class Multinucleatæ corresponds to Siphoneæ in the widest sense. We cannot agree with the authors in regarding Vaucheria as the "culminating genus" of this class. It is inferior to most Siphoneæ in every respect except the heterogamous reproduction.

In the class Cœnobieæ the orders Pandorineæ and Volvocineæ should, we think, have been united, or at least placed in juxtaposition.

A few words on fossil Algæ conclude this section.

The fifth subdivision, Fungi, is very clearly described, in general agreement with de Bary's views. The Fungi are divided into Phycomycetes and Sporocarpeæ, the former including the Oomycetes and Zygomycetes, the latter the Ascomycetes, Uredineæ, and Basidiomycetes. We may note that the Ustilagineæ are included among the Zygomycetes, de Bary's opinion as to the sexuality of the cell-fusions in the former groups being adopted, while Brefeld's opposite view is severely criticized. The phenomena in question are really on the confines of sexuality, and both opinions are tenable. It may be, however, that we have a definite test in the fusion of nuclei, and if Fisch's observations are to be trusted this test goes against the sexuality of the Ustilagineæ.

The account of the Ascomycetes is essentially based on de Bary's work. Due stress is laid on all the cases in which it is possible to find any indication of sexual reproduction. Perhaps it would have been better to point out that there are two sides to the question, and that the views of Brefeld, van Tieghem, and Moeller also have to be taken into account.

The statement that a nucleus has not yet been demonstrated in yeast-cells shows an excess of scepticism. The evidence afforded by Zacharias's observations is as convincing as in the case of any other fungal cells.

The Uredineæ are rather curtly disposed of. In tracing their relationship to the Basidiomycetes, the authors regard the teleutospores and basidiospores as corresponding structures. Several facts may be adduced in support of this view, but on the whole we prefer de Bary's ingenious interpretation, according to which the teleutospores are homologous with the basidia, the promycelium with the sterigmata, and the sporidia with the basidiospores. This comparison rests on very strong evidence, as an inspection of Figs. 130 and 140 in de Bary's "Fungi" will show.

The next subdivision is that of the Mycetozoa. If, as the authors, in agreement with most authorities, state, "we are justified in placing the Mycetozoa outside the limits of the vegetable kingdom" (p. 406), it seems to be time that these organisms were excluded from botanical hand-books.

The last subdivision, Protophyta, is a most heterogeneous group, including the Protococcoideæ, Diatomaceæ, Cyanophyceæ, and Bacteria. In our opinion, the two first-named groups would have been much better placed among the Algæ, and the same probably applies to the Cyanophyceæ, though here there is more room for doubt. This would only leave the Bacteria, and these must eventually accompany the Cyanophyceæ, from which they seem to differ in nothing except the usual absence of chlorophyll. It must be mentioned, however, that the authors themselves fully recognize that the Protophyta are not a natural subdivision.

The work as a whole is a useful summary of Cryptogamic morphology, but there is room for very material emendation. Many inaccuracies occur, some of which have been noticed above, and though these mistakes are no doubt largely due to oversights in revision, they are none the less misleading to the reader. We think also that in some cases, especially as regards the Vascular Cryptogams and the Protophyta, the authors have not made sufficient effort to render their classification as natural a one as possible.

It is especially to be regretted that so few good new figures have been introduced. Nothing adds so much to the freshness and interest of a hand-book as good and original illustrations, while the constant reappearance of familiar text-book figures, however well selected, has become very wearisome, and is unworthy of a living and active science.

We hope that opportunity may be found in a second edition to render this book in every way a satisfactory account of flowerless plants. It should be mentioned that there is a very good and complete index.

D. H. S.

AN ENGLISH RAILWAY.

The Working and Management of an English Railway. By George Findlay, General Manager of the London and North-Western Railway. (London: Whittaker and Co., 1889.)

To write a good book on the working and management of an English railway is no easy matter. The author of such a work must have an intimate knowledge of his subject, and be in a position to take one of our best English railways for his pattern. It would be quite possible to name more than one railway in this country, the management of which would, if described in a book, serve to illustrate how such a task should not be fulfilled. This, however, does not apply to the present volume. It is a pleasure to read a book on the subject by Mr. Findlay, the General Manager of the London and North-Western Railway, for where would it be possible to find a better managed line than the North-Western Railway?

In a volume of 270 pages, divided into sixteen chapters, the author treats departmentally the various sections of staff and plant necessary for the efficient working and control of this vast system of railways. Chapter ii. deals with the management of the line, and it is evident that this is most thoroughly carried out by means of a system of devolution of responsibility. The author says, "It will thus be seen that the chain of responsibility and supervision is a very complete one, and, in fact, the secret of organizing the management of a great service, such as this, is nothing more than a carefully arranged system of devolution combined with watchful supervision." The staff consists of about 55,000 men, including all grades in the service. It is interesting to note that promotion does not depend on seniority, but solely on merit, the best man for the particular post being chosen; and this no doubt is the only way of getting work well done.

In the chapter on the "Permanent Way" the subject is treated historically. The old cast-iron rails laid on stone blocks are illustrated as a relic of the early days of railways, and the reader is gradually led through the various changes and improvements made therein, until he reaches the standard road of the North-Western of to-day, which is as nearly perfect as it can be made with our present knowledge. Signals and interlocking are efficiently dealt with in chapter v. Then the telegraphs are equally well described in chapter vi. The rolling-stock of a railway forms probably the most important part of the necessary plant, and is affected more than anything else by the gradually increasing speeds and weights of trains. Chapters vii. and viii. deal with this important subject. The standard types of locomotives are very well illustrated, but the descriptions might with advantage have been more detailed. The author discusses the necessity for an increase of power in the passenger locomotives to cope with the increased weight of the principal express trains, and the solution of the problem by the introduction of Mr. Webb's fine compound locomotives. The construction and working of these engines are described clearly enough for the benefit of non-professional readers. It would have been interesting to find an account of the Worsdell compound locomotive, which, although not in use on the North-Western, has many points in its favour. Comparing it with Mr. Webb's engine, many engineers consider it the better engine of the two. Perhaps in a future edition Mr. Findlay might add a description of it, with an illustration.

Carriages and different kinds of rolling-stock are well dealt with, and it is evident that the author has taken the utmost pains to get his information up to date. The locomotive works at Crewe, and the carriage and waggon works at Wolverton, are capitally described. With reference to the automatic vacuum brake, described on p. 120, it is evident that this brake is automatic on the coaches *as well as* on the guards' vans. As this is probably of recent introduction, the North-Western Company are to be congratulated on its adoption in their rolling-stock. The earlier vacuum brake fitted was nothing more than the simple non-automatic vacuum brake as far as the coaches were concerned, and was justly condemned by most railway engineers for that reason.

The remaining chapters deal with the working of the trains, shunting and marshalling of goods trains, the working of goods stations, rates, fares, traffic, &c. With regard to all these matters the writer's statements are clear, concise, and to the point.

It would be of great service to the railway world generally if some of the head officials of the best English railways would follow Mr. Findlay's example, and give us some of their stores of experience. Take, for instance, locomotive engineering: where is the student or apprentice to find a book of recent date on the design, construction, and working of the modern locomotive? Let us hope that the infection will spread on the North-Western staff, and that by and by Mr. F. W. Webb, the able Locomotive Superintendent of that railway, will write a book on the department in which he so greatly excels.

Mr. Findlay's book displays so much knowlege and ability that it well deserves to rank as a standard work on the subject. N. J. L.

OUR BOOK SHELF.

Zur Geologie der Schweizeralpen. Von Dr. Carl Schmidt. One Plate. (Basel: Benno Schwabe, 1889.)

THIS pamphlet gives a summary of the views entertained at the present time by many leading Swiss geologists as to the geological history of the Alps. So far as we can see, it does not profess to be more than a compilation, or to contain any original work; but as a summary it is as clear and concise as the subject permits. The author, in the first chapter, briefly sketches the history of the principal types of rock which enter into the composition of the Alps; and, as might be expected at the present juncture, lays much stress upon the results of pressure. Some, indeed, may think that the present moment is rather inopportune for such a memoir as this; for the modifications due to pressure, especially in rocks already crystalline, are still the subject of so much controversy among geologists, that it is difficult to know what may be taken for granted; and there is a danger, if the writer be a disciple of the new school, of confusing the results of demonstration and of hypothesis. A quotation (translated) will indicate the author's point of view better than a general statement. After pointing out that two great rock groups exist in the Alps, one consisting of various granitoid rocks, gneisses, and crystalline schists, the other of limestones, sandstones, and other sediments, he proceeds—"In Switzerland the region which intervenes between the two zones is not very broad. The general strike of this intermediate zone is through Coire, Ilanz, the Greina Pass, Scopi, Airolo, Nufenen, the Rhone Valley, to Martigny, and so through the Val Ferret to the Little St. Bernard. The rocks of this intermediate zone are crystalline sediments, the age of which it is difficult to fix with precision. In the Grisons they have lately been claimed by Gümbel as Palæozoic, in the Valais they have been shown by Lory to be Triassic: that the same, from the Greina Pass to the Nufenen, are Jurassic, can be proved by fossils." This, however, begs the whole question. It has yet to be shown that the Swiss geologists have not confused together, as some maintain, two distinct rock groups, owing to their having mistaken (not for the first time) for crystalline schists, deposits which only simulate the latter, because they are locally composed almost entirely of their *débris*.

But, putting aside theoretical and controversial matters, the author's summary is generally clear. It would, we think, have been more useful if he had condensed somewhat the general discussion in the opening chapter, and dwelt more fully in the others on the many interesting questions of local physiography which are opened up by a study of the Alps. To this objection, however, an exception must be made in the case of the nagelflue, where Dr. Schmidt's remarks are very interesting. In certain of these great masses of conglomerate, pebbles of crystalline rocks are fairly common. These, he states, whether granites, gneisses, or crystalline schists, show no indications of the dynamic metamorphism which is exhibited by similar rocks in the adjoining chain of the Alps. From this observation, if confirmed by further research, it would result that the "schistosity," or secondary foliation, which is so marked a feature in most parts of the Alps, has resulted not from the post-Eocene but from the post-Miocene set of movements.

Die Entstehung der Arten durch räumliche Sonderung. Gesammelte Aufsätze von Moriz Wagner. Herausgegeben von Dr. med. Moriz Wagner. (Basel: Schwabe, 1889.)

OF later years, zoological literature has been significantly full of contributions, advocating now addition to, now subtraction from, the theory of "evolution by means of natural selection" formulated by Darwin—contributions, the chief characteristics of which are that they are mutually destructive, that they are, comparatively speaking, unsupported by any serious array of observed facts, and that none of them meet with more than a few adherents. We do not believe that truth is appreciably advanced by ingenious speculation of that nature; it is certainly in so far retarded that the energy thus expended would have been better applied in placing Darwin's conclusions under severe and prolonged tests, such as those attempted in Fritz Müller's "Für Darwin," and in Weismann's study of the markings of Lepidopteran larvæ. As Semper pointed out long ago (and too much insistence cannot be laid upon it), the present need is not for fine-spun theory—we have theories galore—but for the judicious compilation of facts selected where the leverage will tell, facts which shall either upset or confirm—it matters not which—the theory of natural selection.

The book before us must be classed among the speculative works just mentioned; and the gist of the author's views may be gathered from the following paragraph, written in 1880 (p. 401):—"Every permanent new form (species or variety) commences with the isolation of individual emigrants, separated for a prolonged period from the habitat of some parent species which is in the stage of variability. The active factors in the process are: (1) adaptation of the immigrant colonists to the external conditions of the new habitat (nutrition, climate, soil-composition, competition); and (2) the impression and development of the individual characteristics of the first colonists upon and in their posterity by reason of the breeding between near kin. This formative process ceases as soon as, owing to rapid multiplication, the levelling and compensating effects of intercrossing make themselves felt, resulting in and maintaining that uniformity which characterizes every good species and permanent variety." Wagner's hypothesis exalts the importance of geographical isolation at the expense of natural selection, and thus approximates, both at starting-point and conclusion, to Mr. Gulick's recent theory of "divergent evolution through cumulative segregation" (Journ. Linnean Soc., vol. xx. p. 189), though in detail the respective courses taken by the two writers are by no means identical.

Consisting of a reprint of articles published between 1868–86, mainly in *Kosmos*, *Das Ausland*, and the *Allgemeine Zeitung*, the matter of the book has been long before the public, and its conclusions have been attacked from time to time by Haeckel, Weismann, Oscar Schmidt, and others; a translation of the first, and perhaps the most important article, has appeared in London (Stanford, 1873): criticism of the theory in this place is therefore unnecessary. The present reprint is edited by Wagner's nephew and namesake, in accordance with a wish expressed some time before his death in 1887, and contains, besides the articles previously published, a biographical sketch by Dr. von Scherzer, and editorial introductions; while the last 127 pages are devoted to an attempt of the editor to build certain recent discoveries, such as those of the *Challenger*, into the original structure. It is hardly necessary to say that, being a close-printed German octavo of 667 pages, the book possesses no index.

Sylvan Folk. By John Watson. (London: T. Fisher Unwin, 1889.)

MR. WATSON expresses much contempt for what he calls "the dry bones of science." We are not sure that we quite understand what he means by this expression, but it evidently does not imply that he dislikes results obtained by careful and exact observation. In the present little volume he gives ample proof that he often brings himself face to face with Nature, and that he knows how to interpret many of the innumerable signs and symbols which are readily misunderstood, or altogether overlooked, by less careful inquirers. Mr. Watson is especially happy in his notes upon the ways of birds; but he has also interesting chapters on mice, voles, and shrews, on red deer, fallow, and roe, on British seals, on British fur-bearers, and on "Nature by night." There is not much that is absolutely new in any of the information he has brought together; but his descriptions are so fresh—they suggest so vividly the idea of happy hours spent among attractive scenes in the open air—that they will give genuine pleasure to everyone who reads them. The book will be especially interesting to young readers, who will be glad to learn that it depends very much upon themselves, according to Mr. Watson, whether they shall be on terms of intimacy with the wildest woodland creatures. Mr. Watson thinks that the power of attracting wild creatures was once a much more common possession than it is now.

A Practical Guide to the Climates and Weather of India, Ceylon, and Burmah, &c. By Henry F. Blanford, F.R.S. Pp. 369. (London: Macmillan and Co., 1889.)

THE appearance of this book is very opportune. The Indian Meteorological Office has been in existence for some twenty years, and inasmuch as the region over which its operations extend comprises a very considerable area of the earth's surface, representing climatological conditions of the most varied character, a general *résumé* of the information as to these conditions is one of the most important contributions to climatology that could be made.

Mr. Blanford has well fulfilled his task. He says his work "is not addressed to meteorologists and physicists, ... but more particularly to agriculturalists, medical officers, engineers, pilots and other seafaring men, and to those others of the general public to whom the weather and the climates of India and of its seas are practical and not scientific objects of interest."

The book is divided into two parts: (1) the elements of climate and weather; (2) the climates and weather in relation to health and industry.

The former is naturally the more technical, while the latter appeals to the general public, as it gives a detailed description of the climates of the principal and most frequented hill stations, as well as of the plains, under which latter general head the different provinces or districts receive each a separate notice.

One section is specially devoted to the storms of the Indian Seas. In their discussion Mr. Blanford is a pronounced adherent of the spiral in-draft theory in contradistinction to the old circular theory and the well-known "eight-point rule."

About the most valuable chapter is the last, which is mainly occupied with rainfall and evaporation. The questions relating to these are of paramount importance for the bare existence of millions of the population. Such a famine as that of 1834 in the Doab was sufficient to induce the authorities of the day to construct the Ganges Canal, the greatest work of the kind in the world, and one which has in a great measure corrected the injurious effects of irregularity in the rainfall.

The appendixes give the tabular results of the instrumental records, which are required to substantiate the general statements contained in the previous pages.

The work is a most creditable production, and it will long remain the standard authority on any question bearing on the climate of the Indian Peninsula.

The Unrivalled Atlas. Enlarged Edition (18th). (London and Edinburgh: W. and A. K. Johnston, 1889.)

A NEW and enlarged edition of this atlas has just been published. The forty maps which it contains are well engraved and especially full of information concerning railway communication, whilst the fact that the index contains 20,000 names of places, with their latitude and longitude, testifies to its completeness. An extension of the atlas has been made by the addition of two classical maps, with an index to them, two physical maps of the British Isles and Europe, and two astronomical plates, each being accompanied with descriptive letterpress. A misleading paragraph occurs in the explanation of tidal action. We read: "The moon exerts a much greater influence on the production of tides than the sun; for, though its mass is excessively small in proportion, it is four hundred times nearer the earth." The inference that a beginner would draw from such a paragraph would be that the predominant effect of the moon in causing tides was simply due to its proximity to the earth, whereas the fact cannot be too strongly insisted upon, that it is the differential attraction of the sun and moon upon the earth's surface and centre that causes tidal action. The atlas is complete and trustworthy.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Coral Reefs.

I BELIEVE all the questions asked by Captain W. Usborne Moore in NATURE of June 27 (p. 203) have been already answered in my papers on this subject. However, as I have examined the reefs at Kandavu, Matuku, Ovalau, and other places at the Fiji Islands, I may attempt to answer his questions with reference to these special cases.

According to Mr. Darwin's view, an island equal in extent to the lagoon of an atoll has sunk from view and the circular reef that has grown up marks approximately the position of the ancient coast line. In the case of a barrier reef, land equal in area to the lagoon channels has been submerged, the barrier reef here, too, marking the position of the ancient coast line. The opponents of Mr. Darwin's theory hold that there is no sufficient evidence that any such land once occupied the site of the lagoons and lagoon channels. I believe they might go further, and hold that, had such extensive submergence taken place, these lagoons and reefs would necessarily present features other than those by which they are everywhere characterized in our seas at the present time.

We hold that all the phenomena presented by these coral reefs and islands can be better explained on other principles without calling in subsidence; that slow subsidence or elevation or rest would only modify in a minor way the general features of a reef; that any one of the three kinds of reefs may be formed indifferently in a rising, sinking, or stationary area. In a sinking area the lagoons would probably be relatively deeper, the reefs narrower, and the islands on them small or absent; in a rising area the lagoons would be relatively shallower, the reefs broader, and the islands more numerous or united into a continuous band of land.

In surveying the coasts of any volcanic islands situated in the ocean where there are no coral reefs, Captain Moore must know that these are sometimes surrounded by banks extending much further seawards in one direction than in another. These banks are doubtless formed of the loose materials of the island, which are spread out by wave action. The position of these banks depends on the nature of the rocks in the different parts of the islands; in the case of Graham Island, the whole island was spread out, forming a submerged bank. In addition to the nature of the materials, the depth over the banks depends also on the extent and depth of the surrounding seas. The 20, 50, or 100 fathom line follows sometimes the shape of the coast within, sometimes differs widely from the shape of the coast, just the same as barrier reefs do.

The Fijis are, in my opinion, such a volcanic group, where the shallower waters have now become the home of myriads of lime-secreting organisms. These have built up the wholly submerged banks into atolls, and the banks around islands into barrier reefs, the depth and distance from land most favourable for vigorous coral growth being determined by a variety of local circumstances. When the reef reaches the surface, it spreads seawards. There is, of course, plenty of living coral in the lagoons, but this becomes less and less as the reef becomes more continuous and less oceanic water is admitted. The growth of corals is always, however, much less vigorous and much less rapid in lagoons than on the seaward faces of reefs. The position of the opening in the reef is determined by local conditions, such as the mud from rivers in the case of barrier reefs. I have elsewhere fully explained my view as to the removal of dead coral, and even coral heads and islands, from the lagoons, through solution of the lime by sea-water.

I cannot have seen as much of Kandavu as Captain Moore, but what I did see in no way led me to believe that it was a sinking island;[1] indeed it was here that, not being able to apply Mr. Darwin's theory in explanation of the phenomena of the Kandavu reefs, I commenced to doubt it altogether. The coast around Cape Washington (the western end) appears to be particularly unfavourable for the formation of extensive reefs, because of the high land (2750 feet) and deep water, hence we have only narrow fringing reefs or no reefs. At the north end the extensive banks surrounding the islets are, on the other hand, specially favourable for coral growth, owing to the almost complete absence of rivers and of detritus from the land; here we have what might be called an atoll, except for the presence of the small rocks, which, after reaching the surface, has extended seawards.

If Captain Moore thinks the rock, Solo, was once an island about four miles in diameter and of considerable height, he must explain how in sinking it has left a lagoon around the remaining rock with an average depth of not more that 12 fathoms. He must also explain the nature of the bank extending west from Ono, where there is no continuous barrier.

It is in every way desirable that practical surveyors like Captain Moore should take an interest in these theoretical views, and their observations will be none the less welcome and appreciated whatever side they may take in the controversy. The more observations accumulate the more does it seem to me probable that there never was a barrier reef or atoll formed after the manner required by Mr. Darwin's theory. If Profs. Dana, Bonney, Huxley, and Judd, would mention any one barrier reef and any one atoll that they believe undoubtedly to have been formed in accordance with the subsidence theory, then I think it might be possible within the next few years to undertake a thorough examination of these with the view of testing the rival theories.

Challenger Office, Edinburgh. JOHN MURRAY.

I HAVE been immersed in examinations, and away from London for a few days, so that I did not see Mr. Guppy's letter in NATURE of June 20 (p. 173) till it was too late to reply. I will now only ask space for a few last words. To me the matter does not appear to have "resolved itself into an affair of outposts." The position which I was led to take up from the study of the recent literature on coral reefs, and which I had hoped that I had made clear in my last letter, is this—that till Mr. Guppy can produce cases of *growing reefs* at depths well exceeding 25 fathoms, isolated instances of the occurrence, at such depths, of living corals which are among the reef-builders do not really help him; and that till he can do this he is only supporting hypothesis by hypothesis. For example, I have not seldom, in the Alps, gathered phanerogamous plants, flourishing and in full bloom, at elevations of eleven or even twelve thousand feet above the sea; but I should not direct anyone to this mountain zone who desired to pick a posy of Alpine flowers.

Into the remainder of Mr. Guppy's letter it would be waste of time to enter, or to continue this controversy, for two reasons: one, that evidently Mr. Guppy and myself differ widely as to the nature of hypothesis, and the difference between assumption and proof; the other, that I trust, before another number of NATURE appears, to be among the Alps (with strict orders against forwarding letters or papers), so that any return shots will fail to reach me, until, in this rapidly-moving world, they have passed into the region of ancient history.

June 28. T. G. BONNEY.

BEFORE replying to Captain Moore, I should bear witness to the searching character of his questions, which quite makes up for the fact that during his valuable services of many years abroad he has been, fortunately perhaps, beyond the reach of recent coral reef literature.

However, I would first point out that when he speaks of the second edition of Mr. Darwin's "Coral Reefs," which was published fifteen years ago (1874), as given to the world "after forty years of deep research into various problems of Nature," he surely forgets that after the first edition of 1842 the author had no further acquaintance with coral reefs. Captain Moore also omits to reflect that during the interval between the two editions Dana and Jukes were the only two principal observers that stood up

[1] See "Narrative of the *Challenger* Expedition," vol. i. p. 507.

for Darwin, whilst against them were ranged L. Agassiz, Le Conte, Hunt, Semper, and Rein. One might with equal justice claim for an eminent engineer that a bridge constructed by him as a young man in 1842 and repaired by him when an elderly man in 1874, represented the accumulated experience of a long professional career, notwithstanding that he had never since erected another bridge, and had devoted all his time to works of a very different character, and in spite of the fact that, whilst only two engineers of reputation had in the interval pronounced the bridge to be safe, five others of equal eminence had advised that, owing to its rickety condition, it should be pulled down. If it was a question of personal safety, most people would trust to the opinion of the many.

I will first clear the way by laying stress on the circumstance that neither A. Agassiz nor Murray doubt the reality of subsidence. They only contend that the characteristic form of atolls and barrier reefs is not dependent on it, and that such reefs would be produced by their natural mode of growth alone.

Now, with regard to Fiji, Captain Moore is perhaps not aware that in the writings of Murray, Semper, Geikie, and others, in these columns and elsewhere, the association of the three classes of reefs in the same group, as in Fiji, has often been referred to as opposed to the theory of subsidence. It was the occurrence of all reefs in the Fijis and in the Pelew Group, and the ascertained existence of upraised reefs in the last locality, that amongst other reasons led Murray and Semper to find some different explanation than that of subsidence. Dana saw the difficulty, and tried to avoid it by asserting that small fringing reefs are "often evidence of subsidence, even a greater subsidence than is implied by barrier reefs" (*Amer. Journ. Science and Arts*, 3rd series, vol. viii., p. 316). Semper, however, pointed out that this conclusion at once destroyed the value of the testimony afforded by coral reefs of the movements of the earth's crust, since, if all kinds of reefs can be formed during subsidence, the character of a reef cannot guide us in determining the existence of subsidence or upheaval ("Animal Life," p. 233). Darwin also saw the difficulty of the Pelew Group, where living atolls, barrier reefs, and fringing reefs were associated with upraised ancient reefs; and thus it came about that, when writing to Semper in 1879, he generously observed that, although he still adhered to the theory of subsidence, such cases as that of the Pelew Islands, if of at all frequent occurrence, would make his conclusions of very little value. "Future observers," he went on to say, "must decide between us," &c. (Semper's "Animal Life," p. 456).

I contend that in 1889 Mr. Darwin's condition has already been realized, since we have in the interval proved that in respect to the occurrence in the same locality of all three classes of coral reefs and their association with ancient upraised reefs, the Fijis, the Tongan Group, and the Solomon Islands are but reproductions of the Pelew Group. It will therefore be seen that Captain Moore is in error when he believes that Darwin would not have regarded simultaneous up and down movements in the same group as inconsistent with his theory. Darwin's admission to Prof. Semper in the case of the Pelews shows plainly enough what he would have thought of the Fijis. This difficulty of imagining simultaneous up and down movements in the same group was also perceived by the present Director-General of the Geological Survey, when he remarked some years ago in these columns that "such an association of upheaval with an assumed general subsidence requires, on the subsidence theory, a cumbrous and entirely hypothetical series of upward and downward movements" (NATURE, vol. xxix. p. 107; Proc. Roy. Phys. Soc., viii.).

It is somewhat remarkable that long as the Fiji Group has been known, it is only of recent years that anything has been published concerning its upraised coral reefs and its other evidences of considerable upheaval. Darwin, as late as his edition of 1874, knew nothing of the extensively upraised reefs, and he still coloured the group in his map as in an area of subsidence. Strangely enough, amongst the many errors perpetuated in the edition published in the present year of Mr. Darwin's work, is that relating to this group. In an additional footnote (p. 215) we find no reference to the ancient coral reefs upraised some hundreds of feet in the Lau or Windward Group, which are referred to in the Hydrographic publication of 1882 concerning Fiji, and which were described to me by Lieut. Malan some years ago. We find no reference in this edition of 1889 to the conclusion of Mr. Brady that the Suva soapstone, as indicated by its Foraminifera, was formed in depths of from 150 to 200 fathoms in post-Tertiary times, thus implying an upheaval of from 900 to 1200 feet (Geol. Soc., November 9, 1887). Curious as it may appear, Dana, after his lengthened stay in the group, found proofs of an elevation in the larger islands of only 5 or 6 feet, and was inclined to negative it altogether in the case of the eastern islands ("Corals and Coral Islands," 1872, pp. 342, 346).

Captain Moore refers to the "many evidences of upheaval" in Fiji, and instances the occurrence of shells and coral "at great heights." What evidence has he of subsidence? He points to the form of the reef in various islands, and thus assumes the very question at issue. However, I will leave to Mr. Murray to explain how these reefs attained their characteristic form without the assumed movement of subsidence, of which in fact we can find no direct proof.

H. B. GUPPY.

As Dr. Guppy asks for information with regard to the corals found living at the greater depths round islands in the Indian and Pacific Oceans the following may be of interest.

About two years ago Capt. Wharton, F.R.S., called attention to the Tizard Bank, and last year both it and the Macclesfield Banks were examined by H.M.S. *Rambler*.

The further investigation of the material sent home has shown that the large number of eighteen genera with forty species were found living in depths from 20–44 fathoms outside the reefs, and these species differed with but few exceptions from those in the shallow water.

The following ten genera were found at a greater depth than 30 fathoms—Stylophora, Astræa, Pavonia, Cycloseris, Leptoseris, Stephanaria, Psammocora, Montipora, Alveopora, and Rhodarœa, besides seven small scarcely reef-building genera.

The total number of species collected was 142, so that nearly one-third were represented in over 20 fathoms.

Hibernation of Martins in the Argentine Republic.

PROF. CARLO SPEGAZZINI, an Italian botanist, and quite a trustworthy observer, living at La Plata, the new town in the Argentine Republic, writes from there the following account to my friend the Marquis Giacomo Doria of Genoa:—

"The bird known here by the name of *Golondrina*, and which I think is *Progne domestica*,[1] is subject to hibernation. Last year, while the zinc roof of a small house was being taken up in the month of August, just in the middle of our winter, I found underneath about a hundred martins, all accumulated one over the other and lethargic, but in good health, so that, exposed to the sun, they awoke and flew away very briskly. This year, again, having seen some holes on a *barrancha*, a steep bank over the Plata, I began to dig at them, hoping to find some bats; but there I found several hundreds of the martins of the same kind as above mentioned, clustered and in a state of lethargy. Is such a thing known to naturalists?"

Atmospheric Electricity.

THE interesting accounts of certain electrical phenomena of the atmosphere in NATURE of May 16, 23, and 30, lead me to state that it is a common experience of surveying parties, especially on the high peaks and slopes in the western part of this country to undergo these peculiar electrical sensations. In general these may be described as tingling or pricking sensations, accompanied with hissing or crackling sounds, especially marked if a finger be presented to any metallic object near by. But further than this it has been noticed that whenever a flash of lightning occurs there is a sudden cessation of the distressing electrical effects. The explanation of this is, we think, found in some experiments made at the top of the Washington Monument (elevation 500 feet) during thunderstorms. With a "water dropper collecter," Mascart insulators and quadrant electrometer, we measured the difference of the electrical potential of the air and the ground. The electrometer needle becomes very active with the approach of the "thunder-heads," and after considerable oscillation begins to move steadily in one direction as if subjected to a steadily increasing "pull," and then suddenly, when a potential difference of several thousand volts may be indicated, there is an "instant" drop to zero, and apparent rebound in the other direction, not due to the torsion of the

[1] Or more likely *Progne chalybœa*, Gm.—T. S.

suspending wire-fibre. The drop to zero is simultaneous with each flash of lightning. So certain is this relation that we can time the lightning flashes without seeing them. After the flash the needle begins to again move in one direction, repeating its previous behaviour, so that our electrometer measurements seem to prove that every flash of lightning relieves the state of stress of the air, which we may compare with the glass in a Leyden jar, the cloud and ground being the respective coatings.

We may also get at the same result by noticing the effects of the electrification of the dust, smoke, water, and other matter in the air. Whenever our "collector" was "grounded," the fine stream of water issuing from it preserved a certain even rounded form, breaking into drops some four inches away from the place of exit. Removing the "ground" connection, and the stream being now under the influence of the thunder-clouds, the steadily increasing electrification shows itself in the stream's twisting and splitting into innumerable threads and spray; but with each flash of lightning the distortion instantly ceases, and the stream has its normal character, only to be again distorted.

For the benefit of those wishing to photograph lightning I suggest this as a cheap and easy mode of getting warning when to expose. A small tin case with a nozzle giving a fine thread of water or any form of the "burning match" device, well insulated from the ground, and at some elevation, will indicate by changes in the character of the stream or smoke, the approximate degree of the electrification of the air.

New York, U.S.A., June 20. ALEXANDER McADIE.

Upper Wind Currents over the Equator in the Atlantic Ocean.

REFERRING to the remarks of the Hon. Ralph Abercromby on the above in NATURE of May 30 (p. 101), I would ask for the longitude and latitude for the two crossings of the doldrums, to enable one properly to follow, and eventually work out, the facts. For if our famous meteorologist, on the outer journey, passed within one hundred miles of the West Coast of Africa, the great chain of desert lands, extending many hundreds of miles through Asia to the Sahara in the main weather thoroughfare, would, by its influence, very much contract the width of the calm belt, and otherwise draw the doldrum much north of the line to what would be found more to the westward, where, as it neared the American coast, the breadth of the doldrum belt would very greatly increase; so that, unless the doldrum was crossed at the same longitude, the varying atmospheric conditions should not be put down solely to the sun, or difference of December and May seasons.

Perhaps it is from want of the longitude that I am unable to understand "how low clouds from the south-east drove over north-east trades up to 15° north." All else is exceedingly satisfactory with the law of winds, on the supposition that the return crossing of the doldrum belt took place some hundreds of miles further west, and about half that distance farther south, than on the out journey.

If I may be allowed to digress a little, I would refer to the splendid travels by your correspondent, as published last Christmas under the title of "Seas and Skies in many Latitudes," which in some respects, I think, may be compared with the celebrated *Challenger* Expedition. But, singularly enough, while I am able to follow and accept all the author's research and information, I find myself diametrically opposed to his conclusions. Thus, to quote from p. 428, we have: "Hence we see the proof of the assertion that the trades and monsoons do not meet and force one another to rise, and flow back poleward, but that the two winds coalesce and form one great eastern current over the doldrum." To my mental capacity all the proof is the other way about. If the trades of both hemispheres do not ascend over the calm belt, what other escape or vent is there for them? I am aware that the Meteorological Section of the Krakatão Committee of the Royal Society also favour the idea of a great easterly current ever going west at a certain altitude over the doldrums, but so far as I can find out they do not tell us whence it cometh nor whither or how it goeth. In its circuit going west, we naturally look for its return from the east, and with the constant arrival of fresh winds *viâ* the trades of both hemispheres, it must accumulate if it does not flow back poleward quite as fast as it arrives, for we cannot entertain annihilation of atmosphere any more than of matter. If some other way of escape could be found, we should still have to face the question, Whence comes the supply to the "trades if not from the poles, and whence our prevailing south-westerly winds if not from over the doldrums"? E. FOULGER.

Liverpool, June 18.

P.S.—I do not call in question "the great easterly current over the doldrum," but rather consider its discovery as extremely interesting, it being just what a small school of meteorologists would expect; and it now appears to be left for them to supply a theory for the cause of the direction and also of the motive power of such an atmospheric passage, and possibly for that of the Krakatão dust. E. F.

Patches of Prismatic Light.

I AM curious to know if any of your readers observed the following phenomenon in the sky, and could give any information as to its nature.

When driving with two friends on Saturday evening, June 22, between 6.30 and 7 p.m., in the neighbourhood of Glatton, near Peterborough, we observed on either side of the sun (the sky being almost cloudless) two patches of prismatic light; they appeared to be of nearly the same size as the apparent disk of the sun, and distant from it a hand's span measured from little finger to thumb at arm's length. At the time there were a few light clouds about, but the prismatic patches were not projected on them, as the clouds passed occasionally in front of them, the patches meanwhile shining through the thinnest parts, and reappearing when the clouds had passed, clearly standing out against the sky. There was no appearance of a continuous arch, as in a rainbow, and, unlike a rainbow, the patches were on the same side of the sky as the sun. I may add that the phenomenon was seen by all three of us, and for half an hour after we first noticed it. C. S. SCOTT.

Glatton Hall, Peterborough, June 28.

A Chimpanzee's Humour.

IN a recent lecture Mr. Romanes is reported as having strongly denied the existence of even a trace of any feeling of the ludicrous in the renowned chimpanzee "Sally." It may be worth while to record a small fact observed by me lately, tending, I think, to favour an opposite view.

Being alone with a friend in Sally's house, we tried to get her to obey the commands usually given by the keeper. The animal came to the bars of the cage to look at us, and, adopting the keeper's usual formula, I said, "Give me two straws, Sally." At first she appeared to take no notice, although she had been eyeing us rather eagerly before. I repeated the request with no further result; but on a second or third repetition she suddenly took up a *large bundle* of straw from the floor and thrust it through the bars at us, and then sat down with her back to us. Our request was perhaps unreasonable, seeing that we had no choice morsels of banana with which to reward her. She did not, however, seem ill-tempered at our presumption, and the next instant was as lively as ever. It seems to me that her action on this occasion certainly came very near to an expression of humour. Rather sarcastic humour perhaps it was, but she certainly appeared to take pleasure in the spectacle of something incongruous, and this surely lies at the base of all sense of the ludicrous. HAROLD PICTON.

July 1.

PROF. HUXLEY AND M. PASTEUR ON HYDROPHOBIA.

ON Monday afternoon the meeting called by the Lord Mayor to hear statements from men of science with regard to the recent increase of rabies in this country, and the efficiency of the treatment discovered by M. Pasteur for the prevention of hydrophobia, was held at the Mansion House. Much excellent work was done. Several letters were read from those who were unable to attend. Among these letters was the following from Prof. Huxley:—

"*Monte Generaso, Switzerland, June* 25, 1889.

"MY LORD MAYOR,—I greatly regret my inability to be present at the meeting which is to be held, under your

Lordship's auspices, in reference to M. Pasteur and his Institute. The unremitting labours of that eminent Frenchman during the last half-century have yielded rich harvests of new truths, and are models of exact and refined research. As such they deserve, and have received, all the honours which those who are the best judges of their purely scientific merits are able to bestow. But it so happens that these subtle and patient searchings out of the ways of the infinitely little—of that swarming life where the creature that measures one-thousandth part of an inch is a giant—have also yielded results of supreme practical importance. The path of M. Pasteur's investigations is strewed with gifts of vast monetary value to the silk trader, the brewer, and the wine merchant. And this being so, it might well be a proper and a graceful act on the part of the representatives of trade and commerce in its greatest centre to make some public recognition of M. Pasteur's services, even if there were nothing further to be said about them. But there is much more to be said. M. Pasteur's direct and indirect contributions to our knowledge of the causes of diseased states, and of the means of preventing their occurrence, are not measurable by money values, but by those of healthy life and diminished suffering to men. Medicine, surgery, and hygiene have all been powerfully affected by M. Pasteur's work, which has culminated in his method of treating hydrophobia. I cannot conceive that any competently-instructed person can consider M. Pasteur's labours in this direction without arriving at the conclusion that, if any man has earned the praise and honour of his fellows, he has. I find it no less difficult to imagine that our wealthy country should be other than ashamed to continue to allow its citizens to profit by the treatment freely given at the Institute without contributing to its support. Opposition to the proposals which your Lordship sanctions would be equally inconceivable if it arose out of nothing but the facts of the case thus presented. But the opposition which, as I see from the English papers, is threatened has really for the most part nothing on earth to do either with M. Pasteur's merits or with the efficacy of his method of treating hydrophobia. It proceeds partly from the fanatics of *laissez faire*, who think it better to rot and die than to be kept whole and lively by State interference, partly from the blind opponents of properly-conducted physiological experimentation, who prefer that men should suffer rather than rabbits or dogs, and partly from those who for other but not less powerful motives hate everything which contributes to prove the value of strictly scientific methods of inquiry in all those questions which affect the welfare of society. I sincerely trust that the good sense of the meeting over which your Lordship will preside will preserve it from being influenced by these unworthy antagonisms, and that the just and benevolent enterprise you have undertaken may have a happy issue.

"I am, my Lord Mayor, your obedient servant,

"THOMAS H. HUXLEY.

"The Right Hon. the Lord Mayor,
Mansion House, E.C."

The following letter from M. Pasteur, dated Paris, the 27th ult., was read by Sir H. Roscoe:—

"Dear Colleague and Friend,—I am obliged by your sending me a copy of the letter of invitation issued by the Lord Mayor for the meeting on July 1. Its perusal has given me great pleasure. The questions relating to the prophylactic treatment for hydrophobia in persons who have been bitten and the steps which ought to be taken to stamp out the disease are discussed in a manner both exact and judicious. Seeing that hydrophobia has existed in England for a long time, and that medical science has failed to ward off the occurrence even of the premonitory symptoms, it is clear that the prophylactic method of treating this malady which I have discovered ought to be adopted in the case of every person bitten by a rabid animal. The treatment required by this method is painless during the whole of its course and not disagreeable. In the early days of the application of this method contradictions such as invariably take place with every new discovery were found to occur, and especially for the reason that it is not every bite by a rabid animal which gives rise to a fatal outburst of hydrophobia. Hence prejudiced people may pretend that all the successful cases of treatment were cases in which the natural contagion of the disease had not taken effect. This specious reasoning has gradually lost its force with the continually increasing number of persons treated. To-day, and speaking solely for the one anti-rabic laboratory of Paris, this total number exceeds 7000; or exactly, up to the 31st of May, 1889, 6950. Of these the total number of deaths was only seventy-one. It is only by palpable and wilful misrepresentation that a number differing from the above, and differing by more than double, has been published by those who are systematic enemies of the method. In short, the general mortality applicable to the whole of the operations is 1 per cent., and if we subtract from the total number of deaths those of persons in whom the symptoms of hydrophobia appeared a few days after the treatment—that is to say, cases in which hydrophobia had burst out (often owing to delay in arrival) before the curative process was completed—the general mortality is reduced to 0·68 per cent. But let us for the present only consider the facts relating to the English subjects whom we have treated in Paris. Up to May 31, 1889, their total number was 214. Of these there have been five unsuccessful cases after completion of the treatment, and two more during treatment, or a total mortality of 3·2 per cent., or more properly 2·3 per cent. But the method of treatment has been continually undergoing improvement, so that in 1888 and 1889, on a total of sixty-four English persons bitten by mad dogs and treated in Paris, not a single case has succumbed, although amongst these sixty-four there were ten individuals bitten on the head and fifty-four bitten on the limbs, often to a very serious extent. I have already said that the Lord Mayor in his invitation has treated the subject in a judicious manner, from the double point of view of prophylaxis after the bite and of the extinction of the disease by administrative measures. It is also my own profound conviction that a rigorous observance of simple police regulations would altogether stamp out hydrophobia in a country like the British Isles. Why am I so confident of this? Because, in spite of an old-fashioned and widespread prejudice, to which even science has sometimes given a mistaken countenance, rabies is never spontaneous. It is caused, without a single exception, by the bite of an animal affected with the malady. It is needless to say that in the beginning there must have been a first case of hydrophobia. This is certain; but to try to solve this problem is to raise uselessly the question of the origin of life itself. It is sufficient for me here, in order to prove the truth of my assertion, to remind you that neither in Norway, nor in Sweden, nor in Australia, does rabies exist; and yet nothing would be easier than to introduce this terrible disease into those countries by importing a few mad dogs. Let England, which has exterminated its wolves, make a vigorous effort, and it will easily succeed in extirpating rabies. If firmly resolved to do so, your country may secure this great benefit in a few years; but, until that has been accomplished, and in the present state of science, it is absolutely necessary that all persons bitten by mad dogs should be compelled to undergo the anti-rabic treatment. Such, it seems, is a summary of the statement of the case by the Lord Mayor. The Pasteur Institute is profoundly touched by the movement in support of the meeting. The interest which His Royal Highness the Prince of Wales has evinced in the proposed manifestation is of itself enough to secure its success. Allow me, my dear colleague, to express my feelings of affectionate devotion."

AN INDEX TO SCIENCE.

I HAVE lately received the "Sach Register" of the *Berichte der Deutschen Chemischen Gesellschaft*, 1868-87, in three volumes, indexing the twenty years of publication (thirty-six volumes). The work is admirably done, and is of inestimable value to the student of science generally. German scientific men and scientific Societies are far in advance of the English in the art of making the results of scientific research readily accessible. Witness the admirable "Bibliotheca Zoologica," by Engelmann and Carus, and still continued by Taschenberg; the "Sach Registers" to Liebig's *Annalen der Chemie*, 1832-83, to Poggendorff's (now Wiedemann's) *Annalen der Physik und Chemie*, 1824-87, and to the *Journal für Praktische Chemie*, 1833-87; and the "Repertorium Commentationum a Societatibus litterariis editarum," by Reuss, in sixteen quarto volumes, which last valuable production covers the whole ground down to the end of the last century.

The fact is very suggestive with regard to the English neglect of the scientific knowledge, experiment, and discovery locked up in the long series of English scientific journals to be found in our public libraries. The journals have usually, but not always, a short index at the end of each volume, obliging the student to occasionally spend days and weeks in searching through the series for what has been written on a subject he is investigating. The volumes accumulate on the shelves, and the experiments and investigations are repeated again and again.

The Royal Society, with a lively sense of the necessity for a remedy to the existing chaos, some twenty years ago commenced, and continues at intervals the issue of "A Catalogue of Scientific Papers contained in the Transactions of Societies, Journals, and other Periodical Works from the Year 1800." It is an author-list, and does not at all meet the requirements of the case. It necessitates a knowledge, by the inquirer, of the names of all the men who are likely to have written on the subject of inquiry. Life is not long enough for this. Librarians are occasionally of some assistance in the matter, but they often fail. What occurred lately has occurred to me often: I submitted to a chemist of some note the records of experiments published in 1820, which would have saved him many months of investigation of the same subject if a reference to the previous work had been accessible by index or by personal knowledge. It is the experience of all men of science that days may be spent in obtaining a reference to what may be read in five minutes, usefully or uselessly.

The Royal Society Catalogue originated from a suggestion of the late Joseph Henry, the Director, for thirty years, of the Smithsonian Institution (Washington) for the Increase and Diffusion of Knowledge, who said ("Smithsonian Miscellaneous Collections," vol. xxi. p. 295):—

"One of the most important means for facilitating the use of libraries (particularly with reference to science) is well-digested indexes of subjects, not merely referring to volumes of books, but to memoirs, papers, and parts of scientific transactions and systematic works. I know of no richer gift which could be bestowed upon the science of our own day than the provision of these. Everyone who is desirous to enlarge the bounds of human knowledge should, in justice to himself as well as to the public, be acquainted with what has been previously done in the same line."

Henry afterwards communicated with the British Association on the subject (in 1855). The Association appointed a Committee (Mr. Cayley, Mr. Grant, and Prof. Stokes), who reported:—

"The Committee are desirous of expressing their sense of the great importance and increasing need of such a Catalogue. . . . The Catalogue should not be restricted to memoirs in Transactions of Societies, but should comprise, also, memoirs in the Proceedings of Societies, in mathematical and scientific journals, &c. . . . The Catalogue should begin from the year 1800. There should be a Catalogue according to the names of authors, and *also a Catalogue according to subjects*."

The Committee succeeded in interesting the Royal Society of London in the undertaking, and that body ultimately assumed the direction of the work.

But they have achieved an instalment only of the recommendation of the distinguished Committee at whose suggestion they took action. They have produced an author-list, but the "Catalogue according to subjects" is wanting. All the subjects in the Royal Society's Catalogue should be at once placed under a subject-heading as well as under the author-heading in alphabetical arrangement, as near a concordance as possible by means of cross-references, and should be systematically continued and published annually. What has been done by Mr. Poole, of Chicago, for the great portion of English *general* periodical literature in publishing a subject-list, alphabetically arranged, of the articles contributed to 238 periodicals from 1802-81, and to 141 periodicals in the supplemental volume for 1882-87, should be done for all the scientific publications. The principle of the work is simple, and could be readily carried out. "The main purpose of this (Poole's) work was to meet the average wants of students, literary men, and writers for the press—in other words, to help general scholars, who are many, in preference to the few who give their whole attention to a single topic." From an experience of thirty-two years in libraries, I must say, with all due deference to Mr. Poole, that a subject-index of the scientific journals would be of vastly greater benefit to the community—material benefit, if he pleases. I ought, however, to add my meed of praise to the practical, sensible, and sufficient way in which the work that he attempted has been done.

An attempt at remedying our great literary defect was made by Robert Watt, 1819-24, when he added to the two quarto volumes of an alphabetical list of 40,000 authors in his "Bibliotheca Britannica, or General Index to British and Foreign Literature," an additional two volumes of an index of subjects. This has all the disadvantages of a first attempt. The study of bibliography was little known, and less cultivated, at the time. The book is almost entirely out of date. A great deal more may be said in favour of the combination of authors and subjects in one general catalogue, as successfully achieved by Lieutenant-Colonel Billings in the "Index Catalogue of the Library of the Surgeon-General's Office, United States Army," as far as the letter N, in nine volumes, royal octavo. This is a specimen of cataloguing almost perfect: every article, and every disease, and the complications of every disease, with the various organs, being catalogued and sub-catalogued with their cross-references.

The history of scientific research exhibits a continual tendency towards specialization; and as the sphere of the labourer has become limited each area of research has expanded, so that it has become essentially necessary that every subdivision of knowledge should be digested and arranged. With the co-operation of a few librarians, a subject-catalogue of all scientific literature might be readily undertaken by the Royal Society or the Society of Arts, the publications contained in the British Museum being marked by an asterisk or other sign. Or a system similar to that of the "Smithsonian Catalogue of Scientific and Technical Periodicals (1665-1882)" might be adopted, in which, by means of a check list at the end, it is shown in what American libraries all the periodicals may be found. A good portion of the work is done in such works as have been mentioned: in the indexes to the literature of special subjects in the Smithsonian collections, in the publications of the Harvard University, and in the indexes to the publications of Societies, such as the Chemical, Geological, Zoological, Linnean, Astronomical, Geographical, Engineers, Statistical, the Society of Arts, and the Royal Society, and in the indexes of various periodicals. These should be systematically arranged; the chaos should be organized and classified, to enable the man of science to find out at a glance all that has been published on any branch of his subject, and the work would be of value to the country.

The range of subject-headings should include everything relating to scientific and technical subjects. These would include (taking Comte's classification for convenience in the serial arrangement), Mathematics, Astronomy, Physics, Chemistry, Physiology (or what is commonly understood as Natural History, with the generic term of Physiology or Physio-Philosophy), and Social Physics (including Sociology). These subjects are clear, well defined, and well known to the librarians.

There is nothing so necessary as that scientific thought and method should be embodied, classified, and arranged, preliminary to its organization as a whole. It would quicken the slow process of improvement that has extended over a thousand years. It is wonderful that it should be necessary to say this in the nineteenth century. The need for organization in all departments of science is keenly felt; and the growth of Positivism in these latter days is one of the expressions of that need. Three centuries ago Bacon aimed at the organization of the sciences, holding that the sciences can be advanced only by combining them; that, as natural laws are invariable and uniform, "Physics being the mother of all science," so moral and civil philosophy could not flourish when separated from their roots in natural philosophy.

On national grounds it is necessary that this work should be done, for it is in the interest of the community generally, of the nation, that we should know what we possess. Public libraries and educational institutions are increasing; scientific experiment, discovery, and invention are increasing; and the demand for such a subject-catalogue will increase. Its value to the community would be inestimable. If it is thought advisable that the Royal Society or the Society of Arts should take the work in hand, the work should be subsidized by the Government, for the simple reason that it would be of national value. Scientific research is not so remunerative but that the student may fairly expect facility of access to the labours of those who have gone before. The want of a serviceable key to the vast body of scientific work contained in our literature is daily experienced by cultivators of science. There is a serious necessity that this material should be made more readily accessible for comparison, for verification, and for improvement. Much of it is a monument of shattered hopes, the unsuccessful efforts of poverty and despair; but all of it is suggestive to the earnest student.

No one Society or publisher can take the work in hand without Government support or benefaction. Attempts have been made, such as the attempt of the Royal Society, and that of Agassiz in his "Bibliographia Zoologiæ et Geologiæ," published by the Ray Society, which voluminous work, be it remembered, "was mainly compiled by the Professor for his own private use during the leisure moments of a life of almost incessant scientific research." In whatever hands the work may be placed, there is no doubt that the co-operation of the scientific Societies might be relied upon. With regard to the question of assistance from the Government, the following Minute of the Lords Commissioners of Her Majesty's Treasury, dated November 28, 1864, referring to the Royal Society's Catalogue, is very suggestive:—

"Having regard to the importance of the work with reference to the promotion of scientific knowledge generally, to the high authority of the source from which it comes, and to the labour gratuitously given by members of the Royal Society to its production, my Lords consider themselves justified in having the work printed at the cost of the public, with the understanding that, reserving such a number of copies for presentation as my Lords, in communication with the President of the Royal Society, may hereafter determine, the work shall be sold at such a price as may be calculated will repay the cost of printing.

"Their Lordships, however, desire it to be understood that the work shall go forth to the public under the authority of the Royal Society, by the exertions of whose members this important aid to the study of science has been produced."

J. TAYLOR KAY.

IRIDESCENT CRYSTALS.[1]

THE principal subject of the lecture is the peculiar coloured reflection observed in certain specimens of chlorate of potash. Reflection implies a high degree of discontinuity. In some cases, as in decomposed glass, and probably in opals, the discontinuity is due to the interposition of layers of air; but, as was proved by Stokes, in the case of chlorate crystals the discontinuity is that known as twinning. The seat of the colour is a very thin layer in the interior of the crystal and parallel to its faces.

The following laws were discovered by Stokes:—

(1) If one of the crystalline plates be turned round in its own plane, without alteration of the angle of incidence, the peculiar reflection vanishes twice in a revolution, viz. when the plane of incidence coincides with the plane of symmetry of the crystal. [Shown.]

(2) As the angle of incidence is increased the reflected light becomes brighter and rises in refrangibility. [Shown.]

(3) The colours are not due to absorption, the transmitted light being strictly complementary to the reflected.

(4) The coloured light is not polarized. It is produced indifferently whether the incident light be common light or light polarized in any plane, and is seen whether the reflected light be viewed directly or through a Nicol's prism turned in any way. [Shown.]

(5) The spectrum of the reflected light is frequently found to consist almost entirely of a comparatively narrow band. When the angle of incidence is increased, the band moves in the direction of increasing refrangibility, and at the same time increases rapidly in width. In many cases the reflection appears to be almost total.

In order to project these phenomena a crystal is prepared by cementing a smooth face to a strip of glass, whose sides are not quite parallel. The white reflection from the anterior face of the glass can then be separated from the real subject of the experiment.

A very remarkable feature in the reflected light remains to be noticed. If the angle of incidence be small, and if the incident light be polarized in or perpendicularly to the plane of incidence, the reflected light is polarized in the *opposite* manner. [Shown.]

Similar phenomena, except that the reflection is white, are exhibited by crystals prepared in a manner described by Madan. If the crystal be heated beyond a certain point the peculiar reflection disappears, but returns upon cooling. [Shown.]

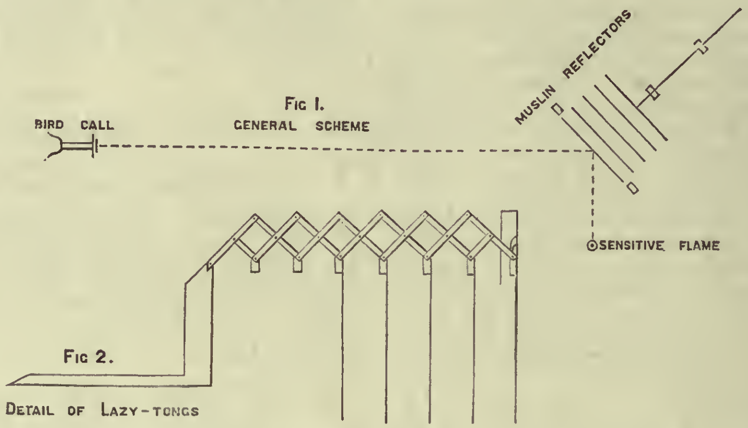
In all these cases there can be little doubt that the reflection takes place at twin surfaces, the theory of such reflection (*Phil. Mag.*, Sept. 1888) reproducing with re-

[1] Abstract of the Friday evening lecture delivered by Lord Rayleigh, F.R.S. at the Royal Institution on April 12, 1889.

markable exactness most of the features above described. In order to explain the vigour and purity of the colour reflected in certain crystals, it is necessary to suppose that there are a considerable number of twin surfaces disposed at approximate equal intervals. At each angle of incidence there would be a particular wave-length for which the phases of the several reflections are in agreement. The selection of light of a particular wave-length would thus take place upon the same principle as in diffraction spectra, and might reach a high degree of perfection.

In illustration of this explanation an acoustical analogue is exhibited. The successive twin planes are imitated by parallel and equi-distant disks of muslin (Figs. 1 and 2) stretched upon brass rings and mounted (with the aid of three lazy-tongs arrangements), so that there is but one degree of freedom to move, and that of such a character as to vary the interval between the disks without disturbing their equi-distance and parallelism.

The source of sound is a bird-call, giving a pure tone of high pitch (inaudible), and the percipient is a high-pressure flame issuing from a burner so oriented that the direct waves are without influence upon the flame (see NATURE, xxxviii. 208; Proc. Roy. Inst., January 1888). But the waves reflected from the muslin arrive in the effective direction, and if of sufficient intensity induce flaring. The experiment consists in showing that the action depends upon the distance between the disks. If the distance be such that the waves reflected from the several disks co-operate,[1] the flame flares, but for intermediate adjustments recovers its equilibrium. For full success it is necessary that the reflective power of a single disk be neither too great nor too small. A somewhat open fabric appears suitable.



It was shown by Brewster that certain natural specimens of Iceland spar are traversed by thin twin strata. A convergent beam, reflected at a nearly grazing incidence from the twin planes, depicts upon the screen an arc of light, which is interrupted by a dark spot corresponding to the plane of symmetry. [Shown.] A similar experiment may be made with small rhombs in which twin layers have been developed by mechanical force after the manner of Reusch.

The light reflected from fiery opals has been shown by Crookes to possess in many cases a high degree of purity, rivalling in this respect the reflection from chlorate of potash. The explanation is to be sought in a periodic stratified structure. But the other features differ widely in the two cases. There is here no semicircular evanescence, as the specimen is rotated in azimuth. On the contrary, the coloured light transmitted perpendicularly through a thin plate of opal undergoes no change when the gem is turned round in its own plane. This appears to prove that the alternate states are not related to one another as twin crystals. More probably the alternate strata are of air, as in decomposed glass. The brilliancy of opals is said to be readily affected by atmospheric conditions.

NOTES.

THE thirty-eighth meeting of the American Association for the Advancement of Science will be held at Toronto. On Tuesday, August 27, at noon, a meeting of the Council will be held at the Queen's Hotel, where will be the hotel head-quarters of the Association. On Wednesday, August 28, the first general session will begin at 10 o'clock in the forenoon in the Convocation Hall, University Buildings. After the adjournment of the general session, the several Sections will organize. In the afternoon the Vice-Presidents will give their addresses before their respective Sections, and in the evening there will be a general session, when the retiring President, Major J. W. Powell, will deliver his address. The sessions will continue until the Tuesday evening following, and on Wednesday morning, September 4, a meeting of the Council will be held. Saturday, August 31, will be devoted to excursions. The meeting will close with excursions extending to September 7. The general sessions and the meetings of the Sections will be held in the University Buildings, where also will be the offices of the local committee and of the permanent secretary during the meeting. *Science* states that arrangements have been made for a discussion in Section B on the "Relative Merits of the Dynamometric and Magnetic Methods of obtaining Absolute Measurements of Electric Currents." Prof. Thomas Gray, of the Rose Polytechnic Institute, will open the discussion with a paper on the subject, and he will exhibit one or more of Sir William Thomson's most recent forms of electric balance. Arrangements have been made by the local committee for the proper care and exhibition of instruments and specimens.

EFFORTS are being made by the American Association for the Advancement of Science to form a National Chemical Society, with its head-quarters at Washington. A meeting will be held to consider the matter during the session of the American Association at Toronto.

THE annual general meeting of the Marine Biological Association was held in the rooms of the Royal Society on the 26th ult. In the absence of Prof. Huxley, the chair was taken by Sir E. Bowman, and there were present, among others, Lord

[1] If the reflection were perpendicular, the interval between successive disks would be equal to the half wave-length, or to some multiple of this.

Walsingham, Prof. Flower, Prof. E. Ray Lankester, Admiral Sir Erasmus Ommanney, Mr. Gassiott, and Mr. Crisp. The report of the Council shows that a most satisfactory amount of work has been done at Plymouth since the Laboratory was opened at the end of June last year. Studies on various matters connected with the fishing industry are being carried on under the instructions of the Council, the most important being the study of the life-history of the common sole, by Mr. Cunningham, and an investigation on the sense-organs of fishes, by Mr. Bateson, which it is expected will throw new light on the bait question. Other naturalists, among whom Mr. Weldon may be specially mentioned, have utilized the Laboratory for carrying on independent biological researches, and much valuable work is being done. The Director of the Laboratory (Mr. Bourne) reports that the arrangements at the Laboratory are very satisfactory, and that the arrangements for the circulation of sea-water in the aquarium have worked well during the year. A substantial increase has been made in the library, a complete set of the *Challenger* publications, presented by the Lords Commissioners of the Treasury, being the most noticeable addition to its shelves. With one exception, the officers, Vice-Presidents, and Council, are the same as last year. Mr. Crisp has been compelled by increasing pressure of work to resign the post of Hon. Treasurer, which he has held with so much profit to the Association since its foundation. His place is taken by Mr. E. L. Beckwith, formerly a Prime Warden of the Fishmongers' Company, and Mr. Crisp retires to the Council *vice* Mr. W. Caine, M.P.

The Council of the Library Association has decided to hold the twelfth annual meeting of the Society in London during the second week in September. The Masters of the Bench of Gray's Inn have placed their Hall, for the third time, at the disposal of the Association.

On the night of June 15, about 10 p.m., there was a shock of earthquake, accompanied by a heavy subterranean rumbling, in the villages around Lake Arresö, in Denmark. Windows rattled and furniture oscillated, and in one place people ran out, believing that a powder-mill had exploded. The sound seemed to come from the east.

On June 12, at 11.16 p.m., a brilliant orange-coloured meteor was seen at Copenhagen. It radiated at τ Leonis, moving slowly towards β Virginis, where it burst into many fragments. It was accompanied by a tail, pointed at the end, about 2° in length.

In 1886 the Prince of Monaco, wishing to study the course of the Gulf Stream, threw into it some copper flasks from the *Hirondelle*. Three of these flasks have come ashore on the south coast of Iceland, two near the Ö Mountains, in the Rangárvall district, and the third at Flöj, in the Arnaes district.

It appears that the meteoric stone found in Scania, and acquired by Baron Nordenskiöld for the National Museum at Stockholm (p. 179), fell on April 6, and that its fall was accompanied by a red flash like lightning and a thunder-like detonation. It weighs 11 kilogrammes, and had made a hole 30 centimetres in depth; but, having recoiled, it lay on the level ground at the edge of the hole. The colour is greyish-black, and the fracture greyish-white. From a hasty analysis made by Herr A. Wingårdh, of Helsingborg, the chief mass appears to consist of manganese, in which are yellow and grey particles of metal. The meteorite seems to have been in a red-hot state, being covered with a glazed coating of fused metal half a millimetre in thickness.

Through the efforts of Dr. Filip Trybom, the Swedish Oyster-culture Society is attempting to acclimatize the American oyster, imported from Connecticut, in several places along the coast of the province of Bohus. The young oysters seem to thrive well.

The Norwegian cod-fishery in Finmarken this spring has been above the average, viz. 16,000,000 fish, against 9,000,000 last year. In Lofoten the fishery was a good average one, yielding 20,000,000 fish. Here the shoals congregated off the fishing-bank, in deep water, some five to ten miles from the shore.

On both sides of the Jösen Fjord, on the west coast of Norway, mountains rise perpendicularly to a height of several thousand feet. One morning, some days ago, stones and rocks, some of which are said to have been as large as a house, began to fall on the western side of the fjord. The avalanche continued for over two hours, accompanied by a noise heard 10 miles distant. A black cloud settled over the fjord, the water of which was in terrible commotion for many hours.

At a recent meeting of the Scientific Society of Copenhagen, Prof. Steenstrup gave an account of the results of his examination, last year, of the great mammoth deposit at Predmost, in Moravia. Dr. Wankel and Prof. Maschka, who have devoted much attention to the subject, are of opinion that the mammoths whose remains are found in this district were killed by man, and that their bodies were dragged thither to be eaten. Prof. Steenstrup, on the contrary, holds that the mammoths themselves sought the locality, and that they must have died from want of water, or from some other cause with which man had nothing to do. The splits in the remains are due, he thinks, to the action of water and sand, and afford no support to the notion that the knuckles were cleft for the sake of the marrow. It is certain that some of the bones have been exposed to the action of fire; but Prof. Steenstrup maintains that the traces of fire may be due to the fact that fires were at one time lighted upon them. On some of them, decorative lines have been scratched, but these may have been made long after the mammoth was extinct in Moravia. The lines, according to Prof. Steenstrup, are identical with the ornamentation of pottery of the Neolithic Age.

Mr. Bosworth-Smith, in a report on the Kolar Gold Field, in Southern India, issued by the Madras Government, records some "finds" of old mining implements, old timbering, fragments of bones, an old oil lamp, and broken pieces of earthenware, including a crucible, the remains of ancient mining operations. He expresses astonishment at the fact that the old miners were able to reach depths of 200 or 300 feet through hard rock, with the simple appliances at their command; and he describes the method which he thinks they pursued, sinking pits at short distances from each other, and leaving a "bar" between to prevent falling in.

Herr Richard Andree has issued a new series of his ethnographical parallels and comparisons. Ten years ago the first series appeared, and now, as then, the system pursued is to select a particular topic and then range over the whole literature of ethnology in search of references to the particular subject and collate them, until, finally, an ethnological monograph on the topic in question is produced. This method of work is of course exceedingly laborious, but it has the merit of being exhaustive and effective. Single subjects are thus worked out, and the results published in some scientific periodical; as soon as one is concluded another is taken up, and so on. By and by material for a volume is accumulated, the various subjects are brought up to date, and the public gets a work on ethnology, conceived on a novel plan, and full of interest. Each topic is pursued all over the earth, from country to country, with marvellous industry. The present volume deals with such topics as red hair, albinos, games, masks, marks of property, superstitions connected with the chase, "tree and man," circumcision, drawing amongst primitive peoples, thunderbolts, money for the dead, emotional expressions and gestures, demoniacs and mental disorders, &c.

THE latest number of the Journal of the Asiatic Society of Bengal (vol. lvii. part ii. No. 4) contains, among other papers, some interesting notes, by Prof. J. Wood Mason, on objects from a Neolithic settlement recently discovered by Mr. W. H. P. Driver, at Ranchi, in the Chota Nagpore district. Among the objects described, and represented on plates, are some chisel-edged arrow-heads similar to those which have been found in Egyptian tombs—in several cases still secured by bitumen to the shaft—and on Neolithic sites in different parts of Europe, including the British Isles.

THE Trustees of the Indian Museum, Calcutta, have issued the first number of a Catalogue, by Prof. J. Wood Mason, of the Mantodea, with descriptions of new genera and species, and an enumeration of the specimens, in the collection of the Museum. This number consists of 48 pages, and is illustrated with 34 woodcuts.

WE have to welcome the first report on Greek climate published in Greek by Prof. Sp. E. Marinos, of Corfu. Some meteorological reports relating to Greece have at times appeared in the Proceedings of the Society Parnassus at Athens, but these have mostly emanated from the late Baron Sina's observatory, directed by Dr. Schmidt, have related to Attica, and have been published in German. The present paper is a short notice of the records of Corfu for 1887 and 1888.

THE Annual Report of the Director of the Mauritius Observatory for the year 1887 shows that the mean temperature of the year was 1°·4 below the average, and that the temperature was below the average in every month, the greatest deviation being 2°·5 in August. No storm passed near the island, which has not been visited by a hurricane since March 1879. During the year 1887 the velocity of thirty miles an hour was reached only once, in June. Rainfall is recorded at seventy-five stations, and Dr. Meldrum states that the comparisons made during the last ten years show conclusively that there is a close connection between the rainfall and the malarial fever on the low lands.

IN his last Meteorological Report for India, Mr. Elliot, referring to sun-spots and weather in India—a subject which has been frequently mentioned in these Reports—says:—"So far as India is concerned, it would appear that it is the period of minimum sun-spots which is associated with the largest and most abnormal variations of meteorological conditions and actions. Thus, exceptionally heavy snow fell in the North-West Himalayas in the winter of 1866, and again in 1876 and 1877. The latter is to some extent described in the Annual Reports on the meteorology of India for these two years. Again, the most striking and disastrous famines of recent years in India have occurred near the period of minimum sun-spots; as, for example, the Orissa famine of 1866, the Behar famine of 1874, and the Madras famine in 1876–77. Similarly, there is a clearly marked tendency for the largest and most intense cyclones to occur shortly before the period of minimum sun-spots; as, for example, the great Calcutta cyclone of 1864, in which 60,000 people were drowned by the storm-wave, and the still larger Backerganj cyclone of 1876, in which 100,000 lives were lost by drowning. As we are now approaching or passing through the same phase of the sun-spot period, it is interesting to inquire whether there are any large abnormal variations common to the present period of minimum sun-spots, and the previous corresponding periods of 1865–66 and 1876–77."

THE Manchester Microscopical Society has published its ninth Annual Report, with a Presidential address, by Prof. Milnes Marshall, on "Inheritance," and a lecture, by Prof. W. Stirling, on "Electrical Phenomena in Animals." The volume also contains many papers and communications by members of the Society.

THE new number of the *Mineralogical Magazine* opens with a valuable paper, by Mr. Fletcher, on crystals of percylite, caracolite, and an oxychloride of lead (daviesite) from Mina Beatriz, Sierra Gorda, Atacama. The number also contains, besides some shorter papers, an article by Prof. Judd, on the processes by which a plagioclase felspar is converted into a scapolite.

THE ninth part of Cassell's "New Popular Educator" has just been published. It contains a good map of the world, showing isothermal lines, and the distribution of races and vegetation.

THE first twelve numbers of *Life Lore*, a monthly magazine of biology, have now been collected in a volume, a copy of of which has been sent to us. The volume contains many brightly-written articles, and should do much to excite the interest of young readers in the more popular aspects of biological science.

PROF. MILTON WHITNEY, Professor of Agriculture and Vice-Director of the Experiment Station of the University of South Carolina, has devised a modification of Six's thermometer for soil temperature. The bulb is 6 inches long, protected by a metallic cylinder perforated with many holes, and is buried in the soil, so that the bulb shall extend from 3 to 9 inches below the surface of the soil—the maximum and minimum scale being of course above the soil, and arranged very much as in the ordinary Six's form. The long bulb allows a good height of scale, while it is narrow enough to respond readily to changes of temperature. In a series of readings the instrument gives exactly the mean of the readings of a 3-, 6-, and 9-inch thermometer of the usual form placed beside it at these respective depths in the soil, besides recording the maximum and minimum temperatures. This length of bulb and depth in the soil was decided on, as it is assumed to be the depth which contains most of the roots of the ordinary cultivated plants. The instrument need only be read once a day, and saves an immense amount of calculation and tabulation attending the tri-daily readings of the 6 to 8 instruments comprising the set of the usual form.

THE Russian Geographical Society is now publishing its Memoirs in parts, each of which contains a separate paper, and is circulated as soon as the paper has been printed. The last parts of the "Memoirs of General Geography" contain the following interesting papers:—"The Agricultural Meteorological Observations in Russia in 1885 and 1886," by Dr. Woeikof, being the observations made at fifty-one different stations in accordance with a scheme issued by the Geographical Society; "On Barometrical Observations at Distant Stations and during Journeys," by R. N. Savelieff; "On the Measures taken in Western Europe for consolidating Shifting Sands, and growing Bushes and Trees upon them," by S. Rauner; and "On the Comparison between Normal Barometers of the Principal Meteorological Stations of Europe," by P. Brounow. It appears that the corrections to be applied to the pressures shown by the barometers of the following stations are as follows (the normal barometer at St. Petersburg being taken for zero):—Berlin, − 0·02 millimetres; Hamburg, − 0·39; Utrecht, − 0·32; Brussels, + 0·23; Paris, + 0·11; Sèvres (Bureau International des Poids et Mesures), + 0·10; Zurich, − 0·06; Vienna, + 0·11.

IN a communication lately made to the Russian Geographical Society, General Annenkoff insisted upon the possibility of the

Transcaspian region being colonized. He pointed out that the girdle of loess which encircles the mountains is quite as productive as the loess in China. The climate is, of course, quite different—not so much on account of the want of rain (the amount of rain at Merv, during the winter months of 1885-86, reached the very high figure of 1654 millimetres), as on account of its absence during the summer months. But the rivers of the region—the Amu, the Tejen, and the Murghab—if their waters were utilized for irrigation, instead of being lost in the sandy deserts, would supply the amount of water necessary for irrigating immense tracts of land. All that is wanted to make of Central Asia a rich oasis of agriculture is human labour and human intelligence. The soil, when irrigated, is not inferior in fertility to the fertile loess fields of China.

THE Inspector-General of Indian Affairs in Canada, in his Report for the past year, urges the continuation of the policy of amalgamating the Canadian Indians as far as possible with the surrounding population, especially by inducing them to adopt agriculture and handicrafts, so that they may acquire a taste for a settled life. The Indians of the Province of Ontario seem to be most successful in reaching this end, and in all cases the tribes show an increase in numbers. There were no serious disturbances during the year, and the only excitement was produced amongst the natives on the Upper Skeena, in British Columbia, owing to the arrest and execution of one of their number for murder. The total number of Indians in the Dominion is given at 124,589; of these, 37,944 are in British Columbia, 26,368 in Manitoba and the North-Western Territory, 17,700 in Ontario, 12,465 in Quebec, 8000 in Athabasca, 7000 in the Mackenzie district, 4016 in Eastern Rupert's Land, 4000 on the Arctic coasts, 2145 in New Scotland, 2038 in the Peace River district, 1594 in New Brunswick, 1000 in the interior of Labrador, and 319 in Prince Edward's Island. 6127 Indian youths and girls attend the schools provided for them, nearly half the pupils belonging to Manitoba and the North-Western Territories; of the 956,000 dollars appropriated for native affairs, the same districts received 876,000 dollars. 21,344 acres of the land set apart for the improvement of Indians were alienated during the year, and 458,283 acres still remain.

THE additions to the Zoological Society's Gardens during the past week include a Black-headed Lemur (*Lemur brunneus* ♂) from Madagascar, presented by Mr. Charles C. Stewart; four Angora Goats (*Capra hircus*, var., ♂ ♀ ♀ ♀) from Barrol, Cape Colony, presented by Messrs. Theophilus Bros.; a Two-spotted Paradoxure (*Nandinia binotata*) from West Africa, presented by Mr. Philip Lemberg; a Ring-necked Parrakeet (*Palæornis torquatus*, yellow var.) from India, presented by Colonel C. Swinhoe; a Common Kestrel (*Tinnunculus alaudarius*), British, presented by Master W. P. Teil; two Goshawks (*Astur palumbarius*), European, deposited; a —— Lemur (*Hapalemur*, sp. inc.) from Madagascar, two Undulated Grass Parrakeets (*Melopsittacus undulatus*) from Australia, purchased; a Thar (*Capra jemlaica*), two Mule Deer (*Cariacus macrotis* ♂ ♂), three American Wild Turkeys (*Meleagris gallo-pavo*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL SOCIETY OF THE PACIFIC.—The second of the publications of this Society has appeared, containing an address delivered before the Society on March 30, 1889, by the President, Prof. Holden, on "The Work of an Astronomical Society." Prof. Holden sketched the state of astronomical science in England immediately prior to the foundation of the Royal Astronomical Society, and quoted freely from its first paper as showing the spirit which should inspire similar organizations elsewhere. The points Prof. Holden especially put forward as to be attained by the new body were the publication of observations, the guidance of amateur workers, especially those who were skilled photographers, the instruction of learners, the formation of an astronomical library, together with all the advantages resulting from free discussion, and the friendly interchange of ideas. The address was able, straightforward and unpretentious, and concludes with the recommendation, "Whatever we do, let us do thoroughly. Whatever we say, let it be well considered. Let us clearly understand the objects for which we are organized, and let us pursue these with entire confidence." With these principles for its guidance, the new Society will not fail of an honourable and useful career.

A NEW COMET.—A new comet was discovered by Mr. E. E. Barnard (Lick Observatory) on June 23·9499 G.M.T., R.A. 20° 13′ 21″, N.P.D. 51° 9′ 16″; daily motion, R.A. +1° 6′, N.P.D. −0° 34′. The comet was only faint.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1889 JULY 7–13.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on July 7

Sun rises, 3h. 55m.; souths, 12h. 4m. 40·0s.; daily increase of southing, 9·5s.; sets, 20h. 15m.: right asc. on meridian, 7h. 7·3m.; decl. 22° 33′ N. Sidereal Time at Sunset, 15h. 19m.

Moon (Full on July 12, 21h.) rises, 13h. 46m.; souths, 19h. 16m.; sets, 0h. 34m.*: right asc. on meridian, 14h. 19·8m.; decl. 8° 49′ S.

OPTICAL TORQUE.[1]

I.

SEVENTY-EIGHT years have elapsed since the first discovery, by Arago, of the remarkable chromatic effects produced by slices of quartz crystals upon light, previously polarized, which was caused to traverse them. These effects were shown, one year later, by Biot, to be caused by a peculiar action of the quartz in rotating the plane of polarization; the amount of the rotation being different for lights of different colours. Ever since then, the rotation of the plane of polarization of light has been a topic familiar to physicists. It has stimulated the devotee of research to an endless variety of experiments and suggestive speculations: it has lured on the mathematician to problems which tax his utmost skill: it has afforded to the lecturer an array of beautiful and striking illustrations. Here, in this place, made classical by the researches and expositions of Thomas Young, of Michael Faraday, and of William Spottiswoode, and last, but not least, by the labours of those eminent men whom we rejoice still to number amongst the living—here, I say, on this classic ground, the rotation of the plane of polarization of light is almost a household word, and its phenomena are amongst the most familiar. We know now that not only certain actual crystals, such as quartz, bromate of soda, and cinnabar, rotate the plane of polarization, but that many non-crystalline bodies—liquids, such as turpentine, oil of lemons, solutions of sugar and of various alkaloids, and even certain vapours, such as that of camphor—possess the same property.

In 1845, at the very culminating point of his unique career of research, Faraday opened a new field of inquiry, linking together for the first time the science of optics with that of magnetism, by his discovery that the rotation of the plane of polarization of light could be effected by the application of magnetic forces. This effect he observed first in his peculiar "heavy-glass," when it lay in a powerful magnetic field. Subsequently he found other bodies to possess similar properties: some of these being magnetic liquids, such as solutions of iron, others being diamagnetic. Time will only permit me in passing to refer to the researches of Verdet, and those of Lord Rayleigh and of Mr. Gordon upon the numerical values of the magneto-optic rotation in these substances. H. Becquerel has extended them to gases, and has shown how the magnetism of the earth rotates the plane of polarization of the light which, previously polarized by reflection from the aërial particles which give the sky its "blue," passes earthward through the oxygen of the air.

Other experimenters have dealt with the rotatory effects (whether crystalline, molecular, or magnetic) in relation to lights of different colours, and have studied the dispersion which arises from the greater actual angle of optical torsion which is produced upon waves of short wave-length (violet and blue) than that which is produced under the influence of equal rotatory forces upon the waves of longer wave-length (red and orange). It has also been demonstrated that the plane of polarization of waves of invisible light, whether those of the infra-red, or those of the ultra-violet species, if they have been previously polarized, can be rotated just as can that of waves of visible light.

In 1877, Dr. Kerr, of Glasgow, discovered a point which Faraday had sought for, but fruitlessly—namely, that in the act of reflection at the pole or surface of a magnet, there is a rotation of the plane of polarization of light. This discovery was completed in 1884 by Kundt, of Strasburg, by the further demonstration, also dimly foreseen by Faraday, that a magneto-optic rotation of the plane of polarization is caused by the passage of previously polarized light through a normally magnetized film of iron so thin as to be transparent.

Lastly, in this brief enumeration, we were shown a month ago, by Oliver Lodge, how the magnetic impulses generated by the rapid oscillatory discharges of the Leyden jar can produce corresponding rapid oscillatory rotation in the plane of polarization of the waves of previously polarized light.

You will not have failed to notice the cumbrous phrase which, whether in speaking of the purely optical effects (of quartz, or sugar, or turpentine), or in speaking of the magneto-optic effects of more recent discovery, I have employed to connote a very simple fact. You may have wondered that any lover of simple English speech should indulge in such sesquipedalian words.

Of course, at this period of the nineteenth century it is no longer open to debate that light consists of waves. The plane of polarization of the waves of light is the plane of polarization of the light itself. The rotation of the plane of polarization is the rotation of the polarized waves, and therefore of the polarized light itself. Yet I must draw attention to the fact that in all the array of discoveries which I have enumerated, that which had been observed was the rotation—whether by crystalline, molecular, or magnetic means—not of natural light, but of light which had by some means been previously polarized. It was not known to Arago or to Biot, to Fresnel, to Faraday, nor even to Spottiswoode or to Maxwell, that natural unpolarized light could be rotated. They may have inferred so, but it was not in their time even demonstrable that a beam of circularly-polarized light could be rotated upon itself in the same sense as that in which a beam of plane-polarized light could be rotated.

That light of any and every kind, however polarized or devoid of that which is called polarization, can be, and in fact is, rotated when it passes across a slice of quartz or along a magnetic field, is a wider generalization of more recent date; but one of the reality of which I hope to convince you before the warning finger of the clock puts a period to my discourse.

In order the better to enable this audience to comprehend the ultimate significance of this discovery, I must claim the indulgence of those amongst them who are already familiar with the subject of the polarization of light, whilst I go back to the most simple elementary matters. Having illustrated the fundamental facts about the plane of polarization of light and its twisting, I shall then go on to methods of precisely measuring the amount of optical torsion produced by the various substances under various conditions. And after dealing with the magnetic as well as the crystalline and molecular methods of producing optical torsion in the case of light that has been previously polarized into a given plane, I shall be in a position to speak of the nature of the torque,[1] or twisting force, which in the several cases produces the torsion; and shall finally endeavour to indicate the scope of the researches by which it is now definitely ascertained that the very same optical forces which are capable of impressing a rotation upon light which has been artificially polarized into a definite plane are also capable of impressing a rotation upon natural, non-polarized light.

At the outset, to elucidate to any who may not comprehend the meaning of the term polarization as applied to wave-motion, I will show a simple apparatus, constructed from my designs by Mr. Groves. In this there are two sets of movable beads, fixed upon stems which pass into a box containing a piece of mechanism actuated by means of a handle. These beads, when I turn the handle, oscillate to and fro in definite directions, and, by their successive motions, give rise to progressive waves. One set of beads, tinted red, executes movements in a plane inclined 45° to the right, another set, silvered, simultaneously executes movements at 45° to the left. There are therefore here two waves, the planes of polarization of their movements being at right angles to one another. Their velocity of march is equal; but in this model, as a matter of fact, their phases differ by one-quarter—that is to say, each successive wave of the one set is always a quarter of a wave-length behind the corresponding wave of the other set. [Model exhibited.]

Now, in the case of waves of natural light from all ordinary sources—sun, stars, candles, gas-flames, or electric light—the waves emitted are not found to be polarized. That is to say, their motions are not executed in any particular plane, nor even in any particular path of any kind; they appear to be absolutely heterogeneous at least so far as this, that no vibration of the millions of millions emitted in a second of time is followed by more (on the average) than about 50,000 vibrations of a similar sort, executed along a similar path—the plane of the polarization, if any, changing after the lapse of such an incredibly short time that for most purposes the vibrations in different directions are as inextricably mixed as if they had all been simultaneously jumbled up. Since, then, natural light is non-polarized or miscellaneous, the production of polarized light must be brought about by the employment of polarizing apparatus or agents which will so operate on or affect the mixed waves as to bring their vibrations into one direction—or, what amounts to the same thing, transmit the light whilst destroying or absorbing those

[1] A Discourse delivered at the Royal Institution, May 17, 1889, by Prof. Silvanus P. Thompson.

[1] The convenient term *torque* was first proposed by Prof. James Thomson, of Glasgow, for the older and more cumbrous phrase "moment of couple," or "angular force." Its general acceptance by engineers justifies the extension of the term to optics. As a mechanical torque is that which produces or tends to produce mechanical torsion, so optical torque may be defined as that which produces or tends to produce optical torsion.

parts of the vibrations which are executed *across* the desired line of vibration. So we have *polarizers* consisting of tourmaline slices; oblique bundles of thin glass plates; black-glass reflectors; and Nicol prisms cut from calc-spar. About the two latter I may be permitted a passing word presently. These objects polarize, *i.e.* turn into one plane, the vibrations of light falling upon them. A rough mechanical illustration may here be permitted me. A long india-rubber cord is passed through the open ends of a box provided with vertical partitions. Fig. 1 shows the arrangement. These partitions confine the motion of the cord, and effectually polarize the vibrations which I now impart to the cord by shaking the end of it to and fro. If the partitions are vertical,

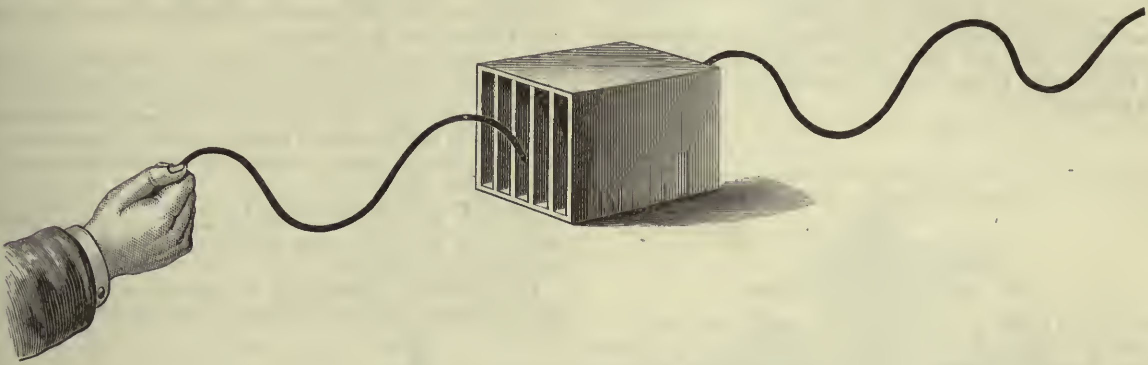

Fig. 1.—Box with partitions to illustrate polarization of vibrations.

the box polarizes, into vertical vibrations only, the miscellaneous vibrations which are sent to it. If rotated until its partitions are horizontal, it polarizes the vibrations into a horizontal position.

Let us now turn to the optical analogue of this experiment. The large Nicol prism which I introduce into the field of the electric-light lantern, polarizes the light, so that the vibrations are executed simply in an up-and-down direction. Your eye will not detect this, the motions being millions of times too rapid. To detect the direction, an analyzer is necessary. For this purpose a second apparatus of the same sort is used, for then, by crossing the positions of the two, the whole of the light is cut off; the second Nicol prism, if set so as to transmit only horizontal vibrations, cutting off the vertical vibrations that are sent through the first prism. So, whilst the first prism serves as

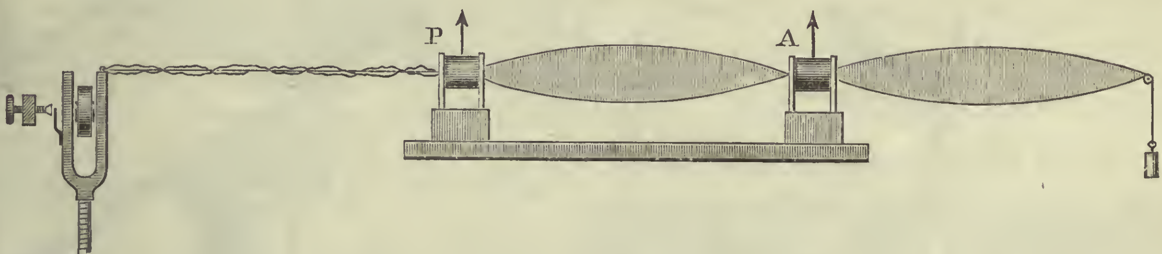

Fig. 2.—Acoustic model illustrating polarization of vibrations. P, the polarizer; A, the analyzer.

a polarizer, the second serves as an analyzer to detect by cutting them off when turned to the proper position, the direction of the polarization which had been previously impressed by the first prism.

Here I may illustrate the action of the analyzer for determining the plane of polarization of the vibrations, by the extinction which it produces when turned to the crossed position. For this purpose I have refined upon the box with partitions, using instead parallel plates of glass mounted in wooden cylinders, whilst for the cord swung by hand I am using Prof. Schwedoff's device, and am producing the vibrations in this silken cord by means of an electrically-driven tuning-fork (Fig. 2). At the first nodal point of the stretched cord a pair of parallel glass plates acts as a polarizer, the cord from that point vibrating in the

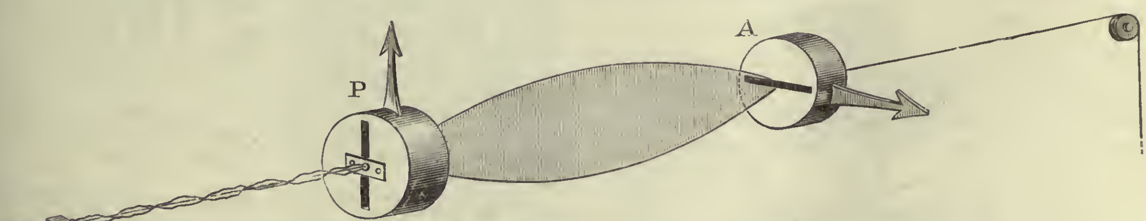

Fig. 3.—Vibrations cut off by turning the analyzer A at right angles to the polarizer P.

plane thus imposed upon it. I can alter this plane at will by rotating the polarizer. This polarizer, P, consisting of a pair of glass plates, is mounted in a cylindrical mount, and is provided with an arrow to indicate their direction. If now at any subsequent node I introduce a second such device, it will act as an analyzer, A. This excellent suggestion is due to M. Macé de Lepinay. In Fig. 2 the polarizer and analyzer are parallel. You see (Fig. 3) how the vibration is extinguished when the positions of analyzer and polarizer are crossed. Half a degree of error in the position of the analyzer produces something less than perfect extinction of the vibrations. Hence it is possible, by this analyzer, to determine the plane of the vibrations to the accuracy of half a degree. I should say that the whole of this model has been constructed by my assistant, Mr. Eustace Thomas.

Now let me show you the optical effect which corresponds to this. Placing a second Nicol prism as analyzer in the path of the polarized waves, I turn it to the position where it cuts off the polarized light. The "*dark field*" so produced by the crossed Nicol prisms corresponds to the motionless cord beyond the crossed analyzer of the acoustic apparatus.

Returning for a moment to two well-known forms of polarizing apparatus, viz. the black glass reflector and the Nicol prism, I may be permitted to refer to some recent attempts to improve upon these devices.

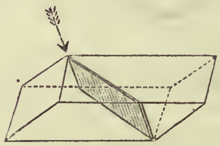

FIG. 4.—Nicol prism: original form.

The Nicol prism, as is well known, consists of a rhomb of Iceland spar cut into two pieces, which are reunited by a film of Canada balsam. As originally devised, it had oblique end faces (Fig. 4), and a comparatively narrow angle (19°) of aperture. These may be noticed in the small example which I here exhibit, which is an original constructed by William Nicol himself. It also has the disadvantage of giving a field in which the directions of the planes of polarization are not strictly parallel to one another throughout its whole extent. Consequently there is never complete extinction of light all over the field at one time. Hartnack and others have attempted to remedy this by giving the prism a different form and using other materials than Canada

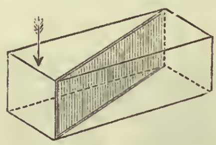

FIG. 5.—S. P. Thompson's modification of the Nicol prism.

balsam. I have from time to time made many attempts to improve upon the original construction. First, I have made the end faces principal planes of section (Fig. 5); secondly, I have made the axis of vision cross the crystallographic axis at right angles, so getting a flatter field, a shorter length, a wider angle, and less loss of light by reflection. Mr. Ahrens, the prism-cutter, on whose able assistance I have relied during the last six or seven years in cutting these prisms, has aided me with his ingenuity in devising a method of cutting up the spar so as to give these advantages with a minimum waste of material. He has further devised a method of putting a polarizing prism together in three instead of two pieces—illustrated in the diagram (Fig. 6)—which

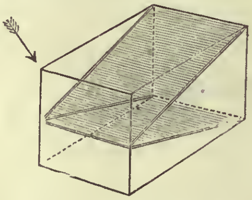

FIG. 6.—Ahrens's triple prism.

gives a still wider angle. The prism which I shall use as analyzer in the next experiments is one of these forms.

Unfortunately at present there is a spar-famine, pieces of Iceland spar of a size and purity suitable for the making of large polarizers such as that I employ being not now procurable at any price. To avoid the excessive cost of large Nicols I have lately got Mr. Ahrens to construct for me a large reflection-polarizer, on the plane of Delezenne, but modified by Mr. Ahrens in detail. In this prism the light is first turned to the proper polarizing angle by a large total-reflection prism of glass, and then reflected back, parallel to its original path, by impinging upon a mirror of black glass covered by a single sheet of the thinnest patent plate-glass to increase the intensity of the light. This form of polarizer, depicted in Fig. 7, is quite equal for projection purposes to a Nicol prism of equal aperture, and is much less costly. This one has 2½ inches clear aperture.

Having so far reviewed the apparatus for polarizing and analyzing, I will return to the apparatus set with its prisms crossed, so that the analyzer completely extinguishes the polarized light emitted from the polarizer.

If in the space between polarizer and analyzer anything be introduced which can either resolve obliquely the polarized vibrations or twist them bodily round, then there will not be complete extinction; the amount of light passing the analyzer depending in the one case on the obliquity of the resolution, in the other upon the degree to which the vibrations are twisted or rotated upon themselves.

The effect of oblique resolution I may illustrate by introducing a slice of tourmaline between the crossed Nicols, and rotating it till it stands at 45°; or, in the acoustic model, by introducing an oblique pair of guide-pins.

The other case—namely, that of producing a bodily twist of the vibrations, rotating the plane of polarization around the

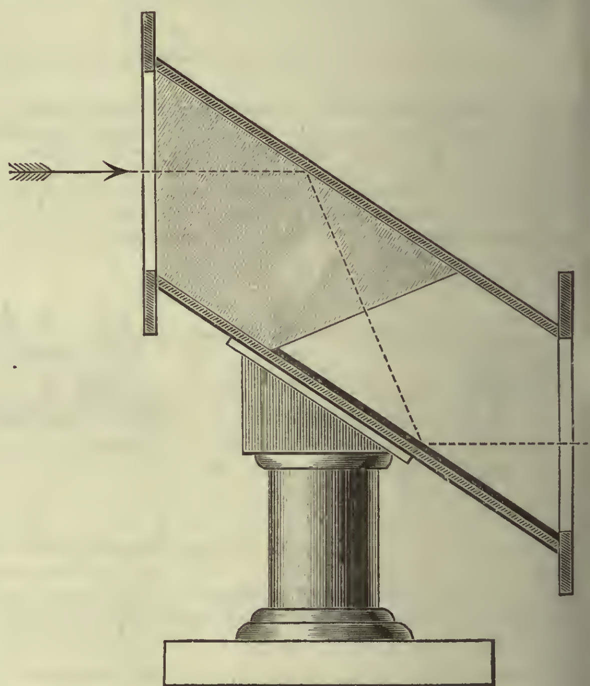

FIG. 7.—Ahrens's reflecting polarizer.

path of the wave—is not so easily illustrated by the model. But it is optically perfectly simple: all that is requisite is to introduce between the crossed Nicols a thin slice of that crystal—namely, quartz—in which this effect of rotating the plane of polarization was first observed.

I take a clear plate of quartz, just 1 millimetre in thickness, and interpose it between the crossed Nicol prisms. You will note how the introduction of this plate of quartz brings *some* light into view.

Suppose we now turn the analyzer to try and obtain extinction: we get tinting. If we put in a coloured glass so as to work with one kind of light only, we shall get extinction at a particular angle. The table of data to which I invite your

Optical Torsion produced by Plate of Quartz.

	1 millimetre.	3·75 millimetres.
	°	°
Red	19	71·2
Orange	21·5	80·6
Yellow	24	90
Green	29	108·7
Peacock	31	116·2
Blue	35·5	133·1
Violet	42·8	161

attention states this amount for the different colours. If we use a piece of quartz so thick that it rotates any particular tint just 90°, that tint will be cut off by the crossed analyzer, and all others will—in greater or less proportion—be transmitted, so that the resulting tint will be complementary to that cut off. For example, a slice just so thick as to twist yellow waves round 90° must be 3·75 millimetres thick. (I may remark, for the benefit of those who think it easier to express this exact thickness in fractions of a British inch, that the quartz which rotates yellow light 90° must have a thickness equal to one-eighth, plus three-sixteenths of an eighth, plus one sixty-fourth of an eighth of an inch.) When such a quartz is placed between the crossed Nicols, the light shown is yellow; but if placed between parallel Nicols (*i.e.* in the bright field), it shows a rich purplish-violet colour, the complementary of the yellow. This particular tint Biot found to be excessively sensitive, the smallest inaccuracy in adjustment between the prisms at once producing a change, the colour appearing too red or too blue, according to the direction in which the analyzer has been turned out of exact adjustment. This tint is accordingly known as the "transition tint" or "sensitive tint," its accurate definition being due to the fact that the human eye is more sensitive to the presence or absence of the complementary yellow than to any other tint in the whole spectrum. If we take, however, a quartz plate twice as thick as this—namely, 7½ millimetres thick—this will give the yellow light a torsion of 180°. Hence this gives the purple transition tint in the dark field, and is yellow in the bright field. A quartz plate 11¼ millimetres thick gives again a transition tint in the bright field. I shall recur presently to the question of the transition tints of the several orders.

One of the familiar facts in this subject is that there are two kinds of quartz crystals, optically alike in every other respect, differing only in this, that one kind produces a right-handed twist, the other kind a left-handed twist. All the pieces of quartz I have so far employed are right-handed specimens. I now introduce two small slices of crystal, each 3¾ millimetres thick, giving the yellow tint when the Nicols are exactly crossed, but you will notice that when we are using the right-handed crystal, the tint grows reddish as the analyzer is turned towards the left, and greenish when the analyzer is turned towards the right; whereas, when I substitute the left-handed slice, the tint grows greenish as the analyzer is turned toward the left, and reddish when it is turned toward the right. If the analyzer is turned through an exact right-angle, we get an extinction of the yellow light, the remaining blue and red rays combining to give us the purple transition tint.

You will have noticed that the way in which we have (approximately) measured the angle of rotation has been first to set the analyzer to extinction, then to introduce the substance which has the property of rotating the beam, then to turn the analyzer again to extinction, and read off its angle. For, of course, the angle through which the analyzer is turned measures the angle through which the plane of polarization has been turned.

It is possible, however, to show in the lantern something like a more obvious rotation of the light by introducing between the Nicols a crystal star, built up of radial pieces of mica, twenty-four in number (Fig. 8). You see in the bright field a white cross with black sectors at 45°. Or, in the dark field we have a black cross with vertical and horizontal arms, the sectors next to those that are black seeming dusky. If now I put in a quartz plate between the star and the analyzer, you see the cross shift round, and it shows colours, because the blue rays are twisted round more than the green, the green than the yellow, the yellow than the red. Repeating the experiment with the 3·75 millimetre quartz which turns yellow waves round just 90°, we get this gorgeous radiation of colours, and our black cross is turned into a yellow one. With the 7·5 millimetre quartz, the black cross is replaced by one of "transition" tint.

The black crosses seen in certain sections of natural crystals, sphæroliths, sections of stalactites, crystallizations of salicine and of Epsom salts, may also be used instead of the 24-rayed star of mica. But best of all I find to be the beautiful black cross which is seen by polarized light in the prepared crystalline lens taken from the eye of a fish. You notice how, when the fish lens is projected and the quartz introduced, the cross turns round.

This is, however, a rough-and-ready way of displaying the rotation, and it is of vast practical importance that precise methods of measuring the angle of rotation should be available—of vast importance, because in several large industries this optical method is applied as a species of handy analysis. I have named a solution of sugar as being an "active" substance. In the industry of sugar-refining, as in that of brewing, the strength of sugar in the liquids is directly measured by measuring its optical effect. Consequently there has been developed a special instrument, the *polarimeter*, for this express purpose.

I have here examples of several practical forms of polarimeters; there are diagrams of several more upon the walls.

The problem of finding the best polarimeter naturally leads to the inquiry what special means are there for making the observation of the angle more precise than by merely observing the extinction of the light, its restoration when the active substance is interposed and the subsequent renewal of extinction when the analyzing prism is turned.

Biot considered that much greater accuracy could be attained by watching for the restoration of the sensitive tint than by

FIG. 8.—Mica disk of twenty-four rays, showing black cross in the dark field.

watching for the mere restoration of extinction of the light. Accordingly we will use the plate of quartz 7·5 millimetres thick, giving the purple tint, to enable us to measure the rotation produced by the tube of sugar solution which is now inserted in the beam of polarized light. You notice how the tint has changed. But I have only to turn the analyzer to an amount equal to that to which the light has been twisted by the sugar, and again I obtain the sensitive transition tint.

The eye is not always, however, alive to minute changes of colour in a single coloured patch; it much more readily distinguishes a minute difference between two tints when both are present at once. Hence Soleil devised the well-known biquartz arrangement, consisting of two pieces of crystal, equal in thickness but possessing opposite rotations. You will notice how the slightest inaccuracy in placing the analyzer causes the two halves of the field to differ in tint. This is especially marked when the tint chosen is the transition purple.

(*To be continued.*)

THE PLANET URANUS.

THAT anomalous section of the solar system, Uranus and its satellites, offers yet a wide field of investigation to astronomical specialists of all kinds. Its figure, its rotation, satellites, and physical constitution altogether, are moot points, which should be more or less settled with the increased optical power now at our disposal.

The circumstances attendant upon the discovery of Uranus in 1781 (Phil. Trans., 1781, p. 492) are matters of common knowledge. The planetary nature of the supposed comet seems to have been first suspected by Maskelyne, and it was this suggestion that induced Lexell to calculate for it a circular orbit in 1781 (Grant's "History of Physical Astronomy," p. 274). The elliptic elements of the planet were first calculated by Laplace in 1782 (*Mém. Acad. des Sciences*, Paris, January 1783).

The first measures of the Uranian diameter were singularly incongruous. Herschel found it in March 1781 to be 2″·53; whilst in the following month he measured it as 4″·52 and 5″·2, (Phil. Trans., 1781, p. 494). A like discordance occurred in the results obtained by other astronomers. Maskelyne fixed the magnitude of the apparent diameter as 3″, whilst Mayer, of

Manheim, estimated it to be as high as 10″ (Grant's "History of Astronomy," p. 275).

The difference between these measures of the diameter of Uranus would seem to be a consequence of the fact that it is always extremely difficult to get the planet clearly defined in the field of the telescope. Herschel himself noted (Phil. Trans., 1798, p. 69), "The Georgian planet is not so well defined as, from the extraordinary distinctness of my present 7-feet telescope, it ought to be. There is a suspicion of some apparatus about the planet."

Herschel several times had the impression that Uranus was surrounded with a ring. One of his observations is contained in the following (Philosophical Transactions, 1798, p. 68):—"My telescope is extremely distinct, and when I adjust it upon a very minute double star, which is not far from the planet, I see a very faint ray, like a ring crossing the planet, over the centre. This appearance is of an equal length on both sides, so that I strongly suspect it to be a ring. . . . I have turned the speculum one quadrant round, but the appearance of the very faint ray continues where it was before, so that the defect is not in the speculum nor is it in the eye-piece." Later observations, however, led Herschel to conclude "that Uranus has no ring in the least resembling that, or rather those, of Saturn."

Following upon the observations as to the existence of a ring round Uranus, are found others relating to its polar compression. The flattening at the poles was first observed by Herschel in February 1794 (Phil. Trans., 1798, p. 69), and announced in the following words: "The planet seems to be a little lengthened out, in the direction of the longer axis of the satellite's orbit;" and again in April of the same year: "The disk of the planet seems to be a little elliptical." Mädler measured the ellipticity in 1843, and found it 1/9·92 (Grant's "History of Astronomy," p. 278). Schiaparelli, in 1883, using two different methods, obtained the results 1/10·98 and 1/10·94 (*Astr. Nach.*, No. 2526). A few measures made by Young in the same year gave an ellipticity 1/14 ("General Astronomy," Young, p. 367). The fact that the ellipticity was in the same plane as the major axis of the satellite's orbit led Herschel to conclude from analogy with Jupiter and Saturn, "That the Georgian planet also has a rotation upon its axis of a considerable degree of velocity" (Phil. Trans., 1798, p. 71). Other observers of the bulging out of the Uranian equator—Schiaparelli, Young, Safarik—agree with Herschel in saying that the plane is coincident with that of the satellite's motion, but the following observations of markings on the surface of Uranus lead to an entirely different conclusion.

Buffham noticed some bright markings on Uranus in 1870–72 (*Monthly Notices*, vol. xxxiii. p. 164), and, from observations of their motion, deduced the time of rotation as twelve hours, but the plane of rotation was *not* coincident with that of the satellite's orbit. This was borne out by observations of dusky bands by Young, in 1883 ("Princetown Observations," 1883); of apparent equatorial belts by the brothers Henry, in 1884 (*Comptes rendus*, t. xcviii. p. 1419); and observations in 1884, at Nice, of a bright spot by Lockyer, Perrotin, and Thollon (*Comptes rendus*, t. xcviii. pp. 717, 967). The plane of rotation, according to these observers, is from 15° to 40° from the trend of the satellite's. Thus the difference between the two sets of observations amounts to nearly half a right angle. Does the error lie in the observation of the belts, or in the measurements of the planet's ellipticity and the satellite's orbit? This is an enigma which yet remains to be solved, and another character of Uranus requiring investigation.

Herschel made the first determination of the mass of Uranus in 1788 (Philosophical Transactions, 1788, p. 369), and found it to be 17·740612 as compared with the earth, or about 1/18,000 that of the sun. Bouvard found a value 1/17,918; Lamont, in 1837, 1/24,605. Lassell's observations of the motion of the satellites gave a value 1/20,897, whilst Struve's observations gave a value 1/26,860. The mass, 1/22,600, found by Newcomb ("Washington Observations," 1873), is probably the most correct, and he estimates that the probable error in the denominator is not more than 100. This mass, revolving round the sun at a mean distance of about 1800 millions of miles, must exert considerable influence upon bodies near it, influence which may often predominate over that of the sun.

But it is the question of Uranian satellites that is so enigmatical. Herschel discovered two on January 11, 1787 (Phil. Trans., 1787, p. 125 *et seq.*), and in 1798 announced the discovery of four more. Regarding the real existence of these four, Herschel remarks (Phil. Trans., 1798, p. 66): "It remains now only to be mentioned that, in such delicate observations as these of the additional satellites, there may possibly arise some doubts with those who are very scrupulous; but as I have been much in the habit of seeing very small and dim objects, *I have not been detained from publishing these observations sooner, on account of the least uncertainty about the existence of these satellites*, but merely because I was in hopes of being able soon to give a better account of them, with regard to their periodical revolutions."

Sir John Herschel observed the two brightest satellites between 1828 and 1832 (Mem. Ast. Soc., vol. viii. p. 1); but "of other satellites," he says, than these, "I have no evidence," although the telescope he was using was precisely similar to that used by his father. A systematic search was made by Lassell for the lost satellites, and a definite announcement of the discovery of two satellites between Uranus and the two brightest was made in 1851 (*Monthly Notices R.A.S.*, xi. 248). He declares, however, that it would have been impossible for Sir William Herschel to have seen these two faint bodies; and although Prof. Holden has attempted to identify the two with two of Herschel's quartett, the balance of evidence is certainly to the contrary, and we are bound to conclude that no one has ever seen the four but Herschel himself.

Herschel announced, in 1798 (Phil. Trans., 1798, p. 48), the retrograde movements of the Uranian satellites in the terse paragraph, "I take this opportunity of announcing that the movement of the Georgian satellites is retrograde." The fact that their orbits were inclined about 80° to the ecliptic plane was discovered in 1788.

Herschel also particularly noticed that the light of the two brightest satellites was subject to considerable fluctuations, and in 1815 (Phil. Trans., 1815, p. 356) he suggests for a cause that given by Newton in the "Principia" to account for the periodical variability of certain stars. His conclusion was:—"The variable brightness of the satellites may be owing to a rotation upon their axes, whereby they alternately present different parts of their surface to our view. These variations may also arise from their having atmospheres that occasionally hide or expose the dark surface of their bodies, as is the case with the sun, Jupiter, and Saturn."

The two inner satellites, Ariel and Umbriel, discovered by Lassell, seem also to fluctuate in brightness, and Newcomb observed in 1875 ("Washington Observations," 1873, p. 43):—"I strongly suspect that Ariel, at least, belongs to that class of satellites of which the brilliancy is variable and dependent on its position in its orbit. The evidence of variability of some kind seems indisputable, as I have repeatedly failed to see it when the circumstances, distance from the planet included, were in every respect favourable, and when Umbriel, though less favourably situated, was visible. On the other hand, there were two occasions, January 28, 1874, and March 25, 1875, when it was surprisingly conspicuous. Unfortunately no systematic record was made of the times when, being near greatest elongation, it was looked for and not seen; but on at least one such occasion its position angle was 180°. An inspection of the observations shows that out of the eight observations only two were made near the southern elongation; while in the two cases where its brightness was most remarkable, the position angles were respectively 348° and 351°."

The time of revolution of Ariel is 2·520378 days at a mean distance of 120,000 miles; its diameter is about 500 miles.

Herschel also observed that these satellites became invisible some distance from the planet's disk (Phil. Trans., 1798, p. 75); thus, on February 22, 1791, the first satellite was lost when 22″ from the planet. This distance was not, however, constant, for on May 2, 1791, the same satellite disappeared at an apparent distance 19″·8. A table is given showing at what distance from the planet the first and second satellites respectively became invisible during a period of seven years. A fact exhibited by this table is that the distance at which the satellites disappeared regularly diminished from 1791 to 1797, until in the latter year the first satellite was traced to 4″·8 from the planet's disk. The reason assigned to account for this phenomenon by Herschel was that the light of the satellites was "put out" by the stronger light of their primary, and regarding this he remarks (Phil. Trans., 1798, p. 78):—"We may avail ourselves of the observations that relate to the distances at which the satellites vanish, to determine their relative brightness. The second satellite generally appears brighter than the first; but as the former is usually lost farther from the planet than the latter we may admit the first satellite to be rather brighter than the second." The diameters of the first and second satellites are about 1000 and 800 miles respectively, hence Herschel's comparative measures were correct. R. A. GREGORY.

BABYLONIAN ASTRONOMY.[1]

I.

CLASSICAL writers seem to be unanimous in considering the Babylonians as the most ancient astronomers; a close examination shows, however, that the statement emanated from one or two writers, and that all the others merely repeated it without taking the trouble of verifying it. The figures given by various authors as to the period covered by the Babylonian astronomical observations are most extravagant, but the disagreement of the authors proves their inaccuracy. In spite of all discrepancies, one fact comes out clearly—that is, the Semitic origin of the Babylonian astronomy. Belus, the eponymic king of Babylon, considered by the classics as the first ruler or even the colonizer of Babylonia, is called the "inventor of astronomy," and Seneca considered the work of Berosus as a translation of that of Belus.

If we turn now to the native documents—the tablets now in the British Museum—we can class them under two distinct periods, those previous to the Greek rule and those contemporaneous with the Seleucids. Some tablets of the first period give us lists of certain astronomical or atmospheric observations, with the events which took place at the same time; the others are mere reports of the official astronomers stating what they observed, as the occurrence or non-occurrence of an eclipse. A characteristic point is that the observations are in no case dated: the day and the month are, indeed, given, but not the year; and this leaves no doubt as to the real character of these documents.

The Babylonians held the belief that the sky was a reflection of what was going on upon the earth: if, therefore, a certain event took place at the time of the conjunction of two stars, the same event would repeat itself when the same conjunction would take place. There were no predictions, but merely statements of real facts taking place at the same time in the sky and upon the earth, the actual date of which was of no consequence, as the object in view was to establish the supposed connection between what happened in the sky and what happened upon the earth—in short, correlative events. It appears also that the Babylonians admitted the existence of a cosmical year—that is, a period after which the same events were to occur again; this period was one of 360,000 years. The number was obtained by a mere play on figures. The basal number of the Semites was six, as the system used to form their numerals shows; by multiplying it by ten (the number of the fingers) they formed the *soss*, 60; by multiplying again by ten was formed the *ner*, 600; and the square of the former gave 3600, the *sar*, or "multitude." The cosmical year was supposed to be formed of 100 *sari*, or the square of the *ner*; this was probably the number given by Berosus to the antediluvian period, 10 *sari* being attributed to each king. From this number were derived those given by the classics as the period of the Babylonian astronomical observations—720,000 years (or two cosmical years) by Epigenes, 1,440,000 (or four cosmical years) by Simplicius; the 490,000 years given by Berosus, according to Pliny, represent one cosmical year and 130,000 years, elapsed in his opinion, of the actual period. It cannot be doubted, however, that the stars have been observed in Babylonia from a very high antiquity, for we have lists of eclipses for almost every day in the year, and as these eclipses actually took place, they prove a long period of observations; some of the astronomical statements also refer to the pre-Akkadian period—that is, earlier than 7000 B.C. If the Babylonians, in spite of this long period of observations, never arrived at any correct knowledge of the motion of the planets and stars, it is no doubt due to their deficient calendar.

Omen-taking being therefore the only object of the Babylonian astronomers, or rather star-gazers, they distributed the stars and planets under the direction of certain gods, according to the influence attributed to them. This has unfortunately thrown much confusion into their nomenclature, for the name of the god is sometimes taken for that of the star which he is supposed to influence, and the same god influences several; in some cases, also, the same star is sometimes under the influence of one god, sometimes under that of another. Besides this, we have many groups of seven stars: the seven *dibbu* or planets, the seven *masu* or double stars, the seven *zikru* or males, &c. The stars were also divided by regions—the twelve stars of the north, and the twelve stars of the south—and associated in groups of two with certain months; the months themselves were associated with certain regions, and were under the guidance of a god.

In all this we see the rudiments or rather germs of astrology; but, as astrology requires a knowledge of the movements of the planets, the Babylonians never arrived at this point—they merely took omens, and to do so they appear to have proceeded exactly as did the augurs of Rome. They described first in the sky a circle with their rod, divided this circle into eight divisions by lines passing through the centre, and then observed the position of the stars in this imaginary geometrical figure, and what kind of phenomena took place, in order to draw from them their omens. Having made his observation, the operator, or priest, then referred to the lists of omens, copies of which have come to us, to ascertain if the same celestial phenomenon had already been noted, expecting as correlative fact the same terrestrial event which had happened in the previous case.

It may be noticed, before concluding, that all the astronomical omen tablets recovered from Nineveh or Babylon are written in the Semitic language; there are no doubt a great many ideograms, but the phonetic complements, the words spelt phonetically, and the grammatical peculiarities show that the idiom used must be Semitic.

[1] Abstract of the first lecture delivered by Mr. G. Bertin at the British Museum.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

DUBLIN.—At the Summer Commencements of the University of Dublin, held in Trinity College, Dublin, on June 27, Mr. F. W. Burbidge, Curator of the Trinity College Botanical Gardens, received the honorary degree of M.A. The Public Orator, Prof. Palmer, called attention to the benefits conferred on botanical science by Mr. Burbidge, by his travels in Borneo, and by his labours in elucidating the natural history of those classic flowers the Narcissi and the Hellebores. The honorary degree of LL.D. was conferred on Mr. Valentine Ball, F.R.S., the Director of the Science and Art Museum, Dublin, and at one time Professor of Geology and Mineralogy in Trinity College, Dublin, whose works on the geology and mineralogy of India, and researches on the identification of the animals and plants of India which were known to the early Greek authors, merited the eulogium pronounced on them by the Orator.

SOCIETIES AND ACADEMIES.

LONDON.

Linnean Society, June 6.—Mr. Carruthers, F.R.S., President, in the chair.—Dr. John Anderson, Mr. J. G. Baker, Dr. Braithwaite, and Mr. F. Crisp, were nominated Vice-Presidents.—Prof. Martin Duncan exhibited under the microscope some beautifully mounted preparations of the ambulacral tentacles of *Cidaris papillata*, and drew attention to the fact, previously unrecorded, that the tentacles of the abactinal region of the test differ in form and character from those of the actinal region. The latter have a well-developed terminal disk, and are richly spiculated; whereas the former have no disk, but terminate distally in a pointed extremity with very few spiculæ. Mr. W. P. Sladen made some remarks on the significance of this dimorphism with reference to its archaic character, and its relation to the primitive forms of Echinoids and Asteroids.—Mr. Narracott exhibited a singular fasciated growth of *Ranunculus acris*, found at Castlebar Hill, Ealing.—Mr. H. B. Hewetson exhibited under the microscope a parasite of Pallas's Sand Grouse (*Syrrhaptes paradoxus*) taken from a bird shot in Yorkshire, and described as a species of *Argas*. Mr. Harting pointed out that an apparently different parasite from the same species of bird had been recently described by Mr. Pickard Cambridge (*Ann. Mag. Nat. Hist.*, May 1889) under the name *Hæmaphysalis peregrinus*.—Dr. Cogswell showed some examples of Jerusalem Artichoke and Potato, to illustrate the spiral development of the shoots from right to left.—Governor Moloney, of the colony of Lagos, exhibited a large collection of birds and insects from the Gambia, the result of twelve months' collecting in 1884-85. The birds, belonging to 134 species, had been examined and named by Captain Shelley. Amongst the beetles, of which 89 species had been collected, he called attention specially to *Galerita africana* and *Tefflus megelii*, and to the Rhinoceros and Stag-horned Beetles. Of butterflies there were 90 species, amongst which the most noticeable and characteristic were the *Acreas* and the pale-green *Eronia thalassina*, said to be typically Gambian. The moths, of which some 220 species had been brought home, were named by Mr. Herbert Druce, and several had proved to be new or undescribed. A portion of this collection had been exhibited at the Indian and Colonial Exhibition of 1886, but had since been carefully gone over and named, and was now exhibited for the first time in its entirety.—Mr. Herbert Druce alluded to some of the Lepidoptera which are most characteristic of the Gambia region; and Mr. Harting made some remarks upon the birds, pointing out the wide geographical range of some of the species which had been collected.—Mr. Clement Reid exhibited several specimens of fossil plants from a newly-discovered Pleistocene deposit at South Cross, South-elmham, near Harleston.—Mr. D. Morris exhibited specimens of the fruit of *Sideroxylon dulcificum*, the so-called "miraculous berry" of West Africa, belonging to the *Sapotaceæ*. Covered externally with a soft sweet pulp, it imparts to the palate a sensation which renders it possible to partake of sour substances, and even of tartaric acid, lime-juice, and vinegar, and to give them a flavour of absolute sweetness. The fruit of *Thaumatococcus* (*Phrynium Danielli*), possessing similar properties, was also shown; and living plants of both had lately been received at Kew from Lagos through Governor Moloney.—Mr. Thomas Christy exhibited growing plants of *Antiaris toxicaria* (the Upas-tree) and *Strophanthus Kombe*, both of them poisonous, to show the similarity of the foliage.—On behalf of Dr. Buchanan White, a paper was then read by Mr. B. D. Jackson, entitled a "Revision of the British Willows."

Royal Meteorological Society, June 19.—Dr. W. Marcet F.R.S., President, in the chair.—Mr. W. Marriott gave a very graphic and interesting account of the recent thunderstorms which have prevailed over this country. On Sunday, June 2, a thunderstorm passed across the country in a northerly direction from Wiltshire about 5 a.m., and reached Edinburgh by 10.44. It travelled at the rate of about 50 miles an hour. It is possible that this storm travelled still further north, and reached Kirkwall at 3.37 p.m. A severe thunderstorm prevailed over the neighbourhood of the Tweed between 11 a.m. and noon, and was accompanied by hail of very large size, some of the stones being 5 inches in circumference. A very destructive storm occurred over the whole of the north-west of England and south of Scotland during the afternoon; much damage was caused by lightning, and very large hail fell over an extensive area. Some of the hailstones measured 7 inches in circumference and weighed 7 ounces. During the night of the same day a severe thunderstorm prevailed over Norfolk, which was also accompanied by very large hailstones, some of which were 5 to 6 inches in circumference. On Thursday, the 6th, thunderstorms prevailed during the afternoon over the whole of the south-east of England; that which passed over the Metropolis about 9 o'clock was remarkable for the brilliant and continuous display of lightning. During the same night and in the early morning of the following day a very destructive storm prevailed over the Eastern Counties, much damage being done by the lightning in the north-west of Norfolk. Severe hailstorms occurred between 2 and 3 a.m., both at Margate and Ipswich. During the afternoon of the 7th, destructive thunderstorms prevailed over the whole of the Southern Counties, much damage being done by lightning, while at Tunbridge Wells there was a most remarkable hailstorm. One of the hailstones which was weighed was actually half a pound in weight. An interesting collection of over forty photographs of lightning taken during the storm on June 6 was also exhibited to the meeting. In addition to the sinuous, ribbon, and meandering flashes of lightning, several photographs showed knotted, multiple, and dark flashes.—The following papers were also read:—The climate of British North Borneo, by Mr. R. H. Scott, F.R.S.—On the variation of the temperature of the air in England during the period 1849 to 1888, by Mr. W. Ellis.—Atlantic weather and rapid steamship navigation, by Mr. C. Harding.—Meteorological phenomena observed during 1875-87 in the neighbourhood of Chelmsford, by Mr. Henry Corder.—Rainfall in China, and meteorological observations made at Ichang and South Cape in 1888, by Dr. W. Doberck.

Geological Society, June 5.—Prof. J. W. Judd, F.R.S., Vice-President, in the chair.—The following communications were read:—Observations on some undescribed lacustrine deposits at Saint Cross, Southelmham, in Suffolk, by Charles Candler (communicated by Clement Reid). Some remarks were made on this paper by Mr. Clement Reid, Prof. Prestwich, and Mr. Lydekker.—On certain Chelonian remains from the Wealden and Purbeck, by R. Lydekker. In the first part of the paper the author described a portion of the hind lobe of a Chelonian plastron from the Wealden, which was remarkable as showing a median row of epidermal shields. The name of *Archæochelys valdensis* was proposed for the form so represented. The new generic term *Hylæochelys* was also proposed for the Purbeck Chelonian described by Sir R. Owen as *Pleurosternum latiscutatum*, and was also taken to include some other forms from the Wealden. The second section of the paper treated of the affinities of *Pleurosternum*. It was concluded that *Digerrhum*, Cope (as represented by the so-called *Platemys Bullocki*), is identical with *Pleurosternum*, of which there appears to be only one Purbeck species. Evidence was brought forward to show that in the adult of *Pleurosternum* the pubis had a facet for articulation with the xiphiplastral; and it was proposed to refer this genus, together with *Platychelys* and *Baëna*, to a new section termed "Amphichelydia," which was regarded as allied both to the true Cryptodira and to the Pleurodira.—On the relation of the Westleton Beds or Pebbly Sands of Suffolk to those of Norfolk, and on their extension inland; with some observations on the period of the final elevation and denudation of the Weald and of the Thames Valley, by Prof. Joseph Prestwich, F.R.S. The author in this, the first part of his paper, described the Westleton beds of the East Anglian coast. He commenced with a review of the work of previous writers, especially Messrs. Wood and Harmer, and the members of H.M. Geological Survey, including Messrs. H. B. Woodward, Whitaker, and Clement Reid. In discussing this work, particular attention was paid to the Bure Valley beds, which were considered as a local fossiliferous condition of the Pebbly Sands; but the term is not so applicable to these sands as that of the "Westleton and Mundesley Beds," which the author proposed in 1881. The Westleton beds were carefully described, as seen in coast-sections in East Anglia, proceeding from south to north, and the following classification was adopted:—

The Westleton and Mundesley series (The Mundesley section of it).	1. Laminated clays, sand, and shingle with plant-remains and freshwater shells (the Arctic forest-bed of Reid). 2. Sand and quartzose shingle with marine shells (the *Leda myalis* bed of King and Reid). 3. Carbonaceous clay and sands with flint-gravel, and pebbles of clay, driftwood, land and lacustrine shells and seeds (the Upper freshwater bed of Reid).
The Forest-bed series of Reid (exclusive of No. 3 of above).	4. A greenish clay, sandy and laminated in places, containing abundant mammalian remains, and driftwood, with stumps of trees standing on its surface (the forest- and elephant-bed of authors; the estuarine division, in part, of Reid). 5. Ferruginous clay, peat, and freshwater remains and gravel (the Lower freshwater bed of Reid).

The Westleton beds were found to rest with discordance on various underlying beds; in places on the Forest series, elsewhere on the Chillesford Clay, whilst occasionally the latter had been partly or entirely eroded before the deposition of the Westleton beds. In the north, where the present series dies out, they come in contact with the so-called Weybourn Crag, which the author supposed to be the equivalent of the Norwich Crag. A similar discordance has been noted between the Westleton beds and the overlying glacial beds, so that the former mark a distinct period, characterized by a definite fauna, and by particular physical conditions. The Westleton beds being marine, and the Mundesley beds estuarine and freshwater, the author proposed to use the double term to indicate the two facies, as has been done in the case of other deposits. But these facies were found to be local, and the most persistent feature of the beds is the presence of a shingle of precisely the same character over a very wide area. By means of this the Westleton beds can be identified far beyond East Anglia, and where there is no fossil evidence, and they throw a considerable light on important physiographical changes. The author described the composition of the shingle, which, unlike the glacial deposits, contained pebbles of southern origin. The paper concluded with a list of fossils, excluding those of the Forest-bed (the stumps of which, the author considered, were frequently in the position of growth). Should the Forest-bed eventually prove to be newer than the Chillesford beds, it was maintained that the former must be included in the Westleton series, and its flora and fauna added to the list, whilst if, on the contrary, the Forest-bed should be proved synchronous with the Chillesford beds it must be relegated to the Crag. The second part of this paper will treat of the extension of these beds into and beyond the Thames Valley, and on some points connected with the physical history of the Weald. The reading of this paper was followed by a discussion, in which Mr. B. H. Woodward, Mr. J. A. Brown, and Mr. Topley took part.

June 19.—Prof. J. W. Judd, F.R.S., Vice-President, in the chair.—The following communications were read:—On tachylyte from Victoria Park, Whiteinch, near Glasgow, by Frank Rutley.—The descent of *Sonninia* and of *Hammatoceras*, by S. S. Buckman.—Notes on the Bagshot Beds and their stratigraphy, by H. G. Lyons.—Description of some new species of Carboniferous Gasteropoda, by Miss Jane Donald; communicated by J. G. Goodchild.—*Cystechinus crassus*, a new species from the Radiolarian marls of Barbados, and the evidence it affords as to the age and origin of those deposits, by J. W. Gregory.—The next meeting of the Society will be held on Wednesday, November 6.

Zoological Society, June 18.—Prof. Flower, F.R.S., President, in the chair.—The Secretary exhibited (on behalf of Mr. J. F. Green) a very fine example of the Common Eel, obtained from a pond in Kent, and measuring upwards of 4 feet in length.—Mr. B. B. Woodward exhibited, and made remarks on, a drawing representing a living example of *Ærope kaffra*, a carnivorous snail from the Cape Colony.—Mr. Woodward also exhibited an example of a fossil shell from the Eocene of the Paris Basin (*Neritina schmideliana*), and a section of it showing the peculiar mode of its growth.—Mr. Eadweard Muybridge, of the University, Pennsylvania, exhibited a series of projections by the oxyhydrogen light, illustrative of the consecutive phases of movements by various quadrupeds while walking, trotting, galloping, &c., and of birds while flying.—A communication was read from Prof. Henry H. Giglioli, containing the description of a supposed new genus and species of Pelagic Gadoids from the Mediterranean, proposed to be called *Eretmophorus kleinenbergi*.—Lieut.-Colonel H. H. Godwin-Austen, F.R.S., read the first of a proposed series of papers descriptive of the land-shells collected in Borneo by Mr. A. Everett, with the descriptions of new species. The present paper treated of the *Cyclostomaceæ*.—Captain G. E. Shelley read a list of birds collected by Mr. H. G. V. Hunter in Masai Land during the months of June, July, and August 1888. The collection (which Mr. Hunter had presented to the British Museum) consisted of examples of ninety-four species, seven of which were described by the author as new to science.—Mr. P. L. Sclater, F.R.S., gave a further description of Hunter's Antelope (*Damalis hunteri*) from specimens obtained by Mr. H. C. V. Hunter on the River Tana, Eastern Africa.—Mr. F. E. Beddard read a paper on the fresh-water and terrestrial Annelids of New Zealand, with preliminary descriptions of new species.—A communication was read from Mr. H. W. Bates, F.R.S., containing descriptions of some new genera and species of Coleopterous insects collected by Mr. Whitehead during his recent visit to Kina Balu. The collection was stated to comprise an unusual proportion of new and remarkable forms.—This meeting closed the session. The next session (1889–90) will begin in November 1889.

Victoria Institute, July 1.—Annual Meeting.—Sir George Stokes, Bart., P.R.S., President, in the chair.—After the reading and adoption of the Report, an address by Prof. Sayce was read by Dr. Wright. It gave a description of what has become known as to the conquests of Amenophis III., the palace and its archives, which have only lately been discovered, and which Prof. Sayce went last winter to investigate on the spot. Of the tablets and inscriptions, he said:—"From them we learn that in the fifteenth century before our era—a century before the Exodus—active literary intercourse was going on throughout the civilized world of Western Asia, between Babylon and Egypt and the smaller States of Palestine, of Syria, of Mesopotamia, and even of Eastern Kappadokia. And this intercourse was carried on by means of the Babylonian language, and the complicated Babylonian script. This implies that, all over the civilized East, there were libraries and schools where the Babylonian language and literature were taught and learned. Babylonian, in fact, was as much the language of diplomacy and cultivated society as French has been in modern times, with the difference that, whereas it does not take long to learn to read French, the cuneiform syllabary required years of hard labour and attention before it could be acquired." A vote of thanks was passed to Prof. Sayce for his address, to Dr. Wright for reading it, and to the President.

Paris.

Academy of Sciences, June 24.—M. Des Cloizeaux, President, in the chair.—On the condition of matter near the critical point, by MM. L. Cailletet and E. Colardeau. The series of experiments here described, and carried out for the purpose of testing the views of Cagniard de Latour, Andrews, Ramsay, and other physicists, tend to show that the critical temperature of a liquefied gas is not that at which the fluid is totally evaporated abruptly within the space containing it, for the liquid state persists beyond this temperature; nor is it the temperature at which a fluid and its saturated vapour have the same density; but it is the temperature at which a fluid and the gaseous atmosphere above it become capable of being mutually dissolved in any proportion, so as to form, when shaken, a homogeneous mixture. This interpretation of the critical point supplies some interesting data on the unbroken continuity of the liquid and gaseous states of matter.—On the heat of formation of the hyponitrites, by M. Berthelot. M. Maquenne's experiments on the hyponitrites, here communicated to the Academy by M. Berthelot, seem to decide the question of the formula of hyponitrous acid, which corresponds with the percentage composition suggested by Divers, but with twice the molecular weight. The complete analysis of the salts of calcium and strontium removes all further doubt on this point.—Restoration of the skeleton of Dinoceras, by M. Albert Gaudry. The specimen here described is that of Marsh's *D. mirabile*, copies of which have been supplied both to the British Museum and to the new gallery of palæontology in the Paris Museum.—On the mastodons found at Tournan, Gers, by M. Albert Gaudry. The numerous remains of mastodons recently found by M. Marty in the Middle Miocene of Tournan, all belong to *M. angustidens*. Amongst them is the most perfect head of any mastodon yet brought to light in Europe. This, with some other important parts, has been secured for the Paris Museum, and affords facilities for determining the specific differences between *M. angustidens* of the Miocene and the *M. americanus* of the Quaternary epoch.—On the occlusion of gases in the electrolysis of the sulphate of copper, by M. A. Soret. Having already shown (*Comptes rendus*, November 5, 1888) that certain relations exist between the quantities of gas occluded in electrolytic copper and the conditions of temperature and acidity of the electrolyte, the author has carried out some further experiments leading to more accurate results, and throwing some light on the action of the electrolysis in this particular case. He finds that the electrolytic copper contains carbon dioxide and hydrogen, the latter of which is in most cases present in largest proportion (five-sixths may be taken as an average), and in all cases when the electrolyte is acid; further, that the brittleness of the deposit of copper is related to the presence of carbon dioxide.—On the compounds of ruthenium and ammonia, by M. A. Joly. The author has already shown that the constitution of the red chlorides of ruthenium was more complex than was supposed by Claus. It results from his further researches that the chloride and all bodies derived from it contain an atom of nitrogen more than was indicated by Claus, and that their formula might be written thus: $Ru . NO . OH . X_2(4NH_3)$.—On the presence of sulphate of soda in the atmosphere, and on the origin of saline dust, by M. P. Marguerite-Delacharlonny. Some facts are here adduced which may give a more general and perhaps a more correct explanation of the presence of the sulphate of soda in the atmosphere than that of M. Parmentier.—Camphor and borneol of rosemary, by M. A. Haller. A new method is described for separating these substances.—Mean altitude of the continents and mean depth of the oceans, by M. A. de Tillo. From the author's minute researches it results that the numerical data hitherto accepted by various authorities require to be modified. He finds the mean elevation of all the continents above sea-level to be 693 metres: northern hemisphere, 713; southern hemisphere, 634; Europe, 317; Asia, 957; Africa, 612; North America, 622; South America, 617; Australia, 240. Mean depths of all the oceans, 3803: Pacific, 4380; Atlantic, 4022; Indian, 3674; northern seas, 3627; southern seas, 3927.

BERLIN.

Physical Society, June 7.—Prof. von Helmholtz, President, in the chair.—Dr. R. von Helmholtz communicated the results of his experiments on the radiating power of flames. The problem which he had set before himself was to determine the relationship between the radiant energy of flames, and the amount of gas consumed for their production. The latter was measured by the fall of the gasometer-globe which contained the gas, the former by means of a bolometer, for each of whose scale-divisions the equivalent value in heat-units had been carefully determined by three different methods. The radiating energy of the flames depended upon a number of conditions which were each severally investigated; as, for instance, the size and shape of the flames, the amount of foreign gases introduced, and the ratio of the amount of oxygen to the amount of gases with which it was mixed. For the purposes of comparative measurements, a moderately high flame was chosen, which produced no smoke and was 6 mm. thick. Luminous flames radiated more energy than non-luminous, and it was proved by an extended series of careful quantitative experiments that the radiating power of the flames was not dependent upon their temperature. From this it follows that Kirchoff's law does not hold good for flames—a result which is, however, quite in accordance with the limitations he put to his law for those cases in which heat is directly converted into radiating energy. In the case of flames it must be borne in mind that chemical affinity comes additionally into play: the speaker entered fully into the influence of this upon the radiation of energy, and endeavoured to make it clear by means of an extremely interesting hypothesis. After this he stated the numerical data which he had obtained for both luminous and non-luminous flames, produced with a series of gases—hydrogen, carbonic oxide, methane, coal-gas, methyl-alcohol, &c. Starting as a basis with Julius's statement that the products of combustion are the only criteria of the amount of radiation, and hence calculating the radiating energy of the flames, he obtained values which corresponded very closely in most cases with those actually observed. Finally he calculated the total useful effect which can be obtained as radiant energy from the gases which are being consumed in the production of the flame. From this he arrived at the interesting result that it is far more economical to use the gases for driving a dynamo which supplies incandescent lamps, and to utilize the energy radiated from the latter, than to burn the gases, and utilize the energy which is radiated out from their non-luminous flames. The communication, as a whole, of which only a short sketch has here been given, contained a large number of very valuable quantitative results. —Dr. Budde spoke on "tautological" contacts in mechanics, and deduced the general conditions under which a close determination of contacts between surfaces and points is unnecessary ("tautological").

Physiological Society, June 14.—Prof. Munk, President, in the chair.—Dr. Openchowski spoke on the researches which he has carried on since 1883 on the movement and innervation of the stomach. The movements were recorded by introducing into the stomach a small bag filled with water and connected with a manometer, the motion of the column of fluid in the latter being recorded graphically. The fundus and first third of the stomach never exhibit any spontaneous peristaltic movements, these being confined to the second and last third, including the pylorus. The centre for the initiation of the motor movements lies in the ganglion cells under the serous coat which extend all over the stomach along the branches of the vagus nerve. The motor and inhibitory centres on which the movements of the cardiac end depend are situated in the brain and spinal cord; the motor centres lie in the corpora quadrigemina and in the spinal cord between the fifth and eighth thoracic vertebræ; the inhibitory centres lie in the corpus striatum, and a few are scattered in the spinal cord. The connection between the cranial centres and the stomach is provided by the vagi; there is no connection between the cranial and spinal centres. The centres for the pyloric end are situated in the same places as those for the cardiac end, but the centres which are inhibitory for the latter are motor for the former, and *vice versâ*. The speaker has studied the act of vomiting very fully. The stomach plays an active part in this act. After paralysis of the stomach, the movements of vomiting may be brought about, but do not lead to an ejection of the stomach's contents. After administering an emetic, such as sulphate of copper, the fundus and first third of the stomach is actively dilated; the pylorus is at the same time relaxed, and the contents of the small intestine are driven into the stomach by the contraction of the intestinal walls, and then, by the strong and progressive contractions of the last two-thirds of the stomach, they are driven on into the first third of the stomach. At this stage the stomach has a pear-like shape, the fundus being unduly distended. The reflex movements of vomiting now occur, and the pressure exerted by the abdominal muscles leads to the emptying of the highly distended fundus. As after paralysis of the stomach, so also after section of the vagi and excision of the stomach and intestines, the movements of vomiting occur when an emetic is administered. No *single* centre for vomiting appears to exist and be actively functional during the act, but there would seem rather to be a combination of co-ordinated centres, whose position has still to be more definitely ascertained.

AFRICAN RIVER LIFE.

A Visit to Stanley's Rear Guard at Major Barttelot's Camp on the Aruhwimi; with an Account of River Life on the Congo. By J. R. Werner. (Edinburgh and London: Blackwood and Sons, 1889.)

THAT, with our present knowledge of its geography and resources, Africa should be considered *the* special field for travellers *en grand*, is not surprising. Nor is it strange that merchants and moneyed men should be attracted to a land so rich in the means and materials of commerce. Immense progress has of late years been made in filling up the blanks for which its maps were notorious up to a very recent generation of school-boys; but the impulse in this direction is not yet expended, and Europe awaits eagerly much-needed enlightenment on the Sahara and Western Soudan, besides those countries of which more is heard, and remains to be heard, in the development of our existing foreign or colonial relations. To the north, Algiers and Egypt; to the south, the Cape of Good Hope and neighbouring territories; and east and west, the coast lines, and outlying islands generally, of the main land, have long since become familiar localities to students of travel and current events. It is only, however, within the last ten or fifteen years that equatorial Africa has been fairly opened out. Across the huge continent Europeans have now placed a broad and continuous girdle, reaching from the mouth of the Congo at Banana to the dominions of the Sultan of Zanzibar. Looked at from west to east, the component parts of this girdle are the French Congo, won to France by M. De Brazza and Belgian concession; the Portuguese Congo, allowed to Portugal in deference to a long-asserted claim, the frequent rejection of which by the English Foreign Office seemed to demand a change of treatment; the Free State of the Congo, founded and acquired by Stanley and a host of explorers and emissaries serving the King of the Belgians, first among promoters of Central African exploration; the wide-spreading German lands obtained from the chiefs of Usagara, Nguru, Useguha, and Ukanio, by three skilful and enterprising negotiators, whose work—like that of the Society of German Colonization—was almost immediately taken under the protection of the Imperial ægis on the signatures being affixed to the Treaty of Berlin; and now the girdle has become deepened by the important addition of the tracts ceded to the chartered Imperial British East African Company. What may be done by the Company dealing with the African Lakes is a problem the solution of which should belong to the combined or separate action of both philanthropists and commercial speculators.

If the progress of mapping out Africa has been marvellously rapid in the second half of the present century, the educational gain to the civilized world from the process is due not only to the labours of practical exploration, but also to the literary skill and ability with which those labours have been recorded. Travellers such as Burton, Speke, Grant, Livingstone, Baker, Johnson, Thomson, and Stanley, have been enabled, by the possession of natural qualifications, to give to the world their personal impressions and experiences with more or less of artistic power, and the advantage to a reading and appreciative public has been consequently great. But a second class of writers must not be ignored, who, without laying claim to the rank of chief explorers or the merit of original discovery, have shown themselves fully capable of strengthening the revelations of the princes of African travel, by chronicling the results of their own lesser, yet always intelligent, nomadism. Of this class Mr. Werner is a good representative. His well-written narrative might well have won attention as a mere description of African river life, without the use of an *ad captandum* title in reference to "Rear Guards."

The author, accepting service as an engineer under the Congo State, embarked from Antwerp in April 1886, arrived at Banána late in May, passed up the river to Boma and Matádi (which has taken the place of Vivi on the left bank), and left the latter station for Stanley Pool, by land, on June 10. After many days of roughing and sickness, he reached the Pool station at Leopoldville, was detained there until the middle of July, and on August 1 came to a halt at Bangala, his prescribed head-quarters. This is one of the more northerly posts of the Free State, and is situated about a third of the way between the Equator and Stanley Falls stations. Here he was seldom allowed to rest for many weeks together; for the little steamer to which he was attached was in constant requisition. In fact, his river expeditions—at one time of a punitive or political, at another of a searching or scientific character—extending, in advance, to Stanley Falls, and, in rear, to Leopoldville, or limited to places within either distance—form the substance of his book.

Mr. Werner's official residence may be described in his own words:—

"Bangala Station stands on the north bank of the Congo, in the town of Iboko, which forms the centre of a ten-mile line of towns and villages inhabited by the Ba-Ngala tribe. This settlement is surrounded on three sides by swamp, and on the fourth the River Congo cuts off all communication except by boat. According to native accounts it is possible in the dry season to go some two days' journey inland; and I should think it quite practicable to penetrate as far as the Oubangi, but as the tribes on the bank of that river are hostile to the Ba-Ngala, I had no means of ascertaining the fact, and I have never been more than six or seven hours' journey in that direction myself. I found the country gently undulating—the rising ground for the most part cleared and cultivated, and the hollows filled with a dense scrub, which, in the wet season, grew out of three or four feet of water, sometimes more. After some three hours' journey inland, all cultivation ceases, and the path runs through one continuous jungle of scrub, there being very few large trees."

Vivid pictures of scenery are not wanting in these pages, and a chapter headed "Exploration of the Ngala," gives an account of a nine days' endeavour to test the navigability and uses of a feeder of the Congo which empties itself into the larger river about forty or fifty miles above Iboko. This expedition was, however, brought abruptly to an end by hostilities on the part of angry and warlike tribesmen. Mention is also made of a large lake supposed to exist in the regions between the Lower Lomami and the head of the Congo, and to be distant only one day's canoe journey from the former. Its appearance in the map accompanying Mr.

Werner's narrative presents a new geographical feature, the warrant for which has probably by this time been confirmed or disallowed. But the chief interest attaching to the book arises from the description of living persons, European or native, who take, or have taken, part in the story of the Congo Free State. The narrative may not always be as gratifying as truthful; nor is the record of that kind of warfare which tells us of the shooting of natives as though they were but large game, quite pleasant reading; but allowance must be made for unrecorded provocations and exigencies, and let us hope that conciliation will have a wider field for exercise when the harder obstacles to peaceful settlement shall have been removed. No civilized being could wish for the renewal of days such as those in which Mr. Werner "saw more than one poor wretch put up his shield, only just in time to receive a ball right through it and himself as well, and come rolling down the clay bank into the river, dead as a door-nail." The author has dwelt, moreover, upon a passage in his own particular career which cannot but leave a painful impression on the mind of his reader. He had been told that Tippoo Tip had threatened mischief to Major Barttelot if certain conditions were unfulfilled, and he had been restrained by circumstances from communicating intelligence of the threat to that gallant and lamented officer. It is easy to understand how this non-revelation of fore-shadowed ill haunted his brain, and how mental distress became aggravated by the sad news of Major Barttelot's death; but he may well derive consolation from the conviction that the reported threat was the outcome of a state of things which must have been fairly appreciated by all Europeans in those days encamped in the neighbourhood of Stanley Falls.

Mr. Werner is no doubt right in assuming that "facility of transport to the coast by means of railways and steamers will do more, by making slave-caravans unprofitable, to put down the curse of Africa," than the extinction of elephants—an hypothesis much favoured by recent writers. Were steam once made available for traffic along the main thoroughfares of the Dark Continent, the necessity for the employment of slaves in the conveyance of ivory would naturally cease, and one source of evil would thus be stopped by the mere force of circumstances—means quite as efficacious as, and more satisfactory than, armed intervention. In the final chapter the author considers with much intelligence and practical sagacity the different lines of communication now being opened out between the coast and the interior of Africa. These are notably, on the east, a land and water route from Uganda to the sea-mouth of the Tana River, passing through or skirting the possessions of the British East African Company: to the westward, the proposed railway to facilitate traffic between Banana and Stanley Falls; and, on the south, communications developing under the far from insignificant agency of the African Lakes Company. Truly, European enterprise is astir in the land; and England, the party most interested in the movement, if she remain content to be the most responsible speculator in its risks, should further seek to become the most important participator in its benefits.

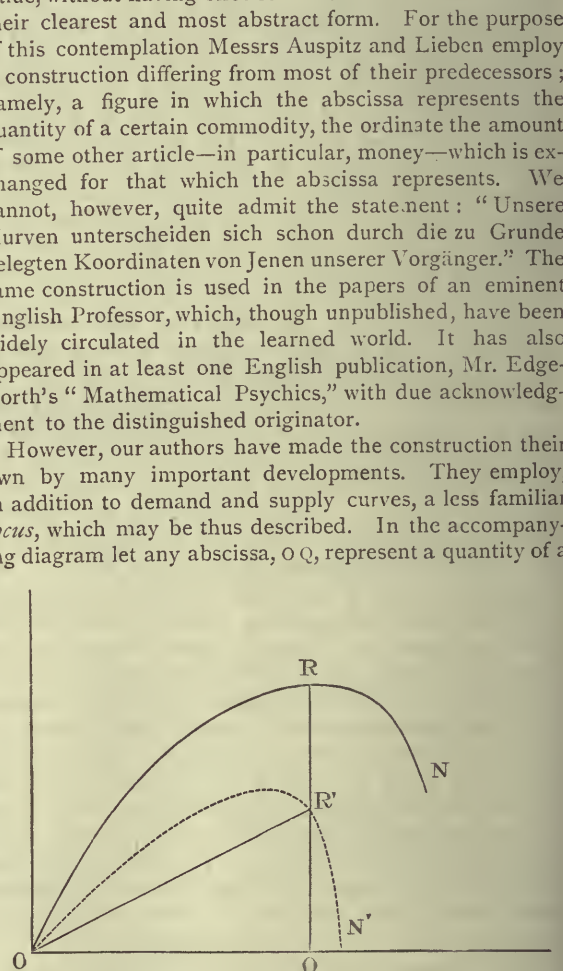
The attraction of this volume is enhanced by photographs and illustrations. Stanley's likeness is excellent, and the sketch of Mata Bwyki highly characteristic.

THE MATHEMATICAL METHOD IN POLITICAL ECONOMY.

Untersuchungen über die Theorie des Preises. Von Rudolf Auspitz und Richard Lieben. (Liepzig: Verlag von Duncker und Humblot, 1889.)

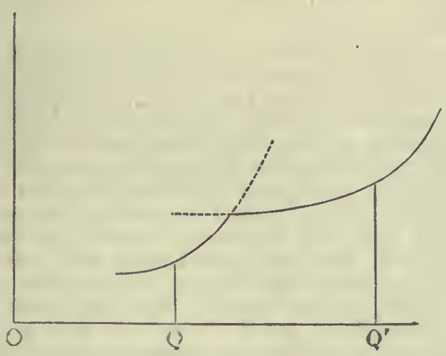
THE usefulness of mathematical reasoning applied to political economy, the value of the methods originated by Cournot and developed by Jevons, may be said to be still *sub judice*. The consideration of Messrs. Auspitz and Lieben's diagrams and symbols tends to confirm the opinion that mathematical analysis is a potent, if not an indispensable, means of obtaining clear general ideas in economics. The metaphysician who twists and turns the terms force and energy without grasping their mathematical signification is not more likely to become entangled in his talk than the practical man who reasons about supply and demand, and cost and value, without having once for all considered the ideas in their clearest and most abstract form. For the purpose of this contemplation Messrs Auspitz and Lieben employ a construction differing from most of their predecessors; namely, a figure in which the abscissa represents the quantity of a certain commodity, the ordinate the amount of some other article—in particular, money—which is exchanged for that which the abscissa represents. We cannot, however, quite admit the statement: "Unsere Kurven unterscheiden sich schon durch die zu Grunde gelegten Koordinaten von Jenen unserer Vorgänger." The same construction is used in the papers of an eminent English Professor, which, though unpublished, have been widely circulated in the learned world. It has also appeared in at least one English publication, Mr. Edgeworth's "Mathematical Psychics," with due acknowledgment to the distinguished originator.

However, our authors have made the construction their own by many important developments. They employ, in addition to demand and supply curves, a less familiar *locus*, which may be thus described. In the accompanying diagram let any abscissa, O Q, represent a quantity of a



certain commodity; and let Q R represent the amount of money which a consumer would be just willing to give in exchange for the commodity O Q: in such wise that it would be indifferent to him whether he procured O Q on such terms, or did not consume the article at all. The *locus* of this point O N is called the utility curve. Correlated with this primary curve is the demand curve O N', which indicates the amount which any individual is willing to purchase at the price represented by the tangent of the angle R′OQ. The advantage which the individual derives from that purchase is represented by the length of the line RR′—that is, supposing money to be a uniform measure of value, which would cease to be true when the transaction is on a very large scale: for instance, the payment of so much as QR would so cripple a person's resources as to render money a more important object to him, to alter his *Wertschätzung des Geldes*. Still, even in this general case, ON is regarded as a "curve of constant satisfaction," which we may describe as much the same as the "line of indifference" of the English publication to which we have referred. By a parity of construction we have the cost curve to represent the amount of money in return for which one would just be willing to produce a certain quantity of an article; and the offer or supply curve indicating the amount which the producer will offer at a certain price.

The curves which we have described represent primarily the effective dispositions of individuals. By superposition of such individualistic curves, we obtain corresponding *collective* curves. The intersection of the collective demand curve and the collective offer curve gives the price. On this point our authors' analysis throws some new light. They point out that most of the curves with which we have to deal are of the nature of an *envelope*, made up of a number of distinct *loci*. Consider the cost curve of the individual, for instance. His dispositions may be represented by two discrete curves, according as we consider different scales of production; say, hand-work and manufacture by machinery, corresponding to the neighbourhood of Q and Q′ respectively, in the accompanying figure. The outer portions of these lines, marked black



in our figure, form the genuine cost curve; from which a similarly composite offer curve may be derived. This sort of discontinuity has not been unnoticed by other writers, in the case of production. But we believe that Messrs. Auspitz and Lieben are the first writers who have maintained that the *locus* on the side of consumption is similarly composite; that the demand curve is made up of several bits, corresponding to different styles of life (*Lebensweise*).

It follows from these conceptions that the demand and supply curve, whose intersection determines price, must be of a simple shape, not re-entrant and crumple-horned, as they have sometimes been represented. Whence we may deduce that—theoretically, and on the supposition of enlightened self-interest—the price which tends to prevail in an ideal market is not only determinate, but unique. There cannot be, as it were, several solutions of the equations of exchange. The interest of this conclusion will be apparent when it is remembered that the contrary statement is advanced as important by Mill, with respect to international trade, and by Prof. Sidgwick, with respect to trade in general.

The curves employed by Messrs. Auspitz and Lieben assist us in conceiving a subject on which many misapprehensions exist—the gain of foreign trade. It takes Mill and Prof. Sidgwick a good many words to prove that it is possible for a country, by a judicious import or export tax, to benefit itself at the expense of the foreigner. The truth is seen much more easily, and in a higher degree of generality, by a glance at the appropriate mathematical diagrams.

The method also adapts itself to the dealings of a monopolist. The influence of a single large dealer in competition with several small ones is represented by a construction of peculiar beauty and originality. If it is true that we are drifting towards a *régime* of trusts, combinations, and monster establishments, surely any ray of new light on this somewhat unexplored field ought to be welcomed. It may be difficult, perhaps, to estimate the positive practical value of this use of the mathematical method. We might compare, perhaps, the function of the sovereign science in respect to the theory of monopolies, with the duties of government in respect to their management—to exercise a general supervision without attempting to control details.

Messrs. Auspitz and Lieben have also treated the case of monopoly in which an individual or combination deals with another economic unit. They of course see the point, which is often missed by the *littérateur*, that, without perfect competition, the determination of price is, within certain limits, indeterminate. On the question, what basis of arbitration—in the absence of the mechanical principle of competition—should prevail, we venture to regard their answer as much more profound than that which has been given by the most eminent English Professors. An agreement to the terms which afford the greatest sum total of utility will tend to come to pass. The utilitarian position thus indicated would coincide with the settlement towards which perfect competition tends, upon a certain condition which our authors have introduced. The condition may be described as proper to perfect competition; namely, that every portion of an article should be exchanged at the same rate. We are not satisfied that our authors are justified in predicating this condition of a bargain, such as that between an employer and a combination of workmen. Nor do we accept the implied optimistic conclusion that, in the abstract at least, the play of competition in the labour market tends to the arrangement which is the best possible for all concerned.

But we are sensible that on points so abstruse it is hardly possible to make our own meaning, or that of our authors, clear, without a more copious use of symbols and verbal explanation than would be here admissible. We regret, also, that, while indicating some salient features of the work before us, we have not been able to bring out the beauty and completeness of the whole. Perhaps no other piece of reasoning which has issued from the mathematical school of economics is so perfectly fitted together. No other of equal originality is equally easy to understand. The intellectual pleasure which is compounded of mathematical exertion and the interest in human affairs is here enjoyed must purely. F. Y. E.

PROFESSOR VON "CRANK."

Richtigstellung der in bisheriger Fassung unrichtigen Mechanischen Wärmetheorie und Grundzüge einer allgemeinen Theorie der Aetherbewegungen. Von Albert R. von Miller-Hauenfels, Professor a. D. in Graz. Pp. 256. (Wien: Manz'sche k.k. Hof-Verlags- und Universitäts-Buchhandlung, 1889.)

It is quite refreshing to come across a real "crank" among the sober Germans. As might be expected, there is a good deal of irregular metaphysics involved in the lucubrations of a German "crank." One would not, however, expect an entire ignorance of the first principles of the mathematics involved. The author of this hardly sufficiently ingenious to be even curious work begins by objecting to the well-known thermodynamic equation for perfect gases—

$$J(C - c) = p\frac{dv}{dt} = R = \frac{pv}{T},$$

because, forsooth, it is not identical with the general differential equation—

$$R = p\frac{dv}{dt} + v\frac{dp}{dt};$$

forgetting that the definition of C, as he himself gives it, assumes that, in the first equation, p is constant. In order to escape this invented difficulty, he loads himself with an equation—

$$JQ = Jcdt + vdp + pdv,$$

which involves the remarkable result that the heat required to warm a gas at constant volume is $JQ = Jcdt + vdp$, while by definition it is $= Jcdt$. It is not necessary to remark that the author carefully neglects to draw this conclusion. His equation is founded on the interesting principle that, when any event produces two different effects on the same organ of sense, each effect must be due to a separate flow of energy. When a mass of gas is warmed at constant volume, and one resists its expansion, one feels two effects with the same organ of sense: (1) the increase of pressure, and (2) the increase of temperature; and it is argued that each must be due to a separate flow of energy. This interesting principle leads to the startling conclusion that the heat required to change a body from one state to another, is independent of the states through which the body passes, and depends only on the initial and final states; and this startling oonclusion involves the equally startling inference that the internal energy of a body *is* a function of the states it has passed through. It would be very interesting to study the difference between water that had frequently passed through some cyclic process, and water which had not: no chemist has yet detected the difference.

It would be multiplying words without wisdom to go through the elaborate bolstering of hypothesis by assumption and unreason required to deduce any semblance to fact from these beginnings. It may however, be worth while to notice something in the second part of this work on the nature of the ether. It is assumed that Fresnel has conclusively proved that an ether consisting of molecules which repel one another would transmit transverse vibrations like light; and, in order to turn the difficulty of the existence of longitudinal vibrations to useful account, it is assumed that these latter exist and are heat. It is hardly necessary to investigate a theory of electric and magnetic forces founded upon such an ether, and upon some curious ideas as to forces flowing from place to place.

And what is the use of spending time looking into such a work as this? It is by studying extraordinary and startling departures from reason, and not the ordinary and familiar ones, that we learn the causes of our aberrations and how to avoid them. It is the same unreasoning prejudice for "I can hardly believe it otherwise," the same neglect to study the meanings of symbols, whether words or letters, the same satisfaction with a theory that leads to some true conclusions, which bristle upon every page of this book, and which are some of the most important factors in the prejudice that ignores the necessity for verification, the muddle-headedness that is content with vague notions, the clinging to an incomplete hypothesis that stands in the way of a true theory, all and each of which are in all and each of us such bars to progress. If the study of Prof. Miller-Hauenfels' errors leads to even a state of preparedness to look out for similar errors in our own work, the study will have been fruitful. G. F. F. G.

OUR BOOK SHELF.

Traité Encyclopédique de Photographie. By Charles Fabre. Vol. I., Part I. (Paris: Gauthier-Villars, 1889.)

This is the first part of an encyclopædic work on the history and development of photographic methods. Its general object is to set forth, not only full particulars of the methods now in actual use, but also a complete story of the gradual improvements which have led up to them. There is little doubt that the rapid progress which has been made in photography has been largely due to the fact that the whole subject is so new, that every investigator who sets himself to work soon becomes familiar with what has gone before, and is thus in a position to consider what further advances are possible. It is certainly not too much to expect that such a work as is contemplated by M. Fabre will do a great deal towards simplifying the acquirement of this knowledge.

It is proposed to issue the work in twenty monthly parts, of which five parts will constitute a volume. The first volume will treat more particularly of the general history of photography and photographic apparatus, special attention being given to the subject of lenses. The second volume will deal with the production of negatives, and the third with positives of every description. The fourth volume will first treat of the methods of enlargement, and then of photographic chemistry and theories of the formation of photographic images. This comprehensive scheme, if well followed out, as no doubt it will be, if we may judge by the excellence of the first part, will obviously constitute a valuable addition to photographic literature.

In the first part the whole subject of lenses is considered, from the chemical composition of the various kinds of glass employed in their construction to the various combinations now used. Spherical aberration, distortion, astigmatism, and chromatic aberration, and their remedies, are all fully considered. A useful bibliography is also appended to each chapter.

Les Levers Photographiques, et la Photographie en Voyage. By Dr. Gustave Le Bon. Part I. (Paris: Gauthier-Villars et Fils, 1889.)

THIS work treats of methods of obtaining by means of photography elevations and plans of monuments, buildings, &c., the intention being to render unnecessary the laborious tasks and long calculations which up to the present time have been unavoidable.

The modifications a camera has to undergo before operations are begun consist of the addition, first, of an india-rubber support fitted between the camera and the tripod, and, secondly, of a graduated ground glass in the place of a plain one. The india-rubber support is to enable the camera always to assume a horizontal position in whatever position the tripod may be; the ground glass thus being parallel to the face of the building which is about to be photographed. There is also an arrangement by which the camera can be rotated. By means of the ground glass the dimensions of objects can be easily measured, and horizontal and vertical angles can be read off.

The first few chapters relate to methods of graduating this glass, and its employment in the measurement of angular distances, also the mode of determining the focal lengths of the lenses employed, and the measurement of the sizes of objects after they have been photographed. Chapter v. treats of the general principles of photographic perspective, followed by the applications of those principles to the solutions of various problems, such as, "To determine the height of an inaccessible tower by a single photograph;" "To obtain without any measurement on the object itself its various dimensions," &c. Lastly, Chapter vi. deals with photographic triangulation and methods of measuring large base lines.

The International Annual of Anthony's Photographic Bulletin. Edited by W. J. Harrison, F.G.S., and A. H. Elliot, Ph.D., F.C.S. (London: Illiffe and Son, 1889.)

THIS is the second issue of an interesting and useful work. The number of articles has been considerably increased, and there is also an increase in the number of tables at the end, which will be of service both to professional and to amateur photographers. Various methods of printing are displayed in the illustrations. Two pretty views are given, one of which is taken with Dallmeyer's long-focus rapid landscape lens, and the other with his wide-angle landscape lens, showing well the effect of these different focus lenses. No pains seem to have been spared to make this issue surpass the first one, and the editors are to be congratulated on the results of their labours.

Industrial Education. By Sir Philip Magnus. (London: Kegan Paul, Trench, and Co.)

THE articles and addresses brought together in this volume form a valuable contribution to the study of one of the most important and interesting questions of the present day. Sir Philip Magnus has not attempted to exhaust his subject, or to deal with it systematically. He merely presents it from various points of view, offering suggestions as to the urgent need for a proper technical training, and as to the methods which may be most fitly used for the attainment of the ends in view. Every page bears witness not only to the writer's general knowledge and ability, but to his practical familiarity with all the aspects of the problems he discusses. One of the best papers in the book is that in which he gives an account of the school system of Bavaria, whose educational arrangements are not so well understood in this country as those of Prussia. No one who reads this paper, and takes into account all that has been done for education in the other States of Germany, will find much difficulty in explaining the fact that in industry and trade the Germans have become our most formidable competitors. Another excellent paper is on mercantile training, and there is also a good paper on technical instruction in elementary schools.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

An Index to Science.

I AM glad to see that Mr. Taylor Kay has again brought forward the question of a subject index to scientific periodicals. I say again, because the proposal to make such an index was suggested by me in a short letter in NATURE, vol. xviii. p. 251, and more fully at the first meeting of the Library Association at Oxford, in October 1878 (Transactions of Library Association, 1878, p. 85). Dr. Garnett also read a paper before the same Association on this subject in 1879, which was fully printed in NATURE, vol. xx. p. 554. In my original letter I suggested making the index from the papers themselves, and not from the Royal Society's Catalogue; my reason for this was the difficulty that must be experienced in indexing many papers, should the indexer have nothing but the title in front of him. Reference to the paper is absolutely necessary in many instances, especially when the title does not fully set forth its contents. Dr. Garnett, however, pointed out that much labour might be saved if the Royal Society would give two copies of its Catalogue of Scientific Papers, which might be cut up to form the copy of the subject-index. There can be no doubt that Dr. Garnett is right, because, by his plan, however many papers it might be necessary to refer to, the amount of labour as regards manuscript would be very materially diminished. The greatest difficulty of all is the money. Mr. Taylor Kay takes comfort in a Treasury Minute of November 1864, and hopes, from that, that help might be obtained from the Government. I am afraid, however, it will damp his ardour to be told that the Government have refused to bear the cost of printing the Catalogue for the decade 1874–83, although the matter is all ready for the press. It seems to me that, as suggested in my original paper, the co-operation of the learned Societies is the only way in which the necessary funds can be obtained.

I gather from Mr. Taylor Kay's paper that he rather suggests a "classified" list of papers. If that be so, I would like to protest against such an undertaking, feeling sure that it will, like all its predecessors, be doomed to failure. What is wanted is an index pure and simple, in which information can be turned up without consideration as to what "class" or "classes" the indexer has thought fit to enter the subject under. Anyone who has used the admirable catalogue of Dr. Billings will at once admit its superiority to any "classified" arrangement, whether it be that of Çomte or of any other philosopher.

The question of this index has been hanging fire too long, and I should be delighted if Mr. Taylor Kay's paper were the means of some active steps being taken to start the work. Poole's Index is a standing answer to those who say it cannot be done. All that we want are willing hands and a long purse: if the scientific Societies or an enterprising publisher will find the latter, I cannot believe the former will be wanting.

JAMES BLAKE BAILEY.

Royal College of Surgeons, July 5.

A Cordial Recognition.

I HAVE just witnessed a curious case of bird instinct which seems worth recording. A gardener living at Zukaleriá, three miles from here, caught in his garden a young but fully fledged sparrow, which he brought to the house of a friend with whom we are staying in Canea, leaving home early in the morning. He presented the bird to one of the children in the house, and it was put in a cage and hung at the window, where it seemed likely to be contented, losing its fright after a few hours. Late in the afternoon an old bird was noticed fluttering about the cage apparently trying to get at the little one, and the young bird on its appearance became frantic to get out to the old one. It was evidently the mother of the young one, as the recognition was too cordial to have been owing to the interest of a strange bird; and when my daughter opened the cage, as she did after a little, they both flew off rapidly in the direction of Zukaleriá. It is impossible that the old bird should have followed the gardener, as we should have seen it earlier in the day.

Canea, Crete, June 27. W. J. STILLMAN.

Seismology in Italy.

I HAVE only lately seen Dr. Johnston-Lavis's article in NATURE (vol. xxxix. p. 329), on the present state of seismology in Italy. I have read it with much interest, and with the greatest satisfaction, because it deals with the most recent works due to the new and serious impulse given to the study by the Government during the last five years. I thank the author for having noticed one of my writings, "Sulla sistemazione delle osservazioni geodinamiche regolari." There is little—hardly anything—absolutely new in this work, because in writing it I desired only to sum up the deliberations of the Royal Geodynamical Commission, to which I had the honour to belong. I also brought together in it all that was really serious and positive in other works, with the intention of dispelling the confusion which unhappily prevailed when this scientific branch was in the power of dilettantism, which had the prerogative of the long-winded style, the charlatanism, and the seismic magic, of which the author of the article justly complains. In a word, I wished to set forth a proper programme, with the ideas which the Commission conceived, and which continue to form the principle of the deliberations of the directing Council for Meteorology and Geodynamics, in which the Commission has been merged. On this serious and well-determined principle the service is continued in the island of Ischia as elsewhere.

In accordance with the just ideas of your correspondent, I must nevertheless make one remark on the subjects which relate more especially to the studies carried on in the island of Ischia; namely, that there is really something of novelty in some of the other writings of mine included in the volume that contains the work commented on.

One of these writings consisted of the theoretical relation I presented in response to the demand of the Royal Geodynamical Commission in the sittings of June 1886. The approval of this work by the Commission contributed to the adoption, for the study of the form of seismic movements, of the mechanical principle of three components adapted to a steady point. This principle was studied, and put into execution, by the mechanicians Brassart of the Central Office of Meteorology and Geodynamics; and while it has tended to simplify completely the methods used in the observation of earthquakes, and to bring to an end the innumerable imperfections of former times, it is not even yet well understood by men of the old school.

Three of my works relate to the variations observed in the temperature of the thermal springs at Porto d'Ischia. A rigorously mathematical analysis has revealed a hydrostatical law in relation to changes in the level of the sea. Later studies which I undertook upon the diagrams of a registering thermometer, and which the Director, Prof. Tacchini, presented to the Accademia dei Lincei on October 7, 1888, proved the influence exerted by the horary state of the tide, while previously some isolated observations had made way for hypotheses of another nature.

Another of my works expounds a new principle for rendering astatic—or nearly so—in a horizontal direction, the steady point in seismographs, and gives a mathematical demonstration of it. Upon this principle, which I conceived in 1886, is apparently based the construction of an instrument by Prof. Ames (see the *American Journal of Science*, February 1888, p. 106); but the fact that he has made the suspension with four threads, instead of three, suffices to prove that he has not formed a precise idea of my original principle, and that he has much less considered it necessary to procure for himself the mathematical proof of it. Some months before the publication of Mr. Ames's work I took care to bring out prominently, on p. 266 of the volume referred to, the error to which one would expose oneself in this way.

Of the ten writings by me in the volume, these are the works to which I attach some importance; and I take the liberty of directing to them the attention of your readers, in the hope of making known the beginnings of the success which is to be achieved through the action of the Italian Government. For the rest, the history of this enterprise is set forth in the abstract of the sittings which forms the introduction of the volume.

GIULIO GRABLOVITZ,
Director of the Osservatorio Geodinamico

Saxicava Borings and Valves in a Boulder Clay Erratic.

WHEN examining a few weeks ago the boulders in the workings of the New Ferry Brick and Tile Company, Cheshire, with Mr. Harnett Harrisson, we discovered a boulder having superficially a scoriaceous appearance, which on examination proved to be of limestone, and perforated with Saxicava and other borings. After careful washing several of the burrows were found to be occupied by the shells of the animal that had made them, both valves complete. The washings that came out of the burrows after careful reduction by pouring off the clay water I found to consist of well-rounded grains of quartz intermixed with a few microscopic drift pebbles and small shell fragments. Some of them were very much rounded and waterworn. Several broken spines of Echinus also occurred.

The stone was taken from a heap picked out of the boulder clay previons to passing it through the machine. There is no doubt as to its origin, as one side is strongly planed and striated in the direction of the longer axis. The extreme measurements are $6\frac{1}{2}'' \times 4\frac{1}{2}'' \times 2\frac{3}{4}''$; weight, 3 lbs. 10 oz. The Saxicava burrows are placed so as to give the idea that the stone had lain on the glaciated side when most of them were made, as they get nearly horizontal towards the glaciated bottom. The termination of one burrow, however, occurs on the planed face. There are also other worm-like burrows which occur on the glaciated face, and one of them has been cut longitudinally for a length of an inch by the plane of glaciation.

It is now about eighteen years since I commenced a study of the glacial deposits of the north-west of England, but have never found a similar example with the burrows occupied, although the low-level boulder clay in which it occurs is almost universally more or less full of shell fragments. The bearing of the discovery on the origin of the low-level boulder clay is obvious.

The history of the stone appears to have been this. It had its origin in the Carboniferous limestone of the north; it has then been rounded into a boulder, has lain upon a shore, and become the seat of operations of molluscan and other burrowers. Afterwards it has been frozen into coast-ice, glaciated by attrition on a pebbly or rocky shore through tidal movement, has been again released from the ice grip, spent another time on the shore resting on its glaciated face, during which period it became perforated with the Saxicava burrows now occupied by the remains of the animal. While still on the shore, fragments of shells of other Mollusca got washed into the occupied and unoccupied perforations, and finally it was again frozen into coast-ice, floated off, and dropped into the bed of the low-level boulder clay sea, where it remained undisturbed until the pick of the brickmaker disinterred it. The boulder clay in which it occurs is plastic, and contains comparatively few stones, and there are no sand seams to be seen in the present face, though I believe they occur at a greater depth below the bottom of the pit.

The special interest of this example lies in the proof it affords of the marine origin of the low-level boulder clay of Cheshire and Lancashire. Some geologists contend that this clay is the bottom of the Irish Sea ploughed up by land ice, but the necessities of a theory that requires such an operation to have taken place in the past when there is an obvious and simple explanation at hand does not commend it to my mind. It is not even proved that such a ploughing up is possible; no examples are adduced where such a phenomenon is going on; it does not account for the structure of the beds of low-level boulder clay; and speaking from eighteen years of close investigation, there is no necessity in the nature of the case for resorting to such an extreme hypothesis.

The age of land ice preceded that of the low-level marine boulder clay, and numerous examples of striated rock surfaces and other phenomena occurring below the low-level marine boulder clay can be quoted in support thereof.

T. MELLARD READE.

Park Corner, Blundellsands, June 5.

Test of Divisibility by any Prime.

IN NATURE of May 30 (p. 115), Mr. Tucker has given the formula:—

$$N = 21M + 10^{n-1}(7Q) = 7Q'.$$

In an exactly similar way we may show that—

$N = 11M + 10^{n-1}(11Q) = 11Q'$, giving a multiplier 1,
$N = 91M + 10^{n-1}(13Q) = 13Q'$, ,, ,, 9,
$N = 51M + 10^{n-1}(17Q) = 17Q'$, ,, ,, 5,

&c., &c., for any number ending in digits 1, 3, 7, or 9.[1]

The general principle may be simply shown as follows:—

We have $17 \times 3 = 5 \cdot 1$, say.

This means (1) that, if *any number* ends in unity, and is also of Form 17M, then all the figures to the left of unity will form a number of Form 17M + 5.

It also means (2) that, if we *multiply the units digit* by 5 (casting out the prime 17, if need be), we get the figures to the left; *e.g.* 2346 ends in 6, and is of Form 17M. Therefore, 234 is of Form 17M + 13 (since $17 \times 8 = 13 \cdot 6$); also, $6 \times 5 = 30$, and $30 - 17 = 13$. The process can be repeated to any extent. Thus, since $234 = 17M + 13$, subtract 13 from 234, giving $221 = 17M_1$. Since 221 ends in unity, therefore 22 is of Form 17M + 5, and, subtracting 5 from 22, we have $17 = 17M_2$. Hence the rule.

From similar considerations I have deduced the following formula, giving the periodicity of $\frac{1}{N}$ where N is a prime:—

If $[\{(uN + 1)/10\}^p + N - 1]/N \equiv I$ (an integer), then p will be the periodicity of 1/N.

Here u means the unit's digit of N, or else the integral quotient of 9 divided by the unit's digit.

Thus for all numbers ending in 9 the formula becomes $[\{(N + 1)/10\}^p + N - 1]/N$, *e.g.* $(2^p + 18)/19$ gives the periodicity of 1/19, &c.

The corresponding formulæ for numbers ending in 7, 3, 1, are, respectively,

$$[\{(7N + 1)/10\}^p + N - 1]/N;\ [\{(3N + 1)/10\}^p + N - 1]/N;$$
$$[\{(9N + 1)/10\}^p + N - 1]/N.$$

Another useful deduction from the same principle is:—

If p be the periodicity of the recurring fraction 1/N (where N ends in 1, 3, 7, or 9), then the test will give the true remainder of any $p + 2$ figures; *e.g.* What is the remainder of $98765 \div 37$?

Since $37 \times 3 = 11 \cdot 1$, our multiplier is 11.

Therefore $9876 - 11 \times 5 = 9821$, and $982 - 11 \times 1 = 971$.

Also $97 - 11 \times 1 = 86 = 37M + 12$. Thus 12 is the remainder.

I find that by this new process the remainder may be obtained in about one-half of the time taken by the ordinary method of division.

ROBT. W. D. CHRISTIE.

Wavertree Park College, Liverpool.

QUARTZ FIBRES.[2]

IN almost all investigations which the physicist carries out in the laboratory, he has to deal with and to measure with accuracy those subtle and to our senses inappreciable forces to which the so-called laws of Nature give rise. Whether he is observing by an electrometer the behaviour of electricity at rest, or by a galvanometer the action of electricity in motion; whether in the tube of Crookes he is investigating the power of radiant matter, or with the famous experiment of Cavendish he is finding the mass of the earth—in these and in a host of other cases he is bound to measure with certainty and accuracy forces so small that in no ordinary way could their existence be detected; while disturbing causes which might seem to be of no particular consequence must be eliminated if his experiments are to have any value. It is not too much to say that the very existence of the physicist depends upon the power which he possesses of producing at will and by artificial means forces against which he balances those that he wishes to measure.

I had better perhaps at once indicate in a general way the magnitude of the forces with which we have to deal.

The weight of a single grain is not to our senses appreciable, while the weight of a ton is sufficient to crush the life out of anyone in a moment. A ton is about 15,000,000 grains. It is quite possible to measure with unfailing accuracy forces which bear the same relation to the weight of a grain that a grain bears to a ton.

To show how the torsion of wires or threads is made use of in measuring forces, I have arranged what I can hardly dignify by the name of an experiment. It is simply a straw hung horizontally by a piece of wire. Resting on the straw is a fragment of sheet-iron weighing ten grains. A magnet so weak that it cannot lift the iron yet is able to pull the straw round through an angle so great that the existence of the feeble attraction is evident to every one in the room.

Now it is clear that if, instead of a straw moving over the table simply, we had here an arm in a glass case and a mirror to read the motion of the arm, it would be easy to observe a movement a hundred or a thousand times less than that just produced, and therefore to measure a force a hundred or a thousand times less than that exerted by this feeble magnet.

Again, if instead of wire as thick as an ordinary pin I had used the finest wire that can be obtained, it would have opposed the movement of the straw with a far less force. It is possible to obtain wire ten times finer than this stubborn material, but wire ten times finer is much more than ten times more easily twisted. It is ten thousand times more easily twisted. This is because the torsion varies as the fourth power of the diameter, so we say $10 \times 10 = 100$; $100 \times 100 = 10,000$. Therefore with the finest wire, forces 10,000 times feebler still could be observed.

It is therefore evident how great is the advantage of reducing the size of a torsion wire. Even if it is only halved the torsion is reduced sixteen-fold. To give a better idea of the actual sizes of such wires and fibres as are in use I shall show upon the screen a series of photographs taken by Mr. Chapman, on each of which a scale of thousandths of an inch has been printed.

The first photograph (Fig. 1) is an ordinary hair—a sufficiently familiar object, and one that is generally spoken of as if it were rather fine. Much finer than this is the specimen of copper wire now on the screen (Fig. 2), which I recently obtained from Messrs. Nalder Brothers. It is only a little over one-thousandth of an inch in diameter. Ordinary spun glass, a most beautiful material, is about one-thousandth of an inch in diameter, and this would appear to be an ideal torsion thread (Fig. 3). Owing to its fineness its torsion would be extremely small, and the more so because glass is more easily deformed than metals. Owing to its very great strength, it can carry heavier loads than would be expected of it. I imagine many physicists must have turned to this material in their endeavour to find a really delicate torsion thread. I have so turned only to be disappointed. It has every good quality but one, and that is its imperfect elasticity. For instance, a mirror hung by a piece of spun glass is casting an image of a spot of light on the scale. If I turn the mirror, by means of a fork, twice to the right, and then turn it back again, the light does not come back to its old point of rest, but oscillates about a point on one side, which, however, is slowly changing, so that it is impossible to say what the point of rest really is. Further, if the glass is twisted one way first, and then the other way, the point of rest

[1] These numbers only can give, when multiplied, all the digits in the units place.

[2] Lecture delivered at the Royal Institution, on Friday, June 14, by Mr. C. V. Boys, F.R.S.

moves in a manner which shows that it is not influenced by the last deflection alone: the glass remembers what was done to it previously. For this reason spun glass is quite unsuitable as a torsion thread; it is impossible to

Scale of 1000ths of an inch for Figs. 1 to 7. The scale of Figs. 8 and 9 is much finer.

FIG. 1.

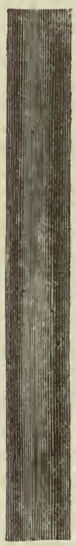

FIG. 2.

say what the twist is at any time, and therefore what is the force developed.

So great has the difficulty been in finding a fine torsion thread that the attempt has been given up, and in all the most exact instruments silk has been used. The natural

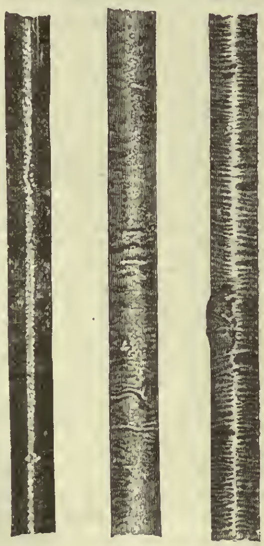

FIG. 3.

cocoon fibres, as shown on the screen (Fig. 4), consist of two irregular lines gummed together, each about one two-thousandth of an inch in diameter. These fibres must be separated from one another and washed. Then each component will, according to the experiment of Gray, carry nearly 60 grains before breaking, and can be safely loaded with 15 grains. Silk is therefore very strong, carrying at the rate of from 10 to 20 tons to the square inch. It is further valuable in that its torsion is far less than that of a fibre of the same size of metal or even of glass, if such could be produced. The torsion of silk, though exceedingly small, is quite sufficient to upset the working of any delicate instrument, because it is never constant. At one time the fibre twists one way, and another time in another, and the evil effect can only be mitigated by using large apparatus in which strong forces are developed. Any attempt that may be made to increase the delicacy of apparatus by reducing their dimensions is at once prevented by the relatively great importance of the vagaries of the silk suspension.

The result, then, is this. The smallness, the length of period, and therefore delicacy, of the instruments at the physicist's disposal have until lately been simply limited by the behaviour of silk. A more perfect suspension means still more perfect instruments, and therefore advance in knowledge.

It was in this way that some improvements that I was making in an instrument for measuring radiant heat came

FIG. 4.

to a deadlock about two years ago. I would not use silk, and I could not find anything else that would do. Spun glass, even, was far too coarse for my purpose; it was a thousand times too stiff.

There is a material invented by Wollaston long ago, which, however, I did not try because it is so easily broken. It is platinum wire which has been drawn in silver, and finally separated by the action of nitric acid. A specimen about the size of a single line of silk is now on the screen, showing the silver coating at one end (Fig. 5).

As nothing that I knew of could be obtained that would be of use to me, I was driven to the necessity of trying by experiment to find some new material. The result of these experiments was the development of a process of almost ridiculous simplicity which it may be of interest for me to show.

The apparatus consists of a small cross-bow, and an arrow made of straw with a needle point. To the tail of the arrow is attached a fine rod of quartz which has been melted and drawn out in the oxyhydrogen jet. I have a piece of the same material in my hand, and now after melting their ends and joining them together, an operation which produces a beautiful and dazzling light, all I have to do is to liberate the string of the bow by pulling the trigger with one foot, and then if all is well a fibre will have been drawn by the arrow, the existence of which can be made evident by fastening to it a piece of stamp-paper.

In this way threads can be produced of great length, of almost any degree of fineness, of extraordinary uniformity, and of enormous strength. I do not believe, if any experimentalist had been promised by a good fairy that he might have anything he desired, that he would have ventured to ask for any one thing with so many valuable properties as these fibres possess. I hope in the course of this evening to show that I am not exaggerating their merits.

In the first place, let me say something about the degree of fineness to which they can be drawn. There is now projected upon the screen a quartz fibre one five-thousandth of an inch in diameter (Fig. 6). This is one which I had in constant use in an instrument loaded with about 30 grains. It has a section only one-sixth of that of a single line of

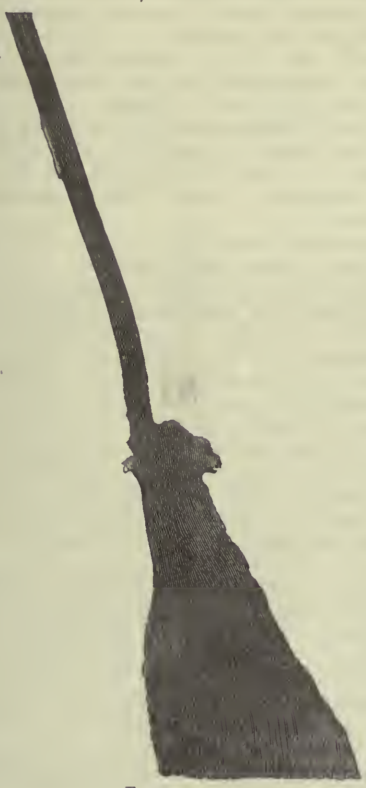

Fig. 5.

silk, and it is just as strong. Not being organic, it is in no way affected by changes of moisture and temperature, and so it is free from the vagaries of silk which give so much trouble. The piece used in the instrument was about 16 inches long. Had it been necessary to employ spun glass, which hitherto was the finest torsion material, then, instead of 16 inches, I should have required a piece 1000 feet long, and an instrument as high as the Eiffel tower to put it in.

There is no difficulty in obtaining pieces as fine as this yards long if required, or in spinning it very much finer. There is upon the screen a single line made by the small garden spider, and the size of this is perfectly evident (Fig. 7). You now see a quartz fibre far finer than this, or, rather, you see a diffraction phenomenon, for no true image is formed at all; but even this is a conspicuous object in comparison with the tapering ends, which it is absolutely impossible to trace in a microscope. The next two photographs, taken by Mr. Nelson, whose skill and resources are so famous, represent the extreme end of a tail of quartz, and though the scale is a great deal larger than that used in the other photographs, the end will be visible only to a few. Mr. Nelson has photographed here what it is absolutely impossible to see. What the size of these ends may be, I have no means of telling. Dr. Royston Piggott has estimated some of them at less than one-millionth of an inch, but whatever they are they supply for the first time objects of extreme smallness the form of which is certainly known, and therefore I cannot help looking upon them as more satisfactory tests for the microscope than diatoms and other things of the real shape of which we know nothing whatever.

Since figures as large as a million cannot be realized properly, it may be worth while to give an illustration of what is meant by a fibre one-millionth of an inch in diameter.

A piece of quartz an inch long and an inch in diameter would, if drawn out to this degree of fineness, be sufficient to go all the way round the world 658 times; or a grain of sand just visible—that is, one-hundredth of an inch long and one-hundredth of an inch in diameter—would make 1000 miles of such thread. Further, the pressure inside

Fig. 6. Fig. 7.

such a thread due to a surface tension equal to that of water would be 60 atmospheres.

Going back to such threads as can be used in instruments, I have made use of fibres one ten-thousandth of an inch in diameter, and in these the torsion is 10,000 times less than that of spun glass.

As these fibres are made finer their strength increases in proportion to their size, and surpasses that of ordinary bar steel, reaching, to use the language of engineers, as high a figure as 80 tons to the inch. Fibres of ordinary size have a strength of 50 tons to the inch.

While it is evident that these fibres give us the means of producing an exceedingly small torsion, and one that is not affected by weather, it is not yet evident that they may not show the same fatigue that makes spun glass useless. I have therefore a duplicate apparatus with a quartz fibre, and you will see that the spot of light comes back to its true place on the screen after the mirror has been twisted round twice.

I shall now for a moment draw your attention to that peculiar property of melted quartz that makes threads such as I have been describing a possibility. A liquid cylinder, as Plateau has so beautifully shown, is an unstable form. It can no more exist than can a pencil stand on its point. It immediately breaks up into a series of spheres. This is well illustrated in that very ancient experiment of shooting threads of resin electrically. When the resin is hot, the liquid cylinders which are projected in all directions break up into spheres, as you see now upon the screen. As the resin cools, they begin to develop tails; and when it is cool enough, *i.e.* sufficiently viscous, the tails thicken and the beads become less, and at last uniform threads are the result. The series of photographs show this well.

There is a far more perfect illustration which we have only to go into the garden to find. There we may see in abundance what is now upon the screen—the webs of those beautiful geometrical spiders. The radial threads are smooth like the one you saw a few minutes ago, but the threads that go round and round are beaded. The spider draws these webs slowly, and at the same time pours upon them a liquid, and still further to obtain the effect of launching a liquid cylinder in space he, or rather she, pulls it out like the string of a bow, and lets it go with a jerk. The liquid cylinder cannot exist, and the result is what you now see upon the screen (Fig. 8). A more perfect

Fig. 8.

Fig. 9.

illustration of the regular breaking up of a liquid cylinder it would be impossible to find. The beads are, as Flateau showed they ought to be, alternately large and small, and their regularity is marvellous. Sometimes two still smaller beads are developed, as may be seen in the second photograph, thus completely agreeing with the results of Plateau's investigations.

I have heard it maintained that the spider goes round her web and places these beads there afterwards. But since a web with about 360,000 beads is completed in an hour—that is, at the rate of about 100 a second—this does not seem likely. That what I have said is true, is made more probable by the photograph of a beaded web that I have made myself by simply stroking a quartz fibre with a straw wetted with castor oil (Fig. 9). It is rather larger than a spider line; but I have made beaded threads, using a fine fibre, quite indistinguishable from a real spider web, and they have the further similarity that they are just as good for catching flies.

Now, going back to the melted quartz, it is evident that if it ever became perfectly liquid it could not exist as a fibre for an instant. It is the extreme viscosity of quartz, at the heat even of an electric arc, that makes these fibres possible. The only difference between quartz in the oxyhydrogen jet and quartz in the arc is that in the first you make threads and in the second are blown bubbles. I have in my hand some microscopic bubbles of quartz showing all the perfection of form and colour that we are familiar with in the soap bubble.

An invaluable property of quartz is its power of insulating perfectly, even in an atmosphere saturated with water. The gold leaves now diverging were charged some time before the lecture, and hardly show any change, yet the insulator is a rod of quartz only three-quarters of an inch long, and the air is kept moist by a dish of water. The quartz may even be dipped in the water and replaced with the water upon it without any difference in the insulation being observed.

Not only can fibres be made of extreme fineness, but they are wonderfully uniform in diameter. So uniform are they that they perfectly stand an optical test so severe that irregularities invisible in any microscope would immediately be made apparent. Everyone must have noticed when the sun is shining upon a border of flowers and shrubs how the lines which spiders use as railways to travel from place to place glisten with brilliant colours. These colours are only produced when the fibres are sufficiently fine. If you take one of these webs and examine it in the sunlight, you will find that the colours are variegated, and the effect consequently is one of great beauty.

A quartz fibre of about the same size shows colours in the same way, but the tint is perfectly uniform on the fibre. If the colour of the fibre is examined with a prism, the spectrum is found to consist of alternate bright and dark bands. Upon the screen are photographs taken by Mr. Briscoe, a student in the laboratory at South Kensington, of the spectra of some of these fibres at different angles of incidence. It will be seen that coarse fibres have more bands than fine, and that the number increases with the angle of incidence of the light. There are peculiarities in the march of the bands as the angle increases which I cannot describe now. I may only say that they appear to move not uniformly but in waves, presenting very much the appearance of a caterpillar walking.

So uniform are the quartz fibres that the spectrum from end to end consists of parallel bands. Occasionally a fibre is found which presents a slight irregularity here and there. A spider line is so irregular that these bands are hardly observable; but as the photograph on the screen shows, it is possible to trace them running up and down the spectrum when you know what to look for.

To show that these longitudinal bands are due to the irregularities, I have drawn a taper piece of quartz by hand, in which the two edges make with one another an almost imperceptible angle, and the spectrum of this shows the gradual change of diameter by the very steep angle at which the bands run up the spectrum.

Into the theory of the development of these bands I am unable to enter: that is a subject on which your Professor of Natural Philosophy is best able to speak. Perhaps I may venture to express the hope, as the experimental investigation of this subject is now rendered possible, that he may be induced to carry out a research for which he is so eminently fitted.

Though this is a subject which is altogether beyond me, I have been able to use the results in a practical way. When it is required to place into an instrument a fibre of any particular size, all that has to be done is to hold the frame of fibres towards a bright and distant light, and look at them through a low-angled prism. The banded spectra are then visible, and it is the work of a moment to pick out one with the number of bands that has been found to be given by a fibre of the desired size. A coarse fibre may have a dozen or more, while such fibres as I find most useful have only two dark bands. Much finer ones exist, showing the colours of the first order with one dark band; and fibres so fine as to correspond to the white or even the gray of Newton's scale are easily produced.

Passing now from the most scientific test of the uniformity of these fibres, I shall next refer to one more homely. It is simply this: the common garden spider, except when very young, cannot climb up one of the same size as the web on which she displays such activity. She is perfectly helpless, and slips down with a run. After vainly trying to make any headway, she finally puts her hands (or feet) into her mouth, and then tries again, with no better success. I may mention that a male of the same species is able to run up one of these with the greatest ease, a feat which may perhaps save the lives of a few of these unprotected creatures when quartz fibres are more common.

It is possible to make any quantity of very fine quartz fibre without a bow and arrow at all, by simply drawing out a rod of quartz over and over again in a strong oxyhydrogen jet. Then, if a stand of any sort has been placed a few feet in front of the jet, it will be found covered with a maze of thread, of which the photograph on the screen represents a sample. This is hardly distinguishable from the web spun by this magnificent spider in corners of greenhouses and such places. By regulating the jet and the manipulation, anything from one of these stranded cables to a single ultra-microscope line may be developed.

And now that I have explained that these fibres have such valuable properties, it will no doubt be expected that I should perform some feat with their aid which, up to the present time, has been considered impossible, and this I intend to do.

Of all experiments the one which has most excited my admiration is the famous experiment of Cavendish, of which I have a full-size model before you. The object of this experiment is to weigh the earth by comparing directly the force with which it attracts things with that due to large masses of lead. As is shown by the model, any attraction which these large balls exert on the small ones will tend to deflect this 6-foot beam in one direction, and then if the balls are reversed in position the deflection will be in the other direction. Now, when it is considered how enormously greater the earth is than these balls, it will be evident that the attraction due to them must be in comparison excessively small. To make this evident the enormous apparatus you see had to be constructed, and then, using a fine torsion wire, a perfectly certain but small effect was produced. The experiment, however, could only be successfully carried out in cellars and underground places, because changes of temperature produced effects greater than those due to gravity.[1]

Now I have in a hole in the wall an instrument no bigger than a galvanometer, of which a model is on the table. The balls of the Cavendish apparatus, weighing several hundredweight each, are replaced by balls weighing $1\frac{3}{4}$ pound only. The smaller balls of $1\frac{3}{4}$ pound are replaced by little weights of 15 grains each. The 6-foot beam is replaced by one that will swing round freely in a tube three-quarters of an inch in diameter. The beam is, of course, suspended by a quartz fibre. With this microscopic apparatus, not only is the very feeble attraction observable, but I can actually obtain an effect eighteen times as great as that given by the apparatus of Cavendish, and, what is more important, the accuracy of observation is enormously increased.

The light from a lamp passes through a telescope lens, and falls on the mirror of the instrument. It is reflected back to the table, and thence by a fixed mirror to the scale on the wall, where it comes to a focus. If the mirror on the table were plane, the whole movement of the light would be only about 8 inches, but the mirror is convex, and this magnifies the motion nearly eight times. At the present moment the attracting weights are in one extreme position, and the line of light is quiet. I will now move them to the other position, and you will see the result—the light slowly begins to move, and slowly increases in movement. In forty seconds it will have acquired its highest velocity, and in forty more it will have stopped at 5 feet $8\frac{1}{2}$ inches from the starting-point, after which it will slowly move back again, oscillating about its new position of rest.

It is not possible at this hour to enter into any calculations; I will only say that the motion you have seen is the effect of a force of less than one ten-millionth of the weight of a grain, and that with this apparatus I can detect a force two thousand times smaller still. There would be no difficulty even in showing the attraction between two No. 5 shot.

And now, in conclusion, I would only say that if there is anything that is good in the experiments to which I have this evening directed your attention, experiments conducted largely with sticks, and string, and straw and sealing-wax, I may perhaps be pardoned if I express my conviction that in these days we are too apt to depart from the simple ways of our fathers, and, instead of following them, to fall down and worship the brazen image which the instrument-maker hath set up.

[1] Dr. Lodge has been able, by an elaborate arrangement of screens, to make this attraction just evident to an audience.—C. V. B.

A NEW SCHOOL OF ORIENTAL STUDIES.

THE Imperial Institute has taken a most important step towards the organization of higher commercial education in London, by effecting an arrangement between University and King's Colleges for the establishment of a new School for Oriental Studies. The close connection between the mercantile interests of this country and of India, Turkey, China, South Africa, and other lands, renders it very desirable that travellers and traders should have full facilities for acquiring, not only a knowledge of the languages of those countries, but also some acquaintance with the habits and customs of the inhabitants. In France and Germany, we find that the wants of this class of students have been fully recognized by the State. The French School of Oriental Languages has been in existence over 100 years, and has recently been reconstructed at an annual expense, for maintenance alone, of £6000; and in 1887 a new school was opened in Berlin, as a special department of the University, which receives a subvention from the Government of over £3000 a year. In England, the economy to the nation of adequately supporting institutions for higher education is not yet understood, and consequently private effort has to step in and relieve the State of a duty which in other countries is discharged in no niggard spirit. The new School of Oriental Studies promises to supply a distinct want. Instruction will be given in the principal Indian languages, in Persian, Burmese, Malay, Arabic, Turkish, Russian, Modern Greek, Chinese, Japanese, and Swaheli. The students will be taught not only to read and write, but also, as far as is possible, to speak those languages; and to this end the Committee contemplate the appointment of native readers and teachers of conversation. It has already been arranged that some of the Professors will preface their courses of linguistic teaching by lectures on the history, the physical and commercial geography, and the economic condition of the countries in which the various languages are spoken. It is hoped that by such means our mercantile and official classes may have the opportunity of acquainting themselves with the life and thought of the different Eastern peoples with whom they may be brought into communication.

The Imperial Institute is to be congratulated on having succeeded in bringing into harmonious working the two London Colleges, to each of which has for many years been attached a staff of eminent Professors of Oriental languages. The Indian School of University College, and the Oriental Section of King's College, have both done useful work; but, mainly from want of proper organization, the classes of many of the Professors have been but poorly attended, and several important modern languages a knowledge of which is now needed have not been included in the prospectus of either school. The Institute has effected an arrangement with the Colleges whereby the Indian and some allied tongues will continue to be taught in Gower Street, whilst the other languages will be taught at King's College, Strand. This is perhaps the first instance of such an arrangement between the two Colleges having been brought about, and suggests the practical advantage of an extension of the system to other branches of learning. It is only by a proper organization of the higher instruction that London can secure the full advantages of University education, and it may be hoped that as soon as a teaching University can be established in London, the two Colleges and the Medical and Science Schools will be found to co-operate with one another, so as to supplement, without unduly interfering with, each other's field of work.

We should add that the new School of Oriental Studies, which will be opened in October next, is under the general management of a special Committee, which comprises among its members Sir Francis Bell, Sir Charles Wilson, Sir Thomas Wade, Sir Frederic Goldsmid, and representatives of the governing bodies and teaching staffs of the two Colleges.

NOTES.

THIS year the French Association for the Advancement of Science will hold its annual meeting in Paris. The session will last from August 8 to 14. A great number of members are expected to attend the meeting, and it is hoped that many foreign men of science may also be present.

THE International Congress which met in Paris in 1887 to make arrangements for the preparation of a photographic chart of the heavens expressed a wish that a similar Congress might meet for the discussion of questions relating to celestial photography in general. M. Janssen and Mr. Common were asked to take such steps as might be necessary for the attainment of this object; and afterwards, by a Ministerial decision at Paris, an organizing Committee, with M. Janssen as President, was appointed. The arrangements have now been completed, and the Congress will be held in Paris from August 22 to September 3. The aim of the Congress will be to determine the methods which are most suitable for each branch of celestial photography, and the means by which the results obtained by these methods can be most effectually published and preserved.

THE Botanical Society of France announces the following programme of the forthcoming Botanical Congress to be held in Paris:—Tuesday, August 20: opening sitting of the Congress at 2 p.m., at the hotel of the Horticultural Society, 84 Rue de Grenelle; reception of foreign members at 8.30 p.m. Wednesday, August 21: sitting at 9 a.m., devoted to the consideration of the first question, on the utility of an agreement between the different Botanical Societies and Museums, for the purpose of drawing up charts of the distribution of species and genera of plants on the globe; and other communications, if time allows. Thursday, August 22: excursion in the neighbourhood of Paris. Friday, August 23: sitting at 9 a.m., devoted to the consideration of the second question, on the characters furnished by anatomy for classification; and other communications, if time allows. In the afternoon a visit to the botanical collections and laboratories of the Museum of Natural History, and of the other large scientific establishments in Paris. Saturday, August 24: sitting at 9 a.m., miscellaneous contributions. In the afternoon a visit to the Exhibition. Sunday, August 25: banquet to the foreign botanists. During the following week several botanical excursions will also be arranged. Special arrangements with regard to railway fares will be made in favour of botanists announcing their intention to be present to M. P. Maury, the Secretary to the Committee of Organization, 84 Rue de Grenelle, before July 25.

THE following are subjects proposed for discussion at the International Zoological Congress, to be held in Paris (August 5–10):—Adoption of rules on the nomenclature of organisms, and of an international scientific language; determination of regions the fauna of which calls for investigation; methods of investigation and procedure in preparation and preservation of animals; the use of embryology in classification; relations between living and fossil fauna. The Secretary's address is 32 Rue de Luxembourg.

AT the International Congress on Hygiene and Demography, also to be held during the Paris Exhibition, there will be discussed:—The administrative and medical regulations framed in different countries in the interests of health and of infantile life; removal and utilization of solid detritus in cities and the country; regulation and distribution of temperature in the dwelling; action of the soil on germs of disease; protection of watercourses and of ground water from pollution by factory refuse; sanitation of ports; accidents through food-stuffs of animal origin containing poisonous alkaloids; statistics of the causes of death in cities.

SOME valuable reports were distributed among the members of the International Agricultural Congress, which finished its labours at Paris the other day. One of them relates to agricultural education. This report is signed by a dozen authors, among whom are MM. Tisserand, Prilleux, and Jamieson, the latter an Englishman.

THE sixty-second meeting of German Naturalists and Physicians will be held at Heidelberg from September 17 to 23. One whole day will be devoted to excursions in the neighbourhood, and on the evening of September 23 the Castle of Heidelberg will be brilliantly illuminated.

AT a meeting of the Council of Dundee University College, held on the 3rd instant, Mr. J. Martin White announced that he had been authorized by Mr. John Bett, merchant, Rohallion, to offer a third of the amount required to found and establish a Chair of Physiology in connection with the Medical School of the College, provided the remaining two-thirds of the amount required be raised. It was mentioned that, to provide a fund adequate for the endowment of the Chair and the furnishing of suitable buildings and equipment, a sum of about £15,000 would be necessary. The foundation of this Chair would enable the College to complete the first two years of a medical curriculum.

A CIRCULAR from Harvard College Observatory, dated June 26, states that the sum of fifty thousand dollars has been received by that Observatory from Miss C. W. Bruce, of New York, to be applied "to the construction of a photographic telescope having an objective of about 24 inches aperture with a focal length of about 11 feet; . . . also to secure its use under favourable climatic conditions in such a way as will best advance astronomical science."

A STATUE of Paul Bert was unveiled at Auxerre on Sunday last. The ceremony was attended by the Annamite Envoys, and M. Spuller represented the French Government.

DR. E. HEINRICHER has been appointed Professor of Botany and Director of the Botanical Garden at Innsbrück; and Dr. H. Ambronn, Professor of Botany at Leipzig.

THE number of working botanists in Portugal is so small that it is with great satisfaction we are able to announce the appointment of Dr. G. von Lagerheim of Stockholm, recently of Freiburg-i-B., as assistant in the botanical laboratory of the Polytechnic School at Lisbon.

IT is stated that the Imperial Museum of Vienna has accepted the eccentric conditions of the bequest of the late Prof. H. G. Reichenbach, of Hamburg, according to which his extensive collection of dried orchids and drawings of orchids shall be placed in sealed packets in the Museum, and shall not be exhibited or in any way used within twenty-five years of his death.

THE *Kew Bulletin* for July consists of an excellent guide to the botanical literature of the British Empire. The primary object of the compilation is to supply useful information on the literature of the systematic, economic, and geographical botany of British Possessions, Dependencies, and Protectorates. The compiler explains that Kew is often called upon to answer questions, on the shortest notice, concerning the vegetation of some remote part of the world, and the best books to consult on the subject. Such questions are not always easily answered, and they frequently entail a considerable expenditure of time. The intention is that the present guide shall supply what is wanted, and everyone who may have occasion to use it will find that it is admirably adapted to its purpose.

MR. THOMAS SCOTT, of the Scientific Department of the Scottish Fishery Board, on June 27, in the Moray Firth, successfully fertilized the ova of the lemon sole (*Pleuronectes microcephalus*) with the milt of the turbot (*Rhombus maximus*). Development proceeded rapidly for three days and a half, when the ova were killed by dust getting into the water, and they sank. At this period the embryo was well formed, development was going on quickly, and hatching would probably have occurred on the seventh or eighth day.

LAST week, the Rev. W. S. Green, Mr. W. de Vismes Kane, and other zoologists, had a successful trawling expedition in the Atlantic, off the Irish coast. They started from Queenstown, in the *Flying Fox*, on Monday, July 1, and returned on Sunday. All the captures were divided and subdivided into different classes, carefully preserved in spirits, and packed in the cases which were used in the *Challenger* Expedition; and they have been forwarded to the Natural History Department of the British Museum, for whose benefit the expedition was organized.

MISS MARIA MITCHELL, well known as a writer on astronomy, died recently in New York. She was the daughter of William Mitchell, astronomer, and was born in Nantucket, Massachusetts, on August 1, 1818. In 1847 she made the discovery of a comet, for which she received a gold medal from the King of Denmark, and other distinctions. During a visit to Europe, in 1858, she was the guest of Sir John Herschel and Sir George B. Airy, and afterwards she visited Leverrier in Paris and Humboldt in Berlin. In 1865 she was called to the Professorship of Astronomy at Vassar College, which, with the post of Director of the Observatory, she retained until January 1888, when she secured a long leave of absence. The degree of LL.D. was conferred upon Miss Mitchell by Hanover College in 1852, and by Columbia College in 1887. She was a member of various scientific Societies, and was the first woman elected to the American Academy of Arts and Sciences. She contributed numerous articles to scientific journals.

THE heat in Russia and other parts of Northern Europe has been intense of late. The Central Observatory at St. Petersburg has not recorded such a high temperature at the same time of the year since 1774.

A SHOCK of earthquake occurred at Guernsey on Monday afternoon, about 2.30. It was not quite so violent as that experienced on May 30. The weather during the whole of the morning was extremely sultry.

ON the evening of January 31 last, about 9 o'clock, the self-recording barometer at the Deutsche Seewarte showed a sudden dip of about 0·04 inch, with a corresponding jump upwards a few minutes afterwards; and in the course of a day or two it was found that the barographs at other stations exhibited a similar phenomenon. Although the disturbance cannot be compared in any way to the air-wave caused by the Krakatão eruption, yet the rapidity of its translation proved it to be a noteworthy meteorological phenomenon, and its behaviour over Central Europe is discussed in an article contributed to the *Annalen der Hydrographie und maritimen Meteorologie* for June, by Dr. E. Herrmann, of the Deutsche Seewarte. The disturbance is traced from Keitum (lat. 54° 54′), where it occurred at 7h. 50m. p.m., Berlin time, on January 31, to Pola (lat. 49° 42′), which it reached at 4h. 38m. a.m. on February 1, having travelled at the rate of about 71 miles per hour. In an easterly and westerly direction the disturbance seems to have been confined to narrow limits. The barometer was high over Southern Europe (30·5 in.), with minima (28·7 in.) over Northern Finland, and between Iceland and Norway. There was no earthquake in Europe at the time, and the cause of the phenomenon remains at present unexplained.

PÈRE CHEVALIER, S.J., Director of the Sikawei Meteorological Observatory, near Shanghai, has issued his monthly Bulletin for August last. It is an unusually interesting number, as it contains a full study, with diagrams, of the two typhoons which were felt at Shanghai and in the south of China. These elaborate studies of the typhoons of the China seas are invaluable, especially when supplemented by the labours of Dr. Doberck, of Hong Kong; of the Japan Observatory; and of that of Manilla, in the Philippine Islands. Père Chevalier has a number of charts showing the tracks of the storms.

THE Committee of the General Board of Studies of the Victoria University of Manchester have issued their report on local lectures during the past three sessions 1886-87 to 1888-89. Twenty courses of local lectures have been delivered, and the Committee state that they have every reason to be satisfied with the results obtained so far. The subjects selected have been very varied, ranging over many branches of literature and science. The local Committees have been of very different constitution, including Committees specially formed for the purpose of the lectures, Literary and Philosophical Societies, mechanics' institutes, and educational institutions of various grades; and the audiences, while mainly drawn from the middle classes, have in some cases consisted entirely of working men. The attendance at the lectures has been well maintained, averaging for all courses about 130.

IN the forty-third Annual Report of the Commissioners in Lunacy, just issued, it is stated that there were, on New Year's Day, 84,340 insane persons under restraint. Of these, 7970 were of the private class, 75,632 were paupers, and 738 were criminals. The Commissioners believe that during recent years medical men have become increasingly unwilling to certify to the insanity of persons requiring treatment, in consequence of the results of recent litigation connected with this part of their duties. The causes of insanity are set forth in a table covering 136,478 cases. These are very diverse. Thus 9569 persons lost their reason from domestic trouble, 8060 from adverse cicumstances, 8278 from over-work and worry, 3769 from religious excitement, and 18,290 from intemperance. The influence of heredity was ascertained in 28,063 cases, and congenital defect in 5881.

A Bill has been introduced into the House of Commons which would, if it became law, prove a great boon to young people in the rural districts. The object is to provide instruction in agricultural and horticultural subjects in public elementary schools, and to afford practical illustration in such teaching. The Industrial Agricultural Education Bill, as it is called, would not only secure for children in rural districts practical instruction on such subjects as fruit, flowers, and vegetable growing, the proper method of keeping cattle, rotation of crops, packing fruit for market, and other matters of equal importance: it proposes, further, that the instruction in these branches shall be carried on after the children leave school. To effect this it is proposed to establish schools at which lessons would be given in the evenings, and on Saturday afternoons. To induce parents to keep their children at school for a longer period, or to send them to the new schools, the promoters of the measure advocate the provision of a small number of scholarships of the value of thirty shillings per annum, and tenable for two years, for children who have passed the fourth standard. They foresee, also, that the ordinary appliances of elementary schools will not be sufficient to secure comprehensive instruction in practical agriculture, and they are bold enough to hope that a special grant will be made by the Education Office or the Science and Art Department for the expenses of such allotments, school gardens, and buildings as may be necessary to make the teaching thoroughly practical. The Bill is backed by Mr. George Dixon, Mr. Henry Fowler, Sir John Lubbock, Mr. Jesse Collings, Sir Bernhard Samuelson, Mr. Howell, Sir John Kennaway, Mr. Robert Reid, and Major Rasch.

Messrs. Trübner and Co. will publish, probably in October, "An Account of the Aborigines of Tasmania, their Manners, Customs, Wars, Hunting, Food, Morals, Language, Origin, and General Characteristics," by Henry Ling Roth, assisted by E. Marion Butler. The work will contain a chapter on the osteology, by Dr. J. G. Garson, and a preface will be contributed by Dr. E. B. Tylor. Numerous autotype plates, from original drawings made by Edith May Roth, will illustrate the text. The edition will be strictly limited to subscribers.

The Delegates of the Clarendon Press will shortly issue Mr. Oliver Aplin's "Birds of Oxfordshire"; the second volume (treating of electro-dynamics) of Messrs. Watson and Burbury's "Mathematical Theory of Electricity and Magnetism"; and a new edition of the fourth volume (on the dynamics of material systems) of Prof. Bartholomew Price's "Treatise on Infinitesimal Calculus."

In the new number of the *Internationales Archiv für Ethnographie* (Band ii., Heft 3) Mr. Felix Driessen gives an interesting account, in English, of tie and dye work, manufactured at Semarang, Java. The article is accompanied by a plate representing the manufacture in all its different stages. Mr. R. Parkinson continues his excellent notes, in German, on the ethnology of the Gilbert Islanders. The valuable German paper, by Dr. F. von Luschan, on a Turkish "Schattenspiel," is also continued. The number, like its predecessors, has many notes on ethnographical museums, collections, and books.

The Department of Mines, Sydney, has issued the first number of what promises to be a valuable publication—*Records of the Geological Survey of New South Wales*. It opens with "Notes on the Geology of the Barrier Ranges District and Mount Browne and Tibooburra Gold Fields," by Mr. C. S. Wilkinson. Messrs. T. W. E. David and R. Etheridge, Jun., contribute an interesting report on the discovery of human remains in the sand and pumice bed at Long Bay, near Botany. There are other papers by the same writers, and by Mr. W. Anderson, Mr. J. C. H. Mingaye, and Mr. H. W. Powell.

Messrs. George Philip and Son have issued the third volume of the well-known series, "Rustic Walking Tours in the London Vicinity." It deals with the west-to-south district, and contains a field-path map, a geographical description, forty-five charts, with ample and plain directions, and an index.

A little book called "Walks in Holland," edited by Mr. Percy Lindley, has just been issued. It presents concisely much information that may be of service to tourists.

The other day the plough of a peasant in the island of Gothland unearthed a valuable treasure, consisting of two large spiral armlets, a buckle, and a long bar used in payment, all of solid silver, together with nearly 400 silver coins. Some of the coins were Anglo-Saxon, and bore the effigy of King Ethelred. The others were German and Cufic coins. The "find" has been purchased by the State.

The richness of the cod fisheries this spring on the coast of Finmarken has clearly shown that these fisheries are not in the least affected by whales. The Government has voted a sum of £850 towards the cost of a Commission for dealing with the much-needed protection of the whale.

The preservation of the eider in Sweden is to be extended from April 24 to May 31. Through strict protection these valuable birds have increased greatly in recent years along the Baltic and the Cattegat.

Dr. Schweinfurth has presented a valuable collection of plants from Yemen to the Christiania Museum.

The late Mr. Wilson, of Gothenburg, has left a legacy of £5500 to that city for the promotion of science, art, and education. He has also left his valuable collections to the Gothenburg Museum. A few years ago Mr. Wilson endowed this institution with a similar sum.

The Finnish naturalist, Dr. J. Kinunen, has set out on a voyage of scientific research to Nova Zembla and adjacent parts.

A new series of double oxalates of the rare metal rhodium and the metals of the alkalies or alkaline earths are described by M. Leidié in the July number of the *Annales de Chimie et de Physique*. The hydrate of rhodium sesquioxide, $Rh_2(OH)_6$, a substance having the peculiar appearance of a black jelly, and which is but slightly attacked by most acids, dissolves readily, when recently precipitated, in a concentrated solution of oxalic acid. On evaporation of this solution, containing presumably rhodium oxalate, no crystalline oxalate is obtained, but only a non-crystallizable transparent mass. If, however, this solution is evaporated along with a solution of neutral oxalate of potassium, sodium, or ammonium, on cooling beautiful garnet-red crystals of a double oxalate are deposited, containing one molecule of the oxalate of rhodium sesquioxide and three molecules of the alkaline oxalate. The potassium salt, $Rh_2(C_2O_4)_3 . 3C_2K_2O_4 . 9H_2O$, separates from solution in red triclinic prisms, very soluble in water. The largest crystals are obtained from a perfectly neutral solution, and may be most readily prepared by saturating a boiling solution of acid potassium oxalate with recently precipitated hydrate of rhodium sesquioxide. It is an evidence of the strength of the combination that the solution gives none of the characteristic tests for rhodium, not being precipitated either by potash or soda, and only partially by sulphuretted hydrogen. The ammonium compound $Rh_2(C_2O_4)_3 . 3C_2(NH_4)_2O_4 . 9H_2O$ is isomorphous with the potassium salt, and crystallizes in smaller red prisms. It is soluble in its own weight of warm water. On the other hand, the sodium salt crystallizes with $12H_2O$, in red prisms which are very efflorescent. The salts containing the alkaline earthy metals are much less soluble, and are generally obtained as crystalline precipitates by decomposition of the potassium salt by the chloride of the metal which it is desired to introduce. It is interesting that these salts are perfectly analogous to the double oxalates of ferric iron and chromium, $Fe_2(C_2O_4)_3 . 3C_2(NH_4)_2O_4$, for instance; but the two series are not isomorphous owing to the difference in water of crystallization. Evidence of similarity between iron and rhodium is of course shown by the fact that their most stable chlorides are those derived from the sesquioxides—namely, Fe_2Cl_6 and Rh_2Cl_6; but the formation of these double oxalates shows that the connection is perhaps closer than has hitherto been supposed. And the interest in this connection is by no means lessened by the fact that iron and rhodium occupy corresponding positions in the eighth vertical group of Prof. Mendeleeff's periodic classification.

THE additions to the Zoological Society's Gardens during the past week include two Indian Jerboas (*Alactaya indica*) from India, presented by Mr. Cuthbert Johnson; a Bonnet Monkey (*Macacus sinicus* ♀, white variety) from India, presented by the Waterbury Watch (Sales) Company, Limited; a Lesser White-nosed Monkey (*Cercopithecus petaurista* ♀) from West Africa, presented by Captain Stewart Stephens; a Brown Bear (*Ursus arctos* ♀), European, presented by Mr. John Foster Spence; a Polar Bear (*Ursus maritimus* ♀) from Spitzbergen, presented by Mr. Arnold Pike; a Python (sp. inc.), presented by Mrs. Bertha M. L. Bonser; a Hybrid Wild Swine (between *Sus scrofa* and *Sus domesticus* ♀) from Spain, presented by Mr. Ralph Banks, F.Z.S.; a Brush-tailed Kangaroo (*Petrogale penicillata* ♂) from New South Wales, presented by Sir Edmund A. H. Lechmere; five Violaceous Night Herons (*Nycticorax violaceus*) from St. Kitt's, W.I., presented by Dr. A. P. Boon, C.M.Z.S.; twelve Aldrovandi's Skinks (*Piestiodon auratus*) from North Africa, two Barnard's Parrakeets (*Platycercus barnardi*) from South Australia, purchased; a Laughing Kingfisher (*Dacelo gigantea*) from Australia, deposited; two Wonga Wonga Pigeons (*Leucosarcia picata*) from New South Wales, and a Red-winged Parrakeet (*Aprosmictus erythropterus*) from Australia, received in exchange; an African Wild Ass (*Equus tæniopus* ♀), and a Collared Fruit Bat (*Cynonycteris collaris*) born in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE LATE PROF. CACCIATORE.—Prof. G. Cacciatore, whose death we have briefly recorded (p. 208), had been associated with the Royal Observatory of Palermo, during nearly the whole of his life. He was born at Palermo on March 17, 1814, his father being the well-known Prof. Nicolo Cacciatore, assistant at one time to Piazzi, and later his successor in the directorship of the Observatory. Gaetano Cacciatore, on the death of his father in 1841, was appointed Director of the Observatory and Professor of Astronomy in the University of Palermo, and he held these positions until 1849, when, having taken a very prominent part in the revolution of the previous year, he was compelled to leave Palermo by the return to power of the Bourbons. In 1860, however, Garibaldi recalled him to his former position. He spared no pains to increase the power and usefulness of the Observatory, and greatly increased its equipment. It was under his direction that the scope of the institution was enlarged, so that in 1880 it was reorganized in three sections—one of Geometrical Astronomy; one of Physical Astronomy, in the modern sense of the word; and the third of Meteorology.

COMET 1889 *d* (SWIFT).—A new comet was discovered on July 5·833 G.M.T., by Prof. Lewis Swift, of the Warner Observatory, Rochester, New York. The comet's place was as follows:—

R.A. = 22h. 52m. 30s. Daily Motion, − 2m.
Decl. = 89° 11′. + 10′.

COMET 1889 *b* (BARNARD, MARCH 31).—This object may soon again be observed in the early morning. The following elements and ephemeris are by Prof. Millosevich, from observations made at the Lick Observatory on March 31, April 15 and 29 (*Astr. Nach.* No. 2907):—

T = 1889 June 10·63608 Berlin M.T.

$$\left.\begin{array}{l}\pi = 186^\circ\ 38'\ 20''\cdot 8\\ \Omega = 310\ 40\ 19\cdot 3\\ \iota = 163\ 49\ 47\cdot 8\end{array}\right\}\text{ Mean Eq. 1889·0.}$$
$$\log q = 0\cdot 353613$$

Error of middle place O − C).
$\Delta\lambda = -1''\cdot 3.$ $\Delta\beta = +5''\cdot 4.$

Ephemeris for Berlin Midnight.

1889.	R.A. h. m. s.	Decl. ° ′	Log *r*.	Log Δ.	Brightness.
July 19 ...	5 7 52 ...	10 59·0 N....	0·3618 ...	0·4706 ...	0·83

The brightness at discovery is taken as unity.

COMET 1889 *c* (BARNARD, JUNE 23).—The following elements for this comet are by Dr. H. Kreutz, from observations at Lick on June 23, at Strasburg June 25, and at Munich June 26; the ephemeris is by Prof. A. Krueger:—

T = 1889 July 2·8884 Berlin M.T.

$$\left.\begin{array}{l}\omega = 75^\circ\ 19'\cdot 5\\ \Omega = 278\ 6\cdot 7\\ \iota = 32\ 50\cdot 2\end{array}\right\}\text{ Mean Eq. 1889·0.}$$
$$\log q = 0\cdot 09248$$

Ephemeris for Berlin Midnight.

31 ...	19 55 58 ...	3 25·0 S. ...	0·4556 ...	0·2733 ...	2·0

The brightness at discovery is taken as unity.

Mr. Barnard, observing this comet on June 3, at 3 a.m., noticed that it showed only one tail and that this *followed* the comet, and therefore pointed almost directly towards the sun. The tail was about a degree in length, and some 2′ or 3′ in breadth; position-angle, 90°. The head of the comet was roundish, with an almost stellar nucleus in an extended condensation, this latter having a position-angle of about 135°.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1889 JULY 14–20.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on July 14

GEOGRAPHICAL NOTES.

THE paper read at the meeting of the Royal Geographical Society on Monday night, by Mr. Basil H. Thomson, was one of unusual scientific interest. It described a visit made by Mr. Thomson last autumn, along with the New Guinea Commissioner, to the Louisiade and D'Entrecasteaux Islands, both within the British sphere. Mr. Thomson's observations on the natives, on the geology and natural history of these islands, are of special value. The first island described is that of Sudest, the largest of the Louisiades. It is forty-five miles long and four to ten wide. It is of a slaty formation, with veins of crystalline quartz running through it in all directions. The eastern portion is mountainous, the highest point, Mount Rattlesnake, being about 3000 feet high. The highest parts are densely timbered, but the low hills near the sea are covered with grass, whose bright green offers a welcome contrast to the sombre tropical forest. Rossel Island is surrounded by a distant barrier reef of irregular form. The natives are dangerous head-hunters, who, however, kept out of the way of the visitors. With some difficulty the densely-timbered island was crossed, and proved a rich field for the botanist. Even at an elevation of 3000 feet a network of native paths was found. At the village, the inhabitants of which had fled, the party stayed the night. The village was scrupulously clean and the paths well kept. The houses were shaped like an inverted boat, built on a platform some 5 feet from the ground; the interior was reached through two trap-doors in the floor. The natives of Rossel suggest a hybrid between the Papuans and the natives of the Solomon Islands. The stone axe has fallen into disuse, its place being taken by blades of iron procured from wrecks. The language bears no resemblance to any known New Guinea dialect nor to the languages of Eastern Polynesia. St. Aignan Island, called by the natives Misima, is more than 100 square miles in area, being about twenty-eight miles long, and varying in breadth from about eight or nine miles on the east end. The west end consists of a great mountain range named Lakia, about 3500 feet above the sea, composed of schistose slate. The eastern part of the island consists of very rugged hills, through which the streams have cut very deep and narrow gorges. They are composed of coral upheaved by volcanic action, and mixed with conglomerate formed from shingle, and with broken layers of schistose slate. Round the eastern coast there is a fringe of coral, upheaved more recently, rising to a height of more than 100 feet, through which the mountain torrents have cut their way right down to sea-level. The natives are of two types, the one evidently Papuan, and the other betraying strong Malay characteristics, such as the straight hair and not prominent features. The limestone hills which compose the centre of the island were honeycombed with caves and densely timbered. From one great wall of limestone sprang a stream which, after 200 yards of daylight, plunged into a great cave in the opposite cliff. The mouth was a perfect arch, 150 feet from floor to roof. At the far end the river thundered down into a black tunnel, through which it passed under the range, emerging into daylight after some three miles of darkness. Normanby Island, the most easterly of the D'Entrecasteaux Group, is a narrow L-shaped mountain range, with deeply furrowed sides and wide valleys excavated by water-wear. It is probably nowhere of greater breadth than ten or twelve miles, and the area about 350 square miles. The highest parts of the island are perhaps 3500 feet above the sea-level. The south-eastern portion is composed of schistose slate varying much in hardness, interlaid with veins of white crystalline quartz, which is free from any compound of iron or other metal. Traces of gold were found in the creeks. Toward the north end of the island the formation is igneous, consisting mainly of limestone, but in some of the river-beds are large beds of basalt and boulders of siliceous stone. The mountains of Dawson Straits, however, differ much in formation from the rest of the island. The rock appeared to be a sort of porphyry, and furnished indications of tin. The natives have strong Papuan characteristics. They wear the usual dress. Mr. Thomson penetrated some miles inland, passing through no less than thirty-one villages, and seeing many others perched on every available spur or ridge, and surrounded by its plantations. These villages were remarkable for their cleanliness. The cultivation is wonderful, and bears witness of their activity and industry. Normanby Island is the eastern limit of the wallaby, of which were found two varieties. It is also the eastern limit of a bird peculiar to the D'Entrecasteaux Group—the largest of the five species of Manucodia, which are still classed with the birds of Paradise. It feeds on insects, and though the strait which divides Normanby Island from the mainland is only ten miles wide, this bird, which is the commonest of all large birds in the D'Entrecasteaux Group, has never crossed to New Guinea. War and the difference of dialect have so completely isolated the various tribes as to make them different peoples as regards everything but their physical characteristics. At a spot not ten miles from a tribe that would barter all they possessed for tobacco and pipes, were people so ignorant of their use that they put the tobacco into a bottle given them, poured water upon it, and drank off the compound. Ferguson Island, the largest of the D'Entrecasteaux Group, is thirty miles long by seventeen broad, with an area of about 500 square miles. There are three great mountain masses on the island: Mount Kilkerran, on the north-east corner, 6000 feet high; the Maybole Range, on the north-west, which is probably 5000 feet above sea-level; and a lower range in the south-west corner, which is apparently unnamed, and which Mr. Thomson was unable to examine. The formation of the Kilkerran and Maybole Ranges is the same, consisting principally of micaceous schist with veins of white quartz intersecting it. In the beds of the rivers were boulders of quartz, and of a slaty rock very rich in silica, and there were boulders of what seemed to be a kind of porphyry. The south-eastern part of Ferguson and the small outlying islands, Goulvain and Welle Islands, are of igneous formation, and Mr. Thomson noticed two extinct volcanoes and some hot springs. This part is densely populated, owing probably to the fertility of the extensive flats of volcanic deposit. The people were in most respects similar to those in Normanby Island. The inland or bush natives have evidently no communication with those on the coast, except as enemies: they knew nothing of firearms. They are true Papuans. At Mount Kilkerran, near Hughes Bay, it was noticed that the sides of the mountain, consisting of great precipices and steep inclines, were dotted with villages up to a height of 10,000 feet, half concealed in clumps of cocoa-nut palms. Six specimens of a variety of *Paradisea raggeana* were obtained in this island. Near Seymour Bay there was a large extent of flat land and sago swamp, in which were found some saline lakes, and some hills giving off sulphur fumes strong enough to discolour the white paint on the vessel, which was lying nearly two miles distant. Some of the hills appeared to be composed of alum and sublimed sulphur. There were also springs of boiling water and boiling mud, and in one instance boiling mud was spouted up from a chimney-like cavity in the hill-side. Goodenough Island, the most westerly of the group, was visited. A great range of mountains running north and south, and culminating in two peaks not less than 7000 feet high, forms the centre of the island. On the east side is a plain some seven or eight miles wide, nearly clear of forest. The formation is slaty schist containing much mica and quartz. On the east side are projections of igneous formation, and on the point nearest to the sulphur springs in Seymour Bay is a small crater, probably not long extinct.

OPTICAL TORQUE.[1]

II.

It will be convenient here for me to refer to some researches, not yet published, which I have made, as to the various orders of transition tints, with the view of ascertaining which of them is the most sensitive—which of them, in fact, shows the greatest change of tint for the smallest amount of rotation. Reference to the diagram on the wall displaying Newton's tints will make clear what I mean by the transition tints of the several orders. The tints obtained from quartzes of varying thicknesses may be considered as approximately identical with the tints of Newton's rings, provided we remember that the air-film which gives any particular tint in Newton's rings is about 1/300,000 part as thick as the quartz which yields the corresponding tint in the polariscope. Better far than any painted diagram, because richer and purer, are the tints now thrown upon the screen by introducing into the field a thin wedge of selenite, displaying the whole of the colours of the first three orders of Newton's scale. You will notice the successive recurrence of purple tints, both in the colours seen in the bright field, and in those seen in the dark field.

First I will show you the transition tints of the first and second orders in the bright field. That of the second order is much less intense than that of the first; and yet it is very sensitive, turning to a green tint whilst the first order purple has only turned to a blue. On the other hand, with reversed rotation of the analyzer it turns to red less rapidly than does the tint of the first order.

Next I take the transition tints of orders I., II., and III. in the dark field. These, though arranged, by means of superposed half-disks of "quarter-wave" plates, to be optically equivalent to biquartzes of two rotations, are really built up of selenite and mica. You will notice how the tint of order I. surpasses in sensitiveness both the others. I cannot here show you on the screen the means by which I have compared the tint of order I. in the dark field with that of order I. in the other set. Suffice it to say that I find the tint of order I. in the dark field—corresponding to 7·5 millimetres thickness—more sensitive than that of order I. in the bright field, which corresponds to 3·75 millimetres thickness.

A method which was at one time supposed to be more precise, was that of placing a spectroscope (or its prism) in front of the

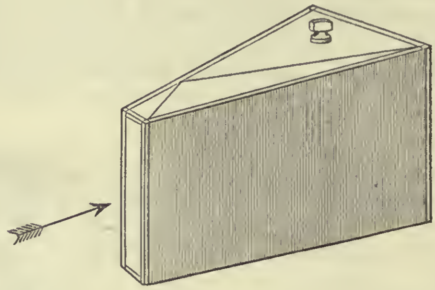

Fig. 9.—Direct-vision prism for projection of spectrum.

analyzer, and watching the motion along the spectrum of the interference bands which are then seen. My three pieces of crystal remain. I introduce a slit in front of them, also a single film of quarter-wave mica, and then a prism to give the spectrum. This prism (Fig. 9), by the way, is a new sort of direct-vision prism, having a single very wide-angled prism of Jena glass inclosed in a cell with parallel ends containing cinnamic ether (first recommended by Wernicke), a liquid which has the same

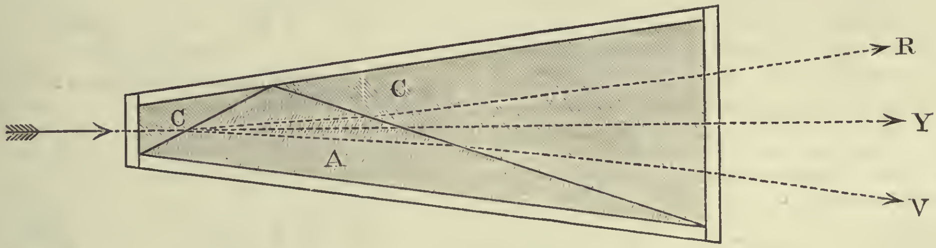

Fig. 10.—Direct-vision prism. A, wide-angled prism of Jena glass; C, cinnamic ether.

mean refractive power, but widely different dispersion. It is preferable to bisulphide of carbon in several respects: first, its odour is a delicate reminiscence of cinnamon; it is barely volatile; and it is whiter than bisulphide. This prism, which is shown also in plan in Fig. 10, was constructed for me by Messrs. R. and J. Beck. It will be seen that the dark bands in the spectrum are nebulous and ill-defined. It is idle to hope to secure accuracy by turning the analyzer until they shift along to a definite point. And there is no advantage in using the higher orders of tints which give more bands; for, though the bands are certainly better defined, their progression across the spectrum for a given amount of rotation is proportionally smaller.

Another suggestion, due to Sénarmont, is to use two sets of superposed wedges of right- and left-handed quartz. Such you now see before you. Instead of starting with extinction you start with coincidence between the upper and lower set of bands. Any rotation of the light shifts the bands, one set moving to left, the other to right. By turning the analyzer through an equal angle coincidence is again obtained.

Another method, used by Wild in his polaristrobometer, is to produce the phenomenon known as Savart's bands (due to the introduction of two crossed slices of quartz cut at a particular angle). The bands disappear when the analyzer is set in a particular direction. Anything that twists the plane of polarization causes them to reappear; but they again fade out when the analyzer is turned through an equal angle.

There is yet another method in polarimetry, due to Soleil, in which the optical torsion due to the sugar is counterbalanced or compensated by introducing a pair of sliding wedges of quartz of the opposite rotation. This device is known as a "compensator." By sliding the quartzes over one another a greater or less thickness of quartz is introduced at will. But I must not stop to illustrate this elegant device.

Yet one other method must be mentioned, and this is certainly the most preferable. It consists in aiding the eye to recognize with precision a particular degree of extinction, by the device, first suggested in 1856 by Pohl, of covering a portion of the visible field with something which slightly alters the initial plane of polarization, so that complete blackness is not obtained at once over both parts of the field. A common device is to cover half the field with a slice of some thin crystal—mica or quartz—so that only one half can be perfectly black at any instant. As an example, here is the field covered half over with a plate of mica of the thickness known as half-wave. The result is that when one half of the field is black the other is light. Adjust the analyzer now to equality. Now introduce something that rotates the light—say a tube with sugar solution in it. At once the balance is upset, and I must, in order to get equality, turn my analyzer.

Of the same class are the polarimeters with special prisms made in two parts slightly inclined to one another. The earliest of these was devised by the late Prof. Jellett, of Dublin, and has been followed by imitations of the same plan by Cornu, by Lippich, and by Schmidt and Haensch. The beautiful "shadow polarimeter," by the latter firm, which I here exhibit, has the divided prism, and a quartz compensator.

I have suggested two simpler methods of accomplishing the same end. In the first place, I have proposed to use *twin-prisms*. These are made on a plan suggested to me by finding that Mr. Ahrens's method of cutting calc-spar for prisms was admirably

[1] A Discourse delivered at the Royal Institution, May 17, 1889, by Prof. Silvanus P. Thompson. Continued from p. 235.

adapted for making such prisms, either with wide or narrow angles between the respective planes of polarization in the two parts of the visible field. Two such twin-prisms, one with 90°, the other with $2\frac{1}{2}$°, between the prisms, are here on the table. In the second place, I have essayed a polarimeter, an example of which is before you, in which an arrangement of twin-mirrors (each set at the polarizing angle, but slightly inclined to one another) is made to yield a half-shadow effect.

Before I leave the subject of quartz I must refer to the famous mathematical theory of Fresnel, who endeavoured to explain its action upon light by supposing that the plane-polarized wave on entering it is split into two waves, consisting of oppositely circularly-polarized light, which traverse the crystal with different speeds. On emerging they recombine to form plane-polarized light, the plane of which, however, depends on the

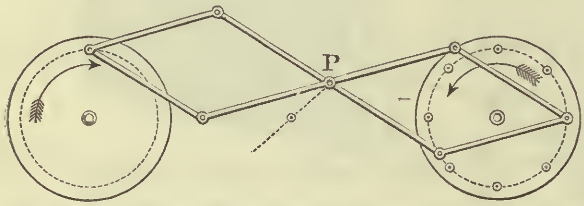

FIG. 11.—Model illustrating recomposition of rectilinear motion from two opposite circular motions.

retardation of phase between the two components. I here introduce a mechanical model to illustrate one of the points in this theory—namely, the recombination of two circular motions to form a straight-line motion. These two disks (Fig. 11), which turn in opposite senses, but at equal rates, represent two circularly-polarized beams of light. The linkages, which connect two pins on these disks, compound their motions at the central point, P, which executes, as you see, a straight line. But now, suppose one of these circular motions to be retarded behind the other, an effect which I can imitate by shifting one of the pins to another position on the disk. Still the resultant motion is a straight line, but it is now executed in a direction oblique to the former. In other words, its plane has been rotated. Of course this model must not be taken as establishing the truth of Fresnel's ingenious theory: it is at best a rough kinematical representation of it.

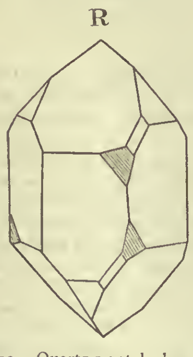

FIG. 12.—Quartz crystal, showing characteristic facets: right-handed.

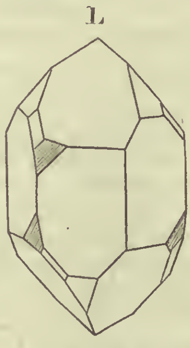

FIG. 13.—Quartz crystal, showing characteristic facets: left-handed.

We have, however, the puzzling fact still to account for that there should be two kinds of quartz crystals, right- and left-handed. Sir John Herschel first showed that natural crystals of quartz themselves often indicated their optical nature, by the presence of certain little secondary faces or facets which lay obliquely across the corners of the primary faces. These are indicated in the diagrams (Figs. 12 and 13), and may be seen in two of the specimens of quartz crystals which lie upon the table. The largest of these is right-handed. The wider generalizations of Pasteur, respecting the crystalline form of optically active substances, show that those substances which exercise an optical torque, whether as crystals or in solution, belong to the class of forms which the crystallographer distinguishes as possessing non-superposable hemihedry. In other words, they all show *skew symmetry*, as if in the growth of them they had been built up in some screw-fashion around an axis, and must therefore be either right-handed or left-handed screws. By piling up a number of wooden slabs in skew-symmetric fashion, I am able roughly to illustrate (Figs. 14 and 15) the difference between the right-handed and the left-handed structure. It is a curious fact, if I am rightly informed, that down to the present date the only substances possessing this skew symmetry are natural substances; that those which the chemist can produce by artificial synthesis are all optically inactive. It is perhaps equally significant that as yet no inorganic substances have been found which will in the liquid state rotate the light. This appears to be a property possessed solely by certain compounds of carbon. Quartz fused in the blowpipe or dissolved in potash shows no trace of rotatory power.

Yet we can have little doubt that this property is bound up in the yet unravelled facts of atomic and molecular structure. In the case of the liquids, such as turpentine and sugar solution, there must be some skew symmetry in the grouping of atoms in the molecule to produce the result. In the case of quartz, there must be a skew in the building of the molecules—there must, to borrow a phrase from the architect, be

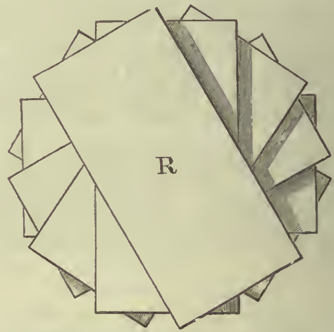

FIG. 14.—Skew-symmetrical arrangement: right-handed.

FIG. 15.—Skew-symmetrical arrangement: left-handed.

an oblique *bonding* of the minute bricks of which its transparent mass is builded. Though we cannot even rebuild it from its solution, we know this must be so, for we can reproduce all the optical phenomena which it exhibits by an actual skew building of thin slices of another non-rotatory crystal. Here is an artificial object (I built it myself) constructed on Reusch's plan, from sixteen thin slips of mica built up in staircase fashion—right-handedly—one above the other, and set symmetrically at equal angles of 45° to one another, the whole set making a cork-screw of two complete turns. In the lantern it behaves just as a quartz of about 9 millimetres thickness would do. It even gives tolerably perfect rings, as quartz does, when viewed by convergent light.

I must now pass hastily onwards to the great discovery of Faraday. Here (Fig. 16) is a magnetizing coil of wire, M, having about 8300 turns, and enclosed in an iron jacket. When it is traversed by a powerful electric current from the dynamo machine, it produces an intense magnetic field along its axis. In this axial position lies a bar of heavy glass, not quite so dense as that which Faraday himself used, but nearly so. The bar lies along the line of light from our lantern, but the polarizer, P (the Ahrens reflector, Fig. 7), and analyzer, A (the Ahrens triple spar prism, Fig. 6), are crossed, so that here is the dark field. On turning on the current, light is at once restored, being twisted to the right when the current circulates right-handedly. To measure the rotation, I must turn the analyzer; and now I find that, owing to the greater rotation of blue waves than of red, complete extinction does not occur. Introducing a half-shadow plate, and using coloured glasses, it is very easy to verify the greater amount of rotation for blue light, and to show that reversing the current reverses the rotation. You will perhaps better understand it if I use (as in Fig. 16) the 24-ray star, S, which I have previously employed. It is now obvious to you that there is a large rotation—over 50° in fact—which is reversed when I reverse the magnetizing current. We have thus repeated the fundamental experiment of magneto-optics. But now we meet with another consideration. Reflect that the circulation of current, if it be taken as right-handed when regarded from one end of the coil, will be left-handed when regarded from the other end of the coil. This is, therefore, no case of skew symmetry: it clearly indicates that something is going on in the glass which tends to twist the light quite irrespective of which way the light enters.

The next magneto-optic phenomenon is that discovered by Dr. Kerr, of the rotation of the plane of polarization by reflection at the surface of a magnet. To observe this at all requires good apparatus and a keen eye. So far as I am aware, it has never been projected on the screen. If I can succeed in doing so, it will only be because I have special means of the most

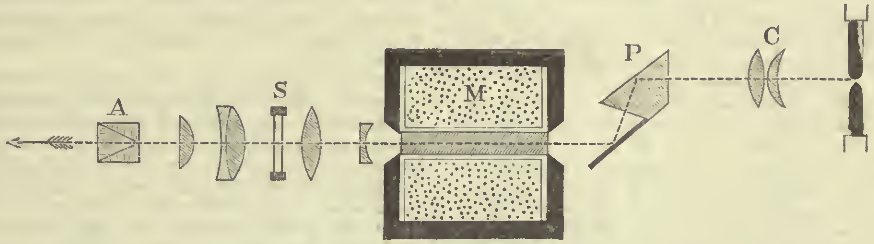

FIG. 16.—Projection of magnetic rotation of plane of polarization. C, condensing lenses; P, reflecting polarizer; M, magnetizing coil surrounding bar of heavy-glass; S, mica disk of twenty-four rays; A, analyzer (Ahrens's triple prism).

favourable character for so doing. We withdraw the bar of heavy glass from the coil, and replace it (Fig. 17) by an iron core polished at its coned end. This will be intensely magnetized when the current is turned on.

Now we must throw the beam of light obliquely down the hollow of the coil, polarizing it by one of my improved Nicol prisms, P, as it goes down. After reflection it is focussed by a lens which sends it through the analyzing prism, A. You see the dim spot of reflected light upon the screen. Now for the current: "on," "off," "on," "off." Reversing its direction ought to double the amount of torsion.

Whilst Mr. Thomas is making the needful arrangements for the next experiment, I may mention that it was found by Kerr that the effect was approximately proportional to the magnetic induction through the iron. I have myself tried some further experiments: for example, using a bar of lodestone instead of an iron core. The light reflected from lodestone is also twisted. I

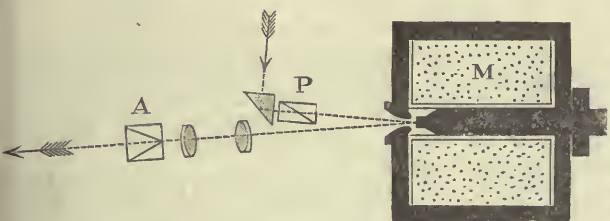

FIG. 17.—Apparatus for projecting rotation of plane of polarization by reflection at pole of magnet. P, polarizer; M, magnetizing coil with coned iron core; A, analyzer.

should expect the ferro aluminium alloy which Sir H. Roscoe showed us a fortnight ago to do the same thing, because that alloy is, as I have found, susceptible of magnetization. But I should not expect manganese steel to rotate the light, because of its singularly non-magnetizable nature.

The experiment of Kundt, transmitting polarized light through a thin transparent film of iron, magnetized normally whilst the light is passing through it, is another difficult of repetition before an audience. The small disks here are covered with films of iron, kindly prepared for me by Mr. Crookes, by squirting them electrically in a high vacuum. But the thin ones barely transmit enough light to make the observation of the effect possible even to the solitary observer. I have observed the effect projected on the screen, using this very coil and these transparent mirrors. It requires, however, an absolutely dark room, and is at best so faint that it would be hopeless to attempt to show it to a large audience. Prof. Kundt has not only observed similar rotations in other magnetic films of nickel and cobalt, but has even shown that the degree of rotation of the light is proportional not to the magnetizing force, but to the resulting magnetic induction. This is a result of utmost importance in considering the theory of the phenomenon. He has further shown that, whereas the magnetic rotations in elementary bodies, whether magnetic or diamagnetic, are in the same sense as that in which the current circulates, the magnetic rotations in compound magnetic bodies, such as a solution of sulphate of iron in water, are in the opposite sense.

These experiments with transparent mirrors of iron raise interesting speculations as to the probable nature of a transparent magnet, if such there could be. It is one of the cardinal points of Maxwell's celebrated electro-magnetic theory of light, that the better a body conducts electric currents, the greater is its tendency to absorb light and become opaque. Now, suppose it were possible to obtain a substance such as to possess greater electric conductivity in one direction than in another, such a substance ought to absorb those vibrations of light which are executed in the direction of the greater electric conductivity more than those in the direction at right angles. In other words, such a substance ought, like the tourmaline, to polarize light by absorption. Now, since the researches of Sir W. Thomson in 1856, we have known that the electric conductivity of iron is altered in the direction of the magnetic lines of force, when it is powerfully magnetized. More recently it has been discovered—I myself observed it in tinfoil, and announced the discovery to the Physical Society a few days before the announcement of the same fact by Righi—that non-magnetic metals alter their resistance in the magnetic field. Notably so do bismuth and tellurium. I had therefore conceived it possible that a film of iron or possibly of tellurium, if strongly magnetized in its own plane, might exhibit polar absorption and act like a tourmaline. Unfortunately, if the effect exists it is so faint as to be yet undiscovered, though I have made many efforts to find such. I have further tried to obtain a similar result by making a transparent magnet out of a film of magnetic oxide of iron, precipitated chemically. In this too I have not succeeded. I have tried to precipitate a transparent film of magnetic oxide in the midst of a transparent jelly. And I have mixed particles of precipitated oxide with melted gelatine so as to get a film. In this way I hoped to get, by placing the preparation in a strong magnetic field, a sort of magnetic structure which would operate upon waves of light. That such a task was not hopeless was shown by two facts: first, that many mere vegetable and animal structures can act as polarizers; and second, that a mere film of paint, such as indigo, can, if a proper mechanical drug is given to it so as to produce structure, also act as a polarizer.

The film of indigo-carmine which I have here, acts nearly as strongly, though not quite as evenly, as a tourmaline slice, and costs but a fraction of a penny.

Well, my films of jelly enclosing particles of magnetic oxide of iron do faintly act on polarized light; but their action is not as marked as that of films of jelly inclosing actual small scraps of iron. This film, when placed across the poles of this electro-magnet, between two Nicol prisms at 45°, shows an action when the magnet is turned on, as you see by the way in which it flashes into light in the dark field. When the jelly is fresh, and of the proper consistency, the action is very strong, but with the rather dry sample before you I fear we can only call the effect a *succès d'estime*.

Incidentally, in the course of these experiments on magnetic films, I came across a new magnetic body unknown hitherto, I believe, to the chemist—namely, a magnetic double oxide of cobalt and iron—a ferroso-cobaltic oxide, I think—a black powder, a sample of which I have here.

It also occurred to me, as a matter of speculation, that if I could strongly magnetize a crystal of ferrous sulphate or nickelous sulphate, whilst viewing it by convergent polarized light I might find some interesting phenomena, which should, if they existed, show some sort of a relation between the direction of the optic axis and that of the lines of the magnetic field. I thought that a longitudinal magnetization might possibly set up a rotatory phenomenon like that in quartz in so far as to disturb the central field between the arms of the black cross; however, not by the most powerful magnetizing could I discover any such effect. Again, I thought that by magnetizing transversely to the optic axis I might possibly succeed in turning the uniaxial crystal into a biaxial, or producing by magnetism an effect resembling the action of heat on crystals of selenite. Owing probably to the small depth of any crystals that can be obtained, I have failed so far to obtain any such effect, though I am convinced that it must exist.

An effect precisely analogous to the magnetic effect which I vainly sought has, however, been lately discovered by Prof.

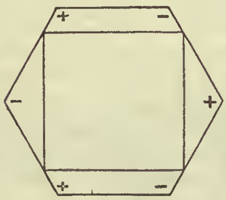

Fig. 18.

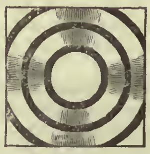

Fig. 19.

Röntgen. I sought a distortion of the optic axis by transversely magnetizing, and I sought it in crystals of sulphate of nickel: he has found a distortion of the optic axis by transversely electrifying, and he has found it in crystals of quartz.

Suppose a piece of a quartz crystal is cut as a square prism, its long faces being principal planes of section respectively parallel to and at right angles to two of the natural faces of the hexagonal prism. Fig. 18 shows the form of the portion cut. The + and − signs in this figure refer to the pyro-electric poles of the crystal. Such a piece viewed by convergent light shows the usual rings and black cross with a coloured centre (Fig. 19). If now two opposite faces be covered with tinfoil, and the crystal be electrified transversely, the rings are distorted into lemniscates, the direction of the distortion changing with the sign of the electrification. It is necessary to use a red glass, or still better sodium light, to observe the changes in form on reversing the sign of the charges. Figs. 20 and 21, 22 and 23, show the changes of form, but these sketches grossly exaggerate the effects. As you see upon the screen, when the charges imparted by this fine Wimshurst machine are rapidly reversed, there is a decided distortion of the rings, but it is small in amount.

Returning to the phenomena of the rotation impressed by magnetism on polarized light, I may point out that the torque which a magnetic field exerts on the light-waves appears to be really an action upon the matter through which the light-waves are passing. It is as though the magnetic field were really a portion of space rotating rapidly on itself, or perhaps as though the ether were there rotating, and that this rotation in some way dragged the particles of matter along with it. It has long been supposed necessary, in order to account for the refractive and dispersive properties of transparent bodies, to consider that their particles are in some way concerned in and partake of the vibrations going on in the ether within them or between their molecules. It is impossible to explain the phenomena of magneto-optic rotation by the supposition that any skew structure is imparted to the medium; for these phenomena, unlike those of quartz, do not exhibit skew symmetry. There seems to be no other way of explaining the magneto-optic torsion of light than by supposing that the molecules of matter in the magnetic field are actually subjected to rotatory actions; as indeed was suggested long ago by Sir William Thomson.

However, there is room here not only for speculation but for experiment. Some day, when facts enough have been collected, we shall be ready to build thereon the wider generalization which at present seems to escape us.

So far we have been applying an optical torque to previously polarized light, and producing a torsion of it. It remains for me yet to describe the means by which, in the hands of Prof. Abbe and Prof. Sohncke, it has been demonstrated that natural, non-polarized light is actually rotated when subjected to an optical torque.

The way of doing this is to make use of the principle of interference. Here is a slit from which a narrow beam of light-waves issues. At a point a little distance away is a Fresnel's biprism which splits up the light (without polarizing it) into two beams, just as if we had two slits or sources of light. These two beams pass along, and meet upon this distant screen, and give us—what? A set of interference fringes, having a bright line down the middle, because this part of the screen is exactly equidistant from the two sources of light.

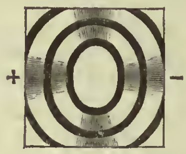

Fig. 20.

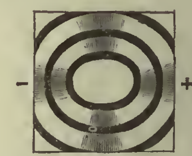

Fig. 21.

Fig. 22.

Fig. 23.

But these dark interference fringes that lie right and left can only exist because, in the first place, the vibrations have travelled unequal paths differing by an odd number of half wave-lengths; and secondly, because (owing to the method adopted of using two images of one slit) the phases of the emitted waves from the two sources are identical.

This being so, let us now introduce across the two interfering beams of light a special biquartz, made of right- and left-handed quartz of only 1·88 mm. thick. This will rotate—*if it rotates natural light at all*—the yellow light in one beam 45° to the right and that of the other beam 45° to the left. The angles will be a little more for green and blue, a little less for red and orange. Consequently we shall not get quite a perfect result for all kinds of colours. But for the main body of the light the result is this: that because the two beams have had their respective vibrations turned so that, whatever their primitive positions, they are now at right angles to one another, they cannot interfere. In other words, if it be true that the quartz rotates natural light, the interference bands will die out. [Experiment shown.]

Here I have the light passing through the biprism only, and giving us this narrow series of interference bands. You must notice carefully—with opera-glasses if you have them—the narrow bright and dark stripes. Now I shift this little diaphragm so that the light passes through the biquartz as well. Instead of sharp interference bands we have merely a dull line of nebulous light. The disappearance of the fringes proves that quartz does twist the not-previously-polarized waves of light.

That the magnetic field can also exert a magnetic torque on non-polarized light is readily proved, at least when one already has the biquartz. Two strips of heavy-glass of exactly equal length and similar quality, such as those I hold in my hand, must be introduced in the respective paths of the two beams: and one at least of them must be surrounded by a magnetizing coil. The biquartz has wiped out the interference fringes; but on magnetizing one of the two pieces of heavy-glass, or on magnetizing the two in opposite senses, the interference bands can be made to reappear. It is in this way that Prof. Sohncke's experiment—hardly suitable for a lecture theatre—was performed. It is in this way that we establish upon an experimental basis the fact that light itself, and not merely the plane of its polarization, experiences an optical torsion when subjected to those forces which, whether crystalline, molecular, or magnetic, exert upon it an optical torque.

BABYLONIAN ASTRONOMY.[1]

II.

THE year—that is, the period bringing back the recurrence of the seasons—is not a primitive means of dividing time, but the result of many observations. The simplest way of marking time is by seasons, and the system is still employed by some savage nations in Africa. A season does not correspond to one year, and more than one may be in a year; seasons, however, generally correspond to the year period. As to the division of the year, it must have varied according to the climate and region, but the simplest is by ten, as ten is the most common dividing number, and such was the one originally adopted by the Semites and Egyptians. This year of ten months, or rather ten parts, has left traces among the Semites and in classical authors. The Babylonians assimilated their first ten kings to the ten parts of the year. At Rome, we are told that the year before Numa Pompilius was composed of ten months only.

A year of ten lunar months is impossible, for after two or three of such periods it would no longer correspond with the seasons. We find, therefore, that the ten parts of the year were composed of thirty-six days distributed in four periods or weeks of nine days. This last division was not, however, official: the days of each of the ten divisions of the year were merely numbered from one to thirty-six; it was at a later date that the days received names from the protecting gods attributed to them.

It is to be noticed that in Egypt the months had no special names; the year was divided, after the reform of the calendar, into three seasons of four months of thirty days, called first, second, and so on, of the season to which they belonged. Popular names were attributed to them afterwards, taken from the religious festivals, but they do not appear in the texts before the Ptolemaic period. The like took place among the Semites: the months were called first, second, third, and so on, but were not distributed into seasons. It was only after the Akkadian invasion that the other names, Nisan, Tyyar, &c., were adopted, and the eighth month never lost its numerical name. In the astronomical omen tablets the primitive nomenclature by numerical order was often preserved.

It is still uncertain at what time the old calendar of ten divisions of thirty-six days was reformed into one of twelve months of thirty days. The change was due to the desire to measure the time by the appearance of the moon. This reform may be due to the influence of the Akkadians, who made the conquest of Babylon about 7000 B.C. These people had a lunar calendar composed of thirteen months of twenty-eight days, giving, therefore, a year of 364 days. It was no doubt more accurate than the Semitic calendar, but the Akkadians adopted their subjects' calendar. The deficiency with the normal solar year of 365 days was made up by means of a supplementary month placed irregularly by the priests when they thought it necessary. That is why we find various intercalary months, and why, in some cases, as late even as Nebuchadnezzar the Great, they occur in three successive years. To make up the deficiency the Babylonians had also a supplementary day called the "heavy 21st," which could be inserted in any month before the normal 21st. We find the mention of such supplementary days in several consecutive months.

The Akkadians, before invading Babylonia, divided their month into four parts or weeks of seven days each. This division had, however, nothing to do at first with the planets, to which the days were assimilated only at a later date. The Akkadians looked on the planets as evil spirits disturbing by their irregular motion the harmony of heaven; and, as evil spirits were the chief objects of their worship, they naturally attributed to each day of the week the name of a planet. When the Akkadians adopted the Semitic month of thirty days, the week of seven days was naturally abandoned in common use, but it was retained for religious purposes with some modification, a new series of four weeks commencing with each month. The Semites rejected the Akkadian names of the days of the week, though they preserved the symbolism attached to them, as is shown by the seven tablets buried under the foundation-stone of Khorsabad.

Our names of the days of the week are derived from the Akkadian assimilation of these days to the planets. There is no doubt as to the order in which the planets were assimilated to the names of the days, if we compare them with the colours of the walls of Ekbatana built by a Medic tribe, which preserved the primitive religion of the Akkadians, and also with the tablets of Khorsabad. The following table will show the correspondence:—

Names of the days and planets.	Colours of the walls of Ekbatana.	Materials of the tablets of Khorsabad.
1 Sunday (the Sun)...	Gold	Gold
2 Monday (the Moon)	Silver	Silver
3 Tuesday (Mars) ...	Orange	Copper
4 Wednesday (Mercury)	Blue	Tin
5 Thursday (Jupiter)	Red	Iron
6 Friday (Venus) ...	Black	Basalt
7 Saturday (Saturn)...	White	Limestone

Iron, corresponding to Thursday, or Jupiter, is represented by a red colour, no doubt on account of the rust, which is red. And we must not be surprised to see Venus represented symbolically by black, for Vesper or the Evening Star is really the *dusky*.

This proves that the week of seven days, which is found all over Asia and Europe, spread, not from Babylonia, but from the country whence came the Akkadians.

[1] Abstract of the second lecture delivered by Mr. G. Bertin at the British Museum. Continued from p. 237.

THE INSTITUTION OF MECHANICAL ENGINEERS.

THE summer meeting of this Institution was held in Paris last week under the presidency of Mr. Charles Cochrane.

The papers offered for reading and discussion were a description of the lifts in the Eiffel Tower, by Mr. A. Ansaloni, of Paris, supplemented by the results of working to date, communicated verbally by Mr. Gustave Eiffel, President of the Société des Ingénieurs Civils; the rationalization of Regnault's experiments on steam, by Mr. J. Macfarlane Gray; on warp-weaving and knitting without weft, by Mr. Arthur Paget; on gas-engines, with description of the Simplex engine, by Mr. E. Delamare-Deboutteville; on the compounding of locomotives burning petroleum refuse in Russia, by Mr. T. Urquhart; and description of a machine for making paper bags, by Mr. Job Duerden.

In the discussion of the first paper, which, as its title shows, was mainly technical in character, the interesting meteorological circumstance of the Eiffel Tower acting as a thunder-cloud discharger was referred to; clouds laden with electricity having passed quietly over the region of the tower, which previously and afterwards flashed with lightning. It was also pointed out that the perpendicularity of the building is not affected by temperature variations, nor by any wind pressure hitherto recorded.

We have not received a copy of the paper by Mr. Gray, who reserves the right of reproducing it, but from the syllabus of papers published by the Institution of Mechanical Engineers, it may be stated that Mr. Gray proposes a new unit of heat, which he compares with the ordinary water-unit, and a new diagram of energy, which he calls the Theta-phi ($\theta\ \phi$) or temperature-entropy diagram, a graphic representation of the Carnot-Clausius fundamental principle, of which the area shows heat-units, the co-ordinates being the temperature, θ, and entropy, ϕ. He compares Regnault's experimental steam-pressures with the pressures calculated by means of his formulæ, showing closer agreement than is obtained by Regnault's most accurate formulæ.

In Mr. Paget's paper the three chief methods of making fabric or cloth or tissue from yarns or threads, viz. ordinary weaving, knitting, and what the author calls warp-weaving, are referred to. The paper describes the method by which shaped goods can be made by warp-weaving, and the machine by which this is effected. The machine, which is of a very ingenious character, comprising several interesting points of construction and detail, is at work at the Paris Exhibition.

Mr. Deboutteville, in his paper, first reviews the gas-engines hitherto proposed or employed. He carries back his researches nearly a century, when the first gas-engine was proposed by Barber, and completes them with a description of the Simplex engine, which he brought out with Mr. Malandin in 1884. This engine is founded on principles laid down by Mr. Beau de Rochas—that, to realize the best results from the elastic force of gas, the cylinders should have the greatest capacity with the smallest circumferential surface, the speed should be as high as possible, the cut-off should be as early and the initial pressure as high as possible. In the author's engine the ignition is effected by a practically continuous electrical spark; the air and gas are mixed in an external receptacle fixed on the cover of the slide, and are drawn in through channels of varied forms so as intimately to mix them. The governors described act on the principle of totally cutting off the supply of gas for one or more strokes whenever an increase of speed occurs. From the tests made with this engine the consumption of gas is low, and it appears to compare favourably with good steam-engines as regards economy of application.

Besides the reading and discussion of papers, the members of the Institution visited the Exhibition, and various works which were opened for this purpose.

SCIENTIFIC SERIALS.

THE numbers of the *Journal of Botany* for June and July are chiefly devoted to articles interesting to students of systematic or geographical botany, especially that of our own islands; the latter number contains a biographical sketch of the late Prof. Reichenbach, by the editor.

THE most interesting article in the *Botanical Gazette* for May is the commencement of a detailed paper by Mr. C. Robertson, on the relations between insects and flowers in regard to American plants. The number for June contains original articles by Mr. H. L. Bolley, on sub-epidermal rusts, and by Mr. J. N. Rose, on the Achenia of *Coreopsis*.

THE *American Meteorological Journal* for May contains abstracts of the papers read at the meeting of the New England Meteorological Society on April 16:—In a paper on lightning and the electricity of the atmosphere, Mr. McAdie gave an account of some kite experiments at the Blue Hill Observatory, near Boston, in which the potential was determined at various heights. He also referred to the observations on the character of lightning at the top of Mount Washington during thunderstorms, and to the effect of the electrification of the air upon water, dust, and other particles in it, and to the possibility of foretelling the moment of a flash of lightning.—Prof. W. M. Davis made a report upon the investigation of the sea-breeze, undertaken in 1887, from observations at 100 stations. One fact shown was that the diurnal range of temperature, which is diminished on the coast by the action of the sea-breeze, is not lessened at the inland stations.—Mr. E. B. Weston read a paper on the practical value of self-recording rain-gauges, referring to the importance of knowing the hourly falls when constructing drainage systems.—Prof. H. A. Hazen continues the discussion upon anemometer comparisons, and upon the question of the probable effect of the momentum of heavy cups, when placed on a whirling machine. He considers that the Robinson anemometer is by far the best instrument ever devised for variable winds.—Lieut. Finley discusses the frequency of tornadoes in Illinois for fifty-four years, ending with 1888. The total number of storms was 141. The month of greatest frequency was May, no month being free from storms. The prevailing direction of movement was north-east.—Prof. Harrington communicates the instructions issued by the Chief Signal Officer for the preparation of forecasts and for their verification. The instructions contain nearly 200 regulations, and are very interesting to those who study weather predictions.
