The oil-bearing strata in Europe belong chiefly to the Tertiary or later geological epochs; so that it is conceivable that in these strata, or in those immediately below them, carboniferous deposits may exist and may be the sources of the oil; but in America and in Canada the oil-bearing sands are found in the Devonian and Silurian formations, which are either destitute of organic remains, or contain them in insignificant quantities. Yet if the immense masses of hydrocarbons have been produced by chemical changes in carboniferous beds, equally large masses of solid carboniferous remains must still exist; but of this there is absolutely no evidence, while cases occur in Pennsylvania where oil is obtained from the Devonian rocks underlying compact clay beds, on which rest coal-bearing strata. Had the oil been derived from the coal, it certainly would not have made its way downwards; much less would it have penetrated an impermeable stratum of clay. The conclusion arrived at is, that it is impossible to ascribe the formation of naphtha to chemical changes produced by heat and pressure in ancient organized remains.

One of the first indices to the solution of the question lies in the situation of the oil-bearing regions. They always occur in the neighbourhood of, and run parallel to, mountain ranges,—as, for example, in Pennsylvania, along the Alleghanies; in Russia, along the Caucasus. The crests of the ranges, formed originally of horizontal strata which had been forced up by internal pressure, must have been cracked and dislocated, the fissures widening outwards, while similar cracks must have been formed at the bases of the ranges; but the fissures would widen downwards, and would form channels and cavities into which naphtha, formed in the depths to which the fissures descended, would rise and manifest itself, especially in localities where the surface had been sufficiently lowered by denudation or otherwise.

It is in the lowest depths of these fissures that we must seek the laboratories in which the oil is formed; and once produced, it must inevitably rise to the surface, whether forced up by its own pent-up gases or vapours, or floated up by associated water. In some instances the oil penetrating or soaking through the surface layers loses its more volatile constituents by evaporation, and, in consequence, deposits of pitch, of carboniferous shales, and asphalte take place; in other cases, the oil, impregnating sands at a lower level, is often found under great pressure, and associated with forms of itself in a permanently gaseous state. This oil may be distributed widely according to the nature of the formations or the disturbances to which they have been subjected; but the presence of petroleum is not in any way connected with the geological age of the oil-bearing strata: it is simply the result of physical condition and of surface structure.

According to the views of Laplace, the planetary system has been formed from incandescent matter torn from the solar equatorial regions. In the first instance this matter formed a ring analogous to those which we now see surrounding Saturn, and consisted of all kinds of substances at a high temperature, and from this mass a sphere of vapours, of larger diameter than the earth now has, was gradually separated. The various vapours and gases which, diffused through each other, formed at first an atmosphere round an imaginary centre, gradually assumed the form of a liquid globe, and exerted pressures incomparably higher than those which we experience now at the base of our present atmosphere. According to Dalton's laws, gases, when diffused through each other, behave as if they were separate; hence the lighter gases would preponderate in the outer regions of the vaporous globe, while the heavier ones would accumulate to a larger extent at the central portion, and at the same time the gases circulating from the centre to the circumference would expand, perform work, would cool in consequence, and at some period would assume the liquid or even the solid state, just as we find the vapour of water diffused through our present atmosphere does now. That which is true of changes of physical condition, Henri Ste. Claire Deville, in his brilliant theory of dissociation, has shown to be equally true with respect to chemical changes; and the cooling of the vapours forming the earth while in its gaseous condition was necessarily accompanied by chemical combinations, which took place chiefly on the outer surface, where oxides of the metals were formed; and as these are generally less volatile than the metals themselves, they were precipitated on to what there then was of liquid or solid of the earth, in the form of metallic rain or snow, and were again probably decomposed, in part at least, to their vaporous condition. The necessary consequence of this action is that the inner regions of the earth must consist of substances the vapours of which have high specific densities and high molecular weights—that is to say, composed of elements having high atomic weights—and that the heavier elementary substances would collect nearer the centre, while the lighter ones would be found nearer the surface. Our knowledge of the earth's crust extends but to an insignificant distance; yet, as far as we do know it, we find that the arrangement above indicated prevails. Hydrogen, carbon, nitrogen, oxygen, sodium, magnesium, aluminium, silicon, phosphorus, sulphur, chlorine, potassium, calcium—substances whose atomic weights range from 1 to 40—became condensed, entered into every conceivable combination with each other, and produced substances the specific gravity of which averages about $2\frac{1}{2}$, never exceeds 4, and are found near the immediate surface of the globe.

But the mean specific gravity of the earth, as determined by Maskelyne, Cavendish, and others, certainly exceeds 5, and consequently the inner portion of our globe must be composed of substances heavier than those existing on the surface, and such substances are only to be found among the elements with high atomic weights. The question arises, What elements of this character are we likely to find in the depths of the earth? In the first place, since gases diffuse through each other, a certain proportion of the elements of high atomic weight will also be found on the surface of the earth. Secondly, the elements forming the bulk of the earth must be found in the atmosphere of the sun—if, indeed, the earth once formed part of its atmosphere; and of all the elements, iron, with a specific gravity exceeding 7, and with an atomic weight of 56, corresponds best with these requirements, for it is found in abundance on the surface of the earth; and the spectroscope has revealed the very marked presence of iron in the sun, where it must be partly in the fluid and partly in the gaseous state; and consequently iron in large masses must exist in the earth; so that the mean specific gravity of our planet may well be 5, the value which has been determined by independent means.

It is not easy, however, to define in what condition the mass of iron which must exist in the heart of the earth is likely to be. Iron is capable of forming a vast number of combinations, depending upon the relative proportion of the various elements present. Thus, in the blast-furnace, oxygen, carbon, nitrogen, calcium, silicon, and iron are associated, and produce, under the action of heat, besides various gases, a carburet of iron and slag, the latter containing chiefly silicon, calcium, and oxygen—that is to say, substances similar to those which form the bulk of the surface of the earth. But these same elements, if there be an excess of oxygen, will not yield any carburet of iron; and the same result will follow if there be a deficiency of silicon and calcium, because of the large proportion of oxygen which they appropriate. In the same way, during the cooling of the earth, if oxygen, carbon, and iron were associated, and if the carbon were in excess of the oxygen, the greater part of the carbon would escape in the gaseous state, while the remaining part would unite with the iron. It is certain that, in the heart of the earth, there must have been a deficiency of oxygen, because of its low specific gravity; and the argument is supported by the fact that free oxygen and its compounds with the lighter elements abound on the surface. Further, it must be presumed that much of the iron existing at great depths must be covered over and protected from oxygen by a coating of slag; so that, taking all these considerations into account, it is reasonable to conclude that deep down in the earth there exist large masses of iron in part at least in the metallic state or combined with carbon.

The above views receive considerable confirmation from the composition of meteoric matter, for it also forms a portion of the solar system, and originated, like the earth, from out of the solar atmosphere. Meteorites are most probably fragments of planets, and a large proportion of them include iron in their composition, often as carbides, in the same form as ordinary cast-iron—that is to say, a part of the carbon is free and a part is in chemical union with the iron. It has been shown, besides, that all basalts contain iron, and basalts are nothing more than lavas forced by volcanic eruptions from the heart of the earth to its surface. The same causes may have led to the existence of combinations of carbon with other metals.

The process of the formation of petroleum seems to be the following:—It is generally admitted that the crust of the earth is very thin in comparison with the diameter of the latter, and that this crust incloses soft or fluid substances, among which the carbides of iron and of other metals find a place. When, in consequence of cooling or some other cause, a fissure takes place through which a mountain range is protruded, the crust of the earth is bent, fissures are formed; or, at any rate, the continuity of the rocky layers is disturbed, and they are rendered more or less porous, so that surface waters are able to make their way deep into the bowels of the earth, and to reach occasionally the heated deposits of metallic carbides, which may exist either in a separated condition or blended with other matter. Under such circumstances it is easy to see what must take place. Iron, or whatever other metal may be present, forms an oxide with the oxygen of the water; hydrogen is either set free, or combines with the carbon which was associated with the metal, and becomes a volatile substance—that is, naphtha. The water which had penetrated down to the incandescent mass is changed into steam, a portion of which finds its way through the porous substances with which the fissures are filled, and carries with it the vapours of the newly formed hydrocarbons, and this mixture of vapours is condensed wholly or in part as soon as it reaches the cooler strata. The chemical composition of the hydrocarbons produced will depend upon the conditions of temperature and pressure under which they are formed. It is obvious that these may vary between very wide limits, and hence it is that mineral oils, mineral pitch, ozokerit, and similar products, differ so greatly from each other in the relative proportions of hydrogen and carbon. I may mention that artificial petroleum has been frequently prepared by a process analogous to that described above.

Such is the theory of the distinguished philosopher, who has framed it, not alone upon his wide chemical knowledge, but also upon the practical experience derived from visiting officially the principal oil-producing districts of Europe and America, from discussing the subject with able men deeply interested in the oil industry, and of collecting all the available literature on the subject. It is needless to remark that Dr. Mendeleeff's views are not shared by every competent authority; nevertheless the remarkable permanence of oil-wells, the apparently inexhaustible evolution of hydrocarbon gases in certain regions, almost force one to believe that the hydrocarbon products must be forming as fast as they are consumed, that there is little danger of th demand ever exceeding the supply, and that there is every prospect of oil being found in almost every portion of the surface of the earth, especially in the vicinity of great geological disturbances. Improved methods of boring wells will enable greate depths to be reached; and it should be remembered that, apar from the cost of sinking a deep well, there is no extra expens in working at great depths, because the oil generally rises to th surface or near it. The extraordinary pressures, amounting t 300 pounds per square inch, which have been measured in som wells seem to me to yield conclusive evidence of the impermea bility of the strata from under which the oil has been forced up and tend to confirm the view that it must have been forme in regions far below any which could have contained organi remains.

The weights and measures in use in this country are a sourc of considerable trouble and confusion. Besides the imperi measures, which are complicated enough, a great number local units are in use, so that unwary strangers are not unfre quently deceived, or, at any rate, if they hope to escape fro mistakes, have to apply themselves to the study of local custom In the scientific world, again, the metric system is now almo exclusively used, and the same may be said of engineers an manufacturers who have to do with foreign countries in whic French measures are in vogue. The same difficulty surroun the measurement of the power of motors. The unit of power indeed, from the nature of the case, common to the who world—it is unit of weight multiplied by unit of height—and with us the foot-pound, or 33,000 times the foot-pound, is generally accepted; but the difficulty lies in determining how the measure is to be applied. Thus, in the case of a water-motor, should the power be calculated by the energy latent in the falling water, or in the actual work given off by the motor? In heat-engines we have to deal with many variables. There is the initial pressure of the working agent, the terminal pressure, the length of stroke, the number of revolutions per minute, the indicated power in the cylinder, the effective power given off, and the adequacy of the means of supplying the working agent. In the early days of steam, when pressures were pretty uniform, and speed bore a certain relation to the stroke, the diameter of a cylinder was a tolerably close index to the power of the engine, and such simple rules as "10 circular inches to the horse-power," which prevailed among agricultural engineers, were tolerably intelligible. But in these days, when pressures, speeds, and rates of expansion vary so greatly, the size of the cylinder, or cylinders, is no longer a guide, and I imagine that most manufacturers have ceased to class their engines by their nominal horse-power. The problem is pretty simple in the case of pumping-engines, for there the nominal power may be taken, as it is in Holland, to be the actual work performed upon the water, and perhaps a similar rule might apply to motors driving dynamos, but for most other purposes no simple law is possible. In my own practice I have, for many years, been in the habit of classing engines by their indicated horse-power per one revolution for every probable initial pressure, below the maximum one for which the engines were designed, and for various rates of expansion. To facilitate the calculations I use curves which give the theoretical horse-power, on the supposition that steam expands according to Boyle's law, for 10,000 cubic inches of steam measured at the moment of exhaust, which is, in fact, the volume of the cylinder in single-cylinder engines, and the volume of the last cylinder in compounds. These curves are calculated for initial pressures rising by 25 pounds, and, in non-condensing engines, for the extreme range of expansion possible, and to fourteen expansions in condensing engines. The true indicated horse-power ranges from 80 per cent. to 85 per cent. of the theoretical, as above stated, the precise percentage depending upon the construction of the engine. As large engines are now almost always compound, the size of the cylinders is no guide to the lay mind; hence, in answering inquiries, it is necessary by some means to get at the actual horse-power expected and to settle the initial pressure, for on this point there is still much timidity among steam-users, so that the engine-builder has to adapt himself in this and other particulars to the needs or prejudices of his customer.

In marine engines, again, the difficulty is still greater, because the only measure of the effective power of the engines is the speed of the ship under given conditions of immersion. But the resistance of ships is a complicated matter, not perfectly ascertained yet, so that the speed attained in any new combination of engines and hull is by no means a certainty; hence some recognized measure of the power of a marine engine, depending only on the measurement of the cylinders and boilers, becomes very desirable.

So strongly has the want of a standard horse-power been felt by shipbuilders and marine engine makers, that the Council of the North-East Coast Institution of Engineers and Shipbuilders appointed a Committee to investigate the subject, and to devise, if possible, a set of rules which would be generally acceptable. The Committee made its report in the spring of 1888. They took as their basis the indicated horse-power, under certain normal conditions, and propose to call this the normal indicated horse-power (N.I.H.P.). The normal conditions are, briefly, the following:—

(1) That the steam, of whatever boiler pressure, is expanded to the same terminal pressure.

(2) That the expansion is effected by all engines with the same degree of efficiency.

(3) That the piston speeds of engines of different lengths of stroke are proportional to the cube root of their respective strokes, and, further, that the actual loaded trial-trip value of piston-speed may be taken as 144 times the cube root of the stroke in inches ($144 \sqrt[3]{S''}$).

(4) That in cases in which the engines and boilers bear to each other such proportions as to prevent condition (1) from being fulfilled without thereby violating condition (3) the coal consumption per I.H.P. will not be affected, but will be constant for the same boiler-pressure.

(5) That the boilers are constructed in accordance with what will be generally recognized as the average practice of the present day in respect of the allowance of steam room in relation to power, the diameter, area, and pitch of tubes, the relation of grate to heating surface, and the area of uptakes and funnel; that average natural chimney draught is used, or, if forced draught be employed, that it does not exceed the natural draught; that the horse-power is proportional to the heating surface (H), and to the cube root of the pressure ($\sqrt[3]{P}$); and, further, that the actual loaded trial-trip horse-power may be taken as equal to one-sixteenth of the heating surface multiplied by the cube root of the pressure $\frac{(H \sqrt[3]{P})}{16}$.

(6) That the efficiency of the engine mechanism is constant, and that the propeller is such as to secure that the engines will utilize the boiler power referred to in condition (5) in the manner prescribed by conditions (3) and (4).

Subject to these conditions the normal indicated horse-power is found by multiplying the square of the diameter of the low-pressure cylinder in inches by the cube root of the stroke in inches, adding to the product three times the heating surface of the boiler in square feet, multiplying the sum by the cube root of the pressure, and dividing the product by 100.

$$\text{N.I.H.P.} = \frac{(D^2 \sqrt[3]{S} + 3H) \sqrt[3]{P}}{100}.$$

It is evident from this formula, and from the conditions, that account is taken of all the variables, and that the boiler is regarded as an integral part of the engine. The report gives several useful formulæ deduced from the above. Whether the expressions given are the most convenient possible for general marine practice or not, I am not competent to say; but it seems to me that a step has been taken in the right direction in the attempt which has been made to measure marine engines by some rational standard. The members of the Committee were all thoroughly practical as well as scientific men; they determined their constants by reference to a large number of successful cases; and I sincerely hope that the question will be pursued by the marine engine builders on the west coast, and by the constructors of land engines. As engineer to the Royal Agricultural Society, I have frequently had to define the power of engines entered for competition for the Society's prizes, and I have experienced the greatest difficulty in laying down rules for the guidance of intending competitors, being fearful, on the one hand, of restricting originality, and, on the other, of admitting engines of greatly varying powers.

I have expressed an opinion that the numerous engineering Societies which exist at this day have it in their power to promote the advancement of mechanical science in a notable manner by appointing Research Committees, or by aiding individual investigations from their abundant means. The North-East Coast Institution of Engineers and Shipbuilders has done good service in their endeavours to establish a practical measure of the power of marine engines, while the Institution of Mechanical Engineers has, for the last ten years, been steadily promoting researches of an eminently practical nature. Their expenditure has reached the handsome sum of £1700, and their Proceedings have been enriched with Reports on the hardening, tempering, and annealing of steel, on the form of riveted joints, on friction at high velocities, on marine-engine trials, and on the value of the steam jacket. The names of those who are acting on these Committees are a guarantee that the investigations conducted by them will rank among the classical works of the profession, and will abundantly justify the liberal expenditure which has been incurred.

It is impossible to conclude the address which I have had the honour of delivering, without an allusion to the most important structure which engineering skill and enterprise has ever attempted. The Forth Bridge is rapidly approaching completion, and on Saturday, September 14, Mr. Baker is to deliver a lecture, in which he will, no doubt, tell us when the great work is likely to be completed. I think that the members of this Section belong sufficiently to the "working classes" to have a claim to admission to the lecture, and to hear from the lips of the creator of the bridge the story of its inception, of its progress, and his hopes as to its completion.

NOTES.

THE International Congress of Astronomy commenced its sittings in Brussels on the 10th inst., under the presidency of M. Hugo Gyldén, Director of the Observatory of Stockholm. Among the English members are Mr. Downing, of the Greenwich Observatory, and Mr. Ranyard, of London. The Minister of Railways welcomed the Congress in the name of the Belgian Government. Munich has been fixed as the place for the next meeting.

INFORMATION has come from the United States of terrible wind and rain storms on the 10th, 11th, and 12th inst., all along the North Atlantic coast, doing immense damage. Coincidently with this came the report of serious internal disturbances in the Yellowstone region, putting the entire geyser system in a violent outbreak. Several long dormant geysers are in a state of furious activity.

A CIRCULAR from the Local Government Board to all the District Boards and Vestries in the Metropolis, an order prescribing a form of notification for use by medical practitioners, and a memorandum for their guidance, have been issued, under the provisions of the Infectious Disease (Notification) Act, 1889. The Act comes into force in the Metropolis on October 30.

THE subject for the Sedgwick Prize Essay at Cambridge to be awarded in 1892 is "On Fossil Plants as Tests of Climatic Conditions." The prize is open to all graduates of the University of Cambridge who shall have resided sixty days during the twelve months preceding October 1, 1891. The essays must be sent to the Registrary of the University on or before October 1, 1891, each bearing some motto and accompanied by a sealed paper bearing the same motto and inclosing the name and College of the candidate.

WE have received from Reykjavik a copy of the rules of a Society just established there, under the presidentship of Prof. B. Gröndal, called the Icelandic Naturalists' Society, the chief aim of which is to found a museum of natural history for Iceland, to be the property of the country. For this purpose it is not only intended to collect specimens of the fauna, flora, and mineral deposits of Iceland, but also to obtain by exchange, or in any other convenient manner, specimens from abroad.

THE *Times of India* reports that a meteorological observatory is to be established at Perim, at the Aden entrance to the Red Sea.

THE annual examination, held under the direction of the State Medicine Syndicate, from the result of which diplomas in public health are granted, will commence at Cambridge on Tuesday, October 1. Any person whose name is on the Medical Register of the United Kingdom may present himself, provided that he is in his twenty-fourth year at least when he presents himself for the first part of the examination, and has attained twenty-four years of age when he presents himself for the second part. The examination in each part occupies two days, and is oral and practical as well as in writing. Candidates may present themselves in either part separately or for both together at their option, but the result of the examination in the case of any candidate will not be published until he has passed both parts. Every candidate who has passed both parts receives a diploma testifying to his competent knowledge of what is required for the duties of a medical officer of health. All applications for admission to the examination, or for information respecting it, should be addressed without delay to Dr. Anningson, Barton Road, Cambridge.

THE additions to the Zoological Society's Gardens during the past week include a Crested Porcupine (*Hystrix cristata*) from India, two Nicobar Pigeons (*Calœnas nicobarica*) from the Indian Archipelago, two Rose-crested Cockatoos (*Cacatua moluccensis*) from Moluccas, a Fork-tailed Jungle Fowl (*Gallus varius* ♂) from Java, presented by Mr. Charles Clifton, F.Z.S.; a Sinaitic Ibex (*Capra sinaitica* ♂) from the Erba Mountains, Suakin, presented by Sir James Anderson; a Zorilla (——) from Suakin, presented by Captain W. W. Bevant; a Vinous Fruit Pigeon (*Carpophaga rufigula*) from the Solomon Islands, presented by Mr. C. M. Woodford; a Wood Owl (*Syrnium aluco*), British, presented by Major Vilett Rolleston, F.Z.S.; an Osprey (*Sandion haliaetus*), European, purchased; a Vulpine Phalanger (*Phalangista vulpina*), born in the Gardens.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1889 *SEPTEMBER* 22–28.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on September 22

Sun rises, 5h. 48m.; souths, 11h. 52m. 33·4s.; daily decrease of southing, 20·8s.; sets, 17h. 57m.: right asc. on meridian, 11h. 58·7m.; decl. 0° 9′ N. Sidereal Time at Sunset, 18h. 4m.

Moon (New on September 25, 3h.) rises, 2h. 13m.; souths, 9h. 57m.; sets, 17h. 27m.: right asc. on meridian, 10h. 2·9m.; decl. 16° 0′ N.

THURSDAY, SEPTEMBER 26, 1889.

THE TERTIARY FLORA OF AUSTRALIA.

Contributions to the Tertiary Flora of Australia. By C. von Ettingshausen. Memoirs of the Geological Survey of New South Wales. (Sydney: Charles Potter, 1888.)

THE work consists of translations from the German originals of two memoirs, published respectively in 1883 and 1886, with explanatory notes on the geology by the Survey officers. Ettingshausen's contribution consists of about 170 pages of "exact determinations of fossils" and a few pages of theoretical considerations and tabulated lists. In these we are informed that the "Tertiary floras" formed one universal flora, which spread over all lands outside the tropics, and "that in this flora all the elements of the different floras of the world are found combined" (p. 3). The "Tertiary period," from this point of view, consists of sub-periods of uniform conditions, susceptible of exact classification and correlation, with an orderly beginning and definite close. From another point of view it is a period of the world's history, so stupendous, so broken and diversified, that we can never hope to reconstruct a complete history from its imperfect records, and to marshal its secrets into exact order. Embraced in its vast folds are sediments, perhaps coæval with our chalk, beginning when much that is now land was the abyssal depths of ocean, and enduring while continents and seas slowly changed their places. Its episodes were the joining hands of widely severed lands and the parting of them again asunder into isolated tracts, until at last it saw the existing continents settling into their present form. So enormous was its duration, that its "newer" periods sufficed to raise and scarp the loftiest mountain ranges of the world; and its close to submerge and re-elevate again and again, to trim, alter, and finally cut into separate islands the insignificant portion of the globe we inhabit as Great Britain. During all which time, floras as distinctive as any of those now existing were swayed hither and thither by the changing climatic conditions accompanying the oscillations of land and water—here picking up recruits on their passage, and there deserted by the worn out; here coalescing with distinct hosts who struggled and thinned, or swelled, each other's ranks, and there dwindling in numbers as stations or habitats became submerged and broken up. As well might we try to arrive at a complete history of the feuds and migrations of Palæolithic man, as of the floras of the "Tertiary period," for at most each country can but contribute a few isolated facts regarding the floras that have passed over it. Thus, though we possess a broken record in the Isle of Wight of 3000 feet of Tertiaries, mostly deposited under conditions extremely favourable to the preservation of plants, this has, in the island, yielded an adequate idea of its forest vegetation for about 6 inches of its thickness. Nevertheless, remains of floras are repeatedly sandwiched in our Eocenes. These begin abruptly, with nothing leading up to them; and if we go to Ireland and Scotland we can supplement them with other 3000 feet of volcanic rocks with still older floras sandwiched among them, but affording no beginning to the "Tertiary formation." And our series ends abruptly, leaving an enormous gap of most critical time unrepresented between Oligocene and Pliocene, yet having revealed flora after flora as utterly distinct from each other as those of the antipodes, and with scarce any elements in common. Thus, however such conditions may have obtained in Carboniferous times, this theory of a uniform flora or fauna spreading, during the Tertiaries, over both hemispheres, from the limits of vegetation to the confines of the tropics, is altogether outside practical science, and simply leads to affinities being discovered between imperfectly preserved common types of vegetable organisms, where none such perhaps exist.

With regard to the 170 pages of "exact determinations of fossils," though no species-makers are so prolific as palæo-phytologists, our author certainly bids fair to beat the record, for *sp. nov.* is attached to as many of the fragments as the limits of the collection would well allow. The three ferns and three monocotyledons are negative, if unsatisfactory, but there would have been one less belonging "undoubtedly to the Monocotyledones," had not a stray Carboniferous specimen been included in the consignment. The single Cycad is a *sp. nov.*, bearing "a remarkable and specific relation" to a North Greenland fossil. The Coniferæ are determined on very poor material, but most are considered as at least allied to Australian forms; yet *Sequoia* is imported when the native *Athrotaxis* would better meet the case. A new genus, *Heterocladiscos*, is actually founded on some insignificant cupressineous foliage only, and another, *Pseudopinus*, is certainly curious if its supposed fruits are cones and not catkins. Of the some 150 new dicotyledons, the vast bulk would be classed as indeterminable fragments by any reasonably cautious palæontologist. The less characterized of these figure as the exotics to Australia, whilst the most satisfactory are found among the Proteaceæ and other Australian forms as *Boronia*, *Eucalyptus*, species of *Piper*, *Ceratopetalum*, &c. Many of the species are founded on single fragments, sometimes without base or tip, and unless the plates do them injustice, with scarcely any visible venation or character.

We cannot judge of the difficulties of collecting, but it certainly appears that if it is worth while to publish anything on fossil plants at the Government expense, it would be worth while to gather proper material for it. When broken specimens of leaves are obtainable, entire ones can as a rule be extracted, and when these are to hand, though exotic genera may well have flourished in Australia as in Europe in bygone ages, it will be surprising if more of them cannot be matched with plants nearer their own home.

J. STARKIE GARDNER.

OUR BOOK SHELF.

Useful Rules and Tables. By William J. M. Rankine. Seventh Edition, revised by W. J. Millar, C.E. (London: C. Griffin and Co., 1889.)

THIS is the seventh edition of a work which at the present day is almost indispensable to engineers in general. The increase and development of mathematics, year by year, and also the greater tendency towards accurate results, call for a book containing all the various rules and tables relating to those parts of mathematical and mechanical science whose application most frequently occurs in the useful arts, and especially in engineering and practical mechanics. In this volume of moderate bulk, such a work has been provided. The use of algebraical symbols has been avoided as much as possible, excepting in those cases in which the rules cannot be clearly expressed without them.

The book is divided into ten parts. The first deals with arithmetic and mensuration, including tables of cubes, squares, logarithms, a summary of the rules in trigonometry, with tables of arcs, sines, &c., concluding with the measurement of areas of surfaces, volumes of solids, and lengths of curves, &c. Part 2 treats of the measures of different nations, with tables and rules relating not only to measures of angles, time, length, surface, &c., but to those of speed, heaviness, pressure, work power, &c. Engineering geodesy, distributive forces and mechanical centres, balance and stability of structures, and strength of materials are included in the next four parts. Part 7 relates to machines in general, and gives rules for the comparison of the motions of different parts of a machine, and for the designing of teeth of wheels, speed cones, &c., with rules relating to work at uniform and variable speed. Parts 8 and 9 treat of hydraulics and heat, together with the steam-engine. The former includes rules for flow of water, prime movers, propulsion of vessels, &c.; the latter consists of tables of elasticity, volume, and specific heat of gases, factors of evaporation, with rules relating to furnaces, boilers, expenditure of heat in cylinders, efficiency of strain, &c.

Part 10, written by Andrew Jamieson, has been revised and considerably extended, and consists of electrical rules, tables, and formulæ. The information has been brought up to date as much as possible, and many points of difficulty, such as directions of currents, magnetic force and motion, are made clear by means of illustrations. Electrical engineering symbols and units of measurement, heat, and light are first given. These are followed by various forms of Wheatstone bridges, apparatus for testing electric light cables, the wire-testing batteries on the General Post Office system, tables of resistance, general data of the different submarine cables and batteries.

In the appendix there is a useful diagram of the mechanical properties of steam, showing the absolute pressure in pounds per square inch, and volumes in cubic feet per pound of dry saturated steam, and the mean absolute pressure, in decimal parts of absolute pressure of admission. A complete index adds greatly to the value of the work; and we may say that the more one looks through the pages of the book the more one is struck by the large amount of useful information collected together in these 456 pages.

Colour. By C. T. Whitmell. (Cardiff: Wm. Lewis, 1888.)

THIS book is designed for the general reader, and is, on the whole, well suited to this class of person. The principal drawback it possesses is unquestionably the want of a good index, while the division into short numbered sections of in many cases a few lines only is very inconvenient, and produces a sensation of discontinuity of subject. Some parts are excellently done, notably the illustrations given of irregular reflection by turbid media, the description of colour produced by absorption, and the part dealing with colour-blindness. In connection with this last subject much extension of our knowledge would no doubt result from systematic observation of the progressive development of colour-blindness in cases of locomotor ataxy.

It is to be regretted that the author did not supply coloured diagrams to at least some of the sections, or failing this it would be more suggestive in the diagrams of light transmitted through different specimens of coloured glass to shade the part representing the absorbed and to leave unshaded that representing the transmitted light. Some preliminary description of the optical apparatus employed would be also serviceable, *e.g.* in section 10 the reader is told the properties of a spectrum produced by a diffraction grating, no reference being made until much later, and then a very incomplete one, as to the principle involved in the formation of the spectrum.

The book is fairly up to date, containing as it does reference to Langley's bolometric observations and to König's researches on the theory of colour vision. Interesting cases are given of errors due to ignorance of scientific principles; and in view of the frequency of their occurrence—perhaps more noticeably from neglect of the effects of refraction than of the principles of colour—it is regrettable that manuals such as Church's, Rood's, or this, are not more generally read by painters.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Sailing Flight of Large Birds over Land.

IT gave me great pleasure to see, by Lord Rayleigh's letter in NATURE of May 9 (p. 34), that the remarks made by me some months ago on this subject were not made in vain.

Ever since 1863, the sailing flight of large birds (which is here very common) has been a subject of observation to me, and odd notes have been sent home to the *English Mechanic* and to the Aëronautical Society (see Sixteenth Report, 1881, pp. 10-17).

Mr. A. Baines, in NATURE of May 2 (p. 9), well describes the sustained sailing of the albatross, indicating what I take to be the *vera causa, i.e.* the rising, kite-like, when it sweeps round to meet the wind, the energy of motion being gained by descending *with it* along an incline. But this problem, as seen among the sea-birds, seems to be complicated by the possibility of lifting action due to the waves; and, in Mr. Baines's letter, by different velocities of the air near the sea surface and at elevations of 20 feet or so. Out here, these two features are not only eliminated, but we see the bird doing more work.

The sea-birds merely sustain for hours a given weight, say twenty pounds, without flapping the wings, whereas the land-birds lift this twenty pounds, in two or three hours, to a height of 1 or 2 miles vertically, as well.

The adjutants (*Leptotilus argala* and *nudifrons*), the cyrus, pelican, vultures of several kinds, and storks, habitually rise here during fine weather, if there is a wind. At first they rise by flapping the wings vigorously, and, when 200 or 300 feet up, gradually begin to sail in huge right- or left-hand spirals, rising 30 or 40 feet at each lap. When seen thus, the wings are rigidly extended, and tail spread, the primary wing-feathers distinctly separated, and a loud musical tone is heard as the bird sweeps round and round overhead. If low down, they can be closely studied through a binocular, but if at a great height, I generally use a telescope, 3″·5 O.G., and terrestrial eye-piece, power 40. With this latter I can follow them, either in a group or singly, until each is a mere speck, and the elevation can be fairly calculated, when the spread of wing is often 8 or 9 feet × 1½.

Our prevailing north-east wind, and also our south-west monsoon, are particularly steady air-drifts of, say, 5 or 6 to 10 miles per hour, and I should doubt very much, if, after 500 feet up, there is any variation in the speed at different heights. The lifting due to occasional waves should also here be out of the question, and under these conditions I would ask Lord Rayleigh where we could possibly obtain the "energy of position" if it is not from the kite-like action? In my former note, to which he refers, I think a small diagram illustrated the slow drift to leeward as the bird rose by sailing in spirals.

I should say, perhaps, that the birds maintain the kite-like incline, *all round the windward portion* of the spiral, thus 
and appear to gain elevation in sweeping round while thus at an angle; at first facing the breeze, and as they sweep round being side on, as per diagram, the centrifugal element coming into play. If very low down, indeed, the bird can be seen to rise distinctly as it wheels round the windward edge of the curve, and reaches its greatest elevation just as it turns tail to wind. Then it seems to shoot along down a slight incline with wings horizontal, and in rounding the leeward part of the spiral, the outer wing is again spiral, thus . The speed of the bird so greatly exceeding that of the wind, renders this necessary to enable it to turn.

Viewed from below, the tracks look circular, and often vary in size a good deal.

In all cases, so far as I have seen, these birds when rising, as they sail round and round, make leeway, say a mile for every 1000 feet rise, or less.

They never rise on a straight course, though they often descend in a straight line, and, after a time, flocks that drift over the hills recover their position over the plains by descending to windward.

But in all these cases of land-birds rising steadily as they sail round and round, there is no possibility of lifting by waves, as at sea, nor yet differences in the *speed of air strata* every 20 feet or so, as they sail at all heights, from 500 feet up to 10,000 or more.

The problem is much more clearly seen, and more wonderful, than in the case of the albatross, and, as far as I can see, the explanation which I gave years ago is the only one feasible. The momentum gained in descending a given distance *with the wind* is expended in lifting the bird kite-like as it turns and *faces* the wind, on the shorter windward course, where also a certain amount of centrifugal reaction comes into play and does some of the *work*.

Bishop's Ring and Allied Phenomena.

Is there any connection between the sunset glows seen by Mr. S. E. Bishop in the Sandwich Islands (see p. 415) and the phenomena which have occurred lately in Western Europe? There has been for two months a feeble reappearance of a great corona round the sun. I do not know whether I can call it Bishop's ring, as it has generally been larger than that caused by the Krakatão dust, and also more dirty-looking in colour, and doubtless at a lower level. Bishop's ring itself had never altogether ceased to be visible about sunset and sunrise, but I had not certainly seen it at any time when the sun has had a considerable altitude for nearly two years, and then only in the clear Alpine air. On May 14 and August 26, 1888, there was indeed a great corona, but on the latter occasion the air was not very clear, so I concluded it probably had some other cause than volcanic dust; and there have been a few other occasions before that when I have had the same impression. On May 14, 1888, it is also questionable whether the circle was caused by volcanic dust.

The present corona appeared all at once on June 30 last, while I was at Macugnaga, at the foot of Monte Rosa; and since that date, both travelling in the Alps and here (since I came home on August 8) it has continued more or less visible at all times of the day when not obscured by mist or smoke, except from the afternoon of July 1 until the afternoon of the 2nd. It is plainest about sunset. It first appeared on cloudy streaks like very thin indefinite cirrus, but these disappeared during July 1. Since it appeared the sky has never been such a pure blue as it was before; this applies to all altitudes from sea-level to 10,000 feet.

I have not seen any remarkable sunset phenomena, so that it seems difficult to connect this circle with the phenomena noticed by Mr. Bishop a fortnight later than this commenced; still the connection is not impossible, as he mentions seeing the central (and by far the brightest) part of the corona.

Although it is improbable that the dust of Krakatão can have entirely settled to the ground, the above description will show that the present phenomenon can hardly be caused by it; but there must be a very extensive diffusion of some kind of dust—it may be one of the kinds alluded to by Prof. Tyndall and others in the discussion which occurred in your pages last year.

Sunderland, September 21. T. W. BACKHOUSE.

OBSERVATIONS OF TWILIGHT AND ZODIACAL LIGHT DURING THE TOTAL ECLIPSE OF THE SUN, DECEMBER 21, 1889.

THE attention of all friends of astronomy and meteorology, and especially of navigators on the ocean, and of meteorological observers in India and Mexico, is respectfully called to the fact that they may make valuable observations during the coming total eclipse of the sun. The observations referred to are of a most elementary character, and pertain to the phenomena of twilight and of the zodiacal light. The importance of the observations to be described was first appreciated by German meteorologists, and the following paragraphs are based upon suggestions made by Prof. Bezold and Dr. Zenker, of Berlin.

On December 22, 1889, at 47 minutes before noon, Greenwich time (which corresponds with 6 hours and 13 minutes a.m. of standard Eastern time) our globe becomes tangent to the long cone that constitutes the shadow of total darkness behind the moon, and we say that "totality has begun on the earth"; this occurs at a point in the Caribbean Sea, north of Venezuela, at about 15° N. lat. and 72½° W. long. In about three hours and a quarter this zone of total eclipse has passed the earth; its last point of contact, or tangency, occurs at a point on the eastern coast of Africa at about 5½° N. lat. and 49° E. long. The path of totality on the earth's surface between these two limits is a narrow belt, about 100 miles broad, and astronomers will station themselves at favourable localities in order to observe the phenomena visible immediately around the sun, but meteorologists and local amateurs residing entirely outside the path of totality can also do good work.

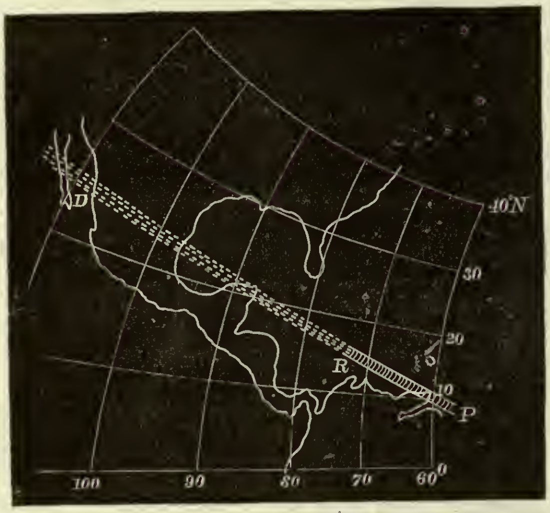
The accompanying diagrams, I., II., III., IV., will illustrate the conditions of the eclipse and the nature of the meteorological observations desired to be made. Thus in diagram I. we see the point R, or the locality where the totality begins to an observer on the earth; at that point the sun rises while it is totally eclipsed, and the band from R to P shows the path of the shadow as it flies eastward. Diagram II. takes up the path at its other end, and shows it still moving eastward from P towards S, where it finally leaves the earth, so that an observer at S sees the sun in his western horizon, but totally eclipsed as it is setting out of sight.

If we now imagine a vertical plane passing through the observer and the eclipsed sun, it will give us a section of the earth, its atmosphere, and the cone of darkness very much as shown in diagrams II. and IV. In diagram II. R represents, as before, the locality where the sun rises eclipsed, the moon is to the east of the observer, and the cone of darkness passes over him towards its apex, which is far off towards the west. Those who are located to the west of R, as at D, looking eastward, cannot see the sun because it is below their horizon; they can see only the light of the morning dawn where the sun is about to rise, but these observers, if they look directly toward the brightest part of the dawn, immediately over the sun, will, on this morning of December 22, find that they are looking right into the shadow of the cone, and will therefore observe that the light of the dawn is for a few minutes much feebler than usual.

Similarly diagram IV. shows the condition of things at the point S, where the observer at sunset has the cone of darkness imediately above him; observers to the east of his location, as at T, will be enjoying twilight, and as they look toward the west, immediately above the sun, they will be looking into the cone of darkness, and will find the twilight correspondingly diminished.

The distance from K to D in Fig. 1, and from S to T in diagram II., represents about 35° or 40° of the great circle, or over 2000 miles on the earth's surface; all persons located in this immense region—namely, all on vessels in the Caribbean Sea and Gulf of Mexico, the Arabian Sea—and all meteorological observers in Northern Mexico, Yucatan, Jamaica, and Western India, should be on the watch for phenomena of the following kind:—

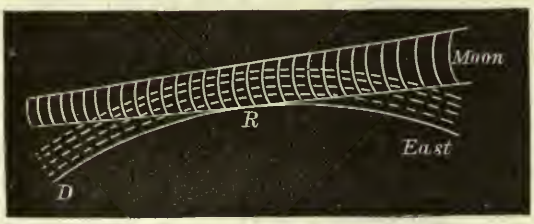
(1) Note when the moon's shadow becomes first or last



I.

visible by the darkness of the high cirrus, haze, or the tops of cumulus clouds or the tops of mountains.

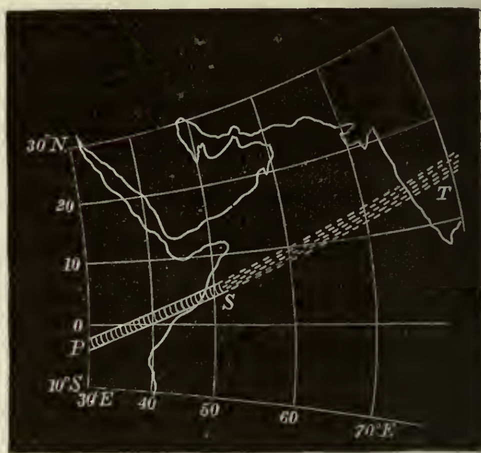
(2) When the darkness is at its maximum, its boundary appears as a curved band of colours convex to the horizon, disturbing the otherwise horizontal arrangement of the illumination that constitutes the dawn or twilight. Note the angular distance of this boundary above the horizon at several points to the right and left of the sun. Note also the colours and their arrangement, both in the twilight proper and in the shaded portions. Note especially how far to the right or left the disturbance of the twilight



II.

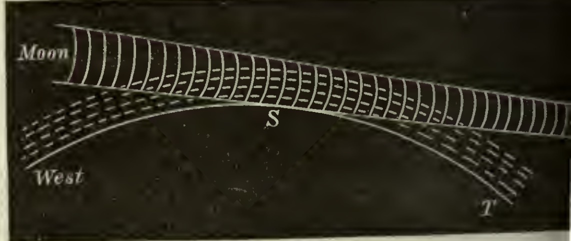
or dawn appears to extend. By distance, of course, is meant apparent angular distance; but if the observer is so located that distant mountain-tops are visible, he should note whether they also show any phenomena due to the moon's shadow.

(3) Owing to the fact that the observers at D and T are looking through a portion of atmosphere that does not receive its ordinary amount of light from the sun, they will be able to see objects that ordinarily would be hidden by the glare of twilight, such as fainter stars, and especially the Milky Way, and the zodiacal light. The latter object is one of special interest. It is desirable that observers should carefully record the appearance of zodiacal light for several days before and after the eclipse, as also on the 22nd itself, in order that we may distinguish between local atmospheric effects and those due to the eclipse. During the morning dawn in the region R D, and during the twilight S T, one should observe that the zodiacal light attains an unusual brilliancy and extent; the points to be noted are, first, how much further up from the horizon, or from the sun, is the beam of zodiacal light visible during the few minutes when the cone of shadow comes between it and the observer;



III.

again, how much nearer down toward the sun does it extend; and, again, how much broader is it toward the right and left? Does its colour appear changed? Sometimes several portions of the zodiacal light appear brighter than the neighbouring regions, therefore observe whether, as seen through the conical shadow, these differences disappear and the whole zodiacal light has a uniform gradation in intensity from the sun outward toward its extremity. Sometimes pulsations or waves of brightness and darkness have appeared to proceed from near the sun, reaching the extremity of the zodiacal light



IV.

in the course of five or ten seconds; note whether any such phenomena are visible.

The zodiacal light has been, on good authority, observed very high above the east and west horizon, so that some maintain that it is continuous through the zenith, and therefore surrounds the earth. This view may possibly be tested by observers located anywhere near the equator and a long way off from the path of totality. Therefore everyone should keep a record of the zodiacal light if he is so located as to see it at all during a few days before and after the eclipse and several hours before sunrise and after sunset. If observations show that the brightness of the zodiacal light is materially diminished during totality, in any part of the region where the moon's shadow darkens the atmosphere, this will go far to show that the zodiacal light originates in the earth's atmosphere; but if, as seen through the shaded air, the zodiacal light appears brighter than ever, it would follow that its location is far from us, and that it is an appendage of the sun.

(4) The observers of the zodiacal light should not fail to record the phenomena sometimes seen on the opposite side of the horizon, and called *Gegenschein*, or the anti-zodiacal light. Similarly, observers of the twilight phenomena should record the appearances in the horizon at the opposite side of the sun, or the so-called anti-twilight arc, or band.

(5) Observers to whom the sun is beyond the horizon, and for whom the atmosphere between them and the sun is not illumined owing to the presence of the moon's shadow, will have a good opportunity, for a few minutes, to see any faint comet that may have been hidden to astronomers by the glare of the sunlight, and, if such should be seen, they should record the apparent altitude and azimuth of the nucleus.

The diagrams I. and III. trace the shadow-cone westward to South California and eastward to India, but this should not prevent observers still further west on the Pacific, or east over India and Japan, from recording and reporting such phenomena as they may observe.

THE BRITISH ASSOCIATION.

SECTION D.

BIOLOGY.

OPENING ADDRESS BY PROF. J. S. BURDON SANDERSON, M.A., M.D., LL.D., F.R.SS. L. & E., PRESIDENT OF THE SECTION.

IT has long ceased to be possible in the course of an annual address in Section D to give an account even of the most important advances which have been made during the preceding twelve months in the various branches of knowledge which are now included under the term Biology. One reason is that each of the biological subjects has acquired such vast dimensions; the other, that the two main branches—Morphology, which strives to explain why plants and animals have assumed the forms and structure which they possess, and Physiology, which seeks to understand how the living organism works—have now diverged from each other so widely as regards subject and method, that there seems to be danger of complete separation of the one from the other.

From this sundering of sciences which a generation ago were intimately united, however inevitable it may be, Physiology chiefly suffers, as being even to the naturalist less attractive and interesting. The study of form and structure has the great advantage that it brings the observer into direct relation with objects which excite his curiosity without requiring too great an effort to understand them. This was the case even when Anatomy was mainly descriptive, and Zoology and Botany occupied themselves chiefly with classification and with definition of species. How much more is it the case now that Anatomy, Zoology, and Botany have become built into one system, of which the Doctrine of Evolution is the corner stone! Morphology, the name now given to this system, has, if I am not mistaken, this advantage over all other subjects of scientific study —that while attractive to the beginner, it is perfectly satisfactory to the mature student. It derives its perfectness from its subject —the *order* of the plant and animal world. For inasmuch as its fundamental conception is the development of all organisms, however complicated, from elementary forms, and as the theoretical development of the plant and animal world (in other words the science of morphology), claims to be nothing more than a synthesis of the observed facts of its actual development, the science is co-ordinate and conterminous with living nature, and strives after a perfection which is that of nature itself.

Physiology is without this source of attractiveness. Its first lessons present difficulties to the beginner which, unless he is contented (as, indeed, ordinary students are) to accept as true what he does not understand, are, to say the least, discouraging; while to the more mature student, who has mastered more or less some part of the subject, it fails to present a system of knowledge of which all the parts are interdependent and can be referred to one fundamental principle, comparable to that of development or evolution.

It is easy to understand that this must be so if we consider the present position of the subject, and the nature of the work which the physiologist has to do. That work is of two kinds. He has first to determine what are the chemical and physical endowments of living matter in general, and of each of the varieties of living matter which constitute the animal and plant organism in particular. Then, these having been investigated, he has to determine how these processes are localized so as to constitute the special function of each structure, and the relation between structure and process in each case. The order I have indicated is the logical order, but in the actual progress of physiology this order has not been followed, *i.e.* there has not been a correlation of structure with previously investigated process, for in former days physiologists spoke of assimilation, secretion, contraction, and the like, as functions of muscles, glands, or other parts, without recognizing their ignorance of their real nature. But now, no one who is awake to the tendencies of thought and work in physiology, can fail to have observed that the best minds are directed with more concentration than ever before to those questions which relate to the elementary endowments of living matter, and that if they are still held in the background it is rather because of the extreme difficulty of approaching them than from any want of appreciation of their importance.

It is to some of these questions that I am anxious to draw the attention of the Section to-day. I feel that I have set myself a difficult task, but think that, even should I succeed very partially, the attempt may be a useful one. And I am encouraged by the consideration that the interest they possess is one which is common to plant and animal physiology, and that if we really understood them, they would furnish a key, not only to the phenomena of nutrition and growth, but even to those of reproduction and development, and by the belief that it is in the direction of elementary physiology, which means nothing more than the study of the endowments of living material, that the advance of the next twenty years will be made.

Nearly fifty years ago, J. R. Mayer's [1] treatise on the relation between organic motion and the exchange of material in living organisms was published in Germany. Although its value was more appreciated by physicists than by biologists, it was in its purpose, as well as in its subject-matter, physiological. In it Mayer showed for the first time that certain functions of the animal body, which up to that time had been considered most vital, are strictly within reach of measurement, *i.e.* referable to physical standards of quantity. He was even able to demonstrate that those quantitative relations between different kinds of energy which physicists were then only beginning to recognize, held good as regards the processes peculiar to the living organism.

Almost immediately after the appearance of this now celebrated work, a series of discoveries were made in physiology, which constituted the period we are now considering an epoch. Mayer himself had proved that muscles in doing work and producing heat do not do so at the expense of their own substance. But this fact could not be understood until Bernard showed that sugar is one of the most important constituents of the blood, and its storage and production a chief function of the liver. Helmholtz next succeeded in proving what Johannes Müller [2] had declared to be nearly impossible—namely, that the time occupied by the propagation of a motor impulse from the brain to a muscle could be measured, and showed it to be proportional to the distance traversed. Next, du Bois-Reymond investigated the electrical phenomena of living beings, and marshalled them under a physical theory which stood its ground against the severest criticism for more than a generation. And finally, the hydrodynamic principles relating to the circulation, set forth by Dr. Thomas Young in his Croonian Lecture forty

[1] J. R. Mayer, "Die organische Bewegung in ihrem Zusammenhange mit dem Stoffwechsel" (Heilbronn, 1845).

[2] Müller's "Physiology," translation of second edition, p. 2[illegible].

years before, were demonstrated experimentally by Ludwig, at the very time when Helmholtz was giving definite form to the great natural philosopher's theory of colour perceptions.

The effect of these discoveries was to produce a complete revolution in the ways of thinking and speaking about the phenomena of life. The error of the past had been to believe that, although the heart resembled a pump, although digestion could be imitated in the laboratory, and comparisons of vital with physical processes could be used for illustration, it was always wrong to identify them. But, inasmuch as it had been learned that sensation is propagated along a nerve just as sound is propagated through the air, only with something like a tenth of the velocity, that the relations between the work done, the heat produced, and the fuel used, can be investigated in the living body just as they are in the steam-engine, it now came to be felt that, in other similar cases, what had been before regarded as peculiarly vital might be understood on physical principles, and that for, the future the word "vital" as distinctive of physiological processes might be abandoned altogether. In looking back, we have no difficulty in seeing that the lines of investigation which were then initiated by such men as Helmholtz, Ludwig, Brücke, du Bois-Reymond, Donders, Bernard, are those along which, during the succeeding generation, the science of physiology advanced; nor can anyone who is acquainted with the literature of that time doubt that these leaders of physiological thought knew that they were the beginners of a new epoch. But such an epoch cannot occur again. We have adopted once for all the right, *i.e.* the scientific method, and there is not the least possibility of our recurring to the wrong. We have no new departure, no change of front in prospect; but even times which are not epochal have their tendencies, and I venture to submit to you, that in physiology the tendency of the present time is characterized by the concentration of the best efforts of the best minds on what I have already referred to as elementary questions. The work of investigating the special functions of organs, which during the last two decades has yielded such splendid results, is still proceeding, and every year new ground is being broken and new and fruitful lines of experimental inquiry are being opened up; but the further the physiologist advances in this work of analysis and differentiation, the more frequently does he find his attention arrested by deeper questions relating to the essential endowments of living matter, of which even the most highly differentiated functions of the animal or plant organism are the outcome. In our science the order of progress has been hitherto and will continue to be the reverse of the order of Nature. Nature begins with the elementary and ends with the complex (first the amœba, then the man). Our mode of investigation has to begin at the end. And this not merely for the historical reason that the first stimulus to physiological inquiry was man's reasonable desire to know himself, but because differentiation actually involves simplification. For just as in manufactures it is the effect of division of labour that less is required of each workman, so in an organism which is made up of many organs, the function of each is simpler.

Physiology, therefore, first studies man and the higher animals and proceeds to the higher plants, then to invertebrates and cryptogams, ending where development begins. From the beginning her aim has been to correlate function with structure, at first roughly, afterwards, when, as I have explained, her methods of observation became scientific, more and more accurately—the principle being *that every appreciable difference of structure corresponds to a difference of function*; and conversely that each endowment of a living organ must be explained, if explained at all, as springing from its structure.

It is not difficult to see whither this method must eventually lead us. For inasmuch as function is more complicated than structure, the result of proceeding, as Physiology normally does, from structure to function, must inevitably be to bring us face to face with functional differences which have no structural difference to explain them. Thus, for example, if the physiologist undertakes to explain the function of a highly differentiated organ like the eye, he finds that up to a certain point, provided that he has the requisite knowledge of dioptrics, the method of correlation guides him straight to his point. He can mentally or actually construct an eye which will perform the functions of the real eye, in so far as the formation of a real image of the field of vision on the retina is concerned, and will be able thereby to understand how the retinal picture is transferred to the organ of consciousness. Having arrived at this point he begins to correlate the known structure of the retina with what is required of it, and finds that the number of objects which be can discriminate in the field of vision is as numerous as, but not more numerous than, the parts of the retina, *i.e.* the cones which are concerned in discriminating them. So far he has no difficulty; but the method of correlation fails him from the moment that he considers that each object point in the field of vision is coloured, and that he is able to discriminate not merely the number and the relations of all the object points to each other, but the colour of each separately. He then sees at once that each cone must possess a plurality of endowments for which its structure affords no explanation. In other words, in the minute structure of the human retina, we have a mechanism which would completely explain the picture of which I am conscious, were the objects composing it possessed of one objective quality only, being colourless, but it leaves us without explanation of the differentiation of colour.

Similarly, if he is called upon to explain the function of a secreting gland, such, *e.g.*, as the liver, there is no difficulty in understanding that, inasmuch as the whole gland consists of lobules which resemble each other exactly, and each lobule is similarly made up of cells which are all alike, each individual cell must be capable of performing all the functions of the whole organ. But when by exact experiment we learn that the liver possesses not one function but many—when we know that it is a storehouse for animal starch, that each cell possesses the power of separating waste colouring-matter from the blood, and of manufacturing several kinds of crystallizable products, some of which it sends in one direction and others in the opposite—we find again that the correlation method fails us, and that all that our knowledge of the minute structure has done for us is to set before us a question which, though elementary, we are quite unable to answer.

By multiplying examples of the same kind, we should in each case come to the same issue, namely, *plurality of function with unity of structure*, the unity being represented by a simple structural element—be it retinal cone or cell—possessed of numerous endowments. Whenever this point is arrived at in any investigation, structure must for the moment cease to be our guide, and in general two courses or alternatives are open to us. One is to fall back on that worn-out *Deus ex machinâ*, protoplasm, as if it afforded a sufficient explanation of everything which cannot be explained otherwise, and accordingly to defer the consideration of the functions which have no demonstrable connection with structure as for the present beyond the scope of investigation; the other is, retaining our hold of the fundamental principle of correlation, to take the problem in reverse, *i.e.* to use analysis of function as a guide to the ultra-microscopical analysis of structure.

I need scarcely say that of these two courses the *first* is wrong, the *second* right, for in following it we still hold to the fundamental principle *that living material acts by virtue of its structure*, provided that we allow the term structure to be used in a sense which carries it beyond the limits of anatomical investigation, *i.e.* beyond the knowledge which can be attained either by the scalpel or the microscope. We thus (as I have said) proceed from function to structure, instead of the other way.

The departure from the traditions of our science which this change of direction seems to imply is indeed more apparent than real. In tracing the history of some of the greatest advances, we find that the recognition of function has preceded the knowledge of structure. Haller's discovery of irritability was known and bore fruit, long before anything was known of the structure of muscle. So also, at a later period, Bichat was led by his recognition of the physiological differences between what he termed the functions of organic and animal life, to those anatomical researches which were the basis of the modern science of Histology. Again, in much more recent times, the investigation of the function of gland cells, which has been carried on with such remarkable results by Prof. Heidenhain in Germany, and with equal success by Mr. Langley in this country, has led to the discovery of the structural changes which they undergo in passing from the state of repose to that of activity: nor could I mention a better example than that afforded (among many others relating to the physiology of the nervous system) by Dr. Gaskell's recent and very important discovery of the anatomical difference between cerebro-spinal nerves of different functions. We may therefore anticipate that the future of physiology will differ from the past chiefly in this respect—that whereas hitherto the greater part of the work has consisted in the interpretation of facts arrived at in the first instance by anatomical methods of research, Histology, once the guide of Physiology, has now become her handmaid.

During the last ten or fifteen years Histology has carried her methods of research to such a degree of perfection that further improvement scarcely seems possible. As compared with these subtle refinements, the "minute anatomy" of thirty years ago appears coarse—the skill for which we once took credit seems but clumsiness. Notwithstanding, the problems of the future from their very nature lie as completely out of reach of the one as of the other. It is by different methods of investigation that our better equipped successors must gain insight of those vital processes of which even the ultimate results of microscopical analysis will ever be, as they are now, only the outward and visible sign.

In what has preceded, I have endeavoured to show that at present the fundamental questions in physiology, the problems which most urgently demand solution, are those which relate to the endowments of apparently structureless living matter, and that the most important part of the work of the immediate future will be the analysis of these endowments. With this view, what we have to do is, first, to select those cases in which the vital process offers itself in its simplest form, and is consequently best understood; and, secondly, to inquire how far in these particular instances we may, taking as our guide the principle I have so often mentioned as fundamental, viz. the correlation of structure with function, of mechanism with action, proceed in drawing inferences as to the mechanism by which these vital processes are in these simplest cases actually carried out.

The most distinctive peculiarity of living matter as compared with non-living is that it is ever changing while ever the same, *i.e.* that life is a state of ceaseless change. For our present purpose I must ask you, first, to distinguish between two kinds of change which are equally characteristic of living organisms—namely, those of growth and decay on the one hand, and those of nutrition on the other. Growth the biologist calls evolution. Growth means the unfolding, *i.e.* development, of the latent potentialities of form and structure which exist in the germ, and which it has derived by inheritance. A growing organism is not the same to-day as it was yesterday, and consequently not quite the same now as it was a minute ago, and never again will be. This kind of change I am going to ask you to exclude from consideration altogether at this moment, for in truth it does not belong to Physiology, but rather to Morphology, and to limit your attention to the other kind which includes all other vital phenomena. I designated it just now as nutrition, but this word expresses my meaning very inadequately. The term which has been used for half a century to designate the sum or complex of the non-developmental activities of an organism is "exchange of material," for which Prof. Foster has given the very acceptable substitute Metabolism. Metabolism is only another word for "change," but in using it we understand it to mean that, although an organism in respect of its development may never be what it has been, the phases of alternate activity and repose which mark the flow of its life-stream are recurrent. Life is a Cyclosis in which the organism returns after every cycle to the same point of departure, ever changing yet ever the same.

It is this antithesis which constitutes the essential distinction between the two great branches of biology, the two opposite aspects in which the world of life presents itself to the inquiring mind of man. Seen from the morphological side, the whole plant and animal kingdom constitutes the unfolding of a structural plan which was once latent in a form of living material of great apparent simplicity. From the physiological side this apparently simple material is seen to be capable of the discharge of functions of great complexity, and therefore must possess corresponding complexity of mechanism. It is the nature of this invisible mechanism that physiology thirsts to know. Although little progress has as yet been made, and little may as yet be possible, in satisfying this desire, yet, as I shall endeavour to show you, the existing knowledge of the subject has so far taken consistent form in the minds of the leaders of physiological thought that it is now possible to distinguish the direction in which the soberest speculation is tending.

The *non-developmental* vital functions of protoplasm are the absorption of oxygen, the discharge of carbon dioxide and water and ammonia, the doing of mechanical work, the production of heat, light, and electricity. All these, excepting the last, are known to have chemical actions as their inseparable concomitants. As regards electricity, we have no proof of the dependence of the electrical properties of plants and animals on chemical action. But all the other activities which have been mentioned are fundamentally chemical.

Let us first consider the relation of oxygen to living matter and vital process. For three-quarters of a century after the fundamental discoveries of Lavoisier and Priestley (1772–76), the accepted doctrine was that the effete matter of the body was brought to the lungs by the circulation and burnt there, of which fact the carbon dioxide expired seemed an obvious proof. Then came the discovery that arterial blood contained more oxygen than venous blood, and consequently that oxygen must be conveyed as such by the blood-stream to do its purifying work in all parts of the body, this advance in the understanding of the process being crowned a few years later by the discovery of the oxygen-carrying properties of the colouring-matter of the blood, in which the present President of the Royal Society took so prominent a part. Finally, between 1872 and 1876, as the result of an elaborate series of investigations of the respiratory process, the proof was given by Pflüger[1] that the function of oxygen in the living organism is not to destroy effete matter either here or there, but rather to serve as a food for protoplasm, which, so long as it lives, is capable of charging itself with this gas, absorbing it with such avidity, that, although its own substance retains its integrity, no free oxygen can exist in its neighbourhood. This discovery, of which the importance is comparable with that of Lavoisier, can best be judged of by considering its influence on other fundamental conceptions of the vital process. The generally accepted notion of effete matter waiting to be oxidized was associated with a more general one, viz. that the elaborate structure of the body was not permanent, but constantly undergoing decay and renewal. What we have now learnt is, that the material to be oxidized comes as much from the outside as the oxygen which burns it, though the reaction between them, *i.e.* the oxidation, is intrinsic, *i.e.* takes place within the living molecular framework.

Protoplasm, therefore, understanding by the term the visible and tangible presentation to our senses of living material, comes to consist of two things—namely, of framework and of content—of channel and of stream—of acting part which lives and is stable, and of acted-on part which has never lived and is labile, that is, in a state of metabolism, or chemical transformation.

If such be the relation between the living framework and the stream which bathes it, we must attribute to this living, stable, acting part, a property which is characteristic of the bodies called in physiological language ferments, or enzymes, the property which, following Berzelius, we have for the last half-century expressed by the word *catalytic;* and use, without thereby claiming to understand it, to indicate a mode of action in which the agent which produces the change does not itself take part in the decompositions which it produces.

I have brought you to this point as the outcome of what we know as to the essential nature of the all-important relation between oxygen and life. In botanical physiology the general notion of a stable catalyzing framework, and of an interstitial labile material, which might be called catalyte, has been arrived at on quite other grounds. This notion is represented in plant physiology by two words, both of which correspond in meaning—Micellæ, the word devised by Nägeli, and the better word Tagmata, substituted for it by Pfeffer. Nägeli's word has been adopted by Prof. Sachs as the expression of his own thought in relation to the ultra-microscopical structure of the protoplasm of the plant cell. His view is that certain well-known properties of organized bodies require for their explanation the admission that the simplest *visible* structure is itself made up of an arrangement of units of a far inferior order of minuteness. It is these hypothetical units that Nägeli has called micellæ.

Now, Nägeli in the first instance confounded the micellæ with molecules, conceiving that the molecule of living matter must be of enormous size.[2] But, inasmuch as we have no reason for believing that any form of living material is chemically homogeneous, it was soon recognized, perhaps first by Pfeffer, but eventually also by Nägeli himself, that a micella, the ultimate

[1] *Pflüger's Archiv*, vol. vi., 1872, p. 43. and vol. x., 1875, p. 251, "Ueber die physiologische Verbrennung in den lebendigen Organismen."

[2] Nägeli, "Theorie der Gährung; Beitrag zur Molecular Physiologie," p. 121 (1879).

element of living material, is not equivalent to a molecule, however big or complex, but must rather be an arrangement or phalanx of molecules of different kinds. Hence the word tagma, first used by Pfeffer,[1] has come to be accepted as best expressing the notion. And here it must be noted that each of the physiologists to whom reference has been made regards the micellæ, not as a mere aggregate of separate particles, but as connected together so as to form a system, a conception which is in harmony with the view I gave you just now from the side of animal physiology, of catalyzing framework and interstitial catalyzable material.

To Prof. Sachs, this porous constitution of protoplasm serves to explain the property of vital turgescence—that is, its power of charging itself with aqueous liquid—a power which Sachs estimates to be so enormous that living protoplasm may, he believes, be able to condense water which it takes into its interstices to less than its normal volume. For our present purpose it is sufficient for us to understand that to the greatest botanical thinkers, as well as to the greatest animal physiologists, the ultimate mechanism by which life is carried on is not, as Prof. Sachs[2] puts it, "slime," but "a very distensible and exceedingly fine network."

And now let us try to get a step further by crossing back in thought from plants to animals. At first sight, the elementary vital processes of life seem more complicated in the animal than in the plant, but they are, on the contrary, simpler; for plant protoplasm, though it may be structurally homogeneous, is dynamically polyergic—it has many endowments—whereas in the animal organism there are cases in which a structure has only one function assigned to it. Of this the best examples are to be found among so-called excitable tissues, viz. those which are differentiated for the purpose of producing (along with heat) mechanical work, light, or electricity. In the life of the plant these endowments, if enjoyed at all, are enjoyed in common with others.

By the study, therefore, of muscle, of light organ, and of electrical organ, the vital mechanism is more accessible than by any other portal. About light organs we as yet know little, but the little we know is of value; of electrical organs rather more; about muscle a great deal.

To the case of muscle, Engelmann, one of the best observers and thinkers on the elementary questions which we have now before us, has transferred the terminology of Nägeli and Pfeffer as descriptive of the mechanism of its contraction. Muscular protoplasm differs from those kinds of living matter to which I have applied the term "polyergic," in possessing a molecular structure comparable with that of a crystal in the respect, that each portion of the apparently homogeneous and transparent material of which it consists resembles every other.

With this ultra-microscopical structure, its structure as investigated by the microscope may be correlated, the central fact being that, just as a muscular fibre can be divided into cylinders by cross-sections, so each such cylinder is made up of an indefinite number of inconceivably minute cylindrical parts, each of which is an epitome of the whole. These, Engelmann, following Pfeffer, calls ino-tagmata. So long as life lasts each minute phalanx has the power of keeping its axis parallel with those of its neighbours, and of so acting within its own sphere as to produce, whenever it is awakened from the state of rest to that of activity, a fluxion from poles to equator. In other words, muscle, like plant protoplasm, consists of a stable framework of living catalyzing substance, which governs the mechanical and chemical changes which occur in the interstitial catalyzable material, with this difference, that here the ultra-microscopical structure resembles that of a uniaxial crystal,[3] whereas in plant protoplasm there may be no evidence of such arrangement.

According to this scheme of muscular structure, the contraction, *i.e.* the change of form which, if allowed, a muscle undergoes when stimulated, has its seat not in the system of tagmata but in the interstitial material which surrounds it, and consists in the migration of that labile material from pole to equator, this being synchronous with explosive oxidation, sudden disengagement of heat and change in the electrical state of the living substance. Let us now see how far the scheme will help us to an understanding of this marvellous concomitance of chemical, electrical, and mechanical change.

It is not necessary to prove to you that the discharge of carbon dioxide and the production of heat which we know to be associated with that awakening of a muscle to activity which we call stimulation, are indices of oxidation. If we take this fact in connection with the view that has just been given of the mechanism of contraction, it is obvious that there must be in the sphere of each tagma an accumulation of oxygen and oxidizable material, and that concomitantly with or antecedently to the migration of liquid from pole to equator, these must come into encounter. Let us for a moment suppose that a soluble carbohydrate is the catalyzable material, that this is accumulated equatorially, and oxygen at the poles, and consequently that between equator and poles water and carbon dioxide, the only products of the explosion, are set free. That the process is really of this nature is the conclusion to which an elaborate study of the electrical phenomena which accompany it has led one of the most eminent physiologists of the present time, Prof. Bernstein.[1] To this I wish for a moment to ask your attention.

Prof. Bernstein's view of the molecular structure of muscular protoplasm is in entire accordance with the theory of Pflüger and with the scheme of Engelmann, with this addition, that each ino-tagma is electrically polarized when in a state of rest, depolarized at the moment of excitation or stimulation, and that the axes of the tagmata are so directed that they are always parallel to the surface of the fibre, and consequently have their positive sides exposed. In this amended form the theory admits of being harmonized with the fundamental facts of muscle-electricity—namely, that cut surfaces are negative to sound surfaces, and excited parts to inactive—provided that the direction of the hypothetical polarization is from equator to pole, *i.e.* that in the resting state the poles of each tagma are charged with negative ions, the equators with positive; and consequently that the direction of the discharge in the catalyte at the moment that the polarization disappears is from pole to equator.

Time forbids me even to attempt to explain how this theory enables us to express more consistently the accepted explanations of many collateral phenomena, particularly those of electrotonus. I am content to show you that it is not impossible to regard the three phenomena—viz. chemical explosion, sudden electrical change, and change of form—as all manifestations of one and the same process—as products of the same mechanism.

In plants, in certain organs or parts in which movement takes place, as in muscles in response to stimulation, the physiological conditions are the same or similar, but the structural very different; for the effect is produced not by a change of form, but by a diminution of volume of the excited part, and this consists not of fibres, but of cells. The way in which the diminution of volume of the whole organ is brought about is by diminution of the volume of each cell, an effect which can obviously be produced by flow of liquid out of the cell. At first sight therefore the differences are much more striking than the resemblances.

But it is not so in reality, for the more closely we fix our attention on the elementary process rather than on the external form, the stronger appears the analogy—the more complete the correspondence. The state of turgor, as it has been long called by botanical physiologists, by virtue of which the framework of the protoplasm of the plant retains its content with a tenacity to which I have already referred, is the analogue of the state of polarization of Bernstein. As regards its state of aggregation, it can scarcely be doubted that, inasmuch as the electrical concomitants of excitation of the plant cell so closely correspond with those of muscle, here also the tagmata are cylindrical, and have their axes parallel to each other. Beyond this we ought perhaps not to allow speculation to carry us, but it is scarcely possible to refrain from connecting this inference with the streaming motion of protoplasm which in living plant cells is one of the indices of vitality. If, as must I think be supposed, this movement is interstitial, *i.e.* due to the mechanical action of the moving protoplasm on itself, we can most readily understand its mechanism as consisting in rhythmically recurring phases of close and open order in the direction of the tagmatic axes,

In submitting this hypothesis I do not for a moment forget that the facts relating to the contractility of plant cells have as yet been insufficiently investigated. No one has as yet shown that when the leaf of the sensitive plant falls, or that of the fly-trap closes on its prey, heat is developed or oxidation takes

place, but it does not seem to me very rash to anticipate that if it were possible to make the experiment to-morrow it would be found to be so.

I have thus endeavoured (building on two principles in physiology, firstly that of the constant correlation of mechanism and action, of structure and function, and secondly the identity of plant and animal life both as regards mechanism and structure; and on two experimentally ascertained elementary relations, viz. the relation of living matter or protoplasm to water on the one hand, and to oxygen and food on the other) to present to you in part the outline or sketch of what might, if I had time to complete it, be an adequate conception of the mechanism and process of life as it presents itself under the simplest conditions. To complete this outline, so far as I can to-day, I have but one other consideration to bring before you, one which is connected with the last of my four points of departure—that of the relation of oxygen to protoplasm, a relation which springs out of the avidity with which, without being oxidized or even sensibly altered in chemical constitution, it seizes upon oxygen and stores it for its own purposes. The consideration which this suggests is that if the oxygen and oxidizable material are constantly stored, they must either constantly or at intervals be discharged, and inasmuch as we know that in every instance without exception in which heat is produced or work is done, these processes have discharge of water and of carbon dioxide for their concomitants, we are justified in regarding these discharges as the sign of expenditure, the charging with oxygen as the sign of restitution. In other words, a new characteristic of living process springs out of those we have already had before us—namely, that it is a constantly recurring alternation of opposite and complementary states, that of activity or discharge, that of rest or restitution.

Is it so, or is it not? In the minds of most physiologists the distinction between the phenomena of discharge and the phenomena of restitution (*Erholung*) is fundamental, but beyond this, unanimity ceases. Two distinguished men, one in Germany and one in England—I refer to Prof. Hering and Dr. Gaskell—have taken, on independent grounds, a different view to the one above suggested, according to which, life consists, not of alternations between rest and activity, charge and discharge, loading and exploding, but between two kinds of activity, two kinds of explosion, which differ only in the direction in which they act, in the circumstance that they are antagonistic to each other.

Now when we compare the two processes of rest, which as regards living matter means restitution, and discharge, which means action, with each other, they may further be distinguished in this respect, that, whereas restitution is autonomic, *i.e.* goes on continuously like the administrative functions of a well-ordered community, the other is occasional, *i.e.* takes place only at the suggestion of external influences; that, in other words, the contrast between action and rest is (in relation to protoplasm) essentially the same as between waking and sleeping.

It is in accordance with this analogy between the alternation of waking and sleeping of the whole organism, and the corresponding alternation of restitution and discharge, of every kind of living substance, that physiologists by common consent use the term Stimulus (*Reiz*, *Prikkeling*), meaning thereby nothing more than that it is by external disturbing or interfering influence of some kind that energies stored in living material are (for the most part suddenly) discharged. Now, if I were to maintain that restitution is not autonomic, but determined, as waking is, by an external stimulus—that it differs from waking only in the direction in which the stimulation acts, *i.e.* in the tendency towards construction on the one hand, towards destruction on the other—I should fairly and as clearly as possible express the doctrine which, as I have said, the two distinguished teachers I have mentioned, viz. Dr. Gaskell [1] and Prof. Hering, have embodied in words which have now become familiar to every student. The words in question, "anabolism," which being interpreted means winding up, and "catabolism," running down, are the creation of Dr. Gaskell. Prof. Hering's equivalents for these are "assimilation," which, of course, means storage of oxygen and oxidizable material, and "disassimilation," discharge of these in the altered form of carbon dioxide and water. But the point of the theory which attaches to them lies in this, that that wonderful power which living material enjoys of continually building itself up out of its environment, is, as I have already suggested, not autonomic, but just as dependent on occasional and external influences or stimuli, as we know the disintegrating processes to be; and accordingly Hering finds it necessary to include under the term stimuli not only those which determine action, but to create a new class of stimuli which he calls *Assimilations-Reize*, those which, instead of waking living mechanism to action, provoke it to rest.

It is unfortunately impossible within the compass of an address like the present to place before you the wide range of experimental facts which have led two of the strongest intellects of our time to adopt a theory which, when looked at *a priori*, seems so contradictory. I must content myself with mentioning that Hering was led to it chiefly by the study of one of the examples to which I referred in my introduction—namely, the colour-discriminating functions of the retina; Dr. Gaskell by the study of that very instructive class of phenomena which reveal to us that among the channels by which the brain maintains its sovereign power as supreme regulator of all the complicated processes which go on in the different parts of the animal organism, there are some which convey only commands to action, others commands to rest, the former being called by Gaskell catabolic, the latter anabolic. To go further than this would not only wear out your patience but would carry me beyond the limits I proposed to myself, viz. the mechanism of life in its simplest aspects. I therefore leave the subject here, adding one word only. The distinction which has suggested to their authors the words on which I have been commenting is a real one, but it implies rather the interference with each other of the simultaneous operation of two regulating mechanisms, than an antagonism between two processes of opposite tendencies carried on by the same mechanism; or, putting it otherwise, that the observed antagonism is between one nervous mechanism and another, and not between two antagonistic functions of the same living material.

Without attempting to recapitulate, I have a word to say by way of conclusion on a question which may probably have suggested itself to some of my audience.

I have indicated to you that although scientific thought does not, like speculative, oscillate from side to side, but marches forward with a continued and uninterrupted progress, the stages of that progress may be marked by characteristic tendencies; and I have endeavoured to show that in physiology the questions which concentrate to themselves the most lively interest are those which lie at the basis of the elementary mechanism of life.

The word Life is used in physiology in what, if you like, may be called a technical sense, and denotes only that state of *change with permanence* which I have endeavoured to set forth to you. In this restricted sense of the word, therefore, the question "What is Life?" is one to which the answer is approachable; but I need not say that in a higher sense—higher because it appeals to higher faculties in our nature—the word suggests something outside of mechanism, which may perchance be its cause rather than its effect.

The tendency to recognize such a relation as this is what we mean by vitalism. At the beginning of this discourse I referred to the anti-vitalistic tendency which accompanied the great advance of knowledge that took place at the middle of the century. But even at the height of this movement there was a reaction towards vitalism, of which Virchow,[1] the founder of modern pathology, was the greatest exponent. Now, a generation later, a tendency in the same direction is manifesting itself in various quarters. What does this tendency mean? It has to my mind the same significance now that it had then. Thirty years ago the discovery of the cell as the basis of vital function was new, and the mystery which before belonged to the organism was transferred to the unit, which while it served to explain everything was itself unexplained. The discovery of the cell seemed to be a very close approach to the mechanism of life, but now we are striving to get even closer, and with the same result. Our measurements are more exact, our methods finer; but these very methods bring us to close quarters with phenomena which, although within reach of exact investigation, are as regards their essence involved in a mystery which is the more profound the more it is brought into contrast with the exact knowledge we possess of surrounding conditions.

If what I have said is true, there is little ground for the apprehension that exists in the minds of some that the habit of

[1] See Gaskell in *Ludwig's Festschrift*, and Hering, "Zur Theorie der Vorgänge in der lebendigen Substanz," pp. 1–22 (Prag, 1888).

[1] Virchow, "Alter und Neuer Vitalismus," *Archiv für pathol. Anat* 1856, vol. ix. p. 1. See also Rindfleisch, "Ärtzliche Philosophie," pp. 10–1 Wurzburg, 1888).

scrutinizing the mechanism of life tends to make men regard what can be so learned as the only kind of knowledge. The tendency is now certainly rather in the other direction. What we have to guard against is the mixing of two methods, and so far as we are concerned the intrusion into our subject of philosophical speculation. Let us willingly and with our hearts do homage to "divine Philosophy," but let that homage be rendered outside the limits of our science. Let those who are so inclined, cross the frontier and philosophize; but to me it appears to be more conducive to progress that we should do our best to furnish professed philosophers with such facts relating to structure and function as may serve them as aids in the investigation of those deeper problems which concern man's relations to the past, the present, and the unknown future.

SECTION H.

ANTHROPOLOGY.

OPENING ADDRESS BY PROF. SIR WILLIAM TURNER, M.B., LL.D., F.R.SS.L. & E., PRESIDENT OF THE SECTION.

TWENTY-SIX years have passed by since the British Association for the Advancement of Science last assembled in this city. Many of the incidents of that meeting are still fresh in my memory, the more vividly, perhaps, because it was the first meeting of the Association that I had attended. The weather, so important a factor in most of our functions, was dry and bright. The visitor, instead of being enshrouded in that canopy of mist and smoke which so often meets the traveller as he approaches your city, was greeted with light and sunshine. The cordial welcome and reception so freely granted by the community, and more especially the princely yet gracious hospitality exercised by the President, your eminent townsman, now Lord Armstrong, are all deeply imprinted on my memory. But, apart from these attractions, which added so much to the amenities of the occasion, the meeting was one of deep interest to all those Members and Associates who were engaged in biological study.

Lyell's famous book on the "Antiquity of Man" had been published shortly before. The essays on the "Origin of Species" by natural selection, by Charles Darwin and Alfred Russel Wallace, had appeared only five years earlier in the Journal of the Linnean Society, and in 1859 Darwin's treatise on the "Origin of Species," in which its illustrious author summarized the facts he had collected and the conclusions at which he had arrived, had been published. Although no President of the British Association had up to that time given his adhesion to the new theory, yet it was clear that men were beginning to see, in many instances perhaps only dimly, how the theory of evolution by natural selection was destined to work a remarkable change, amounting almost to a revolution, in our conceptions of biological questions generally, and their applicability to the study of man.

At that time Anthropology had not assumed so definite a position in the work of the Association as it now possesses. Neither a Department nor a Section was devoted to it, and the subjects which it embraces were scattered abroad, either in the Department of Anatomy and Physiology, in the Section of Geography and Ethnology, in that of Geology, or in that of Statistics. It is true that a vigorous attempt was made about that time to give it a more independent position, but it was not until the Association met in Nottingham, in 1866, that it was assigned a definite Department, and at the Montreal meeting, in 1884, Anthropology assumed the dignity of a Section.

But although the youngest Section of the Association, the Science of Man is not the youngest of the sciences. Long before the British Association came into existence, Man, in his physical, racial, geological, and psychological aspects, had been studied by hosts of able and industrious inquirers. All that the Association has done in establishing a special Section of Anthropological Science has been to bring together, as it were, into a single focus all those workers who apply themselves to the study of man in his various aspects.

As presiding over the proceedings of the Section on this occasion, it is a part of my duty to open its public business with an address. For me, as doubtless for many of those who have preceded me in this honourable office, one's mind has been somewhat exercised in the choice of a subject. In a branch of biological science so vast as Anthropology, in which the room for selection is so ample, the difficulty of making a choice is perhaps still further increased. As a professional anatomist, whose life's work it has been to study the structure of the human body in its normal aspects, to inquire into the variations which it exhibits in different individuals, and to compare its structure with that of various forms of animal life, it at first occurred to me that an address on the physical characteristics of some of the races of men would be appropriate. But further consideration led me to think that such a subject would be too technical for a general audience, and that it might perhaps be productive of greater interest on the part of my auditors if I selected a topic which, whilst strictly scientific in all its bearings, yet appeals more distinctly to the popular mind, and is now attracting attention. Hence I have chosen the subject of Heredity, by which I mean that special property through which the peculiarities of an organism are transmitted to its descendants throughout successive generations, so that the offspring, in their main features, resemble their parents.

The subject of Heredity, if I may say so, is in the air at the present time. The journals and magazines, both scientific and literary, are continually discussing it, and valuable treatises on the subject are appearing at frequent intervals. But though so important a topic of existing scientific thought and speculation, it is by no means a new subject, and certain of its aspects were under discussion so far back as the time of Aristotle. The prominence which it has assumed of late years is in connection with its bearing on the Darwinian Theory of Natural Selection, and, consequently, biologists generally have had their attention directed to it. But in its relations to Man, his structure, functions, and diseases, it has long occupied a prominent position in the minds of anatomists, physiologists, and physicians. That certain diseases, for example, are hereditary was recognized by Hippocrates, who stated generally that hereditary diseases are difficult to remove, and the influence which the hereditary transmission of disease exercises upon the duration of life is the subject of a chapter in numerous works on practical medicine, and forms an important element in the valuation of lives for life insurance.

The first aspect of the question which has to be determined is whether any physical basis can be found for Heredity. Is there any evidence that the two parents contribute each a portion of its substance to the production of the offspring so that a physical continuity is established between successive generations? The careful study, especially during the last few years, of the development of a number of species of animals mostly but not exclusively among the Invertebrata, by various observers, of whom I may especially name Bütschli, Fol, E. Van Beneden, and Hertwig, has established the important fact that the young animal arises by the fusion within the egg or germ-cell of an extremely minute particle derived from the male parent with an almost equally minute particle derived from the germ-cell produced by the female parent. These particles are technically termed in the former case the *male pronucleus*, in the latter the *female pronucleus*, and the body formed by their fusion is called the *segmentation nucleus*. These nuclei are so small that it seems almost a contradiction in terms to speak of their magnitude; rather one might say their minimitude, for it requires the higher powers of the best microscopes to see them and follow out the process of conjugation. But notwithstanding their extreme minuteness, the pronuclei and the segmentation nucleus are complex both in chemical and molecular structure. From the segmentation nucleus produced by the fusion of the pronuclei with each other, and from corresponding changes which occur in the protoplasm of the egg which surrounds it, other cells arise by a process of division, and these in their turn also multiply by division. These cells arrange themselves in course of time into layers which are termed the germinal or embryonic layers. From these layers arise all the tissues and organs of the body, both in its embryonic and adult stages of life. The starting-point of each individual organism—*i.e.* of each new generation—is therefore the segmentation nucleus. Every cell in the adult body is derived by descent from that nucleus through repeated division. As the segmentation nucleus is formed by the fusion of material derived from both parents, a physical continuity is established between parents and offspring. But this physical continuity carries with it certain properties which cause the offspring to reproduce, not only the bodily configuration of the parent, but other characters. In the case of Man we find along with the family likeness in form and features a correspondence in temperament and disposition, in the habits and mode of life, and sometimes in the tendency to particular diseases. This transmission of characters from parent to offspring is summarized in the well-known expression that "like begets like," and it rests upon a physical basis.

The size of the particles which are derived from the parents, called the male and female pronuclei, the potentiality of which is so utterly out of proportion to their bulk, is almost inconceivably small when compared with the magnitude of the adult body. Further, by the continual process of division of the cells, the substance of the segmentation nucleus is diffused throughout the body of the new individual produced through its influence, so that each cell contains but an infinitesimal particle of it. The parental dilution, if I may so say, is so attenuated as to surpass the imagination of even the most credulous believer in the attenuation of drugs by dilution. And yet these particles are sufficient to stamp the characters of the parents, of the grandparents, and of still more remote ancestors on the offspring, and to preserve them throughout life, notwithstanding the constant changes to which the cells forming the tissues and organs of the body are subjected in connection with their use and nutrition. So marvellous, indeed, is the whole process, that even the exact contributions to recent knowledge on the fusion of the two pronuclei, instead of diminishing our wonder, have intensified the force of the expression "*magnum hereditatis mysterium.*"

In considering the question of how new individuals are produced, one must keep in mind that it is not every cell in the body which can act as a centre of reproduction for a new generation, but that certain cells, which we name germ-cells and sperm-cells, are set aside for that purpose. These cells, destined for the production of the next generation, form but a small proportion of the body of the animal in which they are situated. They are, as a rule, marked off from the rest of the cells of its body at an early period of development. The exact stage at which they become specially differentiated for reproductive purposes varies, however, in different organisms. In some organisms, as is said by Balbiani to be the case in *Chironomus*, they apparently become isolated before the formation of the germinal layers is completed; but, as a rule, their appearance is later, and in the higher organisms most not until the development of the body is relatively much more advanced.

The germ-cells after their isolation take no part in the growth of the organism in which they arise, and their chief association with the other cells of its body is that certain of the latter are of service in their nutrition. The problem, therefore, for consideration is the mode in which these germ or reproductive cells become influenced, so that after being isolated from the cells which make up the bulk of the body of the parent they can transmit to the offspring the characters of the parent organism. Various speculations and theories have been advanced by way of explanation. The well-known theory of Pangenesis, which Charles Darwin with characteristic moderation put forward as merely a provisional hypothesis, assumes that *gemmules* are thrown off from each different cell or unit throughout the body which retain the characters of the cells from which they spring; that the gemmules aggregate themselves either to form or to become included within the reproductive cells; and that in this manner they and the characters which they convey are capable of being transmitted in a dormant state to successive generations, and to reproduce in them the likeness of their parents, grandparents, and still older ancestors.

In 1872, and four years afterwards, in 1876, Mr. Francis Galton published most suggestive papers on Kinship and Heredity (Proc. Roy. Soc. Lond., 1872, and Journ. Anthrop. Inst, vol. v., 1876). In the latter of these papers he developed the idea that "the sum-total of the germs, gemmules, or whatever they may be called," which are to be found in the newly fertilized ovum, constitute a *stirp*, or root; that the germs which make up the stirp consist of two groups—the one which develops into the bodily structure of the individual, and which constitutes, therefore, the personal structure; the other, which remains latent in the individual, and forms, as it were, an undeveloped residuum; that it is from these latent or residual germs that the sexual elements intended for producing the next generation are derived, and that these germs exercise a predominance in matters of heredity; further, that the cells which make up the personal structure of the body of the individual exercise only in a very faint degree any influence on the reproductive cells, so that any modifications acquired by the individual are barely, if at all, inherited by the offspring.

Subsequent to the publication of Mr. Galton's essays, valuable contributions to the subject of Heredity have been made by Profs. Brooks, Jaeger, Naegeli, Nussbaum, Weismann, and others. Prof. Weismann's theory of Heredity embodies the same fundamental idea as that propounded by Mr. Galton; but as he has employed in its elucidation a phraseology which is more in harmony with that generally used by biologists, it has had more immediate attention given to it. As Weismann's essays have, during the present year, been translated for and published by the Clarendon Press (Oxford, 1889), under the editorial superintendence of Messrs. Poulton, Schönland, and Shipley, they are now readily accessible to all English readers.

Weismann asks the fundamental question, "How is it that a single cell of the body can contain within itself all the hereditary tendencies of the whole organism?" He at once discards the theory of pangenesis, and states that in his belief the germ-cell, so far as its essential and characteristic substance is concerned, is not derived at all from the body of the individual in which it is produced, but directly from the parent germ-cell from which the individual has also arisen. He calls his theory the *continuity of the germ-plasm*, and he bases it upon the supposition that in each individual a portion of the specific germ-plasm derived from the germ-cell of the parent is not used up in the construction of the body of that individual, but is reserved unchanged for the formation of the germ-cells of the succeeding generation. Thus, like Mr. Galton, he recognizes that in the stirp or germ there are two classes of cells destined for entirely distinct purposes: the one for the development of the *soma* or body of the individual, which class he calls the *somatic* cells; the other for the perpetuation of the species, *i.e.* for reproduction.

In further exposition of his theory Weismann goes on to say, as the process of fertilization is attended by a conjugation of the nuclei of the reproductive cells—the pronuclei referred to in an earlier part of this address—that the nuclear substance must be the sole bearer of hereditary tendencies. The two uniting nuclei would contain the germ-plasms of the parents, and this germ-plasm also would contain that of the grandparents as well as that of all previous generations.

To make these somewhat abstract propositions a little more clear, I have devised the following graphic mode of representation:—

Let the capital letters A, B, C, D, &c., express a series of successive generations. Suppose A to be the starting-point, and to represent the somatic or personal structure of an individual; then *a* may stand for the reproductive cells, or germ-plasm, from which the offspring of A, viz. B, is produced. B, like A, has both a personal structure and reproductive cells or germ-plasm, the latter of which is represented by the letters *ab*, which are intended to show that whilst belonging to B they have a line of continuity with A. C stands for an individual of the third generation, in which the reproductive plasm is indicated by *abc*, to express that, though within the body of C, the germ-plasm is continuous with that of both *b* and *a*. D also contains the reproductive cells, *abcd*, which are continuous with the germ-plasm of the three preceding generations, and so on.

It follows, therefore, from this theory that the germ-plasm possesses throughout the same complex chemical and molecular structure, and that it would pass through the same stages when the conditions of development are the same, so that the same final product would arise. Each successive generation would have therefore an identical starting-point, so that an identical product would arise from all of them.

Weismann does not absolutely assert that an organism cannot exercise a modifying influence upon the germ-cells within it; yet he limits this influence to such slight effect as that which would arise from the nutrition and growth of the individual, and the reaction of the germ-cell upon changes of nutrition caused by alteration in growth at the periphery, leading to some change in the size, number, and arrangements of its molecular units. But he throws great doubt upon the existence of such a reaction, and he, more emphatically than Mr. Galton, argues against the idea that the cells which make up the somatic or personal structure of the individual exercise any influence on the reproductive cells. From his point of view the structural or other properties which characterize a family, a race, or a species are derived solely from the reproductive cells through continuity of their germ-plasm, and are not liable to modification by the action on them of the organs or tissues of the body of the individual organism in which they are situated. To return for one moment to my graphic illustration in elucidation of this part of the theory. The cells which make up the personal structure of A or B would exercise no effect upon the character of the reproductive cells *a* or *ab* contained within them. These latter would not be modified or changed in their properties by the action of the individual organism A or B. The individual B would be in hereditary descent, not from A + *a*, but only from *a*, with which its germ-plasma *ab* would be continuous, and through which the properties of the family, race, or species would be transmitted to C, and so on to other successive generations.

The central idea of Heredity is permanency; that like begets like, or, as Mr. Galton more fitly puts it, that "like *tends* to produce like." But though the offspring conform with their parents in all their main characteristics, yet, as everyone knows, the child is not absolutely like its parents, but possesses its own character, its own individuality. It is easy for anyone to recognize that differences exist amongst men when he compares one individual with another; but it is equally easy for those who make a special study of animals to recognize individual differences in them also. Thus a pigeon or canary fancier distinguishes without fail the various birds in his flock, and a shepherd knows every sheep under his charge. But the anatomist tells us that these differences are more than superficial—that they also pervade the internal structure of the body. In a paper which I read to the meeting of this Association in Birmingham so long ago as 1865,[1] after relating a series of instances of variation in structure observed in the dissections of a number of human bodies, I summarized my conclusion as follows: "Hence, in the development of each individual, a morphological specialization occurs both in internal structure and external form by which distinctive characters are conferred, so that each man's structural individuality is an expression of the sum of the individual variations of all the constituent parts of his frame."

As in that paper I was discussing the subject only in its morphological relations, I limited myself to that aspect of the question; but I might with equal propriety have also extended my conclusion to other aspects of man's nature.

Intimately associated, therefore, with the conception of Heredity—that is, the transmission of characters common to both parent and offspring—is that of Variability—that is, the appearance in an organism of certain characters which are unlike those possessed by its parents. Heredity, therefore, may be defined as the perpetuation of the like; Variability, as the production of the unlike.

And now we may ask, Is it possible to offer any feasible explanation of the mode in which variations in organic structure take their rise in the course of development of an individual organism? Anything that one may say on this head is of course a matter of speculation, but certain facts may be adduced as offering a basis for the construction of an hypothesis, and on this matter Prof. Weismann makes a number of ingenious suggestions.

Prior to the conjugation of the male and female pronuclei to form the segmentation nucleus a portion of the germ-plasm is extruded from the egg to form what are called the *polar bodies*. Various theories have been advanced to account for the significance of this curious phenomenon. Weismann explains it on the hypothesis that a reduction of the number of ancestral germ-plasms in the nucleus of the egg is a necessary preparation for fertilization and for the development of the young animal. He supposes that by the expulsion of the polar bodies one-half the number of ancestral germ-plasms is removed, and that the original bulk is restored by the addition of the male pronucleus to that which remains. As precisely corresponding molecules of this plasm need not be expelled from each ovum, similar ancestral plasms are not retained in each case; so that diversities would arise even in the same generation and between the offspring of the same parents.

Minute though the segmentation nucleus is, yet microscopic research has shown that it is not a homogeneous structureless body, but is built up of different parts. Most noteworthy are the presence of extremely delicate threads or fibrils, called the *chromatin filaments*, which are either coiled on each other, or intersect to form a network-like arrangement. In the meshes of this network a viscous—and, so far as we yet know, structureless—substance is situated. Before the process of division begins in the segmentation nucleus these filaments swell up and then proceed to arrange themselves at first into one and then into two star-like figures before the actual division of the nucleus takes place.[1] It is obvious, therefore, that the molecules which enter into the formation of the segmentation nucleus can move within its substance, and can undergo a readjustment in size and form and position. But this readjustment of material is, without doubt, not limited to those relatively coarse particles which can be seen and examined under the microscope, but applies to the entire molecular structure of the segmentation nucleus. Now it must be remembered that the cells of the embryo from which all the tissues and organs of the adult body are derived are themselves descendants of the segmentation nucleus, and they will doubtless inherit from it both the power of transmitting definite characters and a certain capacity for readjustment both of their constituent materials and the relative positions which they may assume towards each other. One might conceive, therefore, that if in a succession of organisms derived from common ancestors the molecular particles were to be of the same composition and to arrange themselves in the segmentation nucleus and in the cells derived from it on the same lines, these successive generations would be alike; but if the lines of adjustment and the molecular constitution were to vary in the different generations, then the products would not be quite the same. Variations in structure, and to some extent also in the construction of parts, would arise, and the unlike would be produced.

In this connection it is also to be kept in mind that in the higher organisms, and, indeed, in multicellular organisms generally, an individual is derived, not from one parent only, but from two parents. Weismann emphasizes this combination as the cause of the production of variations and the transmission of hereditary individual characters. If the proportion of the particles derived from each parent and the forces which they exercise were precisely the same in any individual case, then one could conceive that the product would be a mean of the components provided by the two parents. But if one parent were to contribute a larger proportion than the other to the formation of a particular organism, then the balance would be disturbed, the offspring in its character would incline more to one parent than to the other, according to the proportion contributed by each, and a greater scope for the production of variations would be provided. These differences would be increased in number in the course of generations, owing to new combinations of individual characters arising in each generation.

As long as the variations which are produced in an organism are collectively within a certain limitation, they are merely individual variations, and express the range within which such an organism, though exhibiting differences from its neighbours, may yet be classed along with them in the same species. It is in this sense that I have discussed the term Variability up to the present stage of this address. Thus all those varieties of mankind which, on account of differences in the colour of the skin, we speak of as the white, black, yellow races and red-skins are men, and they all belong to that species which the zoologists term *Homo sapiens*.

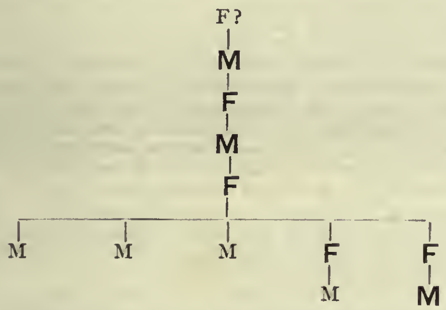
But the subject of Variability cannot, in the present state of science, be confined in its discussion to the production of individual variations within the limitations of a common species. Since Charles Darwin enunciated the proposition that favourable variations would tend to be preserved, and unfavourable ones to be destroyed, and that the result of this double action, by the accumulation of minute existing differences, would be the formation of new species by a process of natural selection, this subject has attained a much wider scope, has acquired increased importance, and has formed the basis of many ingenious speculations and hypotheses. As variations, when once they have arisen, may be hereditarily transmitted, the Darwinian theory might be defined as Heredity modified and influenced by Variability.

This is not the place to enter on a general discussion of the Darwinian theory, and even if it were, the time at our disposal

[1] Transactions of Sections, p. 111, 1865, and Trans. Roy. Soc. Edinburgh, vol. xxiv., 1865.

[1] The observations more especially of Flemming, E. Van Beneden, Strasburger, and Carnoy may be referred to in connection with the changes which take place in nuclei prior to and in connection with their division.

would not admit of it. But there are some aspects of the theory which would need to be referred to in connection with the subject now before us. It may be admitted that many variations which may arise in the development of an individual, and which are of service to that individual, would tend to be preserved and perpetuated in its offspring by hereditary transmission. But it is also without question that variations which are of no service, and, indeed, are detrimental, to the individual in which they occur, are also capable of being hereditarily transmitted. This statement is amply borne out in the study of those important defects in bodily structure which pathologists group together under the name of Congenital Malformations. I do not require to go into much detail on this head, or to cite cases in which the congenital defect can only be exposed by dissection, but may refer, by way of illustration, to one or two examples in which the defect is visible on the surface of the body. The commonest form of malformation the hereditary transmission of which has been proved is where an increase in the number of digits on the hands or feet, or on both, occurs in certain families, numerous instances of which have now been put on record. But in other families there is an hereditary tendency to a diminution in the number of digits or to a defect in the development of those existing. I may give an illustration which occurred in the family of one of my pupils, the deformity in which consisted in a shortening or imperfect growth of the metacarpal bone of the ring finger of the left hand, so that the length of that finger was much below the normal. This family defect was traceable throughout six generations, and perhaps even in a seventh, and was, as a rule, transmitted alternately from the males to the females of the family (*Journ. Anat. and Phys.*, vol. xviii. p. 463)—

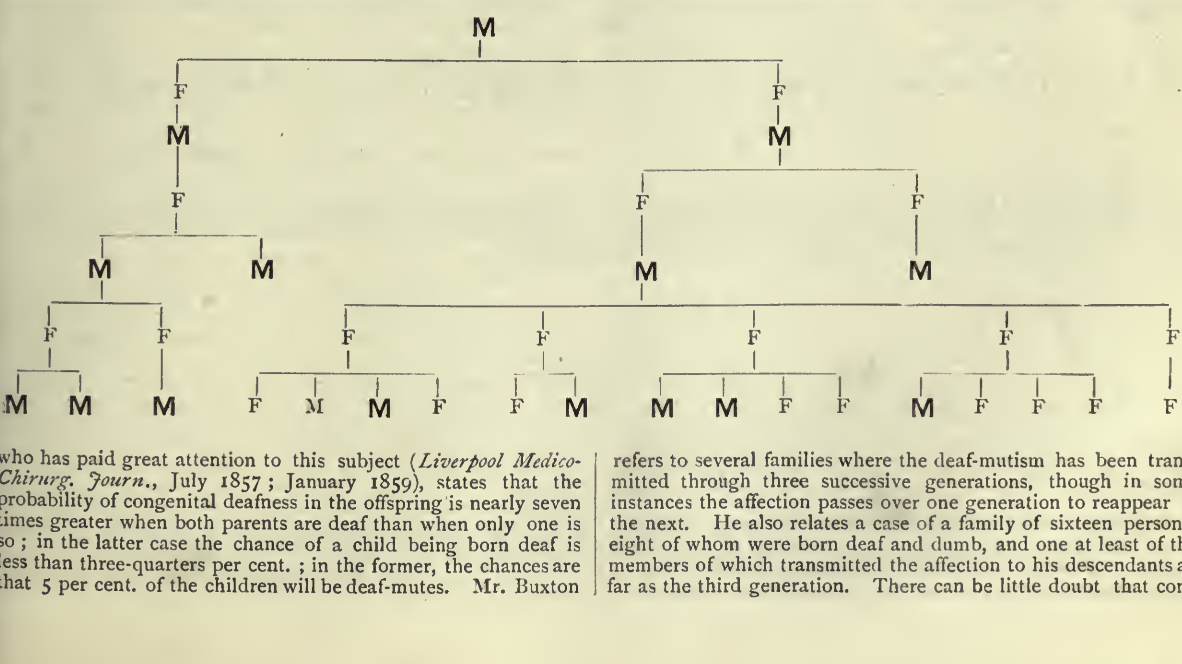


In this and the following diagrams M stands for male, F for female, whilst the block type (**M** or **F**) marks the individual or generation in which the variation occurred.

Another noticeable deformity which is known to be hereditary in some families, and which may be familiar to some of my auditors, is that of imperfect development of the upper lip and roof of the mouth, technically known as hare-lip and cleft palate.

These examples illustrate what may be called the coarser kinds of hereditary deformity, where the redundancies or defects in parts of the body are so gross as at once to attract attention. But modifications or variations in structure that can be transmitted from parent to offspring are by no means limited to changes which can be detected by the naked eye. They are sometimes so minute as to be determined rather by the modifications which they occasion in the function of the organ than by the ready recognition of structural variations. One of the most interesting of these is the affection known as Daltonism, or colour-blindness, which has distinctly been shown to be hereditary, and which is due, apparently in the majority of cases, to a defect in the development of the retina, or of the nerve of sight which ends in it, though in some instances they may be occasioned by defective development of the brain itself. Dr. Horner has related a most interesting family history (cited in "Die Allgemeine Pathologie," by Dr. Edwin Klebs, Jena, 1887), in which the colour-blindness was traced through seven generations. In this family the males were the persons affected, though the peculiarity was transmitted through the females, who themselves remained unaffected. The family tree showed that in the sixth generation seven mothers had children. Their sons, collectively nine in number, were all colour-blind with the exception of one son, while none of their nine daughters showed the hereditary defect. (See diagram below.)

The eye is not the only organ of sense which exhibits a tendency to the production of hereditary congenital defects. The ear is similarly affected, and intimately associated with congenital deafness is an inability to speak articulately, which occasions the condition termed Deaf-mutism. Statisticians have given some attention to this subject, both as regards its relative frequency and its hereditary character. The writer of the article "Vital Statistics," in the Report of the Irish Census Commissioners during the decades ending 1851, 1861, 1871, has discussed at some length the subject of congenital deaf-mutism, and has produced a mass of evidence which proves that it is often hereditarily transmitted. In the Census Report for 1871 (vol. lxxii. Part II., "Report on the Status of Disease," p. 1, 1873), 3297 persons were returned as belonging to this class, and in 393 cases the previous or collateral branches of the family were also mute. In 211 of these the condition was transmitted through the father; in 182 through the mother. In 2579 cases there was one deaf-mute in a family; in 379 instances, two; in 191 families, three; in 53, four; in 21, five; in 5, six; and in each of two families no fewer than seven deaf-mutes were born of the same parents. In one of these two families neither hereditary predisposition nor any other probable physiological or pathological reason was assigned to account for the peculiarity, but in the other family the parents were first cousins. Mr. David Buxton,



who has paid great attention to this subject (*Liverpool Medico-Chirurg. Journ.*, July 1857; January 1859), states that the probability of congenital deafness in the offspring is nearly seven times greater when both parents are deaf than when only one is so; in the latter case the chance of a child being born deaf is less than three-quarters per cent.; in the former, the chances are that 5 per cent. of the children will be deaf-mutes. Mr. Buxton refers to several families where the deaf-mutism has been transmitted through three successive generations, though in some instances the affection passes over one generation to reappear in the next. He also relates a case of a family of sixteen persons, eight of whom were born deaf and dumb, and one at least of the members of which transmitted the affection to his descendants as far as the third generation. There can be little doubt that congenital deaf-mutism, in the great majority of instances, is associated with a defective development, and therefore a structural variation of the organ of hearing, though in some cases, perhaps, the defect may be in the development of the brain itself.

Although a sufficient number of cases has now been put on record to prove that in some families one or other kind of congenital deformity may be hereditarily transmitted, yet I do not wish it to be supposed that congenital malformations may not arise in individuals in whom no hereditary tendency can be traced. It is undoubtedly true that family histories are in many cases very defective, and frequently cannot be followed back for more than one, or, at the most, two generations; so that it is not unlikely that an hereditary predisposition may exist in many instances where it cannot be proved. Still, allowing even for a considerable proportion of such cases, a sufficient number will remain to warrant the statement that malformations or variations in structure which have not been displayed by their ancestors may arise in individuals belonging to a particular generation.

The variations which I have spoken of as congenital malformations arise, as a rule, before the time of birth, during the early development of the individual; but there is an important class of cases, in which the evidence for hereditary transmission is more or less strong, which may not exhibit their peculiarities until months, or even years, after the birth of the individual. This class is spoken of as hereditary diseases, and the structural and functional changes which they produce exercise most momentous influences. Sometimes these diseases may occasion changes in the tissues and organs of the body of considerable magnitude, but at other times the alteration is much more subtle, is molecular in its character, requires the microscope for its determination, or is even incapable of being recognized by that instrument.

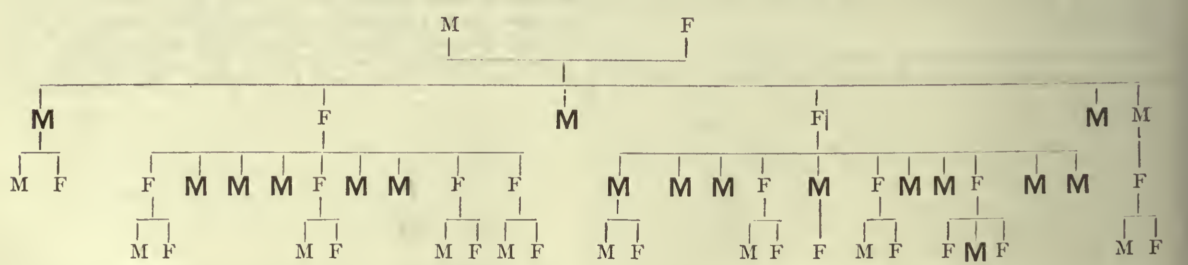
Had one been discussing the subject of hereditary disease twenty years ago, the first example probably that would have been adduced would have been tuberculosis, but the additions to our knowledge of late years throw some doubt upon its hereditary character. There can, of course, be no question that tubercular disease propagates itself in numerous families from generation to generation, and that such families show a special susceptibility or tendency to this disease in one or other of its forms. But whilst fully admitting the predisposition to it which exists in certain families, there is reason to think that the structural disease itself is not hereditarily transmitted, but that it is directly excited in each individual in whom it appears by a process of external infection due to the action of the tubercle bacillus. Still, if the disease itself be not inherited, a particular temperament which renders the constitution liable to be attacked by it is capable of hereditary transmission.

Sir James Paget,[1] when writing on the subject of cancer, gives statistics to show that about a quarter of the persons affected were aware of the existence of the same disease in other members of their family, and he cites particular instances in which cancer was present in two and even four generations. He had no doubt that the disease can be inherited—not, he says, that, strictly speaking, cancer or cancerous material is transmitted, but a tendency to the production of those conditions which will finally manifest themselves in a cancerous growth. The germ from the cancerous parent must be so far different from the normal as after the lapse of years to engender the cancerous condition.

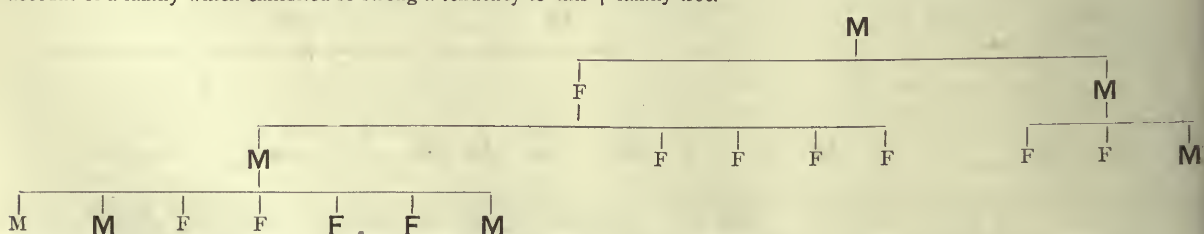
Heredity is also one of the most powerful factors in the production of those affections which we call gout and rheumatism. Sir Dyce Duckworth, the latest systematic writer on gout, states that in those families whose histories are the most complete and trustworthy the influence is strongly shown, and occurs in from 50 to 75 per cent. of the cases; further, that the children of gouty parents show signs of articular gout at an age when they have not assumed those habits of life and peculiarities of diet which are regarded as the exciting causes of the disease.

Some interesting and instructive family histories, in which the hereditary transmission of a particular disease through several generations has been worked out, are recorded by Prof. Klebs in his "Allgemeine Pathologie." I may draw from these one or two additional illustrations. Some families exhibit a remarkable tendency to bleed when the surface of the body is injured or bruised, and the bleeding is stopped with difficulty. The hæmorrhagic tendency is not due to the state of the blood, but to a softening or degeneration of the walls of the blood-vessels, so that they are easily torn. In one family, the tree of which is here subjoined, this peculiarity showed itself in one generation in three out of four males; in the next generation, in thirteen out of fourteen males; whilst in the immediately succeeding generation only one out of nine males was affected; so that it would seem as if the tendency was fading away in it. It is remarkable that throughout the series, though the transmission of the affection went through the female members, they themselves remained free from it.

The bleeding family Mampel, recorded by Dr. Lossen.



Another illustration may be taken from the well-known disease of the eyeball called cataract. Dr. Appenzeller has given an account of a family which exhibited so strong a tendency to this affection that the males were affected in four generations, though the females did not entirely escape, as is shown in the subjoined family tree.



In neither of these families can it be said that the structural lesion itself is transmitted, but that the tendency or predisposition to produce it is inherited. The germ-plasm, therefore, in these individuals must have been so modified from the normal as to carry with it certain peculiarities, and to induce the particular form of disease which showed itself in each family.

[1] "Lectures on Surgical Pathology," third edition, revised and edited by the author and W. Turner (London, 1870).

In connection with the tendency to the transmissibility of either congenital malformations or diseases, consanguinity in the parents, although by no means a constant occurrence, is a factor which in many cases must be taken into consideration.[1] If we could conceive both parents to be physiologically perfect, then it may be presumed that the offspring would be so also; but if there be a departure in one parent from the plane of physiological perfection, then it may safely be assumed that either the immediate offspring or a succeeding generation will display a corresponding departure in a greater or less degree. Should both parents be physiologically imperfect, we may expect the imperfections if they are of a like nature to be intensified in the children. It is in this respect, therefore, that the risk of consanguineous marriages arises, for no family can lay claim to physiological perfection.

When we speak of tendencies, susceptibilities, proclivities, or predisposition to the transmission of characters, whether they be normal or pathological, we employ terms which undoubtedly have a certain vagueness. We are as yet quite unable to recognize, by observation alone, in the germ-plasm any structural change which would enable us to say that a particular tendency or susceptibility will be manifested in an organism derived from it. We can only determine this by following out the life-history of the individual. Still it is not the less true that these terms express a something of the importance of which we are all conscious. So far as Man is concerned, the evidence in favour of a tendency to the transmission of both structural and functional modifications which are either of dis-service, or positively injurious, or both, is quite as capable of proof as that for the transmission of characters which are likely to be of service. Hence useless as well as useful characters may be selected and transmitted hereditarily.

I have dwelt somewhat at length on the transmissibility of useless characters, for it is an aspect of the subject which more especially presents itself to the notice of the pathologist and physician; and little, if at all, to that of those naturalists whose studies are almost exclusively directed to the examination of organisms in their normal condition. But when we look at Man, his diseases form so large a factor in his life that they and the effects which they produce cannot be ignored in the study of his nature.

Much has been said and written during the last few years of the transmission from parents to offspring of characters which have been "acquired" by the parent, so that I cannot altogether omit some reference to this subject. It will conduce to one's clearness of perception of this much-discussed question if one defines at the outset in what sense the term "acquired characters" is employed; and it is the more advisable that this should be done, as the expression has not always been used with the same signification. This term may be used in a wide or in a more restricted sense. In its wider meaning it may cover all the characters which make their first appearance in an individual, and which are not found in its parents, in whatever way they have arisen—

(1) Whether their origin be due to such molecular changes in the germ-plasm as may be called spontaneous, leading to such an alteration in its character as may produce a new variation; or,

(2) Whether their origin be accidental, or due to habits, or to the nature of the surroundings, such as climate, food, &c.

Prof. Weismann has pointed out with great force the necessity of distinguishing between these two kinds of "acquired characters," and he has suggested two terms the employment of which may keep before us how important it is that these different modes of origin should be recognized. Characters which are produced in the germ-plasm itself by natural selection, and all other characters which result from this latter cause, he names *blastogenic*. He further maintains that all blastogenic characters can be transmitted; and in this conclusion, doubtless, most persons will agree with him. On the other hand, he uses the term *somatogenic* to express those characters which first appear in the body itself, and which follow from the reaction of the *soma* under direct external influences. He includes under this head the effects of mutilation, the changes which follow from increased or diminished performance of function, those directly due to nutrition, and any of the other direct external influences which act upon the body. He further maintains that the somatogenic characters are not capable of transmission from parent to offspring, and he suggests that in future discussions on this subject the term "acquired characters" should be restricted to those which are somatogenic.

Thus one might say that blastogenic characters arising in the germ would be acquired in the individual by the action of the germ upon the soma; so that if we return again to the graphic illustration previously employed, the germ-plasm represented by the small italic letters *abcd* would act upon the soma represented by the capital letters A, B, C, D. Somatogenic characters, again, arising in the soma, would be acquired by the action of the soma A, B, C, D, upon the contained germ-plasm *abcd*. But whether those acquired characters expressed by the term somatogenic can or can not be transmitted has been fruitful of discussion.

That the transmission of characters so acquired can take place is the foundation of the theory of Lamarck, who imagined that the gradual transformation of species was due to a change in the structure of a part of an organism under the influence of new conditions of life, and that such modifications could be transmitted to the offspring. It was also regarded as of importance by Charles Darwin, who stated[1] that all the changes of corporeal structure and mental power cannot be exclusively attributed to the natural selection of such variations as are often called spontaneous, but that great value must be given to the inherited effects of use and disuse, some also to the modification in the direct and prolonged action of changed conditions of life, also to occasional reversions of structure. Herbert Spencer believes[2] that the natural selection of favourable varieties is not in itself sufficient to account for the whole of organic evolution. He attaches a greater importance than Darwin did to the share of use and disuse in the transmission of variations. He believes that the inheritance of functionally produced modifications of structure takes place universally, and that as the modification of structure by function is a *vera causa* as regards the individual, it is unreasonable to suppose that it leaves no traces in posterity.

On the other hand, there are very eminent authorities who contend that the somatogenic acquired characters are not transmissible from parent to offspring. Mr. Francis Galton, for example, gives a very qualified assent to this proposition. Prof. His, of Leipzig, doubts its validity. Prof. Weismann says that there is no proof of it. Mr. Alfred Russel Wallace, in his most recent work,[3] considers that the direct action of the environment, even if we admit that its effects on the individual are transmitted by inheritance, are so small in comparison with the amount of spontaneous variation of every part of the organism that they must be quite over-shadowed by the latter. Whatever other causes, he says, have been at work, natural selection is supreme to an extent which even Darwin himself hesitated to claim for it.

There is thus a conflict of opinion amongst the authorities who have given probably the most thought to the consideration of this question. It may appear, therefore, to be both rash and presumptuous on my part to offer an opinion on this subject. I should, indeed, have been slow to do so had I not thought that there were some aspects of the question which seemed not to have been sufficiently considered in its discussion.

In the first place, I would, however, express my agreement with much that has been said by Prof. Weismann on the want of sufficient evidence to justify the statement that a mutilation which has affected a parent can be transmitted to the offspring. It is, I suppose, within the range of knowledge of most of us that children born of parents who have lost an eye, an arm, or a leg, come into the world with the full complement of eyes and limbs. The mutilation of the parent has not affected the offspring; and one would, indeed, scarcely expect to find that such gross visible losses of parts as take place when a limb is removed by an accident or a surgical operation should be repeated in the offspring. But a similar remark is also applicable to such minor mutilations as scars, the transmission of which to the offspring, though it has been stoutly contended for by some, yet seems not to be supported by sufficiently definite instances.

I should search for illustrations of the transmission of somatogenic characters in the more subtle processes which affect living organisms, rather than those which are produced by violence

[1] I may especially refer for a discussion of this subject to an admirable essay, by Sir Arthur Mitchell, K.C.B., "On Blood Relationship in Marriage considered in its Influence upon the Offspring."

and accident. I shall take as my example certain facts which are well known to those engaged in the breeding of farm-stock or of other animals that are of utility to or are specially cultivated by man.

I do not refer to the influence on the offspring of impressions made on the senses and nervous system of the mother, the first statement of the effects of which we find in the book of Genesis, where Jacob set peeled rods before the flocks in order to influence the colour and markings of their young; though I may state that I have heard agriculturists relate instances from their own experience which they regarded as bearing out the view that impressions acting through the mother do influence her offspring. But I refer to what is an axiom with those who breed any particular kind of stock, that to keep the strain pure, there must be no admixture with stock of another blood. For example, if a shorthorned cow has a calf by a Highland sire, that calf, of course, exhibits characters which are those of both its parents. But future calves which the same cow may have when their sires have been of the shorthorned blood, may, in addition to shorthorn characters, have others which are not shorthorned but Highland. The most noteworthy instance of this transmission of characters acquired from one sire through the same mother to her offspring by other sires is that given in the often-quoted experiment by a former Lord Morton.[1] An Arabian mare in his possession produced a hybrid the sire of which was a quagga, and the young one was marked by zebra-like stripes. But the same Arabian had subsequently two foals, the sire of which was an Arab horse, and these also showed some zebra-like markings. How, then, did these markings characteristic of a very different animal arise in these foals, both parents of which were Arabians? I can imagine it being said that this was a case of reversion to a very remote striped ancestor, common alike to the horse and the quagga. But, to my mind, no such far-fetched and hypothetical explanation is necessary. The cause of the appearance of the stripes seems to me to be much nearer and more obvious. I believe that the mother had acquired, during her prolonged gestation with the hybrid, the power of transmitting quagga-like characters from it, owing to the interchange of material which had taken place between them in connection with the nutrition of the young one. For it must be kept in mind that in placental mammals an interchange of material takes place in opposite directions, from the young to the mother as well as from the mother to the young.[2] In this way the germ-plasm of the mother, belonging to ova which had not yet matured, had become modified whilst still lodged in the ovary. This acquired modification had influenced her future offspring, derived from that germ-plasm, so that they in their turn, though in a more diluted form, exhibited zebra-like markings. If this explanation be correct, then we have an illustration of the germ-plasm having been directly influenced by the soma, and of somatogenic acquired characters having been transmitted.

But there are other facts to show that the isolation of the germ-cells or germ-plasm from the soma cells is not so universal as might at the first glance be supposed. Weismann himself admits that in the Hydroids the germ-plasm is present in a very finely divided, and therefore invisible, state, in certain somatic cells in the beginning of embryonic development, and that it is then transmitted through innumerable cell generations to those remote individuals of the colony in which sexual products are formed. The eminent botanist Prof. Sachs states that in the true mosses almost any of the cells of the roots, leaves, and shoot axes may form new shoots and give rise to independent living plants. Plants which produce flowers and fruit may also be raised from the leaves of the *Begonia*. I may also refer to what is more or less familiar to everybody, that the tuber of the potato can give rise to a plant which bears flowers and fruit. Now in all these cases the germ-plasm is not collected in a definite receptacle isolated from the soma, but is diffused through the cells of the leaves of the *Begonia* or amidst those of the tuber of the potato, and the propagation of the potato may take place through the tuber for several generations without the necessity of having to recur to the fruit for seed. It seems difficult, therefore, to understand why, in such cases, the nutritive processes which affect and modify the soma cells should not also react upon the germ-plasm, which, as Weismann admits, is so intimately associated with them.

[2] See, for example, Essays by Profs. Harvey and Gusserow and Mr. Savory; also my "Lectures on the Comparative Anatomy of the Placenta" (Edinburgh, 1876).

Those who uphold the view that characters acquired by the soma cannot be transmitted from parents to offspring undoubtedly draw so large a cheque on the bank of hypothesis that one finds it difficult, if not impossible, to honour it. Let us consider for one moment all that is involved in the acceptance of this theory, and apply it in the first instance to Man. On the supposition that all mankind have been derived from common ancestors through the continuity of the germ-plasm, and that this plasm has undergone no modification from the *persona* or *soma* of the succession of individuals through whom it has been transmitted, it would follow that the primordial human germ-plasm must have contained within itself an extraordinary potentiality of development—a potentiality so varied that all those multiform variations in physical structure, tendency to disease, temperament, and other characters and dispositions which have been exhibited by all the races and varieties of men who either now inhabit or at any period in the world's history have inhabited the earth, must have been included in it. But if we are to accept the theory of Natural Selection, as giving a valid explanation of the origin of new species, then the non-transmissibility of somatogenic acquired characters has a much more far-reaching significance. For if all the organisms, whether vegetable, animal, or human, which have lived upon the earth have arisen by a more or less continuous process of evolution from one or even several simple cellular organisms, it will follow, as a logical necessity of the theory, that these simple organisms must have contained in their molecular constitution a potentiality of evolution into higher and more complex forms of life, through the production of variations, without the intermediation of any external force or influence acting directly upon the soma. Further, this must have endured throughout a succession of countless individual forms and species, extending over we know not how many thousands of years, and through the various geological and climatic changes which have affected the globe.

The power of producing these variations would therefore, on this theory, have been from the beginning innate to the germ-plasm, and uninfluenced in any way by its surroundings. Variations would have arisen spontaneously in it, and, for anything that we know, as it were by accident, and without a definite purport or object. But whether such variations would be of service or dis-service could not be ascertained until after their appearance in the soma had subjected them to the test of the conditions of life and the environment.

Let us now glance at the other side of the question. All biologists will, I suppose, accept the proposition that the individual soma is influenced or modified by its environment or surroundings. Now, if on the basis of this proposition the theory be grafted that modifications or variations thus produced are capable of so affecting the germ-plasm of the individual in whom the variation arises as to be transmitted to its offspring—and I have already given cases in point—then such variations might be perpetuated. If the modification is of service, then presumably it will add to the vitability of the individual, and through the interaction between the soma and the germ-plasm, in connection with their respective nutritive changes, will so affect the latter as to lead to its being transmitted to the offspring. From this point of view the environment would, as it were, determine and regulate the nature of those variations which are to become hereditary, and the possibility of variations arising which are likely to prove useful becomes greater than on the theory that the soma exercises no influence on the germ-plasm. Hence I am unable to accept the proposition that somatogenic characters are not transmitted, and I cannot but think that they form an important factor in the production of hereditary characters.

To reject the influence which the use and disuse of parts may exercise both on the individual and on his offspring is like looking at an object with only a single eye. The morphological aspect of organic structure is undoubtedly of fundamental importance. But it should not be forgotten that tissues and organs, in addition to their subjection to the principles of development and descent, have to discharge certain specific purposes and functions, and that structural modifications arise in them in correlation with the uses to which they are put, so as to adapt them to perform modified duties. It may be difficult to assign the exact value which physiological adaptation can exercise in the perpetuation of variations. If the habit or external condition which has produced a variation continues to be practised, then, in all probability, the variation would be intensified in successive generations. But should the habit cease or the external condition be changed, then, although the variation might continue to be for a time perpetuated by descent, it would probably become less strongly marked and perhaps ultimately disappear. One could also conceive that the introduction of a new habit or external condition the effect of which would be to produce a variation in a direction different from that which had originally been acquired, would tend to neutralize the influence of descent in the transmission of the older character.

By accepting the theory that somatogenic characters are transmitted we obtain a more ready explanation how men belonging to a race living in one climate or part of the globe can adapt themselves to a climate of a different kind. On the theory of the non-transmissibility of these acquired characters, long periods of years would have to elapse before the process of adaptation could be effected. The weaker examples, on this theory, would have had to have died out, and the racial variety would require to have been produced by the selection of variations arising slowly, and requiring one knows not how many hundreds or thousands of years to produce a race which could adapt itself to its new environment. We know, however, that this process of the dying out of the weakest and the selection of the strongest is not necessary to produce a race which possesses well-recognizable physical characters. For most of us can, I think, distinguish the nationality of a citizen of the United States by his personal appearance, without being under the necessity of waiting to hear his speech and intonation

It may perhaps be thought that, in selecting the subject of Heredity for my address, and in treating it, as I have to a large extent done, in its general biological aspects, I have infringed upon the province of Section D. But I am not prepared to admit that any such encroachment has been made. Man is a living organism, with a physical structure which discharges a variety of functions, and both structure and functions correspond in many respects, though with characteristic differences, with those which are found in animals. The study of his physical frame cannot therefore be separated from that of other living organisms, and the processes which take place in the one must also be investigated in the other. Hence we require, in the special consideration of the physical framework of Man, to give due weight to those general features of structure and functions which he shares in common with other living organisms. But whatever may have been the origin of his frame, whether by evolution from some animal form or otherwise, we can scarcely expect it ever to attain any greater perfection than it at present possesses.

The physical aspect of the question, although of vast importance and interest, yet by no means covers the whole ground of Man's nature, for in him we recognize the presence of an element beyond and above his animal framework.

Man is also endowed with a spiritual nature. He possesses a conscious responsibility which enables him to control his animal nature, to exercise a discriminating power over his actions, and which places him on a far higher and altogether different platform than that occupied by the beasts which perish. The kind of evolution which we are to hope and strive for in him is the perfecting of this spiritual nature, so that the standard of the whole human race may be elevated and brought into more harmonious relation with that which is holy and divine.

REPORTS.

Report (Second) of the Committee appointed for the purpose of Collecting Information as to the Disappearance of Native Plants from their Local Habitats. Prof. Hillhouse, Secretary.

As intimated at the close of the Report for 1887,[1] the Committee has given its attention in the first instance to Scotland, and appends hereto such portion of the materials placed at its disposal as, for any reason, it considers desirable to publish. It has excluded a considerable number of plants of little interest, and especially such as the records show to be recent introductions, casuals, escapes, &c., the loss of which is only a return, therefore, to an earlier, but still recent, state. There is little doubt that the list, even thus restricted, will be considerably amplified hereafter.

The plants recorded are numbered in accordance with the "London Catalogue," eighth edition, in which the distribution census of each plant will be found. Nearly all of the records are on the authority of some competent botanist resident in the locality, and whose initials, or some distinguishing initials, are appended. As has been pointed out by more than one correspondent, scarce plants occasionally well-nigh disappear in particular seasons, and hence the records of other than frequent visitors are not fully reliable.

[1] The Committee was unable to report in 1888, having lapsed by accident.

The attention of botanists is particularly drawn to the records under the numbers 52, 264, 374, 406, 570, 575, 687, 910, 932, 993, 1018, 1020, 1478, 1695, and 1772, as giving examples of divers ways, often very curious and interesting, in which plants can become extinct.

The attention of the Committee's correspondents has been, in the main, confined to complete or threatened extinction; but in addition to this there is a general consensus of opinion that the rarer and more conspicuous Alpine plants are less abundant than they used to be. Amongst the localities specially mentioned are Clova and Ben Lawers; such plants (in addition to those given in the list) as *Saxifraga cernua*, *Alsine rubella*, *Gentiana nivalis*, &c., are notably less frequent than twenty years ago. Strange rumours have been communicated to the Committee as to the disappearance of plants from accessible habitats within the range of some of the deer "forests," but it is unable to verify these statements. Most of the correspondents agree, however, that the injudicious action of botanists themselves, and of botanical exchange clubs, has been a potent factor in the changes which have taken place. It is too often forgotten that the very rarity of a plant is the sign, and in great degree also the measure, of the acuteness of its struggle for existence, and that when a plant is in a state of unstable equilibrium with its environment, a small disturbance may have disproportionately great effects.

It will be observed that the "dealer" and "collector" figure largely, especially in connection with the disappearance of ferns. Thus one of the correspondents indicates (and offers to name) a dealer who has extirpated, or well-nigh extirpated, a considerable number of species in the district of Dumfries, and whose conduct he had brought under the notice of the local Natural History Society, of which the correspondent is Secretary. "He had also removed and sold almost all of the plants of *Nymphæa alba* from the lochs of this district before discovery; but now, I am happy to say, he is forbidden access to any estate in this district under penalty of prosecution for trespass." The attention of Natural History Societies may well be drawn to this case, as it happily illustrates at the same time one phase of the disease and a cure.

"Summer visitors" do not appear to be directly responsible for much damage, as their wanderings are probably over too restricted an area to produce much effect. There is no doubt, however, that they provide the larger portion of the customers of the "collector," and so are indirectly answerable for his ravages. The temptation to bring home some rare and beautiful fern, like *Aspidium* (*Polystichum*) *Lonchitis*, as a relic of a northern trip, is too great to be resisted, though something may possibly be done by persuading tourists that equally good plants, taken up with all proper care, and at a season when transplanting is not dangerous, can be obtained from any great fern nursery, for a price which is practically lower, often much lower, than that charged upon some Highland railway platform or roadside.

The Committee feels, however, that neither local dealers nor their customers are as a rule amenable to any ordinary appeal or to sentimental considerations, and would suggest therefore that the local Natural History Societies or Field Clubs should keep careful guard over any rare plants to be found within their respective spheres of action, and by appeal to the owner, or in other preferable way, should endeavour to effect their preservation. At the same time, many correspondents draw attention to the insertion by gardening periodicals of the advertisements of collecting dealers, and express the hope that the amount of revenue derived from these advertisements is not so great as to negative the possibility that the gardening journals may be induced, by discontinuing their insertion, to strike a heavy blow at a process which is depriving many districts of our land of one of their chief natural beauties.

39 *Trollius europæus*, L. Extinct in Mid-Aberdeen, &c. (W. W. and J. M.).

52. *Nymphæa alba*, L. Almost extirpated from lochs in the district round Dumfries by a dealer (J. W.). Has disappeared from the district of Birnie, near Elgin, by drainage (G. and T. A.).

58. *Meconopsis cambrica*, Vig. Believed to be extirpated from banks of Water of Leith and Currie, Midlothian (G. A. P.).

59. *Glaucium flavum*, Crantz. Recorded in 1776 for sea-shore at Bay of Nigg, near Aberdeen, but not since 1800 (J. W. H. T.). Found sixty years ago at Montrose Links; not now (R. B.).

184. *Dianthus Armeria*, L. Occurred, though not abundantly, in rough pasture near Glencarse Station, Perthshire; has been entirely destroyed through the cultivation of the ground (F. B. W.). This was one of its most northern stations.

207. *Lychnis viscaria*, L. Blackford Hill, Midlothian; now very rare (G. A. P.). Arthur's Seat, Edinburgh; supposed to be extirpated (G. A. P.),

208. *Lychnis alpina*. Is now becoming rare in its habitats on Clova Mountains (G. A. P.).

263. *Hypericum perforatum*, L. Formerly grew plentifully near Cromarty Nursery, but has ceased to exist, as the ground is now used for agricultural purposes (T. A.). This was one of its most northern stations.

264. *Hypericum quadrangulum*, L. Has wholly disappeared from the vicinity of Fortrose, Ross-shire, having been eaten by cattle or trodden down (T. A.). This was one of its most northern stations.

368. *Lotus pilosus*, Beeke. Extinct round Alford, Mid-Aberdeenshire, from cultivation (W. W.).

374. *Oxytropis uralensis*, D.C. Grew in abundance near Invergordon, Ross-shire, but on one occasion the medical man of the town saw a man digging it up with a trowel, and it is now extinct (T. A.).

375. *Oxytropis campestris*, D.C. Rocks at Bradoony, Clova; now very rare; extirpated from all accessible parts of the rocks (G. A. P.).

406. *Lathyrus niger*, Wimm. Has well-nigh disappeared from its station at Killiecrankie Pass owing to the late guide to the Pass showing it to all tourists. An appeal to the proprietor might save the rest of the specimens, of which very few stations exist (F. B. W.).

501. *Agrimonia Eupatoria*, L. Becoming very scarce in Glen Urquhart, Inverness-shire (Gr.). This was one of its most northern stations.

525. *Pyrus Aria*, Sm. One specimen only (? *P. fennica*, L.) known in Arran; now lost through injury (G. A. P.). Lost also from one or two other stations on the Western Highlands, and now very rare in Scotland.

570. *Sedum reflexum*, L. Found freely on a wall at Birnie, Elgin; disappeared through repairs (G.). Not native.

575. *Drosera anglica*, Huds. Extinct in Kincardine (M.). Extinct round Alford, Mid-Aberdeen, through drainage (W. W.).

577. *Hippuris vulgaris*, L. Extinct round Alford, Mid-Aberdeen, but still appears on the borders of Banffshire.

611. *Eryngium maritimum*, L. Found in the early part of the century on the sandy coast at St Cyrus, near Montrose, and at St. Fergus, Peterhead, but extinct in both localities from unknown causes (J. W. H. T. and R. B.).

687. *Linnæa borealis*, Gronov. Has been cleared from near Dingwall, Ross-shire, owing to the wood in which it grew having been cut down and the ground cultivated (T. A.). Formerly grew at Kingsmills, but has been destroyed through cultivation (G. A., *fide* T. A.). These are two of the most northern British stations.

812. *Silybum Marianum*, Gaertn. Has gone from the rocks near Tarbet-ness Lighthouse, Ross-shire (D.). This plant is very rare in Scotland.

887. *Lactuca* (*Mulgedium*) *alpinum*. This plant was found (probably abnormally) on the Coreen Hills at about 700 feet, but is now extinct (W. W.).

910. *Vaccinium Oxycoccos*, L. Formerly grew in a piece of mossy land on the uplands north of Mealfourvouny, a hill of Old Red Sandstone conglomerate above 3000 feet, but whether the plants were of recent introduction or last survivors, they have disappeared (Gr.).

926. *Phyllodoce taxifolia*, Salisb. (*Menziesia cærulea*). The only British habitat of this plant is the Sow of Athol, and it has now been nearly extirpated, for sale (K. and F. B. W.). The habitat is within sight of a gamekeeper's house, so that its protection would be easy if the Duke of Athol, the owner, could be moved to that effect.

929. *Pyrola media*, Sw. Has disappeared from White Hills, Colvend, Kirkcudbrightshire, through sheep grazing (J. M. A.).

932. *Moneses grandiflora*, Salisb. (*Pyrola uniflora*, L.). Extirpated from Woodhead Hill, Traqueer, Dumfriesshire (J. W.). Once not uncommon on the Muirhead of Scone; now very rare, from extirpation by botanists and others (F. B. W.). Formerly abundant within 4 miles of Forres; now extirpated; also from the wood at Brodie, near Forres, from the wood being cut down, and from Coul Woods, near Strathpeffer. It is also disappearing from Rothiemurchen, in this case from the rapacity of collectors (K.).

945. *Primula scotica*, Hook. Marsh near Edinburgh, Pentland Hills; practically extirpated (G. A. P.).

984. *Asperugo procumbens*, L. Has not been found for some years near the village of Balnahuish, on the Dornoch Firth (D.). This was its most northern station.

993. *Mertensia maritima*, Don. Shingle at Bay of Nigg, Aberdeen; almost extirpated from shingle being removed to form concrete blocks used in building a pier some years ago (J. W. H. T.).

1006. *Echium vulgare*, L. Nearly extinct, through cultivation, in the Black Isle, between Inverness and Fortrose, Ross-shire (T. A.).

1018. *Atropa Belladonna*, L. Has disappeared from Renlop Abbey, near Birnie, by extraction, on account of the accidents it had caused (G.). Has not been seen for some years at the Old Kutt, near Ganlude (T. A.). This eliminates two of the few Scottish stations.

1020. *Hyoscyamus niger*, L. Appeared in two or three places in the neighbourhood of Avoch, a fishing village on the Moray Firth, but disappeared in a few years. Informant "thinks it would come up again if the ground were deeply trenched. Some years ago an old elm was blown down and the root blasted, and for two succeeding summers *H. niger* grew luxuriantly in the hole caused by the tearing up of the root of the tree" (S. R., *fide* T. A.).

1092. *Utricularia vulgaris*, and 1094, *U. minor*, L. Extinct in Central Aberdeen (J. M. and W. W.).

1161. *Ajuga pyramidalis*. Has disappeared from In. Achilty, Dingwall, Ross-shire (T. A.).

1424. *Paris quadrifolia*, L. There is one station near the town of Inverness; nearly extinct, through the publicity of its habitat, this being one of the chief resorts of the population (T. A.). This is one of its most northern stations.

1431. *Juncus balticus*, Willd. Loch of Park, and Links north of Aberdeen; never plentiful, and not seen for some years. Cause of disappearance doubtful (J. W. H. T.).

1457. *Sparganium ramosum*, Curtis; *S. simplex*, Huds.; *S. affine*, Sch.; and *S. minimum*, Fr. All apparently extinct in Mid-Aberdeen (W. W.).

1478. *Scheuchzeria palustris*, L. The only Scottish station for this plant, a marsh near Methven (known botanically as "Methven bog"), has been lost; perhaps from the outlet becoming blocked, so that more water collected than the plant could stand, but more probably from the settlement there of a large colony of about 3000 black-headed gulls, the result being the destruction of all but the rankest vegetation (chiefly *Carex ampullacea*). Very careful searching during the last three years has failed to show a trace of the plant (F. B. W.).

1590. *Carex limosa*, L. Has disappeared from Maxwell-town Loch, Kirkcudbrightshire, through drainage (J. M. A.).

1695. *Melica uniflora*, Retz. Is not now found by the side of the burn at Golspie, Sutherland, probably from the hollow, caused by the upturned stool of a large tree which has been blown over, draining the spot where it grew (J.). This was its most northern Scottish station.

1766. *Cryptogramme crispa*, R. Br. (Parsley fern). Extirpated from several localities in the vicinity of Dumfries (J. W.). Abundant thirty years ago on an ancient hill-fortress near Brechin; now extirpated by traders (R. B.).

1772. *Asplenium viride*, Huds. Nearly extinct in district of Black Isle, between Inverness and Fortrose, through drainage and cultivation (T. A.). Has been extirpated from its old habitats in Glen Urquhart, Inverness-shire, by an itinerant fern-collector who squatted in the neighbourhood and took all he could find; but new habitats have been discovered (Gr.).

1773. *Asplenium Trichomanes*, L. Not now found in the woods of Knockespock Clatt, Mid-Aberdeen (W. W.).

1776. *Asplenium germanicum*, Weiss. Nearly eradicated from Stenton Rock, near Dunkeld (F. B. W.).

1777. *Asplenium septentrionale*, Hull. Probably extirpated, or nearly so, from Arthur's Seat, Edinburgh (G. A. P.). Nearly eradicated from Stenton Rock, near Dunkeld (F. B. W.).

1779. *Athyrium alpestre*, Milde. Now very rare in Clova Mountains, and mostly in accessible places (G. A. P.).

1781. *Ceterach officinarum*, Desv. Almost extirpated from Orchard-town Tower, Kirkcudbrightshire, by fern-hunters (J. M. A.). Used to grow on the walls of Drumlanrig Castle, one of the seats of the Duke of Buccleuch, Dumfriesshire, but not now found there (T. A.).

1782. *Scolopendrium vulgare*, Symons. Almost extirpated from several places in Kirkcudbrightshire by fern-hunters (J. M. A.). Extirpated from several places in the vicinity of Dumfries (J. W.) On the burns falling into Loch Ness there is now only one in which this plant is to be found, owing to the ravages of the itinerant fern-collector referred to under 1772. It still exists, however, in inaccessible stations (Gr.).

1783. *Woodsia ilvensis*, R. Br. Well-nigh extirpated by fern-hunters from the Moffat district (J. W.).

1787. *Cystopteris montana*. This plant, though not at present really uncommon round Aberfeldy, will not improbably be made very scarce by fern-collectors. It has disappeared altogether from one of the stations in which it was first found in Britain (F. B. W.).

1788. *Polystichum Lonchitis*, Roth. Almost extinct on Meal-fourvouny Mountain, Inverness-shire, through the action of fern-collectors, and especially of the one referred to under 1772 and 1782 (Gr.). Has been cleared from the Raven's Rock, near Strathpeffer, Dingwall, Ross-shire, by summer visitors (T. A.). Was plentiful near Castleton, Braemar, formerly, but the guides learned that they could sell it at a shilling a plant, and it is now difficult to get (T. A.).

1803. *Phegopteris* (*Polypodium*) *Robertiana*, A. Br.; *Polypodium calcareum*, Sm. Once abundant in the *débris* of an old limestone quarry near Aberfeldy, but now nearly eradicated. Fern-hunting visitors and tourists are largely to blame for this, but the destruction has been completed by persons who collect ferns for sale. That the species is not altogether lost in the district is, however, shown by the fact that a few weeks ago a local fern-hunter was offering plants for sale, and at the same time plants of 1787, *Cystopteris montana* (F. B. W., July, 1887).

1806. *Osmunda regalis*, L. Has disappeared from Ballingear Glen, New Galloway, and from other places, as Colvend, through the ravages of fern-hunters (J. M. A.). Extirpated from several localities in the vicinity of Dumfries (J. W.). Has entirely disappeared from Loch of Park, and nearly from the cliffs south of Aberdeen, in both of which localities it was formerly plentiful. Fern-collectors are mainly responsible (J. W. H. T.).

1809. *Botrychium Lunaria*, Sw. Formerly very local in the Pentlands; now extirpated (G. A. P.).

1818. *Equisetum hyemale*, L. Extinct in Mid-Aberdeen (J. M.).

Report of the Committee appointed for the purpose of co-operating with the Scottish Meteorological Society in making Meteorological Observations on Ben Nevis. Mr. Buchan, Secretary.

The work of carrying on the observations hourly, by night as well as day, has been carried on by Mr. Omond and his assistants during the year with the same enthusiasm and unbroken continuity as in time past; and the five daily observations in connection with the Ben Nevis Observatory have been made at Fort William by Mr. Livingston with the greatest regularity and care.

As in the previous year, the state of the health of the observers, occasioned by their continuous residence at the top of the mountain, where exercise in the open air is practically impossible during the greater part of the year, rendered it again necessary to give them relief during the winter and spring. The services of Mr. Drysdale were again secured for six months; Mr. R. C. Mossman, the Society's observer for Edinburgh, gave his services as observer for six weeks in April and May; and Mr. McDonald, Edinburgh, has given a month's service as observer in July and August of this year. Messrs. Omond and Rankin, during the time they were relieved from the work of the Observatory, took part in the work of the office of the Scottish Meteorological Society, and gave material assistance, more particularly in the reduction, preparation for press, and discussion of the Ben Nevis observations.

The photographing of clouds and other meteorological phenomena has been actively prosecuted at the Observatory, and results of considerable interest and importance have been already obtained. Selections from the photographs were exhibited by the Scottish Meteorological Society and by the Royal Meteorological Society during the winter session. Of these photographs four are submitted with this Report—viz. (1) a photograph of St. Elmo's fire; (2) a cloud photographed at midnight of June last year; (3) a remarkably fine photograph of a cloud, partly made up of flattened masses, which is occasionally formed in mountainous districts; and (4) photographs of crystals on the Observatory and instruments outside.

Mr. Rankin has extended and amplified his investigation of the cases of St. Elmo's fire recorded at the Observatory; and the results, which are interesting and suggestive, have been published in the Journ. Scot. Meteor. Soc.

Mr. Omond has entered on an investigation of the relations of the wind direction on the top of Ben Nevis to the sea-level isobaric of the district at the time, and to the storms advancing on the Atlantic towards North-Western Europe, as shown on the daily weather charts of the northern hemisphere published by the Meteorological Institutes of Germany and Denmark.

This is properly only the commencement of a large discussion of the Ben Nevis observations in some of their more practical aspects, which will be undertaken and pushed forward next year on the plan referred to in last year's Report, as rapidly as the means at the disposal of the Directors of the Observatory will admit.

This season (1889) the snow disappeared from the summit of the mountain in the middle of May, being about a month earlier than in any previous year, and seven weeks earlier than in 1885; and during the month of June the spring near the Observatory, and about 60 feet lower down, frequently ran dry, so that for some time water had to be carried on horseback a distance of two and a half miles.

The Directors have had under consideration a proposed systematic observation of the numbers of dust particles in the atmosphere with the instrument recently invented by Mr. John Aitken, and they are of opinion that the Ben Nevis Observatory is the best place for making the observations in the most satisfactory manner. Mr. Aitken will himself superintend the construction of the two instruments which are required, and will see to the placing of the stationary one in the Observatory, and its connections with the atmosphere outside, in suitable positions, and give directions as to the portable one designed as a check instrument, and for observations made at various distances from the Observatory. Application has been made for a grant from the Government Research Fund to aid in carrying on this novel and important research.

Mr. Aitken recently visited the Observatory, and ten observations of the numbers of dust particles on the top of the mountain were made by Mr. Omond and himself, with the results that the numbers per cubic centimetre rose from 350 at noon to 500 at 3 p.m. This result of the first observation is interesting and suggestive. The purest air previously obtained by Mr. Aitken anywhere was on the Ayrshire coast, and on that occasion the numbers were 1260 per cubic centimetre. It may be also observed that the numbers on Ben Nevis rose from noon to 3 p.m., the observations being made at the time of the day when aërial currents from lower levels ascend along the heated sides of the mountain to the Observatory.

In January last the Directors accepted an offer from the Meteorological Council that, on being satisfied that provision had been made for the maintenance of a Low Level Observatory at Fort William, they would supply and erect in the Observatory the self-registering instruments and otherwise complete the ordinary outfit of meteorological instruments, and make an annual grant of £250 towards its maintenance, and also continue the grant of £100 yearly under the present arrangement.

Since last Report, the Directors have received a legacy of £500 bequeathed to the Observatory, by the late Mr. R. M. Smith, who was one of the Directors; and a grant of £1000 from the Association of the Edinburgh International Exhibition of 1886 from the Surplus Fund of the Exhibition. A suitable site for the Low Level Observatory was procured in Fort William, and plans of the buildings were prepared by their architects, Messrs. Sydney Mitchell and Wilson, which were submitted to the Directors and the Meteorological Council, and approved of. The building is now well advanced, and it is expected that the Observatory will be opened towards the end of the autumn.

The Directors of the Observatory and your Committee in their successive Reports from 1884 insisted on the absolute necessity of combining the double observation for all forecasting purposes, and inquiries in connection therewith; in other words, of combining with the observation at the top of Ben Nevis that made at the same instant near sea-level at Fort William. With the opening of the Low Level Observatory in November will commence a new era in the work of the Ben Nevis Observatory. It will then be possible, by the double set of horizontal meteorological gradients and vertical meteorological gradients thus obtainable, to examine more fully and rigorously the atmospheric changes which precede, accompany, and follow the passage across these islands of the cyclones and anticyclones of North-Western Europe.

The minimum temperature on Ben Nevis for the year was 7°·2, being the lowest yet observed since the Observatory was opened in 1883. The maximum was 61°·1 in June, which closely agrees with the maxima of previous years, except that of 1887, which rose to 67°·0. It is also to be noted that so late as September temperature rose to 57°·6.

The registrations of the sunshine recorder showed 970 hours of sunshine during the year, the smallest number of hours for any month being 8 for November, and the largest 250 in June, being nearly half the possible sunshine. The number of hours for the four years now observed, beginning with 1885, were 680, 576, 898, and 970. The contrast of the sunshine of 1886 with that of 1888 is thus very striking.

The amount of rainfall for the year was 132·46 inches, the month of least rainfall, 3·76 inches, being June, and of greatest, 20·60 inches, being November. The number of days on which precipitation was *nil*, or less than the hundredth of an inch, was 118. The number of rainless days for the last three years have been 159, 128, and 118. From all the observations yet made, it is seen that a fall, equalling at least 1·00 a day, has occurred on an average of one day in nine.

Atmospheric pressure was this year again above the annual average, the mean at sea-level being 29·889, or 0·055 higher. The lowest mean at the Observatory, 25·035 inches, occurred in March, and the highest, 25·590 inches, in September; the difference being 0·555 inch. At sea-level at Fort William the extreme monthly means were 29·636 inches in November, and 30·132 in September; the difference being 0·496 inch.

NOTES.

MR. GRIESBACH, of the Geological Survey of India, shortly proceeds to Beluchistan to exploit for coal; and Mr. Oldham, also of the Geological Survey, is also going to Beluchistan to investigate and report upon oil fields which are believed to exist there.

THE Iron and Steel Institute has assembled this year in Paris at the rooms of the National Industry Encouragement Society, and its first sitting was held on the 24th inst., under the presidency of Sir J. Kitson. The paper which attracted most attention on the first day was one by M. Schneider, of Creuzot, and M. Hersent, ex-President of the French Civil Engineers' Society, on the Channel Bridge, which gave an elaborate account of the scheme. The route chosen as the line, stretching over the shallowest parts of the Channel and connecting the shores where closest to each other, commences at a point near Cape Gris Nez, passes over the Colbart and Varne banks, and terminates near Folkestone. The Colbart and Varne banks are situated near the centre of the Channel, about 6 kilometres apart, the depth of the water at that point not exceeding 7 or 8 metres at low water, and they are separated from each other by a depression about 25 to 27 metres deep. Between the Varne and the British coast the depth does not exceed 29 metres, but near Colbart the bottom sinks somewhat abruptly down to 40 metres. It then attains 55 metres about midway across, when it begins gradually to rise. In these parts the chief difficulties would be encountered in laying the foundations. The result of repeated experiments is that the ground is found to be sufficiently solid to support very extensive works, and the borings lately made in connection with the proposed tunnel have confirmed preceding experiments as to the position and nature of the bottom as published by M. de Gamond. The metal proposed to be used is steel. The amount of metal and machinery to be provided would represent an aggregate weight of about 1,000,000 tons. The spans of metal would be 500 metres in length across the Channel, supported on columns resting at different depths on the bottom of the sea. A rough calculation gives 380,000,000 francs for masonry supports, and 480,000,000 francs for the metallic superstructure—in all, 860,000,000 francs, or £34,400,000. The time required for the undertaking was fixed at about ten years.

THE eleventh Congress of the Sanitary Institute was opened at Worcester on the 24th inst. In connection with the Congress an exhibition of sanitary appliances and apparatus is being held at the Skating Rink, where also lectures on cookery are given by Dr. Strange. The Presidential address was delivered by Mr. G. W. Hastings, M.P., and referred mainly to recent legislation affecting sanitary science.

THE International Oriental Congress, which was held this year during the first and second weeks of the present month, in Stockholm and Christiania, was well attended, and was especially noticeable for the enlightened and warm interest taken in the proceedings by the King. Representatives of Oriental learning from the chief countries were His Majesty's personal guests, the members of the Congress present were on several occasions specially entertained by him, and in other marked ways the King showed his desire to honour science and learning in the persons of the assembled Oriental scholars. The *Times* is the only one of the English daily papers in which the proceedings have been followed regularly, and in the last letter on the subject, its Correspondent, who has been far from a prophet of smooth things in reference to all the proceedings, says that "this eighth International Oriental Congress was favoured above all its predecessors by the right royal splendour with which the ruler of the two countries entertained his guests, by the warm interest which the citizens took in the foreign *savants*, by the care and kindly forethought with which all the arrangements for our comfort had been planned and were carried out, and last (not least) by the grand and lovely natural features of the places which the members visited. Perhaps at future Congresses care will be taken that there be less of empty Oriental parade, by which no palpable literary object can be gained, and that greater facilities be given for placing without delay within the reach of members an abstract of the proceedings in each Section. However, in the face of such boundless hospitality and such personal sacrifices on the part of our hosts, it would be ungracious were we to take exception to what are after all but small matters of detail."

A LARGE number of papers of great philological and general interest were read, as will be readily gathered from the following list of the Sections, with their respective Presidents and Vice-Presidents:—Section I. Modern Semitic: Presidents—Baron Kremer, of Vienna; M. Schefer, of Paris; M. de Goeje, of Leyden. Section II. Ancient Semitic: President—M. Fehr, of Stockholm; Vice-Presidents—M. Chivolson, of St. Petersburg; M. Oppert, of Paris. Section III.: Presidents—M. Max Müller, of Oxford; M. Weber, of Berlin; M. Spiegel, of Erlangen. Section IV.: President—Brugsch Pasha; Vice-Presidents—M. Lieblein, M. Reinisch. Section V.: President—M. Schlegel, of Leyden; Vice-President—M. Cordier, of Paris. Section VI.: President—M. Kern, of Leyden; Vice-President: Mr. R. N. Cust, of London.

A CORRESPONDENT sends us the following instance of "Science as she is wrote," which he thinks worth preserving. It is extracted from an eloquent description of the icebergs near the coast of Newfoundland, which appeared in the *Daily Telegraph* of September 17, and was signed "Edwin Arnold":—"The icebergs are unfortunately most to be expected in those summer months when alone the navigation is open. The first heats of the brief but hot Arctic sunshine set in rapid motion the glaciers of Labrador and Greenland. These vast storehouses of gathered and consolidated snow glide to the edge of the tremendous precipices of the Winter Lands, and, falling over them in monstrous masses, crash into the deep water with shocks which send thunder-peals through the still Polar air, and perturb the ocean far and near with rolling waves. Then, committed by this awful launch to the southward-going currents, the great broken glittering mass goes solemnly sailing away in the unwonted sunshine. As it floats, the water, warmer than the air, melts its lower portion gradually, and detached pieces also fall from the visible part, until equilibrium becomes destroyed, and the colossal block capsizes with a second shock, startling the ocean for leagues around."

We have received from the Mansion House a copy of the pamphlet relating to the Mansion House Fund for the Pasteur Institute. Besides a full report of the meeting held on July 1, it contains an excellent introduction describing the aims and needs of the fund, written by the Lord Mayor, and statistics of the work done by anti-rabic institutions in France and elsewhere. The last paragraph of the Lord Mayor's introduction is itself an ample justification of the appeal which he makes, for in it he reports that during July and August he sent over to Paris seventeen poor persons who had been bitten by mad dogs. There they have been treated free of charge, as usual by M. Pasteur. The Honorary Secretary to the Fund is Dr. Rueffer, 26 Torrington Square, London.

The syllabus of the eighth course of lectures and demonstrations for sanitary officers at the Sanitary Institute during the coming winter has been issued. The introductory lecture, on the general history, principles, and methods of hygiene, by Sir Edwin Chadwick, will be delivered on October 8, and the course will be continued every Tuesday and Friday at 8 p.m. until November 15. Amongst the lectures are: water supply, by Dr. Louis Parkes; drainage and construction, by Prof. H. Robinson; ventilation, by Sir Douglas Galton; sanitary appliances, by Prof. Corfield; scavenging, by Mr. Percy Boulnois; food, by Mr. Cassal; infectious diseases and methods of disinfection, by Mr. Shirley F. Murphy; general powers and duties of inspectors of nuisances, by Mr. J. F. J. Sykes; and sanitary law, by Mr. Wynter Blyth.

The carrier pigeon has just been turned to a curious use in Russia, according to the *Novoe Vremya*. It is to convey negatives of photographs taken in a balloon. The first experiment was made from the cupola of the Cathedral of Isaac, and the subject photographed was the Winter Palace. The plates were packed in envelopes impenetrable to the light, and then tied to the feet of the pigeons, who safely and quickly carried them to the station at Volkovo.

The current issue of the *Kew Bulletin* opens with a memorandum on the use of the flowers of *Calligonum* as an article of food in North-Western India. From a note from Mr. Duthie, of the Botanical Department of Northern India, it seems that the flowers of the *Calligonum polygonoides*, locally known as *phog*, are gathered and used by the poorer classes. They are either mixed with flour, in the proportion of a third *phog* to flour, or are eaten separately with salt and condiments, to which those who can afford it add a little glue. The flowers are swept up as they fall, and are kept for a night in a closed earthenware vessel, so as to fade. Sometimes they are kneaded up in the thin atta, about a fourth flowers to three-fourths atta, and baked in cakes and eaten. The flowers sent home have been analyzed by Prof. Church, who states that the chief peculiarity of these flowers, from a dietetic point of view, is their richness in nitrogenous compounds, and that there is rather a close resemblance in composition between *phog* and the seeds of the edible amaranths and buckwheats, only sugar replaces starch. There are also a short note from Dr. Ernst, of Caracas, Venezuela, on the earliest mention of coca, and a memorandum on the *Buazé* fibre, which the natives living around Lake Ngami use to make fishing-nets. The efforts which are being made to catalogue and publish the notices of Chinese plants scattered through botanical literature and to enumerate in systematic order the species of which specimens are to be found in the British Museum and in Kew, are described. Finally, there are two notes on vine cultivation and the Phylloxera, one being the substance of the report, made by Mr. Dyer in 1881, of the conclusions of the International Congress at Bordeax, which he attended as the representative of certain Colonial Governments; and the other a report on the vineyards of the Cape Colony, by M. Mouillefert, Professor of Viticulture in the French School of Agriculture at Grignon.

According to the Naples Correspondent of the *Daily News*, the scientific excursion to the volcanic regions of Italy, which commenced on the 14th inst., under the direction of Dr. H. J. Johnston-Lavis, of Naples, is exciting great interest. The affair is under the special patronage of Signor Boselli, the Minister of Public Instruction, of several Italian communes, and of the London and Italian Geological Societies. The general director is Dr. Johnston-Lavis, and the secretary in London is Dr. J. Fullerton. The visits to the various notable places will be personally conducted by Prof. Struver, of Rome; Prof. Silvestri, of Catania; Profs. Sacchi and Bassani, of Naples; Dr. Johnston-Lavis, and several others. The English, Belgians, and Italians who joined in the excursion were received at Naples, which was the starting-point, on the Sunday, by the Syndic of Naples, who also intends to give a banquet to the visitors, tickets for the theatres, and to show them other attentions during their visit to the city. Serious business commenced on the 16th inst., with a voyage to the Æolian Islands and Sicily the culminating point of this part of the programme being an ascent of Etna, which is fixed for the 29th inst. A special steamer or steam yacht will be either engaged or lent for this journey. The return to Naples will take place on the 30th inst. From the 1st to the 14th of October the head-quarters will be Naples. During this time excursions will be made to the Phlegiæan Fields, Vesuvius, the craters of Campania, the islands, and the coast towns of the Gulf, and visits paid to the sights of the city, the museums, while lectures, conversaziones, and garden parties will afford relaxation from the harder scientific work. On the 15th and 16th the volcanic groups of Monte Rocca-Monfina and the celebrated monastery of Monte Cassino will be visited, and from the 17th to the 29th Rome and its volcanic neighbourhood will be examined. Among the notable spots to be visited are Capo di Bove, Monte Tuscolo, Monte Porzio, Rocca-di-Papa, Monte Cavo, Lago di Albano, Nemi, Monte Mario, Bagno di Tivoli, Tivoli, Monte Cimmino, Monte Venere, and the crater of Vico, Frascati, and many famous villas. On the 30th of October the members will separate at Viterbo, going each their own way. The Minister of Public Instruction has accorded many facilities, such as reduced fares to the intending travellers, and the director and secretaries are using every effort to render the tour a complete success. Apart from the scientific interest of the excursion, it will afford an unexampled opportunity for becoming acquainted with some of the most beautiful and picturesque parts of Italy and Sicily.

In a Report presented to the Foreign Office by the British Consul at Florence, there is a very full account of the forests on the north-eastern boundary of Italy, which in that region are superintended by a large staff of officials. In the mountainous regions the maintenance of the forests is an absolute necessity, but, unfortunately, many slopes have become quite denuded through reckless cutting in the past. The actual extent of forest area has, however, increased since the sixteenth century, but energetic measures are now needed to prevent many of the woods deteriorating any further. Complaints are made by those who are anxious to preserve the forests that the peasants are not taught the value of them, and that in the elementary schools the principles of woodcraft and agriculture are never taught. Of the whole area under timber, the State owns only 3·42 per cent., while the *communes* possess 79·93 per cent., and private owners 16·63 per cent. As a rule the communal management is very reckless, and the forests have suffered so much that it has been seriously considered that the woods should be divided up amongst the peasants; but it is more than probable that this remedy would prove worse than the disease. The timber in the Cadore country is said to be the best in the world. Amongst the trees of the region are—the common Norway spruce, which flourishes at an altitude of 2400 metres above the level of the Adriatic, and grows to a height of about 30 metres; a variety of the Norwegian spruce, resembling the beech in its fibres, with harder wood, shorter leaves, and smaller cones than the common spruce; the common silver fir, which grows in the mountains 1500 metres above the Adriatic, and reaches a height of 25 metres; the common larch, the Scotch fir, the Mugho pine, the Swiss stone pine, the beech, and the walnut.

FROM the general results of the Swiss census of December 1, 1888, which have already been worked out, it seems that the total population is 2,934,055, against 2,846,102 in 1880. The German-speaking element increased from 2,030,792 in 1880 to 2,092,562, which, taking into account the normal growth of the population, was no relative increase, the proportion in both cases being precisely 71·3 per cent. of the whole. The French, on the other hand, increased from 608,007 to 637,940, which was also a relative increase of 21·4 to 21·7 per cent.; while the Italian declined actually as well as relatively, the numbers being 161,923 in 1880 and 156,602 in 1888, or 5·7 and 5·3 per cent. respectively. The decline of the Italians in the Cantons of Uri and Schwyz is explained by the return home of a large number of Italian workmen engaged in the St. Gothard Railway; but it is not so easy to explain why there is a large decrease in the Germans in the Cantons of Berne and Neuchâtel, while the French have increased. In general the French increase in Switzerland seems to be at the expense of the Germans, while the German element recovers its place at the expense of the Italian.

WE have received a "Guide to Technical and Commercial Education," drawn up by the executive Committee of the Dundee and District Association for the Promotion of Technical and Commercial Education. It is intended to fulfil one of the objects for which the Association was promoted, viz. "To draw up a syllabus for the district, in which shall be suggested such courses of education as shall be most suitable for particular trades; and further, to indicate (*a*) the number of years required for the complete education, (*b*) the total cost, and (*c*) the institutions in which the necessary instruction may be obtained." We draw special attention to this "Guide," as it cannot fail to be of the utmost use to similar Associations elsewhere, especially as it is drawn up with reference to the Science and Art examinations and those of the City Guilds. A definite order of study is suggested and recommended in a number of subjects, such as commerce, civil, mechanical, and electrical engineering, architecture, art industries, textiles, ship-building, gas manufacture, &c. The courses have evidently been compiled with great care and patience, and with the aid of practical men in the various subjects treated.

AMONGST the books to be published by Messrs. Crosby Lockwood and Son during the coming publishing season are:—"The Art of Paper Manufacture," by Alexander Watt; "A Hand-book on Modern Explosives," by M. Eissler; "Engineering Estimates, Costs, and Accounts," by a General Manager; "The Mechanical Engineer's Office Book," by Nelson Foley, second edition; "The Practical Engineer's Hand-book," by Walter S. Hutton, third edition; "Electric Light, its Production and Use," by J. W. Urquhart, third edition; "The Fields of Great Britain," a text-book of agriculture adapted to the Syllabus of the Science and Art Department, by Hugh Clements, second edition. And the following new editions in Weale's Rudimentary Scientific Series:—"Metallurgy of Iron," by H. Bauerman; "The Mineral Surveyor and Valuer's Complete Guide," by W. Lintern; "Stationary Engine Driving," by Michael Reynolds; "Irrigation and Water Supply," by Prof. John Scott.

MR. T. J. P. JODRELL, of Yeardsley, Cheshire, sometime of Stratton Street, London, whose death, as recently announced in the *Times*, took place on the 3rd inst., in his eighty-second year, was the founder of the Jodrell Fund, a capital sum of £6000 having been given by him to the Royal Society in the year 1876 for scientific purposes.

THE additions to the Zoological Society's Gardens during the past week include a White-fronted Lemur (*Lemur albifrons* ♂) from Madagascar, presented by Mr. C. O. Pelly; a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mr. H. B. Wedlake; a Brown Bear (*Ursus arctus*) from Russia, presented by Mr. Frank Dugdale; a Crested Porcupine (*Hystrix cristata*) from Africa, presented by Mrs. Lucas-Shadwell; three African Lepidosirens (*Protopterus annectans*) from the River Gambia, West Africa, deposited; a Burchell's Zebra (*Equus burchelli* ♀), from South Africa, four Larger Tree Ducks (*Dendrocygna major*), three Indian Tree Ducks (*Dendrocygna javanica*) from India, a Tuberculated Iguana (*Iguana tuberculata*) from Brazil, purchased; a Red Kangaroo (*Macropus rufus* ♂), two Cockateels (*Calopsitta novæ-hollandiæ*), a Crested Pigeon (*Ocyphaps lophotes*), a Nicobar Pigeon (*Calænas nicobarica*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

COMET 1889 *e* (DAVIDSON).—The following ephemeris for Greenwich midnight for this object is in continuation of that given in NATURE for August 29 (p. 424):—

1889.	R.A. h. m. s.	Decl. ° ′	Log Δ.	Log *r*.	Brightness.
Sept. 29	17 14 19	32 6·5 N.	0·1635	0·1940	0·03
Oct. 3	17 21 53	32 38·5	0·1829	0·2064	0·02

The brightness at discovery is taken as unity.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1889 *SEPTEMBER* 29—*OCTOBER* 5.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on September 29

Sun rises, 5h. 59m.; souths, 11h. 50m. 11·7s.; daily decrease of southing, 19·5s.; sets, 17h. 41m.: right asc. on meridian, 12h. 23·9m.; decl. 2° 35′ S. Sidereal Time at Sunset, 18h. 16m.

Moon (at First Quarter October 2, 2h.) rises, 11h. 8m.; souths, 15h. 40m.; sets, 20h. 4m.: right asc. on meridian, 16h. 14·4m.; decl. 18° 29′ S.

GEOGRAPHICAL NOTES.

On the 12th inst. the administration of the Congo State received intelligence by way of Zanzibar that Mr. H. M. Stanley, on leaving the basin of the Albert Nyanza, endeavoured to make his way southwards by passing to the west of the Victoria Nyanza, but was unsuccessful. He then went northwards, and reached the eastern shore of the lake, Emin Pasha accompanying him. Mr. Stanley made a long stay on the borders of the lake, awaiting supplies from Msalala and Jabora, for which he had sent. He left Emin Pasha on the eastern shore of the lake several months ago, and proceeded in the direction of Mombassa. Mr. Stanley is expected to reach the eastern coast of Africa towards the end of October next.

According to information received at Lloyd's from Tromsö, dated September 9, the German travellers Kukenthal and Walter, belonging to the Bremen Arctic Expedition, who were shipwrecked last spring in the *Bertina*, have arrived safely at Tromsö.

M. Joseph Martin, the French explorer, known in connection with his late expedition to Eastern Siberia, recently left Pekin with a small escort for Tibet, intending to proceed along the Great Wall, subsequently passing through the towns of Liang-Chow and Sining and the province of Koko-Nor, where he expects to arrive next spring. The object of the expedition is of a purely scientific character.

Mr. Frederick Jeppe, of Pretoria, has recently issued, through Dulau and Co., an excellent map of the Transvaal and neighbouring territories on the scale of 15·78 miles to an inch. It includes not only the Transvaal, but the Orange Free State and all the countries between these and the coast, from Delagoa Bay down to Pondoland. It goes north to close on the Zambesi, including Matabeleland, Bechuanaland, Griqualand West, and the northern parts of Cape Colony. There are, moreover, a number of special inset maps. The physical features, mountains, rivers, &c., are laid down clearly and in detail. The gold-fields are coloured yellow, the topography is almost exhaustive, and the map is really a gazetteer of the extensive and important region which it embraces. Mr. Jeppe gives a list of the various authorities which he has used in the compilation of his map, and these are the best and latest available.

SOCIETIES AND ACADEMIES.

Paris.

Academy of Sciences, September 9.—M. Des Cloizeaux, President, in the chair.—On the fixation of atmospheric nitrogen, by M. Berthelot.—Observations on the formation of ammonia and volatile azotised compounds at the expense of vegetable earth and of plants, by the same. He traces the researches, initiated by him six years ago, establishing the fixation, by earth and plants, of free nitrogen of the air, with the aid of mineral matters and living organisms. Analysis of the liquid condensed within a bell jar inclosing earth, or earth with vegetation, proves the exhalation (of ammonia, &c.) above referred to; and like the ptomaïnes, &c., produced by animals in a closed space, the products are toxical to the organisms yielding them.—On the nitrification of ammonia, by M. Th. Schlœsing. Small quantities of gaseous nitrogen (negligible in agricultural practice), are liberated during the oxidation of ammonia in soil. The author shows that the nitrification of ammonia put into a soil in the form of sulphate, may be effected very quickly, when favoured by the nature of the soil, its humidity and its temperature. In slow combustion of the organic matter of soil, through the agency of the nitric ferment, much more oxygen is used in burning the carbon and hydrogen, than in nitrification of the nitrogen. But in a soil enriched with ammonia, the activity of the ferment is much increased, in conveying oxygen to the ammonia, and it seeks from organic matter only the carbon needed for its development and multiplication.—On the bacteriological study of the lesions of contagious peripneumonia of the ox, by M. S. Arloing. He distinguishes a bacillus and three kinds of micrococci.—On some observations made at the Observatory of Algiers, by M. Ch. Trépied. The separation of the nucleus of Brooks's comet, affirmed by the Mount Hamilton observers, could not be certainly made out. This Observatory, begun in the spring of 1885, on a height (350 metres) overlooking Algiers, has now all its instruments except a photographic equatorial. M. Trépied notes that the telescopic image of a star, during the sirocco, becomes a continuous luminous spot, the intensity diminishing outwards; an effect, doubtless, of dust.—Observations of Brooks's comet and its companion, made at the Observatory of Algiers with the 0·50 m. telescope, by MM. Rambaud and Sy.—The spectro-photography of the invisible parts of the solar spectrum, by M. Ch. V. Zenger. He describes as advantageous combinations, prisms of quartz and anethol; of quartz and calcareous spar; of the latter and sulphide of carbon; and of rock salt and anethol. One prism of rock salt, with two of anethol, gives nine times more dispersion, and the red part is six times more dispersed between A and D, than by a 60° prism of rock salt.—Researches on sulphites, by M. P. J. Hartog.—On a new monobromized camphor; on the constitution of monosubstituted derivatives of camphor, by M. P. Cazeneuve. The new compound is obtained similarly to the chlorine compound, got by the action of hypochlorous acid, and has similar properties.—On phenoldisulphonic acid, by M. S. Allain-Le Canu.—Influence, on bare soil, of gypsum and clay, on the conservation of nitrogen, the fixation of atmospheric nitrogen, and nitrification, by M. Péchard. The sulphate of lime retains the ammonia in the state of sulphate, and contributes indirectly to the production of nitric acid, by keeping the nitrogen in a form easily nitrifiable; also directly, (in a way not well understood) by its power of deoxidation and reoxidation. Gypsum and clay, both added to sandy soil, concur in fixing ammonia; the former keeps the fixing power of the latter active by removing its ammonia in the state of sulphate easily nitrifiable (clay alone is rather adverse to nitrification).—Manufacture of red glasses for windows (twelfth and thirteenth centuries), by MM. Ch. Er. Guignet, and L. Magne. A microscopic examination of these old glasses shows that various effects were obtained by making two glasses act on each other. In one case of interior twisted marbling, *e.g.*, a yellowish glass (charged with iron protoxide) reddened only at its contact with the enveloping mass of greenish-blue glass (copper-oxide). In another case (parallel marbling), each pellicle of yellow glass is reddened at its two faces. M. Henrivaux has adopted a similar method at St. Gobain.

September 16.—M. Des Cloizeaux, President, in the chair.—On an adynamic gyrostatic constitution for the ether, by Sir William Thomson. He describes a system of small spheres, connected by rods, with terminal cups moving on the spheres, and, at their middle part, two gyroscopes, with outer rings at right angles to each other.—On an application of the electric transmission of force, made at Bourganeuf, by M. Marcel Deprez. Further details are given of the system, which has worked well since May. The high tension generator, driven by a turbine, has two rings on one shaft, excited by two rectilinear inductors parallel to the axis, having the four poles quite free. The receiver is similar. The machines for light are of the Gramme type; and with a line resistance of 23 ohms, about 50 per cent. of the force imparted to the generator is recovered in light.—Determination of the microbe producing contagious peripneumonia of the ox, by M. S. Arloing. Of the four he describes, he finds the *Pneumobacillus liquefaciens* (as he calls it) the essential element in the virus.—Observations of Brooks's comet and its companion, at Algiers Observatory, by M. Rambaud.—On the occultations of Jupiter's satellites, by M. Ch. André. With three different telescopes at Lyons, the time of contact determined differed to the extent of 2½ minutes; immersion being noted earlier, and emersion later, with the smaller instrument; also the apparent complete visibility of the satellite, continued after contact (as others have observed), is referred to. This is thought to be due to a zone of diffracted light, spread by the object-glass round the geometrical image of the planet, covering the focal image of the satellite.—On the calculations of Maxwell, relative to movement of a rigid ring round Saturn, by M. O. Callandreau.—On the heat of vaporization of carbonic acid near the critical point, by M. E. Mathias. He uses the heat of dilution of sulphuric acid in the water of the calorimeter, as a compensating source of heat, and finds Clapeyron's formula satisfactorily verified. At the critical point the latent heat, L, is rigorously *nil*.—On the use of the new Edison phonograph as a universal acoumeter, by M. Lichtwitz. With it, one may form *phonograms*, to serve as acoumetric scales, with vowels, consonants, syllables, words and phrases, &c., according to their intensity and acoustic value (as determined by O. Wolf). The sound-source being nearly constant, could be used to compare the hearing of different patients, or the same patient at different times. A set of uniform phonograms could be got by placing phonographs at a fixed distance from a reproducing instrument. Thus aurists in all countries could compare results.—Catadioptric objectives applied to celestial photography, by M. Ch. V. Zenger. Two correction lenses of magnesium glass, of the same focal length, one concave and the other convex, are inserted, the focal length of the system being identical with that of the spherical mirror. The time of exposure is reduced to a third or a quarter, for stars of a given size.—Some supplementary thermal data, by M. J. Ossipoff. Thermal formation of salts of phenylene diamines, by M. Léo Vignon. Comparing the heat of neutralization of the three diamines by hydrochloric acid, he finds orthophenylene diamine to show less than the meta isomer; which, again, shows less than the para. The bisubstituted derivatives of benzine studied by Berthelot and Werner present a similar case.—On the alcoholic fermentation of honey and the preparation of hydromel, by M. G. Gastine. Solutions of honey generally give but poor alcoholic fermentation. The author verified an idea that this is because the ferments, in a medium so poor in mineral and azotized matters, miss the conditions necessary to their evolution.—Physiological action of the poison of the terrestrial salamander, by MM. Phisalix and Langlois. The characteristic symptom is convulsion; and the poison acts successively on the cortical, bulbar, and medullary cells. Temperature rises rapidly, and dyspnœa occurs, followed by asphyxia. Arterial tension is increased.—Cyclone of Jougne, on July 13, 1889, by M. Ch. Dufour. This appeared at 1.15 p.m., on a very hot, calm, cloudy day, in the canton of Doubs, and tore along eastwards 6 km., with a rattle like thunder, lasting two to three minutes. Of many trees uprooted, those at the outset lay mostly east to west; those further on, mostly west to east. The width of region devastated grew from 100 to 250 metres. The intensity seems to have varied in this space, and to have been greater on the right than on the left side (probably through the velocity of translation being added to that of gyration in the former case). Curiously, the weather changed at the time of the cyclone, from dry and warm to cold and wet.

Stockholm.

Royal Academy of Sciences, September 11.—A new arrangement of the species of the cod-fishes, by Prof. A. F. Smitt.—On types of weather-maps, and on the latest dispositions as to the circulation of the meteorological observations of the Meteorological State Institute to the public in general, by Prof. R. Rubenson.—On the genus Prisciturben, Kunth, by Prof. G. Lindström.—Analytic construction of the integrals of a linear homogeneous differential equation of a circular ring, which does not include any singular place, by Prof. G. Mittag-Leffler.—Analytic construction of the invariants of a linear homogeneous differential equation, by the same.—Contribution to the history of the mathematical studies in Sweden during the sixteenth century, by Dr. G. Eneström.—On the constitution of the cumenyl-propin-acid, by Prof. O. Widman.—On hydro-canel-carbon-acid and some of its derivatives, by the same.—A contribution to the question of the re-adjustment of the atoms within the propyl group, by the same.—Derivatives of the ortho-amid-benzyl-alcohol, by Prof. Widman and Dr. Söderbom.

PSYCHOLOGY OF PROTOZOA.

The Psychic Life of Micro-organisms: a Study in Comparative Psychology. By Alfred Binet. Translated from the French by Thomas McCormack. (Chicago: The *Open Court* Publishing Company, 1889.)

Psycho-physiologische Protisten-Studien: experimentelle Untersuchungen. Von Dr. Max Verworn. (Jena: Gustav Fischer, 1889.)

THE first of these two works on the psychology of Protozoa is disappointing. Its main object, as indicated in its title, is to investigate the claims which from time to time have been put forward on behalf of unicellular organisms to the possession of consciousness and a certain low order of mental life. Therefore, looking to the position which M. Binet has gained as a successful worker in other departments of psychological inquiry, we were prepared at his hands to meet with a judicious treatment of facts in the light shed by a specially instructed mind. But, far from this, what we do meet with is the special pleading of an advocate who seems to hold a brief on behalf of his little friends, and is determined to force them into a position of intellectual prominence, no matter at what cost of psychological absurdity. Indeed, were it not that the title-page declares the authorship of this work, no one could possibly have supposed that it had been written by a man who had ever opened an elementary text-book on mental science.

In justification of so severe a criticism one or two quotations may be supplied. With regard to suprise and fear he says:—"We may reply upon this point, that there is not a single infusory that cannot be frightened, and that does not manifest its fear by a rapid flight through the liquid of the preparation. If a drop of acetic acid be introduced beneath the cover-glass, in a preparation containing quantities of Infusoria, the latter will at once be seen to flee in all directions like a flock of frightened sheep." His test to prove memory is—"Every time an animal repeats the same action under influence of the same excitations, that fact proves that the animal is possessed of memory." His one criterion of instinct is—"Preadaptation to an end not present, but remote." After such examples, it would be needless to adduce more.[1] In no part of the book is any distinction drawn between activities as reflex or automatic, and conscious or intentional; therefore, if a Protozoon performs any action which is in the smallest degree adaptive, the fact is always taken as in itself sufficient evidence of intelligent volition. Thus, to go no further than the above quotations from his preface, it never seems to have occurred to M. Binet that "rapid flight" in the presence of a stimulating agent may be due to causes other than "fear"; that every excitable tissue (whether *in situ* or excised) which repeats the same action under influence of the same excitation is not forthwith accredited by an experimental physiologist with any psychological "memory"; or that the heart need not necessarily be supposed to beat by "instinct," because each diastole is a "preadaptation" to the next systole.

But not only do we everywhere encounter this astonishing disregard of the most elementary principles of psychology: we are equally surprised at what may be termed a void of general sagacity. For example, in M. Binet's own opinion the strongest evidence he has to adduce in favour of intelligence on the part of "micro-organisms" consists in the behaviour of spermatozoa and spermatozoids towards ova and ovules. Thus, for example, he does not hesitate to say, by way of a general conclusion on this matter, "In fine, the spermatic element, in directing itself toward the ovule to be fecundated, is animated by the same sexual instinct that directs the parent organism towards its female"! In particular, he quotes the interesting researches of Prof. Pfeffer, who found that spermatozoids are strongly attracted by certain solutions (malic acid, &c.), so that they will crowd into a pipette filled with these solutions, even though the latter be strong enough to cause their death. Now, to any ordinary common-sense it must appear that in these facts we have evidence pointing directly away from the hypothesis of intelligent adjustment, and therefore towards the simpler hypothesis of some kind of chemical—or physiological—affinity.

Upon the whole, then, as we have said, M. Binet's work is disappointing; and, we may now add, the disappointment arises not only on account of its astonishing weakness in psychology, but also from its want of full acquaintance with the literature of the subject, and an absence of any original investigations on the part of the author himself.

Of quite a different stamp is the work of Dr. Verworn. Charged throughout with the experimental work of a physiologist, and with the analytical powers of a well-instructed mind, these "Protisten-Studien" are of much value both from a scientific and a philosophical point of view. Like M. Binet, Dr. Verworn has set himself primarily to consider the question as to whether, or how far, the Protozoa ought to be accredited with mental faculties. Therefore a considerable part of his elaborate treatise is devoted to an exposition of those psychological principles, a clear definition of which is so essential to any adequate treatment of this question. The exposition is judicious, and leads to the general conclusion that we have no evidence at all of even the lowest degree of mental life on the part of any of the unicellular organisms. In this connection we may remark that, while M. Binet quotes from an earlier paper Dr. Verworn's observations on the "house-building" habits of *Difflugia urceolata* as one of the most unequivocal examples of Protozoon intelligence, Dr. Verworn himself here furnishes a crushing refutation of this view. For he finds, as a result of experiments with powdered glass, that the *Difflugia* will crawl about among the particles without collecting any, so long as it is left undisturbed; but when irritated by shaking, its pseudopodia retract, and, while doing so, exude sticky little drops, which cause any minute particles over which they happen to pass to adhere and be carried along with the retracting filament, until

[1] Perhaps it is fair to M. Binet to state that these examples are drawn from his preface, which is mainly concerned with an attempt to show that the present writer has not done justice to the mental endowments of the Protozoa. This criticism the present writer has fully answered in the *Open Court*, July 11, 1889.

eventually, upon the total retraction of pseudopod, they are deposited on the substance of the organism. Thus the "house" is built by purely mechanical means, without any "intelligence" or "volition" on the part of *Difflugia*. In the *Contemporary Review* for April 1873, the late Dr. Carpenter alluded to similar habits of a certain marine Protozoa, saying: "The deep-sea researches on which I have recently been engaged have not exercised my mind on any topic so much as on the following." He then describes what he regarded as a selective choice by the Protozoa of *finer* particles of sand by some species, and *coarser* particles by other species, for the purpose of building into the structures of their shells. No doubt, however, if the process were carefully observed, it would be found that this apparently selective choice is really due to the size or quality of the adhesive drops on the pseudopodia, which may very well differ slightly in these respects among the different species.

Much the larger portion of Dr. Verworn's work is, as its title conveys, occupied with an account of his experimental researches. These are thoroughly systematic and fairly exhaustive. First there are thirty pages describing the natural or spontaneous movements characteristic of well-known forms belonging to all the main divisions of the Protozoa. Next there follow a hundred pages dealing with the author's experiments in stimulation, arranged under the headings—luminous, thermal, mechanical, auditory, chemical, and electrical. Lastly, there are over fifty pages describing a number of experiments in various forms of section and artificial division of sundry unicellular organisms. The whole of this part of the research is exceedingly good, and must be studied by everyone who is engaged in practical work. From this point of view the two most interesting facts are, we think, the following. It is a general law of excitable tissues that the principal seat of excitation is the kathode on closing a galvanic circuit, and the anode on opening it. But Dr. Verworn finds that among the Protozoa the reverse of this otherwise general rule obtains. It appears that this curious observation was first made by Kühne as long ago as 1864; but Dr. Verworn has done good service in now calling attention to it, corroborating, and extending it to other unicellular organisms.

The second fact to which we allude is, that when a galvanic current is closed through a drop of water containing a number of Protozoa (*e.g. Paramecium*, *Coleps*, *Colpoda*, *Stentor*, *Halteria*), they will all begin to travel rapidly and directly to the negative pole, and, if the current be left closed for a few seconds, will all become congregated thereat. On now opening the current they will all begin to travel towards the positive pole, but then soon segregate. It was proved that this is not any merely physical phenomenon, but a truly vital one: the Protozoa of the genera named will invariably swim towards the kathode on closing, remain at the kathode so long as the current continues to pass, and swim towards the anode as soon as the current is opened. Even when the kathode is a copper wire, which causes the death of all the Protozoa that approach it, they will equally well congregate in its vicinity, there to perish; and by using a movable kathode of harmless material, the Protozoa may be led about like a flock of sheep following their shepherd. To this curious physiological property on the part of Protozoa, Dr. Verworn has assigned the name "Galvanotropism." But one would like to be informed as to the strength of the current employed, *e.g.* if it were sufficient to induce electrolysis. If the current used was a very weak one, would it not be interesting to try the effect of greatly strengthening it?

The experiments in section were all devoted to testing the value of the nucleus as a co-ordinating centre of movements, ciliary and otherwise. The results were uniformly opposed to the views of Rossbach, Engelmann, and others who have regarded the nucleus in this light—the un-nucleated portions of several Protozoa continuing to exhibit all the same spontaneous movements as the nucleated. It is to be regretted that the author did not more completely extend these researches to an investigation of the functions of the nucleus in respect of nutrition and regeneration, where so much still remains to be done. But we may hope that this is perhaps to follow.

GEORGE J. ROMANES.

OUR BOOK SHELF.

Treatise on Trigonometry. By W. E. Johnson, M.A. (London: Macmillan and Co, 1889.)

WE have here a work which should prove very serviceable to those who are commencing the subject with the hope of proceeding to more advanced mathematics, and also to those wishing to revise their study of trigonometry and to extend it beyond the limits of an ordinary elementary text-book.

The volume is divided into two parts, geometrical and analytical, the former dealing with geometrical applications, the latter with the purely theoretical and analytical side of the subject. The first part deals with the properties of points and circles connected with triangles and rectilinear figures, trigonometrical ratios and their fundamental relations; chapter ix. treats of the geometry of the triangle, including the nine-point circle, the cosine and ex-cosine circles; and in chapter x. we have formulæ for circles and rectilineal figures. In the algebraical part, logarithms, ratios of compound and multiple angles, developments of formulæ for the sums of angles, factorization and summation, are dealt with. In chapter xviii. the proof of the binomial theorem is a modification of Euler's, thereby making it depend directly on the index theorem. Chapter xxi. consists of the application to trigonometrical formulæ of imaginary and complex quantities, and chapter xxii. of a geometrical interpretation of imaginaries.

Short digressions have been made into geometry, algebra, and theory of equations in various parts of the work, thus bringing out more clearly the train of reasoning that is necessary to establish and expound the principles that lie at the foundation of mathematics, to which, in trigonometry, the student is first introduced.

At the end of each chapter is a copious supply of examples, and the book concludes with a set of miscellaneous examples and answers to the above.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Taming the Puma.

As I believe that the puma, or Rocky Mountain lion, is usually considered one of the most intractable and untamable of animals, the following brief account of what I have just seen here, at the close of a brief tour in the Yellowstone National Park, may be of interest:—

Three years ago, Messrs. Wittich Bros., of this city, found some puma cubs in the valley of the Yellowstone River, twenty-five miles from this city. As cubs they showed those spots on the skin to which Mr. Muybridge called our attention at the Royal Society *soirée*, last May, as seen in his photographs of the adult animal, though not in that case visible to the eye. One of these cubs soon died, but the other is now three years old, and is perfectly under the control of Mr. W. F. Wittich, who devoted eighteen months to training her. I saw many proofs of this in his store this evening. The beast not having been fed for twenty-four hours, he trailed pieces of raw meat over her nose and mouth, which the puma never attempted to eat until the word was given, as to a dog. Occasional attempts were made, but a twist of the ear by Mr. Wittich was sufficient to control her. When meat was placed a few yards off, the puma fetched it by word of command, and permitted the meat to be taken from her mouth by Mr. Wittich, who fondled it as he would a cat. A very fine dog, a cross between a pure setter and a pure St. Bernard, five years old, named "Bruce," is on intimate, and even affectionate, terms with the puma, who allowed him to remove meat placed upon her jaws, and to eat it. On one occasion, the puma (who is often allowed to range the house), the dog, and Mr. Wittich, slept together in the same bed, and Mr. Wittich was aroused by the puma attacking some one who roused him in the early morning. When the puma is tied up, the dog always goes to sleep alongside her, and kisses her, the puma responding with a short sharp bark of greeting. The puma follows Mr. Wittich through the streets of this Western city, but has torn to pieces several strange dogs, when unaccompanied by her friend "Bruce." I inclose you a photograph of the dog in the act of removing meat from in front of the puma's jaws; her paws are done justice to, but not the length of her tail. Prior to the exhibition, Mr. Wittich requested the spectators (about ten in number) to remain perfectly still, as the beast (which was loose) noticed, and was angered by, any movement on their part.

Mr. Wittich believes that this is the only puma known to be in captivity, and comparatively tame. In training her he has chiefly used the whip, which she only feels on the nose, ear, and under the tail; he assures me he has made his own teeth meet through her skin in several other parts of her body without her showing any signs of sensation. Her memory is short, and three weeks' intermission of the performance necessitates much extra training and trouble.

I may perhaps add that Mr. W. R. Goodall, an English gentleman who has been living nearly three years ten miles from here on a ranche, assures me that perfect reliance can be placed on Mr. Wittich's statements. What my fellow-travellers and I saw ourselves was sufficiently marvellous, and I am not ashamed to add that we felt somewhat relieved when the animal, which had circulated freely among us, was chained up again! WM. LANT CARPENTER.

Livingston, Montana, U.S.A., August 30.

On some Effects of Lightning.

THE terrific storm which passed over Essex on the night of Monday, the 2nd inst., should give many interesting examples of the effects of lightning. I was at Upminster, 2½ miles from Romford, on the morning following, and had the opportunity of examining a windmill for corn-grinding which had been struck. Perhaps the details may prove of some interest.

The owner, Mr. J. Abraham, and a friend witnessed the flash, which occurred at about 1 a.m., from a window not far from the mill. They describe it as a mass or network of flame, which threw off thousands of sparks like fireworks. After the flash a light appeared on the sail for a few seconds, and they feared the mill would catch fire, but it went out, extinguished, as they suppose, by the heavy rain (I recorded 4·00 inches in seven hours in a field a mile away). I consider it remarkable that the mill was not fired. The splintered wood and cracked boards do not, however, at any attainable point show signs of charring.

The mill is octagonal, and of wood, standing on about 8 feet of brickwork. The joints of the weather boards at the angles are protected by thin sheet lead in strips about 6 × 3 inches, bent over the edge of each board to the next and nailed. At the base of the wooden part is a platform 10 feet wide, and the angle which this makes with the body is also protected with sheet lead. The strips up the angles are connected with this ring round the base, and from the ring again many strips are nailed radially to the edge of the platform. A chain was hanging from top to bottom of the mill, nearly touching the weather boards at the top, and hanging within 2 inches of the boarded ground floor at a distance of about 4 feet from the circumference in the south radius. The upper cap of the mill is revolvable. The sails faced south-east, and were set diagonally.

All the effects of the flash seem to me to indicate that it passed from earth to cloud. One branch of it passed through the iron chain, fusing the links at the points of contact, sufficiently to make them hold together when first disturbed. The flash burst through the weather boarding at the top, breaking the boards away outwards, and then reached one of the iron levers used for opening and closing the shutters of the sails. I was surprised to find no traces of the flash on the boards at the ground. The bottom link of the chain was fused, and there all trace ceased.

A second branch joined the first at the iron lever, coming in the direction described in what follows. Against the north-north-west angle of the platform runs a leaden valley gutter between two outbuildings. The flash seems to have sprung, from some old iron, lying on the ground, to this gutter, and run along it. A small portion went along under the edge of the platform to the west-north-west angle, and then along one of the radial strips. The larger portion entered at once at the north-north-west angle along a radial strip, tearing up the end of it and bending it over on to the platform. On reaching the ring of lead at the base it went round it in both directions, tearing up the lead at every junction, and bending it in the direction of the current. It then ascended by the south-south-east and east-south-east angles only, tearing up each lead strip and curling the end over upwards.

The portion ascending by the south-south-east angle joined that from the inside chain at the place where the boards were burst off. That ascending by the east-south-east angle made a path of its own to the sail lever by perforating a board of the weathering apron which depends from the revolving top of the mill. This perforation, seen from the nearest point I could attain, was evidently from within outwards. The board is cracked from the free edge to the point of perforation, but not badly nor further.

On reaching the ironwork of the sails the whole charge passed along the lever of the north-east sail, and on reaching the end of the metal entered the wood. The framework of this was shattered, the shutters smashed and thrown about, bolts broken, and the main shaft splintered. Large pieces were thrown 50 yards and more into an adjoining field.

The charge appears to have left the sail before reaching the extreme end, but as the miller was awaiting the arrival of the Insurance Company's inspector he did not wish to have the sail lowered, and I could not inspect it.

In a few places the lead was partly melted. At some holes where nails were put in, little circles half an inch in diameter were melted cleanly out, and in one place I found the head of a nail partly fused.

I was surprised to find so little damage done to the mill, and think it is a very good illustration of Mr. Tomlinson's remarks in NATURE of August 15 (p. 366), where he suggests that a building to be well protected should have a network of conducting material attached to it. ARTHUR E. BROWN.

31 Vanbrugh Park, Blackheath, September 10.

WITH regard to the two lightning-struck trees near St. Albans, the twisting mentioned by Mr. Pickering is probably not in any way due to the fact that the stroke was dealt by lightning. It is easily accounted for on mechanical principles, even assuming that the toughness of the timber was exactly equal in every part. If the centre of gravity of the dislocated top of the tree lay outside of a certain plane passing through the point of explosion (the position of this plane depending on the tenacity of the stem at that level), such twisting would be inevitable; much as in an earthquake dislocated columns must always be twisted unless the friction of the dislocated surface is equivalent on each side of a certain line running parallel to the direction of motion.

If Mr. Pickering has an opportunity, he might perhaps be able to ascertain whether or no the "core" of each tree is "not exactly in the middle of each stem, but rather to the side remote from that to which the top has fallen" (see my former letter). If this is the case, it would be strong proof that the explosion actually took place in the core. I shall probably have no opportunity of visiting the spot again for many months.

My recollection is that there are no trees within several feet of the line joining the two damaged ones, which stood in what now looks like an opening in the wood. Mr. Pickering can perhaps check this also. A. F. GRIFFITH.

15 Buckingham Place, Brighton.

IN several letters lately published in NATURE, an explosion in or by a tree trunk is mentioned. Such an explosion occurred here during the great storm of July 12 last. The lightning struck an old crab-tree, at the base of the trunk, and exactly at the ground-line. The crab was growing on the top of a grassy bank. The lightning tore the bank open from top to bottom, tore open and splintered the roots of the crab, and threw pieces of roots and turf, all in one direction, for 21 feet; the turf was in large pieces, of about a foot cube.

A tiled barn near here was, at the same time, struck in a peculiar manner. The lightning struck the upper tiles near a gable; one tile was torn out and hurled away, and several other tiles were neatly perforated with round holes, each about ¼ inch in diameter; the tiles were red, and the holes were burnt grey all round. The wooden pegs belonging to the perforated tiles were blackened by the heat. W. G. S.

Dunstable.

On the Remarkable Form of Hailstones.

WITH reference to the description given in NATURE (vol. xl. pp. 151 and 272) of the hailstorm at Liverpool, it will probably be interesting to bring under notice an early account of the remarkable forms often possessed by hailstones; it is to be found in the *Edinburgh Philosophical Journal* for 1824, vol. xi. p. 326. The writer of the said article states that "in the second part of the eleventh volume of the 'Nova Acta Physico-Medica Academiæ Cæsareæ Leopoldinæ Carolinæ Naturæ Curiosorum,' Dr. Nögerath informs us, that, on May 7, 1822, a tremendous hail-shower fell in and around Bonn. . . . The general size of the hailstones was about one inch and a half in diameter, with a weight of nearly 300 grains. When whole, which was not generally the case, the general outline was elliptical or compressed globular, and the form *cerebral*, or resembling the brain of a warm-blooded animal. . . . More frequently the form was lenticular, and appeared polished on the two ends, as if by friction. The masses had a concentric lamellar structure; in the centre was a white, nearly opaque, nucleus, of a round or elliptical form, around which were arranged concentric layers, which increased in translucency from the innermost to the outermost. They at the same time exhibited a beautiful stellular fibrous arrangement, caused by rows of air-bubbles disposed in radii. . . . Captain Delcross, in the thirteenth volume of the 'Bibliothèque Universelle,' describes hailstones having the concentric lamellar structure and stellular fibrous arrangement. . . .The surface was provided with pyramidal forms. . . . When the edges and the angles of the pyramids are melted down, the *cerebral* form is produced; when the masses of hail, having the structures described, burst asunder, the fragments have a pyramidal form, and then forms what has been described under the name of *pyramidal hail*." The writer then proceeds to describe hailstones which fell on June 27, 1823, at Aberdeen. "They (the hailstones) were included, almost universally, each by five sides or surfaces, four plane, constituting the sides of an irregular pyramid, and one spherical in place of a base. . . . The spherical surface appeared, to the depth of one-twentieth or one-thirtieth of an inch, to be solid as it was transparent. The rest of the hailstone was opaque, consisting of crystals or minute columnar forms, perpendicular to the spherical surface." Eight figures, illustrative of the different kinds of hailstones, are given (Plate ix.).

Miss Holt refers to the metallic taste and the flavour of ozone possessed by those which fell at Liverpool. The presence of NH_3 in hailstones was long ago established by Mène (*Comptes rendus*, May 19, 1851). J. SHEARSON HYLAND.

14 Hume Street, Dublin.

Erinus hispanicus (?) on the Roman Wall.

THE accompanying note on this alien Scrophulariaceous plant will, I think, be of interest to many of your readers, more especially to those who, as members of the British Association, took part in the excursion on Thursday last from Newcastle to the Roman Wall.

The plant occurs on some Roman remains at Chesters, Chollerford, Northumberland, the residence of Mr. John Clayton. In the recent editions of Dr. Bruce's "Hand-book to the Roman Wall," it is named *Erinus hispanicus*, but it appears to have been previously known as *E. alpinus*. In endeavouring to determine its authoritative name, I have ascertained that the plant was called *E. hispanicus* by Persoon ("Synopsis"), who regarded it as a doubtful species, whereas all other authors regard it as a variety of *E. alpinus*. There is a specimen, apparently of this plant, in the Oxford Herbarium, collected by Endress ("Plantæ Pyrenaicæ exsiccatæ, Annis 1829–30 lectæ") which he calls *E. alpinus*, var. *lanuginosus*; Grenier and Godron ("Flore Française") call it *E. alpinus*, var. *hirsutus*; Lange calls it *E. alpinus*, var. *villosus*; and Willkomm and Lange, in their "Flora Hispanica," follow Grenier and Godron, giving the other names as synonyms. It will doubtless be best to accept Willkomm and Lange's conclusion, and adopt the name *E. alpinus*, var. *hirsutus*, Grenier et Godron.

I may add that *E. alpinus*, L., is mentioned, in Babington's "Manual of British Botany," as occurring near Tanfield, in Yorkshire, a locality which is also given in the last edition of Hayward's "Botanist's Pocket-Book." However, in Arnold Lees's "Flora of West Yorkshire" (1888), it is stated that this plant has disappeared from Tanfield. Consequently Chesters is now the only English locality for *Erinus*, and the only form is the var. *hirsutus*. SYDNEY H. VINES.

Oxford, September 23.

Noctilucous Clouds.

THE recent communications in NATURE in relation to apparently self-luminous cloud-like bands in the skies after nightfall, call to mind the analogous phenomena of noctilucous clouds involving the whole visible firmament.

We are indebted to the indefatigable industry and zeal of the illustrious Arago for the collection of the scattered facts relating to the phenomena of self-luminous clouds of divers kinds.[1] According to the records collected by him, noctilucous bands and zones of clouds are sometimes associated with the electrical manifestations accompanying distant thunderstorms. To this class belong the luminous phenomena noticed by Rozier on August 15, 1781, and by Nicholson on July 30, 1797. In other cases, the association of the phenomena with electrical disturbances, is by no means obvious. To this class belong the luminous clouds observed by Beccaria over his observatory at Turin; likewise the luminous appearances witnessed by Deluc near London, and also those observed by Major Sabine over the Isle of Skye in Scotland. In all these cases, the noctilucous condition of the clouds was localized and confined to bands or zones in limited portions of the sky. But under certain conditions this apparently self-luminous property of the nocturnal clouds involves the entire visible hemisphere. It is to this latter aspect of the noctilucous phenomena that I desire to call attention.

Omitting the consideration of the exceptionally rare and anomalous phenomena of so-called phosphorescent "dry-fogs," as those of 1783 and 1831, in which the luminosity was so pronounced as to enable one to read ordinary print at midnight, we come at once to the generally recognized phenomenon of that faint diffused cloud-luminosity which enables the "country doctor," with comparative security, to perform his lonely midnight drives on cloudy moonless nights. Frequently the glow is so faint that it is only possible to observe it at a distance from cities and large towns, in places where the air is free from smoke, and where the darkness of the sky is not affected by the general illumination due to gas and electric lights.

The conditions under which the phenomena most conspicuously manifested themselves to my observations were during the incipient stages of the autumnal north-east storms occurring

[1] *Annuaire du Bureau des Longitudes pour l'An* 1832, pp. 246–50; *ibid.*, 1838, pp. 279–85. "Œuvres Complètes de Arago," vol. iv. pp. 70–77. Arago's "Meteorological Essays," translated by Sabine, pp. 48–53 (London, 1855).

near the sea-coast of Georgia (U.S.A.). In these three-days cyclonic storms, before the rain begins and usually before the lowest strata of air are sensibly disturbed by the upper currents, the low-lying dense masses of clouds coming from the north-east scud across the skies with great rapidity. Under these circumstances, during moonless nights, the general illumination is sufficient to plainly indicate the road to the traveller, even when it is bordered by tall overhanging trees. Under ordinary circumstances, an equivalent degree of cloudiness would have compelled the traveller to abandon all attempts at guiding the horse, and to rely entirely upon the superior acuteness of the nocturnal vision of his equine companion. In such storms, the cloudiness involves the entire firmament, and there are no electrical manifestations. To the traveller, the general illumination apparently surpasses that of a starlight cloudless night.

Now the question is, What is the origin and source of this general nocturnal illumination on cloudy moonless nights? No degree of cloudiness seems to completely obliterate the faint illumination. For, as Arago intimates, even when the heavens are overcast, during moonless nights, and the stars are hidden by an unbroken mass of the most dense clouds, there is a sufficiency of diffused light in the open country to prevent the difficulty and inconvenience which would attend any attempt to walk in the Cimmerian darkness of a cavern.

It is a popular opinion that the clouds act like ground-glass lamp-shades in diffusing the aggregate starlight, so as to produce a faint illumination from all parts of the sky, and thus obliterating shadows on the surface of the earth due to the greater amount of light radiated from the more luminous regions of the celestial vault. But Arago justly maintains that when we consider the immense effect of clouds in weakening the dazzling light of the sun on particular days in winter, it is scarcely possible to admit that the faint diffused light, which, on a cloudy night, guides the steps of the traveller, comes from the stars. In other terms, in view of the loss from reflection and absorption, the amount of starlight penetrating the cloud-canopy seems to be quite inadequate to account for the degree of general illumination observed at the surface of the earth. If we exclude the stellar origin, there remains no other explanation of the nocturnal light of a clouded sky, except the admission that the clouds themselves have a luminosity of their own. This is the view taken by Arago.

But since, for all degrees of obscuration, more or less of the starlight incident upon the canopy of clouds must penetrate it, and be diffused at the surface of the earth, this source of luminosity must be looked upon as a *vera causa*. Its adequacy to explain the observed illumination in any given case will depend upon the density of the overcasting cloudy masses and upon the sensitiveness of the human organ of vision. Hence it seems to be more rational to conclude that some portion of the nocturnal luminosity of clouds may be due to the faint diffused starlight; but that, when the amount of illumination from comparatively dense noctilucous clouds surpasses that of clear moonless nights, we are warranted in assigning them self-luminous properties. This seems to have been the condition of the low, dense, and rapidly-drifting clouds observed by me during the incipient stages of north-east storms on the Atlantic coast. Moreover, the fact that an equal degree of cloudiness is not always attended with an equal amount of illumination points to the same conclusion. In other words, it seems to be reasonable that the degree of luminosity sometimes manifested in the deep winter nights, when the whole heavens are overcast with dense clouds, is vastly too great to be due to diffused stellar light, and is more probably ascribable to the greater or less self-luminous properties of the clouds themselves.

In the case of isolated clouds, augmented nocturnal brightness may be due to well-known local causes, independent of self-luminosity. For example, the source of the brightness of the clouds observed by Prof. Piazzi Smyth in 1882 and 1883, was traced by him to the reflection of the gas-lights of the city of Edinburgh, from water-drops in the clouds (NATURE, vol. xxviii. p. 239). In like manner, the bright nocturnal clouds observed by Mr. T. W. Backhouse and others in 1886 (NATURE, vol. xxxiv. pp. 239, 312, 386) were probably due to bands of lofty clouds illuminated by the lingering sunlight.

But even in cases in which the noctilucous condition of the clouds is general, it is more than possible that the starlight illumination may be reinforced by the prolonged twilights due to the reflection of sunlight from attenuated solid particles suspended in the supra-cirrus strata of the atmosphere, such as were manifested after the Krakatão eruption in the autumn of 1883. Moreover, in certain cases the stellar illumination may be strongly augmented by cloud-obscured auroral lights. These several possible sources of extra-stellar illumination of the sky during cloudy nights seem almost to preclude the necessity of the assumption of the existence of the condition of self-luminosity of clouds under any circumstances.

But, admitting the occasional self-luminous condition of clouds, the question is, What are the physical causes of their luminosity? It is customary to refer such obscure luminous phenomena to phosphorescence or to electricity. But it must be confessed that, in the absence of definite knowledge of the physical causes of the phosphorescence of clouds, on the one hand, or of distinct electrical manifestations in such clouds, on the other, such explanations, so far from enlightening us, would seem to be more akin to illustrating the obvious by the obscure.

Seafaring men must have had numerous opportunities of observing nocti'ucous clouds in various latitudes under every degree of obscuration; but I do not, at present, recollect any reference to such observations on the ocean. In "The Voyage of H.M.S. *Challenger*," in the "Memorandum of Meteorological Observations," under head "Weather," there is a record of the "visibility of distant objects"; but I have been unable to find any night-observations of visibility ("Narrative," vol. ii. p. 300 *et seq.*).

Berkeley, California, August 30. JOHN LE CONTE.

ON BOSCOVICH'S THEORY.[1]

WITHOUT accepting Boscovich's fundamental doctrine that the ultimate atoms of matter are points endowed each with inertia and with mutual attractions or repulsions dependent on mutual distances, and that all the properties of matter are due to equilibrium of these forces, and to motions, or changes of motion produced by them when they are not balanced; we can learn something towards an understanding of the real molecular structure of matter, and of some of its thermodynamic properties, by consideration of the statical and kinetic problems which it suggests. Hooke's exhibition of the forms of crystals by piles of globes, Naviers's and Poisson's theory of the elasticity of solids, Maxwell's and Clausius's work in the kinetic theory of gases, and Tait's more recent work on the same subject—all developments of Boscovich's theory pure and simple—amply justify this statement.

Boscovich made it an essential in his theory that at the smallest distances there is repulsion, and at greater distances attraction; ending with infinite repulsion at infinitely small distance, and with attraction according to Newtonian law for all distances for which this law has been proved. He suggested numerous transitions from attraction to repulsion, which he illustrated graphically by a curve—the celebrated Boscovich curve—to explain cohesion, mutual pressure between bodies in contact, chemical affinity, and all possible properties of matter—except heat, which he regarded as a sulphureous essence or virtue. It seems now wonderful that, after so clearly stating his fundamental postulate which included inertia, he did not see inter-molecular motion as a necessary consequence of it, and so discover the kinetic theory of heat for solids, liquids, and gases; and that he only *used* his inertia of the atoms to explain the known phenomena of the inertia of palpable masses, or assemblages of very large numbers of atoms.

It is also wonderful how much towards explaining the crystallography and elasticity of solids, and the thermo-elastic properties of solids, liquids, and gases, we find without assuming more than one transition from attraction to repulsion. Suppose, for instance, the mutual force between two atoms to be repulsive when the distance between them is $< Z$; zero when it is $= Z$; and attractive when it is $> Z$: and consider the equilibrium of groups of atoms under these conditions.

[1] Abstract by the Author of a communication to Section A of the British Association, on Friday, September 13, at Newcastle.

A group of two would be in equilibrium at distance Z; and only at this distance. This equilibrium is stable.

A group of three would be in stable equilibrium at the corners of an equilateral triangle, of sides Z; and only in this configuration. There is no other configuration of equilibrium except with the three in one line. There is one, and there may be more than one, configuration of unstable equilibrium, of the three atoms in one line.

The only configuration of stable equilibrium of four atoms is at the corners of an equilateral tetrahedron of edges Z. There is one, and there may be more than one, configuration of unstable equilibrium of each of the following descriptions:—

(1) Three atoms at the corners of an equilateral triangle, and one at its centre.

(2) The four atoms at the corners of a square.

(3) The four atoms in one line.

There is no other configuration of equilibrium of four atoms, subject to the conditions stated above as to mutual force.

In the verbal communication to Section A, inportant questions as to the equilibrium of groups of five, six, or greater finite numbers, of atoms were suggested. They are considered in a communication by the author to the Royal Society of Edinburgh, of July 15, to be published in the Proceedings before the end of the year. The Boscovichian foundation for the elasticity of solids with no inter-molecular vibrations was slightly sketched, in the communication to Section A, as follows.

Every infinite homogeneous assemblage[1] of Boscovich atoms is in equilibrium. So, therefore, is every finite homogeneous assemblage, provided that extraneous forces be applied to all within influential distance of the frontier, equal to the forces which a homogeneous continuation of the assemblage through influential distance beyond the frontier, would exert on them. The investigation of these extraneous forces for any given homogeneous assemblage of single atoms—or of groups of atoms as explained below—constitutes the Boscovich equilibrium-theory of elastic solids.

To investigate the equilibrium of a homogeneous assemblage of two or more atoms, imagine, in a homogeneous assemblage of groups of i atoms, all the atoms except one held fixed. This one experiences zero resultant force from all the points corresponding to it in the whole assemblage, since it and they constitute a homogeneous assemblage of single points. Hence it experiences zero resultant force also from all the other $i - 1$ assemblages of single points. This condition, fulfilled for each one of the atoms of the compound molecule, clearly suffices for the equilibrium of the assemblage, whether the constituent atoms of the compound molecule are similar or dissimilar.

When all the atoms are similar—that is to say, when the mutual force is the same for the same distance between every pair—it might be supposed that a homogeneous assemblage, to be in equilibrium, must be of single points; but this is not true, as we see synthetically, without reference to the question of stability, by the following examples, of homogeneous assemblages of symmetrical groups of points, with the condition of equilibrium for each when the mutual forces act.

Preliminary.—Consider an equilateral[2] homogeneous assemblage of single points, O, O′, &c. Bisect every line between nearest neighbours by a plane perpendicular to it. These planes divide space into rhombic dodekahedrons. Let A_1OA_5, A_2OA_6, A_3OA_7, A_4OA_8, be the diagonals through the eight trihedral angles of the dodekahedron inclosing O, and let $2a$ be the length of each. Place atoms Q_1, Q_5, Q_2, Q_6, Q_3, Q_7, Q_4, Q_8, on these lines, at equal distances, r, from O; and do likewise for every other point, O′, O″, &c., of the infinite homogeneous assemblage. We thus have, around each point A, four atoms, Q, Q′, Q″, Q‴, contributed by the four dodekahedrons of which trihedral angles are contiguous in A, and fill the space around A. The distance of each of these atoms from A is $a - r$.

Suppose, now, r to be very small. Mutual repulsions of the atoms of the groups of eight around the points O will preponderate. But suppose $a - r$ to be very small: mutual repulsions of the atoms of the groups of four around the points A will preponderate. Hence for some value of r between O and a, there will be equilibrium. There may, according to the law of force, be more than one value of r between O and a giving equilibrium; but whatever be the law of force, there is one value of r giving *stable* equilibrium, supposing the atoms to be constrained to the lines OA, and the distances r to be constrainedly equal. It is clear from the symmetries around O and around A, that neither of these constraints is necessary for mere equilibrium; but without them the equilibrium might be unstable. Thus we have found a homogeneous equilateral distribution of 8-atom groups, in equilibrium. Similarly, by placing atoms on the three diagonals, B_1OB_4, B_2OB_5. B_3OB_6, through the six tetrahedral angles of the dodekahedron around O, we find a homogeneous equilateral distribution of 6-atom groups, in equilibrium.

Place, now, an atom at each point O. The equilibrium will be disturbed in each case, but there will be equilibrium with a different value of r (still between o and a). Thus we have 9-atom groups and 7-atom groups.

Thus, in all, we have found homogeneous distributions of 6-atom, of 7-atom, of 8-atom, and of 9-atom groups, each in equilibrium. Without stopping to look for more complex groups, or for 5-atom or 4-atom groups, we find a homogeneous distribution of 3-atom groups in equilibrium by placing an atom at every point O, and at each of the eight points A_1, A_5, A_2, A_6, A_3, A_7, A_4, A_8. This we see by observing that each of these eight A's is common to four tetrahedrons of A's, and is in the centre of a tetrahedron of O's; because it is a common trihedral corner point of four contiguous dodekahedrons.

Lastly, choosing A_2, A_3, A_4, so that the angles A_1OA_2, A_1OA_3, A_1OA_4 are each obtuse,[1] we make a homogeneous assemblage of 2-atom groups in equilibrium by placing atoms at O, A_1, A_2, A_3, A_4. There are four obvious ways of seeing this as an assemblage of di-atomic groups, one of which is as follows:—Choose A_1 and O as one pair. Through A_2, A_3, A_4 draw lines same-wards parallel to A_1O, and each equal to A_1O. Their ends lie at the centres of neighbouring dodekahedrons, which pair with A_2, A_3, A_4 respectively.

For the Boscovich theory of the elasticity of solids, the consideration of this homogeneous assemblage of double atoms is very important. Remark that every O is at the centre of an equilateral tetrahedron of four A's; and every A is at the centre of an equal and similar, and same-ways oriented, tetrahedron of O's. The corners of each of these tetrahedrons are respectively A and three of its twelve nearest A neighbours; and O and three of its twelve nearest O neighbours. By aid of an illustrative model showing four of the one set of tetrahedrons with their corner atoms painted blue, and one tetrahedron of atoms in their centres, painted red, the mathematical theory which the author had communicated to the Royal Society of Edinburgh, was illustrated to Section A.

In this theory it is shown that in an elastic solid constituted by a single homogeneous assemblage of Boscovich atoms, there are in general two different rigidities, n, n_1, and

[1] "*Homogeneous assemblage of points*, or *of groups of points*, or *of bodies*, or *of systems of bodies*," is an expression which needs no definition, because it speaks for itself unambiguously. The geometrical subject of homogeneous assemblages is treated, with perfect simplicity and generality by Bravais, in the *Journal de l'École Polytechnique*, cahier xix. pp. 1–128 (Paris, 1850).

[2] This means such an assemblage as that of the centres of equal globes piled homogeneously, as in the ordinary triangular-based, or square-based, or oblong-rectangle-based, pyramids of round shot or of billiard balls.

[1] This also makes A_2OA_3, A_2OA_4, and A_3OA_4 each obtuse. Each of these six obtuse angles is equal to $180° - \cos^{-1}(1/3)$.

one bulk-modulus, k; between which there is essentially the relation

$$3k = 3n + 2n_1,$$

whatever be the law of force. The law of force may be so adjusted as to make $n_1 = n$; and in this case we have $3k = 5n$, which is Poisson's relation. But no such relation is obligatory when the elastic solid consists of a homogeneous assemblage of double, or triple, or multiple Boscovich atoms. On the contrary, any arbitrarily chosen values may be given to the bulk-modulus and to the rigidity, by proper adjustment of the law of force, even though we take nothing more complex than the homogeneous assemblage of double Boscovich atoms above described.

The most interesting and important part of the subject, the kinetic, was, for want of time, but slightly touched in the communication to Section A. The author hopes to enter on it more fully in a future communication to the Royal Society of Edinburgh. WILLIAM THOMSON.

NOTES.

THE model of a memorial to Prjevalsky, which is to be erected on the shore of Lake Issyk-kul, is being exhibited at St. Petersburg. It represents a rock, upon which an eagle is descending, having a map of Asia in its talons, and an olive branch in its beak. The monument will have the inscription: "To the first explorer of Nature in Central Asia."

THE Durban Correspondent of the *Times* telegraphs that the Cape Government has decided to adopt Prof. Seeley's proposal for a geological survey under his charge. He believes that other eruptive diamond-bearing tracts like Kimberley exist elsewhere.

IT is understood that a sum of £2000 has been presented to the University of St. Andrews for the purpose of erecting buildings and equipping a chemical laboratory in connection with the Chemical Chair in the United College of St. Andrews.

THE late Alderman George, of Leeds, has bequeathed £10,000 to the Yorkshire College.

THE Harveian Oration will be delivered at the Royal College of Physicians by Dr. James E. Pollock, at 4 o'clock precisely, on Friday, October 18.

THE Queen has been pleased, on the recommendation of the Secretary for Scotland, to appoint Mr. R. Fitzroy Bell, advocate, to be Secretary to the Scottish University Commissioners, constituted under the Universities (Scotland) Act of last session.

ON Monday the International Congress of the Ethnographic Sciences was opened in Paris, at the Trocadéro, under the presidency of M. Jules Oppert, Member of the Institute and Professor at the College of France. In opening the proceedings M. Oppert defined the province of ethnography, and enumerated six sections into which the Committee of the Congress had divided the ethnographic sciences. These were: (1) general ethnology; (2) ethics and sociology; (3) ethnographic pyschology; (4) comparative religion, with a sub-section devoted to Buddhism; (5) philology; and (6) archæology and the fine arts.

THE Congress on Hydrology and Climatology meets in Paris to-day. After the meeting there will be an excursion to the Vosges.

AT the Colonial Exhibition in Paris, visitors may now obtain pamphlets, issued by the French Government, concerning the different colonies, their resources, and the advantages they offer to immigrants. Those relating to the Victoria and the New Zealand exhibits are very good.

AT St. Petersburg, on September 7, several Pulkova astronomers and geodesists took advantage of the ascent of a balloon, belonging to the Technical Society, to test the accuracy of barometrical measurements. The aëronauts, who reached a height of 1800 metres, took with them, besides chronometers and various meteorological instruments, a barometer, a barograph, and an aneroid; and they obtained, in addition to the curve of the barograph, the various heights at which the balloon stood during its ascent and descent for twenty-eight different moments. The heights obtained from these measurements will be compared with those found by geodetical angular measurements, which were made at five different places as far distant from one another as Cronstadt, the St. Petersburg University, Kolpino, and Pargolovo; that is, at distances of more than thirty miles between the extreme stations. The geodetical measurements thus secured are now being calculated.

THE Brussels Correspondent of the *Times* points out that the number of foreign students at the German Technical High Schools is steadily increasing, especially at Berlin, where, last year, there were thirteen English students preparing for the professions of mechanical and mining engineers, architects, and chemists.

WE regret to announce the death, at Manila, on July 28 last, of Senor Don Sebastian Vidal, Inspector-General of the Philippine Island Forests and Director of the Manila Botanic Garden. He held the post for a considerable period, and was the author of numerous important works on Philippine botany. He paid two visits to this country in his official capacity; a first of two months' duration, in the autumn of 1877, and a second of four months', in 1883–84. Both periods were spent at Kew in working up the Philippine flora; and he deposited in the Herbarium a set of no less than 4062 specimens for future reference. His published works are:—"Catalogo metódico de la Plantas Leñosas observadas en la Provincio de Manila," 1880; "Rĕsena de la Flora del Archipiélago Filipino," 1883; "Sinopsis de Familias y Generos de Plantas Leñosas de Filipinas," 1883, with an atlas of 100 folio lithographed plates; "Phanerogamæ Cumingianæ Philippinarum," 1885; and "Revision de Plantas Vasculares Filipinas," 1886. The two latter were the result of his last visit to Kew, and he was assisted in their preparation by Mr. R. A. Rolfe of that establishment. Senor Vidal was the first to investigate the Philippine flora since the time of Blanco (when geographical botany as a science was practically non-existent), and we owe to him, not merely a widely extended knowledge of its constitution, but also the establishment of the fact that the Philippine flora, though substantially Malayan in character, yet presents a number of very important peculiarities. We cannot but announce the death of so energetic and promising a worker with profound regret, and hope that his successor will carry on the work with the same amount of success.

AN Indian native paper announces that the Newab of Junagadh has communicated with the Meteorological Department of the Government of India offering to start an observatory at Verawal, and to make suitable arrangements for the exhibition of storm signals for apprising the shipping of the port of the advent of storms in the Arabian Sea. The Dewan of His Highness has offered a building for housing the meteorological instruments, and proposes to erect a shed for the reception of the thermometers on a site near the seashore of Verawal, and to assist generally the Meteorological Department to start an observatory.

MR. HOWARD CUNNINGHAM, the Honorary Curator of the Wiltshire Museum, writes complaining that the monoliths of Stonehenge are being defaced by the names and initials of visitors, and that the inclosure has become "like a pigsty," owing to the litter of broken bottles and other relics of the British holiday-maker. The state of one of the most ancient and interesting of our monuments is said to be far worse than it was fifteen years ago, and there is nobody at present to look after it.

According to Mr. W. C. Wilkinson, of New York, there is a lamentable decay of what he calls "the reading habit" of the American community. He has addressed to the *Nation* a letter in which he says that if the census taken could next year require people everywhere to name the books they had read during the previous twelve months, the result would probably show that not one person in a hundred in the United States had been the reader of even a single book. Some time ago Mr. Wilkinson took a leisurely drive from the Hudson to the Genesee, "through one of the most enlightened and most thriving belts of country in the Empire State of the Union," and during the journey he tried in various ways to find out from a considerable number of people the nature and extent of their recent familiarity with books. "I found the fact superfluously made out," he says, "that, so far at least as rural regions may be taken to represent in this respect the country at large, not many persons in comparison to the whole number of our population are book-readers."

The *Century Magazine* for October contains some interesting reminiscences of Sir John Herschel by the late Miss Maria Mitchell, who, during her visit to England in 1857, was for some time his guest. "I could scarcely believe," she says, "when I saw Sir John Herschel in his family, guessing conundrums with the children, playing at spelling, and telling funny anecdotes, that he was the same man of whom one had said to me when I first landed in England, 'He is living at Hawkhurst, not very well, and not very good-natured.' Probably the expression on his countenance of physical suffering had been mistaken for ill temper. He was remarkably a gentleman; more like a woman in his instinctive perception of the wants and wishes of a guest." Sir John told "pleasant little anecdotes of some self-made astronomers who came to him with most absurd notions, such as the non-existence of the moon—founded upon the reading of his works! And one good soul sent to him to have a horoscope cast, and inclosed a half-crown. Another wrote to him asking, 'Shall I marry, and have I seen her?'"

An ethnographical work on the Caroline Islands, by J. S. Kubary, is about to be published, in three parts, at Leyden. The full title is "Ethnographische Beiträge zur Kenntnis des Karolinen Archipels." The work is said to present the results of much observation and study, and it will contain many illustrations prepared from the author's original sketches.

In the new number of the *Internationales Archiv für Ethnographie* (Band ii. Heft. iv.), Dr. Luschan concludes his valuable and interesting paper on the Turkish "Schattenspiel," and Dr. O. Schellong gives a graphic account of the so-called Barlum Festival in Kaiser Wilhelm's Land. Dr. Schellong's paper is an important contribution to our knowledge of the customs of the Melanesians.

According to the scheme adopted by the Italian Royal Commission to commemorate the work of Columbus, a "Raccolta Colombiana" will be published, in six volumes, devoted to (1) the writings of Columbus; (2) Columbus and his family; (3) the discovery of America; (4) navigation and cartography of the discovery; (5) monographs (Italian precursors and continuers of the work of Columbus); (6) bibliography. This work will apparently be the outcome of a large amount of diligent research.

The Congress on Education, organized under the patronage of, and with a subvention from, the Paris Municipal Council, has concluded its sittings. It was attended principally by teachers, and there were nearly as many women as men. A considerable number of Russian and Polish teachers were present, together with a few delegates from Belgium, England, Italy, and Switzerland. The tone of the debates soon rendered it evident (the *Times* Correspondent says) that by free education the Congress meant freedom from clerical and official control. The general spirit animating the Congress was well expressed by the resolutions carried. The first was to the following effect:—"That public education should have for its object the perfecting of society by the integral culture of man; it should have a scientific character, and should employ the experimental and deductive methods of observation; it should aim at preparing mankind, from a moral, social, industrial, and agricultural point of view, for a better future, and a state of society where inequality and injustice, privileges and the exploitation of man by man, ignorance and superstition, will tend more and more to disappear. By integral education it is meant that all forms of instruction shall be equally accessible to all pupils, whether rich or poor." The Swiss delegate explained that in several cantons the pupils had free meals as well as free education. In the governing of educational matters the Congress thought there was danger in allowing any one particular class of interests to predominate. Parents especially were looked upon with suspicion as being too often opposed to progress, which was more likely to be initiated by the school teachers, the municipalities, or the State. The Congress voted that these four elements should together decide educational matters. It also pronounced itself in favour of mixed schools, where boys and girls should work side by side at the same lessons, and be sometimes taught by men and sometimes by women. A great deal of evidence was given to show that this developed the spirit of emulation and produced a higher tone of morality than the separate system. Mme. Héliga Löwy gave a pathetic account of the tyranny prevailing in Russian Poland, where boys were flogged and expelled from school if overheard speaking their native language, and explained the measures taken by the Russian Government to prevent the growth of education, quoting an official decree stating that knowledge spread too rapidly among the people, and that this menaced social order.

At the Sanitary Conference at Worcester last week a very interesting paper on sewage and fish was read by Mr. Willis Bund, a well-known barrister and authority on inland fishery matters, and Chairman of the Severn Fishery Board. His suggestion was that the standard of purity for effluents from sewage works should be that the effluent should be purified to such an extent that no effect would be produced upon fish that frequented the stream into which the effluent flowed. Incidentally Mr. Willis Bund gave much interesting information on fish and sewage in this country. Dividing the rivers of the country into those in which *Salmonidæ* are found and those where they are not, he said that curiously enough, up to the present time, with one exception (York), all sewage works had been placed on rivers from which *Salmonidæ* were absent. It had for a long time been the fashion to say that the effluent from sewers did not injure fish life, because fish were often seen feeding at the sewers' mouths, but fresh sewage was limited, and the class of fish usually found near sewers and drains were known as coarse or white fish—roach, dace, chub, &c.; but it was a fact that the *Salmonidæ* did not feed at the entrance to sewers, and were not found there. Speaking broadly, he said the fish that inhabit the English rivers are divided into two great classes—*Cyprinidæ*, or fish of the carp family, and *Salmonidæ*, or fish of the salmon family. The first are resident in fresh water; the latter comprise migratory species. The first are far more tenacious of life than the second, and will live and even thrive under circumstances in which the second would die at once. Curiously enough, sewage experiments have been made almost exclusively on members of the *Cyprinidæ*, and usually on fish that are the hardiest and most difficult to kill of that family; and yet more curiously, the fish usually selected for experiment is a fish not indigenous to British waters, but one of the hardiest of all the *Cyprinidæ*—the gold-fish. It is difficult to say what amount of impurity a gold-fish will not live in. Yet it is on this fish that the experiments of the effect of sewage and impure effluents are usually made, probably because the gold-fish can be bought more cheaply and more easily than almost any other live fish. Hitherto the rivers on which sewage works had been erected had either had no fish at all in them or had had the hardiest member of the *Cyprinidæ*. He thought that those who were interested in river pollution would be doing useful work by preparing a classified list of the rivers of England and Wales, thus—(*a*) rivers not containing fish ; (*b*) rivers containing *Cyprinidæ* only ; (*c*) rivers containing *Cyprinidæ* and non-migratory *Salmonidæ* ; (*d*) rivers containing migratory *Salmonidæ*. For each class a minimum standard of purity should be agreed to.

THE Ceylon papers announce the death of an elephant named Sella, which had served the Public Works Department for over sixty-five years. Originally Sella belonged to the last of the Kings of Kandy, Sri Wickrema Raja Singha, and was one of about 100 elephants which passed to the British Government in 1815, when the Kandyan dynasty was overthrown and the whole island passed under British rule. It was supposed at that time that Sella was fifteen years of age, but this was uncertain. In 1880 it was decided that all the elephants belonging to the Public Works Department should be sold, and Sella fell to a well-known resident of Colombo, Mr. de Soysa. The animal aided in several *keddah* operations for the capture and taming of wild elephants, but became totally blind about three years ago. He continued, however, to work at the plough until within a short time of his death. After death the tusks were removed, and measured 5 feet in length. Sella himself was 8 feet high.

THE autumn gathering organized by the promoters of the University Extension Scheme in Edinburgh began on the 24th ult., and it will go on till October 5. The objects of the gathering are officially stated to be to make known the advantages of the University Extension Scheme, to afford to those who have not received a University education some experience of University life and practice, and to consider the propriety of organizing "reading centres" in Scotland in connection with the National Home Reading Union. The promoters have been fortunate in securing the assistance of some of the most eminent literary men and men of science in Edinburgh, including Profs. Masson, Tait, Crum Brown, Cossar Ewart, and Geikie ; while the syllabus offers a very attractive programme in the five departments of physical science, biological science, political science, history and ethics, literature and art and music. There are forty-five lecturers in all, and the lectures, numbering upwards of fifty, will be delivered on nine days. The opening lectures on the 24th, by Profs. Kirkpatrick and Crum Brown, were attended by about 100 persons, and Prof. Tait at his lecture on Wednesday had an audience of some 200, and on all these occasions the larger proportion were ladies.

THE twelfth annual meeting of the Midland Union of Natural History Societies was held in Oxford on the 23rd and 24th ult. The visitors, who were rather numerous, met the Oxford Society at the University Museum in the Parks at half-past one o'clock on Monday. The company was divided into small parties, who were conducted to the various places of interest. The annual meeting followed, under the presidency of Mr. E. B. Poulton, F.R.S., who subsequently delivered the Presidential address, taking for his subject "Heredity." In the evening a *conversazione* was held, at which about four hundred persons were present, including all the leading members of the University now in Oxford. The large lecture-room of the Sheldonian Theatre was crowded with an audience to hear Dr. Tylor's description of the savage methods of obtaining fire. Sir Henry Acland afterwards made a brief speech, pointing out the great progress which science had made in Oxford. Many objects of interest were also exhibited, including some specimens of sand grouse, and specimens of the whole of the grasses of Oxfordshire. Mr. H. Balfour explained the principal objects in the Pitt-Rivers anthropological collection in the Museum, and Mr. Poulton described the local specimens of geology. The afternoon of the second day was spent at the Radcliffe Observatory.

PROF. GIGLIOLI was the delegate for Italy to the Ornithological Congress held at Vienna, in 1884, under the presidency of the late Crown Prince Rudolph of Austria—a Congress at which, the *Times* report stated, "England was conspicuous by its absence." The subjects which the programme of this Congress set forth were of so trivial a nature that it is scarcely to be wondered at that English ornithologists, who seem to fight shy of Congresses as a rule, scarcely deemed it worth while to journey to Vienna to discuss such problems as the origin of the common fowl, &c. Nevertheless, the results of that Congress were really of great importance. Not only were several first-class memoirs presented to the meetings, but the institution of an International Committee for the purpose of creating stations of observation on the distribution and migrations of European birds was a distinct step in advance, and had no more important work than that of Prof. Giglioli resulted from this determination, it would alone have justified the meeting of the Congress. As a matter of fact, however, these *réunions* of zoologists, such as the one that has just taken place in Paris, are the means of bringing together men who might not otherwise meet; and as a vehicle for the interchange of ideas, and of forming acquaintances which result in the permanent benefit of the institutions to which the Congressmen belong, they are to be greatly encouraged. Prof. Giglioli was appointed, on his return, official ornithologist for Italy by the Minister of Agriculture, Industry, and Commerce, and he at once enlisted a valuable corps of coadjutors in different parts of the Italian peninsula, and the records of these observers are now presented to us in a substantial volume which is entitled "Primo resoconto dei risultati della inchiesta ornitologica in Italia." A map of Italy, which accompanies the volume, marks the places where observations have been made—about 200 in number, with nearly 300 observers. Taking, therefore, his own "Avifauna Italica" as a groundwork, Prof. Giglioli follows the same order in making his record of observations, so that anyone studying the birds of Italy can find out exactly what has been done in the way of discovery since the appearance of the above-mentioned work—an admirable advantage to the student of geographical distribution.

THE University College of North Wales has issued its Calendar for the year 1889–90.

THE additions to the Zoological Society's Gardens during the past week include a Red-handed Tamarin (*Midas rufimanus*) from Surinam, presented by Miss Gladys E. Meyrick ; two Black-footed Penguins (*Spheniscus demersus*) from South Africa, presented by Mr. Harding Cox, F.Z.S. ; a Peregrine Falcon (*Falco peregrinus*) captured in the Red Sea, presented by Mr. T. J. Taylor ; a Common Pintail (*Dafila acuta*), European, presented by Mr. R. Terrot ; a Himalayan Bear (*Ursus tibetanus*, ♂) from Northern India, two Common Cassowaries (*Casuarius galeatus*) from Ceram, a Laughing Kingfisher (*Dacelo gigantea*) from Australia, deposited ; six Californian Quails (*Callipepla californica*, 2 ♂ 4 ♀) from California, purchased ; a Malaccan Parrakeet (*Palæornis longicauda*, ♂) from Malacca, a Malabar Parrakeet (*Palæornis columboides*, ♂) from Southern India, a Californian Quail (*Callipepla californica*, ♂) from California, a Virginian Colin (*Ortyx virginianus*, ♂) from North America, received in exchange ; four Long-fronted Gerbilles (*Gerbillus longifrons*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

Mr. Tebbutt's Observatory, Windsor, New South Wales.—Mr. Tebbutt, who, it will be remembered, published a short account of his observatory about a year and a half ago (Nature, vol. xxxvii. p. 400), has resolved to supplement it by a brief annual report, the first of which reports, that for 1888, he has now just issued. The record of his work during the year shows him to have been fully as active as formerly; the list of observations, including, in addition to routine meridian and meteorological work, 56 occultations of stars, besides those of Venus and Saturn, the occultation of 47 Libræ by Jupiter, 75 phenomena of Jupiter's satellites, 230 comparisons of Jupiter and β^1 Scorpii at their conjunction; 164 observations of Pallas on 17 nights, 215 of Comet Sawerthal on 23 nights, 63 of Encke's comet on 10 nights, and 187 of Comet Barnard (1888, September 2) on 20 nights, besides measures of 24 double stars. Faye's comet was seen on December 3, but no determination of place was obtained. The whole of the observations were made by Mr. Tebbutt himself, who has a well-earned reputation for accuracy, and it is with a just and natural satisfaction that he alludes to the use made of his observations by Dr. Kreutz in his discussion of the orbits of the comets of 1880 and 1882, and by Von Haerdtl of that of Winnecke's comet. During the present year, 1889, Mr. Tebbutt proposed to continue observations of the same nature as in 1888, with especial attention to lunar occultations.

The Variable η Argûs.—Mr. Tebbutt mentions in his report the recent increase in light which has been shown by η Argûs, and to which he had already called attention in the *Astronomische Nachrichten*. Dr. Thome now supplements this statement in the same publication, No. 2922, in which he gives the Cordoba observations of the star. From these it appears that the star ran steadily down in brightness from 1871 to 1887, and that since then there has been a fairly rapid recovery, also steady in character. The star has at the same time shown a remarkable change as to colour: before minimum it was a dull scarlet, now it is bright orange; indeed it was the change in colour rather than any increase in brightness which first attracted Dr. Thome's attention. This change he first noticed on March 20, 1887; the last observation previous having been made in July 1886, from whence he infers that minimum fell about October or November 1886. "But if," he adds, "we have here, as seems probable, a type of Mr. Lockyer's binary meteor swarms, March 20 would correspond nearly with the beginning of collisions, and opposition may have occurred years earlier." Dr. Thome estimates the minimum brightness as 7·65; taking the maximum brightness in 1843 as − 1·0 mag. (between Sirius and Canopus), the total range will be 8½ magnitudes in a period of forty-three or forty-four years.

Dr. Thome considers that the observations since 1811, if reduced to the same scale, might no longer show secondary maxima.

The Rotation Period of the Sun.—Mr. Henry Crew, who published about eighteen months ago (Nature, vol. xxxvii. p. 495) a determination of the rotation period of the sun by means of the relative displacement of lines in the solar spectrum when observed at the east and west limbs, has recently undertaken a fresh series of observations for the correction or confirmation of those made last year. It will be remembered that Mr. Crew found that his earlier observations gave an increase in the angular velocity with increase of latitude, in opposition to the results obtained by Carrington and others from the observation of sun-spots, and which showed the greatest angular velocity for the equator and its neighbourhood. Mr. Crew now finds that his earlier result needs revision, for there was apparently a systematic error connected in some way with the date of observation. The new series, however, still points to a shorter rotation period for the higher latitudes, the mean value for the rotation period at lat. 45° being 18 hours shorter than at the equator. Having regard to the smallness of this amount and the uncertainty of the observations, Mr. Crew concludes that "no certain variation of period with latitude has been detected by the spectroscope." He calls attention, however, to the wide difference in the values of the equatorial period as obtained by different methods. Hornstein and others, from the variations in the daily range in the barometer, fixed the sidereal rotation period as 24·12 days; Braun and Hornstein, from the variation of the magnetic elements, deduced the values 24·18 and 24·51 respectively; Carrington obtained from sun-spots 24·97 days; Wilsing, from faculæ, 25·23; whilst Crew's value from the spectroscopic method is the longest of all—26·23 days. Mr. Crew makes the suggestion that the different methods really deal with different strata of the sun, and that those portions of the sun which affect the variations of the barometer and of terrestrial magnetism are more deeply seated than the sun-spots, which, again, lie lower than the faculæ, the angular velocity of rotation diminishing on this view from the more central portions of the sun outwards.

Comet 1889 *d* (Brooks, July 6).—The following elements for this comet have been derived by Dr. Otto Knopf from observations made at Mount Hamilton on July 8, Dresden July 30, and Vienna August 19:—

T = 1889 September 26·9997 Berlin M.T.

$$\left.\begin{aligned} \pi - \Omega &= 341^\circ\ 56'\ 26''\cdot 6 \\ \Omega &= 18\ 14\ 21\cdot 2 \\ \iota &= 6\ 3\ 24\cdot 0 \end{aligned}\right\}\ \text{Mean Eq. } 1889\cdot 0.$$

$$\phi = 28\ 33\ 52\cdot 4.$$

$$\log q = 0\cdot 292550 \qquad \log a = 0\cdot 575004.$$

$$\mu = 486''\cdot 969 \qquad \text{Period} = 7\cdot 286 \text{ years.}$$

Ephemeris for Berlin Midnight.

GEOGRAPHICAL NOTES.

THE Hon. Secretary of the South Australian branch of the Geographical Society recently received the following telegraphic message from Mr. Tietkens, who is in command of an Expedition engaged in exploring the interior. The telegram came from Charlotte Waters, and is published by the *Colonies and India*. It says:—"The Expedition under my command arrived at Erldunda on July 22, the party being all well. The Expedition left Glen Edith on May 10. While there for four days and five nights almost incessant rain fell. Forty miles west of Glen Edith we discovered and named Cleland Hills and Gill's Creek, flowing south for twelve miles. The extent of good country is limited. We also discovered and named Beetson Hills, where there were three miles of running water, the extent of available country also being limited. In east longitude 128° 45′ and south latitude 23° 20′, we discovered and named the Kintore Range, the highest peaks of which are Mount Leister and Mount Strickland, 1500 feet above the plains. Here we experienced three days' heavy rains. In south latitude 23° 22′ and east longitude 128° 15′, we discovered and named Lake Macdonald, after the hon. secretary of the Victorian branch of the Society. It extends westerly to east longitude 127° 50′, the south shore being in latitude 23° 40′. South of the Kintore Range we visited and named Davenport Hill, and thence we travelled in a south-easterly direction to Blood's Range, the highest peaks of which were named Mount Harris and Mount Carruthers, being 1400 feet above the plains. Mount Unapproachable, in Long's Range, marks the west extremity to Lake Amadeus, its south shore, south of Mount Olga, being in latitude 24° 39′. At Lake Amadeus the camels partook of a poisonous plant, from the effects of which one died. At Mount Olga the other was unable to travel. After a week's rest the Expedition left there and visited Ayer's Rock. Mr. Goss's marked tree has been burnt down by the blacks. Near Mount Connor we discovered a small spring, and travelling northward from there discovered and named Basedow Range; from there travelled easterly over better country until we arrived here, receiving a most cordial and hospitable reception from Messrs. Warburton and Tomlin. To Mr. Warburton's kindness we are indebted for conveying this message to the telegraph line. The general character of the country passed over has been Spinifex, sand-hills, and plains, with extensive forests of Casuarina. Rock reservoirs, native wells, and a few clay-pans were the only descriptions of water met with."

ONE of the most important of recent exploring Expeditions has been that under Sir William Macgregor, the Administrator of British New Guinea, who has recently ascended and examined the Owen Stanley Range, over 13,000 feet above the sea. Several attempts have been made to reach the summit within the past few years; Sir William therefore deserves much credit, all the more that his natural history observations are very full and valuable. Sir William is an accomplished naturalist, so that any exploring work he may undertake is sure to be of scientific value. He left Port Moresby in May, accompanied by his secretary, and when the Expedition was finally made up there were about forty natives. Only five, however, went up to the top with Sir William, who spent three or four days examining the ridge. The summit was reached on June 11. The climate Sir William describes as foggy and unpleasant up to 8000 feet; but above that clear blue sky and beautiful climate, "one of the finest in the world." The party were ten days over 10,000 feet, and never had a cloud above them. The sea coast was visible on both sides, that on the north being the most distant. But the country is much smoother on that side, and the ascent of the mountain from the north apparently unobstructed and easy. From the point of Mount Victoria in the east to Mount Lilley in the west is a continuous, unbroken crest of thirty miles, which was traversed by Sir William, who spent three days and a half on the summit. His eyes were gladdened by the sight of daisies, buttercups, and forget-me-nots, and he brought away with him a quantity of white heath which reminded him of his native mountains. Big icicles amazed his native companions, who thought their mouths were burnt when they attempted to bite this, to them, novel product of Nature. Larks were plentiful, similar in flight and song to those of the old country. Specimens of the flora were naturally collected by an enthusiastic naturalist like Sir William, and amongst them also probably several novelties will be found. There are no trees within 1000 feet of the top, which is bare rock or covered with grass. There are no snakes or other pests on the main range, but unfortunately game is very scarce also. The temperature ranged from freezing-point to 70° in the sun. The southern aspect of the range is drained exclusively by the Vanapa River, the head of which was crossed at an elevation of 10,130 feet. No natives live on the mountains above 4000 feet, although they hunt as high as 9700 feet. All those met with at the base were extremely friendly. Nothing, however, would induce any of them to accompany the party up the mountain. They grow tobacco, peas, beans, many kinds of potatoes, yams, and bananas, and of these they gave Sir William as much as he wanted. They are certainly Papuan. The party returned to Port Moresby on June 25. Sir William was in perfect health the whole time, though, as usual, the natives had their little complaints. Another account states that Sir William found the top of the crest very uneven, consisting of immense masses of rock separated by deep chasms. The long-tailed bird of paradise was shot at from 5000 to 9000 feet altitude. On the top of one of the mountains what is believed to be a new bird of paradise was obtained, golden yellow on the back, with a black velvet breast and belly. As to the botany, the variety was very small, but what there was was new.

M. YADRINTZEFF's Expedition returned to Kiakhta on August 16, after having reached the sources of the Orkhon River, and determined the position of Kara-korum. It also discovered the ruins of two large cities (one of them having a circumference of thirteen miles), as well as of the palaces of the Khans of Mongolia, and their cemeteries, where numerous statues and important inscriptions were found.

THE BRITISH ASSOCIATION.

REPORTS.

Report (Eighteenth) of the Committee appointed for the purpose of investigating the Rate of Increase of Underground Temperature downwards in various Localities of Dry Land and under Water. Prof. Everett, Secretary.

Very important observations have been published (*Neues Jahrbuch für Mineralogie*, &c., 1889, Bd. 1) during the past year by Herr Dunker, whose observations in a very deep bore at Sperenberg were embodied in our Report for 1876. The new observations were taken at Schladebach, near Dürrenberg, in a bore of greater depth and smaller diameter than at Sperenberg, and with similar precautions against convection currents. The depth was 1748 metres, the bore passing through new red sandstone (Buntsandstein), magnesian limestone (Zechstein), Lower Permian sandstone (Rothliegendes), and coal-measures (Steinkohlengebirge), to the Upper Devonian beds (Oberdevon).

It was tubed to the depth of 1240 metres. For the first 584 metres the diameter was 120 millimetres; for the next 104 m. it was 92 mm.; then for 393 m. it was 72 mm.; and for the next 159 m. it was 50 mm. From this point to the bottom the diameter gradually diminished to that of a man's little finger. The diamond borer was the instrument employed in sinking it.

India-rubber bags, such as were used at Sperenberg for preventing convection currents, being deemed unsuitable for such a narrow bore, a plugging of moist clay was employed, constructed as follows:—

On a cylindrical rod, which might be of tough wood for bores of moderate depth, but was of iron in the actual observations, are two wooden disks of such size that there is only just room for them to move in the bore. The lower disk is fixed, and the upper movable on the rod. The part of the rod below the fixed disk has a length equal to that of the water-column which it is desired to isolate. The maximum thermometer with which the temperatures are taken has its bulb half-way down this portion of the rod. It is fastened beside the rod if there is room for it; and when the bore is too narrow for this arrangement, the thermometer is placed in a metal box which may be described as forming part of the rod, the rod being divided into two portions screwed to the two ends of the box. The movable disk is removed to a measured distance from the fixed one, and the space between them is then filled with clay which has been made plastic by kneading it with water, so that it forms a cylinder with the two disks.

When the pole presses on the bottom of the bore, part of the weight of the boring rods is supported on the upper disk, thus squeezing the clay against the sides of the bore and forming a water-tight plug.

The above description applies especially to the taking of observations at the bottom of the bore. When it was desired to isolate a column of water at a considerable distance from the bottom, the apparatus employed consisted of two portions. The above description applies to the upper portion, and the lower portion was similar to it but inverted, resting upon rods which extended to the bottom. The two masses of clay in this case cut off a water-column between them.

Experiments with a model, in which the bore was represented by a cylindrical glass vessel 26 cm. high and 55 mm. wide, filled with water, showed that the isolation was very good, and that it remained so though the immersion lasted more than ten hours. In tearing away the clay from the vessel a portion of the clay fell into the water, but such an accident occurring in the bore would be of no consequence.

The construction of the isolating apparatus was intrusted to Bore-Inspector Köbrich, under whose management the observations were to be carried out.

Besides the thermometer in the isolated water-column, there was a second maximum thermometer in the open water just above the upper plug, for comparison, the height of its bulb above that of the principal thermometer being 2·8 m.

The thermometers were very similar to those employed at Sperenberg. They were overflow-thermometers, generally without scales, and were inclosed (for protection against pressure) in a hermetically sealed case of stout glass with an external diameter of 15 mm. To take the reading, the thermometer, after being drawn up, was put with a normal thermometer into a vessel of water at a temperature a little below that which was expected. Warm water was then gradually added, and the whole kept stirred till the mercury in the overflow-thermometer reached the open end. The temperature at this moment was then read by the other thermometer.

The first observations taken were in the untubed portion of the bore, which at that time extended from the depth of 1240 m. to 1376 m.; and as the bore was deepened to 1748 m. the observations were continued. In this way the last sixteen observations of Table I. were obtained, forming a series at intervals of 30 m. from 1266 m. to 1716 m. of depth.

A pause which subsequently occurred in the sinking of the bore, through having to wait for a new tube, was utilized for taking the observations which form the remainder of the table. We have thus a complete series of observations, at equal intervals of 30 m., from the depth of 6 m. to that of 1716 m.: 8°·3 R. at 6 m., and 45°·3 R. at 1716 m.

The table is arranged in five columns. The first column contains the natural numbers from one to fifty-eight, for convenience of reference to the observations at the fifty-eight different depths; the second column contains the depths in metres; and the third column, the temperatures observed at these depths in isolated water-columns. The fourth column contains the excess of the temperature so observed above the temperature observed by means of the secondary thermometer in the free water just above the plug. The fifth column contains the differences between the successive numbers in the third column—in other words, the increase of temperature for each 30 m. of depth.

The smallness of the effect of isolation, as shown in the fourth column of the table, is very noteworthy, its greatest value being 1° R., and its average value about ¼ of 1° R. At Sperenberg it amounted in several cases to about 3° R. The smallness of the effect in the present case is attributable to the narrowness of the bore, which tells in two ways: there is more frictional resistance to the movement of the water; and the thermal capacity of a given length of column is less in comparison with its surface of contact with the sides of the bore.

As a further experiment on the prevention of convection, a wooden plug was driven into the bore at the depth of 438 m., thick mud was introduced till it filled all the bore above this plug, and observations were taken with a maximum thermometer in the mud at depths from 426 m. to 126 m. A second plug was then driven in at the top of the tubing, which was 120 m. beneath the surface of the ground, and the observations were continued upwards from 118 m. to 6 m. The observations thus taken in the mud are given. They are rather higher than those previously obtained at the same depths, the greatest difference occurring at the depth of 276 m., where it amounts to 0°·9 R. Herr Dunker suggests that the difference may have arisen from insufficient time being allowed for the mud to take the permanent temperature.

Upon the whole it is clear that in this great bore the disturbing effect of convection is very small, and that, such as it is, it has been almost annihilated by the very efficient system of plugging adopted. The series of observations now before us, extending as it does by regular stages from the surface to a depth of 5630 feet, in a new bore where there has not been time for the original heat to be lost by exposure, forms undoubtedly the most valuable contribution ever made to the observation of underground temperature. The official to whose initiative the observations are due is Chief-Mining-Captain Huyssen, of Berlin. The expense of sinking the bore was £10,000 sterling, the time required for hauling up the boring rods was ten hours, and their united weight was 20 tons.

On plotting the temperatures so as to exhibit temperature as a function of depth, the curve obtained approximates very closely to a straight line. A straight line joining its two ends meets the curve several times in the part corresponding to the tubed portion of the bore, which is about three-fourths of the whole; while in the remaining fourth (forming the deepest portion of the bore) all the temperatures except the first and last lie above the straight line. In this statement it is to be understood that depth is represented by distance laid off horizontally, and temperature by distance laid off vertically upwards.

The question whether the curve on the whole bends upwards or downwards is of some interest, because it is equivalent to the question whether the rate of increase is accelerated or retarded as we go deeper. The evidence on this point is undecisive. The curve for the untubed portion, from 1266 m. to 1716 m., lies slightly above its chord; but the curve from either 6 m. or 36 m. to 1500 m. lies for the most part below its chord.

Taking the observation at 36 m. as the first which is free from atmospheric disturbance, and comparing it with the deepest observation of all, which is at 1716 m., we have an increase of 36°·5 R. in 1680 m. This is a difference of 82°·1 F. in 5512 feet, which is at the rate of 1° F. in 67·1 feet.

Herr Dunker, after an elaborate discussion of the question whether the curve on the whole bends upwards or downwards, arrives at the conclusion that it is best represented by a straight line. He applies the method of least squares to find the slope of this straight line, on the assumption that it passes accurately through the point determined by the observation at 36 m., and he thus obtains a mean rate of increase of 0·0224276 of a degree Réaumur per metre, which is equivalent to 1° F. for 65·0 feet.

The Secretary has been in correspondence with Mr. George Westinghouse, Jun., of Pittsburg, President of the Philadelphia Company, with the view of obtaining observations of temperature from some of the deep oil and gas wells belonging to the Company. Mr. Westinghouse has purchased three of the Committee's maximum thermometers, and has intrusted the taking of the observations to Mr. A. Cummins, the Company's Mining Engineer and Geologist. Some attempts have been made at observation, but owing to press of business they have not been thoroughly carried out. Mr. Cummins states that "there has been a constant strain to bring up the supply of gas to the requirement of the city's needs, and every hour of delay is watched very jealously."

The most successful attempt was made in a well at Homewood, in the city of Pittsburg, known as the Dilworth well, where the following results were obtained:—

Depth in feet.	Temperature F.	Air at surface.
	°	°
3600	96	70
3710	89	76
3920	102	60
4002	108	62
4215	111	62
4295	114	62

The well was sunk to a depth of 4625 feet, but no observations were made except at the depths specified. The thermometer remained only from five to ten minutes during each test; and as there were only 40 feet of water in the well, the observations must have been taken in air. The diameter of the well was 6 inches. The rock was chiefly slate, and was bored by "jumping." The mean air temperature at Pittsburg is 52° F., and the height above sea-level about 900 feet. Comparison of the mean surface-temperature (taken as 52°) with the temperature 114° recorded at 4295 feet shows an increase of 62°, which is at the rate of 1° F. for 69·3 feet; but comparisons of the observations *inter se* would give a rate about twice as rapid as this; hence no safe conclusion can be drawn. After the hurry and worry of the gas business is over, Mr. Cummins hopes to get the temperature of some deep wells in a way that will be satisfactory.

We may mention, as a contribution to the literature of underground temperature, the recent publication of results obtained at the Old Observatory, Allahabad, with thermometers whose bulbs were at the depths 3 feet, 1 foot, and ½ inch respectively. Harmonic reduction has been applied to deduce both the annual and the diurnal variation, and from the former a fairly consistent determination of "diffusivity," or quotient of conductivity by capacity, has been obtained. Its value, 0·0054 C.G.S., is smaller than any values that have been found elsewhere. The soil is a sandy loam, which in dry weather becomes almost as hard as brick. The observations extend over six years, and similar observations are now being carried on at the New Observatory. The gentleman who is responsible for the reductions and the description of the observations is Mr. S. A. Hill, B.Sc., Meteorological Reporter to the Government for the North-West Provinces.

Report of the Committee appointed for the purpose of investigating the Best Methods of ascertaining and measuring Variations in the Value of the Monetary Standard. Prof. Edgeworth, Secretary.

This consists of a Supplementary Memorandum by the Secretary, designed as a supplement to the Memorandum appended to the First Report of the Committee. The object of that Memorandum was to distinguish the different definitions which the proposed problem might present; and to construct the formula appropriate to each phase of the investigation. The analysis of contents is as follows:—(1) Prof. Newcomb's method; (2) Prof. Foxwell's method; (3) Mr. Giffen's methods; (4) Mr. Bourne's method; (5) Sir Rawson Rawson's method; (6) Prof. Edgeworth's method; (7) Ricardo's method.

The conclusion of the Memorandum runs as follows:—

It may be useful to enumerate and summarily characterize the principal definitions of the problem, or "standards,"[1] which have been discussed in this and the preceding Memorandum. An alphabetical order will be adopted, the order of merit being not only invidious, but also impossible in so far as different methods are the best for different purposes.

1. The *capital standard* takes for the measure of appreciation or depreciation the change in the monetary value of a certain set of articles. This set of articles consists of all purchasable things in existence in the community, either at the earlier epoch or at the later epoch, or some mean between those sets. This standard is due to Prof. Nicholson. It is stated by him (in terms a little less general than those here adopted) in his book on "Money." It is discussed in the sixth and the tenth sections of the former Memorandum.

2. The *consumption standard* takes for the measure of appreciation or depreciation the change in the monetary value on a certain set of articles. This set of articles consists of all the commodities consumed yearly by the community either at the earlier or the later epoch, or some mean between those two sets. This standard has been recommended by many eminent writers, in particular by Prof. Marshall in the *Contemporary Review* of 1887. It is proposed by the Committee as the principal standard. It is discussed in the second section of the former Memorandum.

3. The *currency standard* takes as the measure of appreciation or depreciation the change in the monetary value which changes hands in a certain set of sales. These sales comprise all the commodities bought and sold yearly at the earlier epoch or at the later epoch, or some mean between those quantities. This standard appears to be implicit in much that has been written on the subject, but to have been most clearly stated by Prof. Foxwell. It is discussed in the second section of this Memorandum.

[1] The methods discussed in connection with the names of Mr. Giffen, Mr. Bourne, and Sir Rawson Rawson are rather solutions than statements of the problem.

4. The *income standard* takes as the measure of the appreciation or depreciation the change in the monetary value of the average consumption, or in the income per head, of the community. This standard is proposed in the fourth and fifth sections of the former Memorandum.

5. The *indefinite standard* takes as the measure of appreciation or depreciation a simple unweighted average of the ratios formed by dividing the price of each commodity at the later period by the price of the same commodity at the earlier period. The average employed may be the arithmetic mean used by Soetbeer and many others, or the geometric mean used by Jevons, or the median recommended by Prof. Edgeworth. This standard is recommended by the practice of Jevons[1] and the theory of Cournot.[2] It is discussed in the eighth and ninth sections of the former Memorandum, and the fifth section of the present one.

6. The *production standard* is a designation which may be applied to a method which is related to the currency standard very nearly as the income standard is related to that based on consumption. The production standard takes as the measure of appreciation or depreciation the change in the monetary value *per head* of the total amount of things produced in the community yearly. This standard is proposed by Prof. Simon Newcomb in his "Political Economy." It is discussed in the first section of this Memorandum.

7. The *wages* (and *interest?*) *standard* takes as the measure of appreciation or depreciation the change in the pecuniary remuneration of a certain set of services—namely, all (or the principal) which are rendered in the course of production, throughout the community, during a year, either at the initial or the final epoch; or some expression intermediate between the two specified. The theoretical basis and practical construction of such a standard are indicated in Ricardo's "Principles of Political Economy" (ch. xx. and elsewhere), in Prof. Marshall's evidence before the Gold and Silver Commission ("Parliamentary Papers," 1888, C.), and in the papers contributed by Mr. Giffen to the second volume of the Bulletin of the International Statistical Institute. The standard is discussed in the last section of this Memorandum.

Report (Second) of the Committee appointed for the purpose of reporting on the present state of our knowledge of the Zoology and Botany of the West India Islands, and taking steps to investigate ascertained deficiencies in the Fauna and Flora. Mr. D. Morris, Secretary.

This Committee was first appointed in 1887, and re-appointed in 1888. At a meeting held on December 5, 1888, it was decided to invite the co-operation of Dr. Günther, F.R.S., a member of the sub-committee appointed for a similar purpose by the Government Grant Committee of the Royal Society, and Colonel

[1] Most of Jevons's celebrated calculations ("Currency and Finance," ii., iii., and iv.), and in particular his calculation of the probable error incident to his result (*ibid.* p. 157), involve this conception.

[2] Cournot has considered our problem in each of the five volumes in which he has treated of, or touched on, political economy ("Dictionary of Political Economy," Art. "Cournot"). It is sufficient here to refer to the first and the last of those works, the "Recherches" of 1838 and the "Revue Sommaire" of 1876—the Alpha and almost the Omega of economic wisdom. From these it is clear that variation in the "absolute" or "intrinsic" value of money, in Cournot's view, corresponds to the "indefinite standard" as defined in Section viii. of the predecessor to this Memorandum. Cournot illustrates the variation due to a change on the part of money, by that change in the position of the earth with respect to the stars, which is due to the motion of the earth. In this analogy the stars are treated as "points" ("Recherches," Art. 9). No account is taken of their mass. The context shows that Cournot contemplates a simple average of distances between the earth and each star; not a *weighted* average, or the distance between the earth and the *centre of gravity* of the stars. In his later works he expressly declares against, or at least thinks unbefitting highest place, the measure of what he calls the "power of money" ("Revue Sommaire," Sect. 3), that is, in our terms, the consumption standard; the analogy of which is the distance of the earth from the *centre of gravity* of the stars, or rather of certain select stars—say those which are nearest to our human sphere. The currency standard, of which the analogy is the distance of the earth from the *centre of gravity* of all stars whatever, does not seem to have been entertained by Cournot.

Cournot, alluding to Jevons's treatment of the problem in "Money," not unjustly takes him to task for not having distinguished "assez nettement" variations in the "intrinsic value of money" (of which the measure is our indefinite standard) from variations in the "power of money" (of which the measure is our consumption standard) ("Revue Sommaire," p. 121). Referring to Jevons's proposal to construct a *tabular standard of value*, Cournot expresses his approbation in words which may fittingly conclude the present study:—"Ce sont là des idées qu'il faut laisser mûrir. Quand le moment sera venu de construire effectivement *l'étalon monétaire*, les géomètres pourront y trouver une application intéressante de leur *théorie de moyennes*, telles qu'ils l'ont déjà construite pour les besoins de l'astronomie et de la physique."

Feilden, of the Army Pay Department, at that time acting as Local Secretary to the Committee at Barbados.

The services of Mr. G. A. Ramage were retained as collector at Dominica and St. Lucia, and several collections were received from him during the past year. Owing to ill-health Mr. Ramage returned to this country in June last, and he has now retired from the post of collector to the Committee. Mr. F. Du Cane Godman has generously assisted the work of the Committee by sending out, at his own expense, the well known naturalist and collector, Mr. H. H. Smith, to the Island of St. Vincent, to make collections in as many branches as possible of natural history. These collections have not yet reached this country, but it is anticipated that they will prove of considerable value.

Colonel Feilden obtained numerous botanical and zoological specimens in Barbados and the neighbouring islands. He has published a paper on the reptiles, and another on birds; papers on the Mammalia and land Mollusca will follow. He also obtained a living specimen of the green monkey of Western Africa, which has become feral in Barbados (*Cercopithecus callitrichus*). This was presented by the Committee to the Zoological Society of London.

Dr. H. A. Alford Nicholls, Local Secretary to the Committee at Dominica, has rendered valuable assistance, and he will be engaged for six weeks this autumn in exploring Montserrat and the isolated rock called Redonda, which is a dependency of Antigua.

The particulars of the collections received during the past year are as follows:—

Zoology.—The zoological specimens obtained by the Committee up to June 1889, including those collected by Mr. Ramage in Dominica and St. Lucia, have been placed in the hands of specialists for examination and determination. Mr. Oldfield Thomas has determined the Mammalia, Dr. Sclater the birds; Dr. Günther has published a paper on the reptiles, Mr. E. A. Smith three papers on the Mollusca, Mr. R. I. Pocock two on the Myriopoda and Crustacea, and Mr. Kirby one on the Phasmidæ.

Botany.—The botanical specimens collected by Mr. Ramage in Dominica and St. Lucia, up to May 1889, have been determined at Kew; the flowering plants by Mr. R. A. Rolfe, the ferns by Mr. J. G. Baker, and the cellular cryptogams by Dr. Cooke and Mr. C. H. Wright.

From Dominica about 394 species were received, of which (excluding the cryptogams) about 40 could only be provisionally determined; and of these a few, perhaps about half, are probably undescribed. The great majority belong to already well-known species, most of which were previously known from the island.

From St. Lucia about 189 species have been sent, of which (excluding the cryptogams, as before) over 30 were not determined, and possibly about half of these may prove to be undescribed. This island was less completely known than Dominica, and several additions to our knowledge of its flora have been made by Mr. Ramage. During the working up of the collections a strong affinity with Dominica, and perhaps still more so with Martinique, has become apparent. From the latter island large collections are well represented at Kew, though the materials have never been thoroughly worked up.

The specimens which it was not found possible to determine belong for the most part to large genera of woody plants, as Guttiferæ, Leguminosæ, Myrtaceæ, Myrsineæ, Laurineæ, and a few others, which renders it the more probable that a fair proportion of them may prove undescribed.

The number of novelties is perhaps not so great as was originally expected, and this may arise either from the ground having been worked over before, or, what is perhaps more probable, from the fact that a considerable uniformity prevails in the flora of this chain of islands, with a corresponding paucity in endemic types.

The Committee would draw particular attention to the botanical and zoological bibliography of the Lesser Antilles prepared under its direction, and published as an appendix to the Report for 1888. This bibliography has been widely distributed in the West Indies and in Europe, and has proved of considerable service in carrying out the objects for which the Committee was appointed.

Report (Fifth) of the Committee appointed for the purpose of considering the best means of Comparing and Reducing Magnetic Observations. Prof. W. Grylls Adams, Secretary.—The Committee report the establishment of regular magnetic observatories, where continuous photographic records of the magnetic elements are taken, at the United States Naval Observatory at Washington, and also at Los Angeles in California. The instruments used are of the Kew pattern, with the same time-scale, and the scale-coefficients for horizontal and vertical force instruments at Washington are very nearly those recommended by the Committee in their Third Report (1887), and which are in very near agreement with those at Vienna, St. Petersburg, and some other observatories. The Committee report, further, that the plan proposed by them in their Third Report for the Comparison and Reduction of Magnetic Observations, has been adopted at the United States Naval Observatory at Washington, which is now prepared to take part in the general scheme of co-operation proposed by the Committee. Copies of the photographic registers of the three elements for April 21–30, May 1–31, and for June 1–30 have been forwarded to the Committee from Washington, with tables of scale and temperature coefficients. There are also forwarded two prints showing the reduction of the declination for the year 1888, by means of a graphic composite curve, made by tracing over one another with a pantograph the daily curves of the month, and then drawing a curve through them to show the monthly means. There are also forwarded from Washington a set of prints showing the comparison of the disturbances of declination and horizontal force at Washington for ninety-nine days of 1888, and another set of prints showing the comparison of disturbances of declination on certain selected days at Washington, Los Angelos, and Toronto, all reduced to the same time-scale of 30·6 mm. for two hours, *i.e.* the time-scale of instruments of the Kew pattern. The Committee are more than ever of the opinion expressed in their Third Report, "that the establishment of regular magnetic observatories at the Cape of Good Hope and in South America would materially contribute to our knowledge of terrestrial magnetism." The Committee consider that it would be desirable to publish annually in a collected form for certain selected days the curves of the three magnetic elements, *i.e.* declination, horizontal force, and vertical force, taken at the different English and Colonial Magnetic Observatories, choosing for selection in 1888 the days for which the curves are published in the "Greenwich Observations."

Report (Fourth) of the Committee appointed for the purpose of promoting Tidal Observations in Canada. Prof. A. Johnson, Secretary.—The Committee refer to a previous Report, in which it was announced that the then Minister of Marine (the Hon. G. Foster) had directed that some preliminary investigations should be made by Lieut. Gordon, R.N., who was to put himself in communication with Prof. Darwin. The Minister, however, said that the existing expenditure on hydrographic surveys made it necessary to postpone for the time the consideration of further steps concerning tidal observations. The Committee was re-appointed last year to keep the subject before the notice of the Government, in the hope that this systematic tidal work would be begun this year. In May last an interview was obtained with the Hon. C. Tupper, the present Minister of Marine, at which Sir Wm. Dawson was present. The Minister expressed himself as entirely favourable to the institution of the proposed tidal observations, but said that the financial position as regards the expenditure on hydrographic surveys was the same as last year, and that therefore no further steps could be taken as yet in the matter. It is believed that since the interview some of the expenditure in hydrographic surveys has ceased, and as there is reason to believe that other Cabinet Ministers are in favour of the proposed measure, the Committee deem the prospects of carrying it into execution very satisfactory. There is no doubt about the anxiety of shipmasters to have the tidal investigations set on foot immediately, and the Royal Society of Canada deem the matter of such great practical importance, that at their last meeting they appointed a special Committee to give energetic support to the action of this Committee.

Report of the Committee appointed for the purpose of continuing the Inquiries relating to the Teaching of Science in Elementary Schools. Prof. Armstrong, Secretary.—This year has been one of continued depression in regard to the teaching of science in elementary schools, and of disappointment in regard to legislative action. The return of the Education Department for this year shows again a diminution in the teaching of the science subjects. The statistics of the class subjects for six years are given, and show an actual decrease in elementary science, and a comparative decrease in geography. The return of scholars individually examined in the scientific specific subjects shows an actual or relative falling off in every subject except mechanics and chemistry. The rapid and serious decrease of attention paid to these science subjects is shown by the percentage of children who have taken them, as compared with the number of scholars that might have taken these subjects, viz:—In 1882–83, 29·0 per cent.; in 1883–84, 26·0 per cent.; in 1884–85, 22·6 per cent.; in 1885–86, 19·9 per cent.; in 1886–87, 18·1 per cent.; in 1887–88, 16·9 per cent.; and it must be remembered that children who have taken two of these subjects count twice over. The Government laid upon the table of the House a new Code, which would have had a slightly beneficial effect upon the teaching of science; but it has been entirely withdrawn. The Government has introduced no Technical Instruction Bill this year—except just at the last moment—and that does not apply to "scholars receiving instruction in an elementary school in the obligatory or standard subjects prescribed by the minutes of the Education Department." It was hurried through the Committee and final stages during the last week of the session. Sir Henry E. Roscoe, however, reintroduced his Bill with some modifications, and it passed the second reading at a comparatively early period of the session; but the Government would only give facilities for its progress through the House on the understanding that very serious changes were to be made in it. As he could not accept these, it has not passed the Committee stage; and it was ultimately withdrawn. Mr. Samuel Smith has again brought in a Continuation Schools Bill; but there has been no opportunity of discussing it since the first reading, and it was therefore withdrawn. The subject has, however, grown in the estimation of the public; and the whole question of the teaching of science in State-aided schools requires to be pressed more and more upon the Legislature.

Report of the Committee on Electrical Standards. R. T. Glazebrook, F.R.S., Secretary. (Slightly abridged.)

The Committee report that the work of testing resistance coils has been continued at the Cavendish Laboratory. A table of the values found for the various coils is given. Further steps have been taken towards the construction of an air condenser. As stated in the last Report, Dr. Alexander Muirhead kindly placed at the disposal of the Committee, for the purpose of experiment, three such condensers which he had constructed. A series of tests of these condensers was carried out by the Secretary and laid before a meeting of the Committee in London on April 15. It was then decided to adopt Dr. Muirhead's form of condenser for the new instruments of the Committee, and two instruments, each having a capacity of 0·01 microfarad, have been ordered from the Cambridge Scientific Instrument Company. They are not yet finished; a detailed description of their design is therefore left to the next Report.

A second subject of investigation has been the specific resistance of copper. During the year Mr. T. C. Fitzpatrick has made a large series of experients to determine this, and the Committee desire to thank cordially those manufacturers and others who have given their assistance in this research. Before publishing his results, Mr. Fitzpatrick is desirous of experimenting on some copper which is being prepared for him by chemical means—all which has been used hitherto has been electrically deposited—and of attempting still further to purify some of the copper already in his possession. Two members of the Committee, Sir W. Thomson and Mr. Preece, were present at the recent Electrical Congress in Paris. As an English equivalent of the resolutions there passed, the Committee have adopted the following resolutions, which they hope will meet with general acceptance:—

(1) The name of the practical unit of work shall be the joule. The joule is equivalent to 10^7 C.G.S. units of work. It is the energy expended during 1 second by a current of 1 ampere when traversing a resistance of 1 ohm.

(2) The name of the practical unit of power shall be the watt. The watt is the rate of working of a machine performing 1 joule per second. The power of a machine could naturally be expressed in kilowatts instead of in horse-power.

(3) The name of the practical unit of light intensity shall be the candle.

The candle is equal to the twentieth part of the absolute standard of light as defined by the International Conference of 1884.

(4) The name of the practical unit of induction shall be the "quadrant." 1 quadrant is equal to 10^9 cm.

(5) The "period" of an alternating current is the duration of a complete oscillation.

(6) The "frequency" of an alternating current is the number of complete oscillations per second.

(7) The "mean current" through a circuit is the time average of the current, and is defined by

$$\text{mean current} = \frac{1}{T}\int_0^T i\,dt,$$

i being the current at each instant of the time T.

(8) The effective current is the square root of the time average of the square of the current. Thus

$$\text{effective current} = \sqrt{\left\{\frac{1}{T}\int_0^T i^2 dt\right\}}.$$

(9) The effective electromotive force is the square root of the time average of the square of the electromotive force. Thus

$$\text{effective electromotive force} = \sqrt{\left\{\frac{1}{T}\int_0^T e^2 dt\right\}},$$

e being the actual electromotive force at each instant of the time T.

(10) The impedance is the factor by which the effective current must be multiplied to give the effective electromotive force. Thus, in the case of a circuit of resistance R ohms, and self-induction L quadrants in which a simple harmonic electromotive force of frequency $\frac{n}{2\pi}$ is acting, impedance $= \sqrt{R^2 + L^2n^2}$.

(11) In an accumulator the positive pole is that which is connected with the positive pole of the machine when charging, and from which the current passes into the external circuit when discharging.

The Committee are of opinion that they should be reappointed with the addition of the name of Prof. J. Viriamu Jones.

Report on the Present State of our Knowledge in Electrolysis and Electro-chemistry. By Mr. W. N. Shaw.

The following is an abstract:—

I. General electrolytic phenomena.

For a typical specimen we cannot suppose an electrolytic liquid otherwise than a mixture of solutions of chemical compounds, though the amount of all but one constituent of the mixture may be so small as to be regarded merely as impurities which it would not even be possible to detect by ordinary chemical means; thus von Helmholtz said in his Faraday lecture he has detected the polarization corresponding to the decomposition of a quantity of water of the order 1×10^{-11} gramme, and Gore (Proc. Roy. Soc., June 14, 1888) has shown the effect of chlorine upon the E.M.F. of a zinc platinum voltaic couple in distilled water is such that the presence of one part of chlorine in 1000 million parts of water could be detected thereby. Pure water, since Kohlrausch's experiments, is now looked upon as probably not conducting at all. Ratio of conductivity to that of mercury $= 0·71 \times 10^{-10}$ at 21°·5 C., and its sensitiveness to small quantities of impurity approximated to that of the sense of smell, since, when exposed in a room containing tobacco smoke, its conductivity doubled in three hours.

II. Laws and principles generally accepted.

(*a*) The electro-magnetic action of the current passing through an electrolyte is the same as if the electrolyte were replaced by a metallic conductor of the same size and shape and of such resistance that it could be substituted for the electrolyte without altering the current in the rest of the circuit.

(*b*) There are electrolytes in which the conduction of electricity from the electrode to the electrolyte, and again from the electrolyte to the electrode is entirely "convective" in the sense that no electricity can pass into an electrolyte or out of it again without causing a deposit of a certain number of constituent ions at the anode and the opposite ions at the kathode, *i.e.* in certain electrolytes no conduction takes place without chemical decomposition. This holds for a large number of electrolytes, possibly for all. It is not yet substantiated that it is true for all electrolytes, but the evidence is continually accumulating in that direction.

(*c*) The conduction of electric currents through electrolytes follows Ohm's law. Reference is made to Chrystal's experiments on metallic conduction, and Fitzgerald and Trouton's on electrolytic conduction.

One point is the experimental evidence for the deduction from Maxwell's theory of light, that electrolytes being transparent should behave as dielectrics for rapidly alternating electromotive forces. There are two ways of approaching the question—

(1) To find the length of light wave for which electrolytes are opaque.

(2) To find the rapidity of electrical vibration for which the electrolytes cease to conduct.

With reference to (2), Prof. J. J. Thomson says electrolytes still conduct when the rapidity of alternation is 300 millions per second.

(*d*) The only immediate effect of the passage of the current upon the body of a homogeneous electrolyte is to alter the temperature, and the alteration of temperature takes place in accordance with Joule's law.

Full references to the literature of the subject are given in the Report.

Report of the Committee appointed to make a digest of the Observations on Migration of Birds at Lighthouses and Light-vessels which have been carried on during the past nine years by the Migrations Committee of the British Association. Mr. John Cordeaux, Secretary.—The Committee have to report that one of their number, Mr. W. Eagle Clarke, of the Museum of Science and Art at Edinburgh, has, with the approbation of the Committee, undertaken to prepare the digest of the observations; and all the materials for making the same, including 1500 skeleton maps of the British Islands, provided for the purpose, have accordingly been placed in his hands. The labour of reducing the observations, to show in a concise form and on strictly scientific lines the results of the investigation which was carried on from 1879 to 1887 inclusive, will be easily understood to be enormous; and when it is borne in mind that this heavy work can only be carried on after official hours, your Committee feel that no apology is necessary for the non-completion of the digest this year.

Report of the Committee appointed to arrange an Investigation of the Seasonal Variations of Temperature in Lakes, Rivers, and Estuaries in various parts of the United Kingdom in co-operation with the Local Societies represented on the Association. Dr. H. R. Mills, Secretary.—It is inadvisable to attempt at present to summarize the results of observations made, as although more than a year's observations are available on some rivers, it is only a few months since the work has been begun on others. At the end of another year it is expected that sufficient data will be found to justify a comprehensive report on the subject. Several members of the Committee have taken much trouble in collecting observations. Dr. Sorby has been good enough to collect and discuss a great mass of temperature observations which he had made from his yacht *Glimpse*, in the estuaries of the south-east of England during the summer months of five successive years. This will be published separately. Prof. Fitzgerald took charge of the observations in Ireland, where he induced a number of observers to take up the work. Mr. Willis Bund had already inaugurated similar researches on the Severn. Rev. C. J. Steward and Mr. Isaac Roberts rendered important services in their districts. A circular was sent to all the Corresponding Societies in connection with the Association, requesting their co-operation, and favourable replies were received from several, intimating that observations had been commenced. The instructions issued to observers are given as an appendix to the present Report.

Report of the Committee on Solar Radiation.—The actinometer devised by the late Prof. Balfour Stewart, for the continuous measurement of solar radiation which was described in the Report of the Association for 1887, is now ready for preliminary trials, the internal thermometer with a flat bulb of green glass having been made since the date of that Report. The construction of this thermometer occasioned a good deal more trouble than had been anticipated. No attempt has at present been made to render the instrument self-recording, as it would obviously be unwise to incur the outlay which any construction for this purpose would involve, until the result of preliminary trials was such as to encourage a hope that the instrument might really be useful if rendered self-recording.

Report of the Committee appointed for the purpose of taking steps for the Investigation of the Natural History of the Friendly Islands, or other Groups in the Pacific visited by H.M.S. "Egeria." Mr. S. F. Harmer, Secretary.—The Committee have not yet received information which puts them in a position to give any detailed report of the work which is being done in connection with the above subject. The grant has been paid to Mr. J. J. Lister, who reached Tonga on March 19. After devoting two months to the investigation of the natural history of that group, Mr. Lister joined H.M.S. *Egeria*, on her arrival at Tonga, with the intention of visiting Samoa, where, by the latest accounts, he was carrying on his researches.

THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

THE thirty-eighth annual meeting of this body was held in the fourth week of August at Toronto, Canada. This is the third time in the history of its existence that the meeting-place selected has been on British territory—the first and second being at Montreal in the years 1857 and 1882.

The arrangements for the entertainment of the visitors were all of that free, open-handed, generous character peculiar to New-World hospitality. A large and representative Local Committee was appointed, and through their instrumentality many facilities for comfort and pleasure were obtained; such, for example, as reduced railway fares, the withdrawal of all Customs duties on instruments, specimens, &c., for use at the meetings, a daily luncheon given gratis at the place of meeting, excursions at reduced rates to Niagara, to the Muskoka Lakes, to the Huronian district, and even across the continent to the Pacific coast. There were also the usual number, or perhaps even more than the usual number, of garden parties, evening entertainments, and small excursions to outlying localities of geological, entomological, or botanical interest. Two public lectures were also given, the subject of the first being the evolution of music, of the second, the geological history of Niagara.

Among those present who took an active part in the proceedings were Prof. James D. Dana; Sir Daniel Wilson, the President of University College, in the Convocation Hall and Lecture Rooms of which the majority of the Sections met; Sir William Dawson, of Montreal; Dr. Charles C. Abbott; Prof. N. H. Winchell, of Minneapolis; Major J. W. Powell, of Washington, the retiring President; T. C. Mendenhall, of Washington, the President for this year; Messrs. Carpmael, Ramsay, Wright, and London, of University College; Profs. Hall and Newberry, who, with Prof. Dana, were the first three Presidents of the Association; Mr. Macoun; Dr. T. Sterry Hunt; Prof. Alexander Winchell, author of "World Life"; Prof. Heilprin, author of "The Geographical and Geological Distribution of Animals," &c.; Messrs. Minot, Morse, Newton, and many others of note. Nor must be omitted the names of Mr. F. W. Putnam, the permanent Secretary; and the following Vice-Presidents of the Association: R. S. Woodward, H. S. Carhart, W. L. Dudley, J. E. Denton, C. A. White, G. L. Goodale, Colonel G. Mallery, and C. S. Hill.

Many sincerely regretted the absence of the learned and genial Professor E. J. Chapman, of University College.

Not much time was wasted at the first meeting in the inevitable speeches and addresses of welcome, and within a couple of hours of the time when the general session was called to order by the venerable Professor Dana, on Wednesday morning, August 28, the various Sections met to organize, preparatory for the delivering in the afternoon of the Vice-Presidential addresses—the Vice-Presidents of the Association being chosen from, and acting as Presidents of, the several Sections.

The majority of these addresses were of a general or historical character. Mr. Carhart, in the Section of Physics, reviewed the theories of electrical action; Mr. Goodale, in the Biological Section, spoke of protoplasm; in the Department of Anthropology, Colonel Mallery dealt with the somewhat curious and little heard of, though not novel, theory of the Hebrew origin of the Indians of North America, discussing the arguments in behalf of that theory, especially the very problematical ground that the plane of civilization and thought of the Indians of to-day was parallel to that of the Israelites of the Old Testament.

Section of Anthropology.

A very large number of the papers read in the Section of Anthropology quite naturally referred to the Indians of the American continent. The following is a list of the more important of these:—

The Huron-Iroquois, by Sir Daniel Wilson.

Evidences of the Successors of Palæolithic Man in the Delaware River Valley, by Dr. Charles C. Abbott.

The Winnipeg Mound Region, by Dr. George Bryce, of the Winnipeg College.

New Linguistic Family in California, by H. Henshaw.

Onodaga Shamanic Masks, by De Cost Smith (Onodaga is a county in the State of New York).

The Phonetic Alphabet of the Winnehago Indians, by Miss Alice C. Fletcher.

The Medawiwin or Grand Medicine Society of the Ojibway, by W. J. Hoffman.

Notes on Aboriginal Fire Making, by Walter Hough.

Aboriginal Mounds of North Dakota, by Henry Montgomery.

The Iroquois White Dog Feast, by Rev. W. M. Beauchamp.

Algonkin Onomatology, by A. F. Chamberlain, of University College, Toronto.

Government of the Six Nations, by O-ji-ja-tek-ha.

Results of Explorations about the Serpent Mound of Adams Co., Ohio, for which a grant was made by the Association, by F. W. Putman.

Aboriginal Monuments of North Dakota, by Henry Montgomery.

Steatite Ornaments from the Susquehanna River, by Atreus Wanner.

Notes on the Eskimo of Cape Prince of Wales, Hudson's Strait, by F. F. Payne, of the Observatory, Toronto.

The following is a brief abstract of Sir Daniel Wilson's interesting paper on the Huron-Iroquois—a branch of a subject in which the writer has for many years conducted important and successful researches:—

The Huron-Iroquois of Eastern Canada.—On the occasion of the first meeting of the American Association for the Advancement of Science in the province of Ontario, it was perhaps a matter of interest to the members of the Anthropological Section to have some special notice of the aborigines of this region to the north of the great lakes. Sir David Wilson accordingly noted that the Indians found in this province on its first occupation by English settlers, as well as those now settled on their reserves in Ontario, are nearly all later intruders than the Anglo-Canadian occupants of the soil. On the Grand River the Six Nation Indians have now been settled for upwards of a century, and have made great progress in civilization. They include the Mohawks, Oneidas, Onondagas, Cayugas, Senecas, and Tuscaroras. But they followed the loyalist British colonists, with whom they had taken part in the War of Independence; and the first of them still preserve the prized heirloom brought with them when they forsook their old native valley of the Mohawk—the silver communion service, inscribed "A.R. 1711. The gift of Her Majesty, Ann, by the Grace of God, of Great Britain, France, and Ireland, and of her plantations in North America, Queen, to Her Indian Chappel of the Mohawks." But though the Six Nation Indians have occupied their reserves on the Grand River for little more than a century, they belong to the great Huron-Iroquois stock, of which Canada is the original home. The speaker accordingly gave a detailed account of the first direct knowledge of the Hurons of the St. Lawrence Valley derived from Jacques Cartier's narrative of his two voyages. He first entered the St. Lawrence in 1535, when he found the palisaded Indian towns of Stadacone and Hoschelaga, on the sites of Quebec and Montreal. We owe to him a vocabulary of their language which proves them to have been Wyandots or Hurons. But when Champlain followed, in 1615, the whole region was a desert. An account was then given of the Huron settlements visited by Champlain on the Georgian Bay, and their extermination by the Iroquois in 1648. Next the traditions of the race were referred to, all in legendary fashion, embodying the myth of their emerging from the heart of a mountain between Quebec and the Great Sea. Their country thus reached, apparently, to the Labrador frontier, contiguous to the Eskimo country. Skulls of the Hurons and Iroquois were produced, including a cast of that of the famous Mohawk chief, Brant; and attention was drawn to the striking contrast which their predominant dolichocephalic type presented to that of the prevalent American type of skull. In this respect the Huron-Iroquois head-form approximates to that of the Eskimo, and the special aim of the paper was to show the reasons for believing in an admixture at some remote date of this American stock with the Eskimo, who have been invariably recognized by ethnologists as a distinct type from the true Indian of the northern continent.

The Rev. Mr. Beauchamp's contribution on the Iroquois white dog feast had some points of interest. Among the Iroquois, the Senecas and Onondagas alone, the writer showed, seemed to have observed the annual white dog feast, and that only within recent times. It combines some features of both the dream and war feasts, of which it is the successor, and is the beginning of the new year. Penitential exercises take up a portion of the time, with games and various performances of the false faces. His sins confessed and forgiven, his appointed offering made and the fire rekindled on his hearth, the Indian was prepared to enter hopefully on a new year, especially if dreams and games had turned out well. The feast has now lost some of its most striking features, and will very soon altogether pass away.

Section of Geology and Geography.

The Section of Geology and Geography also devoted much of its time to topics of American interest. Mr. Charles White, in his address as Vice-President, touched on "The Mesozoic Division of the Geological Record as it is exhibited on this Continent," referring more particularly to the principal subdivisions of the Mesozoic that have been recognized in North America, their inter-delimitation, their division as a whole from the Carboniferous system beneath and the Cænozoic above. He held that the Mesozoic strata of the Atlantic coast region consist of a probable representation of the Upper Trias of Europe, a possible one of the Upper Jura, a probable slight one of the Middle Cretaceous, but with a hiatus between the latter and the Eocene.

Another paper in this Section, dealing in comparisons of Cis- with Trans-Atlantic formations, was that of Prof. H. S. Williams, of Cornell University, Ithaca. He gave an account of his examination of the English Devonian rocks, under the leadership of Messrs. Ussher and Townshend Hall, during the visit of the International Congress of Geologists in 1888. Comparison of the rocks and fossils with those of Eastern North America led to the conclusions (*a*) that the fossils are very closely allied to the species of the New York Devonian, although in the great majority of cases passing under different names; and (*b*) that the rocks, in their appearance, composition, and order, are as different as two distinct systems well can be. The great Devon limestone of South Devonshire and Cornwall furnished the fossils upon which Lonsdale based his conclusion that the fauna was intermediate between the fossils of Murchison's Silurian system and those of the Carboniferous limestone, which led to the establishment of a "Devonian" system. When other European localities had furnished more perfect sections of this system, the fauna of this limestone was recognized as the Middle Devonian fauna, and that of Marwood, Pilton, Sloly, &c., as an Upper Devonian fauna. But neither the order of sequence of the rocks nor the separation of the fossils into well-defined faunas can be satisfactorily determined by study of these Devonian rocks alone. Although they have furnished geological nomenclature with a name for the system, they are far from being typical of the Devonian system, as known to most geologists. Comparison of the faunas of the European Devonian faunas with those of the Appalachian basin leads to the hypothesis that the marine life of the two areas had different histories. There is a continuity in the succession from lowest to highest zones of the system in Europe which we do not find in the American series. It is evident that the American Lower and Middle Devonian faunas are more distinct from the corresponding faunas of Europe than are the "cuboides" and later Devonian faunas of the two areas. To account for these facts it is conjectured that a barrier separated the two districts during the lower and middle stages of the Devonian, and that with the "cuboides" stage an incursion of European species began from the European area westward or north-westward, penetrating the Appalachian basin. The mingling of species was not complete, and was stopped altogether by the elevation which terminated the marine Chemung fauna of the New York area. The author also found evidence for the belief that the early Carboniferous faunas advanced northward in the central and Appalachian basins to take the place of the Hamilton and Chemung faunas, which in large measure ceased.

Mr. Frank Leverett, of the U.S. Geological Survey, read a paper on the glacial phenomena of North-Eastern Illinois and Northern Indiana. The paper opens with an explanation of the methods of study already employed, and other methods to be employed in deciphering the history of the drift. A brief discussion is given of the features and phenomena included under the term moraine as restricted in the paper. Among these features, knobs and basins, swells and says, smooth ridges of till and boulder belts, may be included (though such topography and features are under some conditions non-morainic), but the till plain, "or ground moraine," is not included.

The moraines here discussed are terminal to the *ice* but not to the drift-covered portions of these States. Four evidences of advances in the production of later moraines are cited: (1) buried soils *in situ* between till sheets; (2) changes of direction in flow as shown by striæ; (3) change in form of ice-lobe as indicated by the distribution of the moraine belts and shiftings of the re-entrant and lobate portions; (4) evidence of push or advance in the moraine itself.

The number of distinct moraines varies because of partial coalescence or of local obliteration of portions of certain moraines by later advances. For this reason correlation is difficult. Aside from the difficulty cited there is an increase in the complexity in passing from older to newer moraines. In the older ones the interlobate portions are short, and the moraines can be traced around continuously from one lobe to another through the re-entrant portions. But in newer moraines the terminal loops meet on opposite sides of large interlobate moraines, and correlation is made only after critical study of their connections, over-riding, overwash, &c.

Suggestions are made upon the subject of progressive lobation, but caution is urged against advancing general schemes too early. The study has not been carried far enough to make it possible to draw conclusions of that high order to which future extension of the work will lead.

Before the leading time-intervals in this district can be properly outlined, wider correlations must be made and erosion studies must be carefully prosecuted by competent investigators of erosion phenomena.

Section of Economic Science and Statistics.

Not the least interesting of the papers of this Section was one on "Food Moulds the Race," by Mrs. Nellie S. Kedzie, of the Department of Household Economy and Hygiene in the Kansas State Agricultural College. Mrs. Kedzie traced Irish discontent to the fact that, as she states, whereas "the population of England take on an average 4½lbs. of meat per day," the Irishman eats but 2½ oz. per week. "A hungry man is an angry man," Mrs. Kedzie affirmed, and added, "What wonder that the Irish have grown rebellious, suspicious, and lawless"!

A more serious and important paper in this Section was that of Mr. F. Lester Ward on "The Sociological Position of Protection and Free Trade." The author advocated a protective tariff, and his arguments may be briefly summed up thus:—A protective tariff is a means employed by the State to encourage activities beneficial to that State. The principle is that of inducing certain individuals to put forth energies resulting in benefit to the community at large. Against the argument that public money should not thus be given to private individuals, Mr. Ward urged that the public funds thus spent were analogous to the moneys spent in salaries to Government officials—the end was the same in both cases, viz. the public welfare. A protective tariff tended to make the State self-sustaining. The statesman is not a humanitarian; his duty is the weal of his own country. He is justified, therefore, in advocating measures of self-defence. But as with individuals, so with States: those acts which are performed for the object of self-defence conduce to the welfare of the collective whole. There is no such thing as free competition. The term itself implies friction. It requires intelligent interference to preserve competition free. Competition left to itself promotes monopolies. The protective tariff prohibits the unnecessary transportation of commodities. This results in economy.

But the paper that attracted the largest amount of attention in this Section was that of Mr. B. E. Fernow, chief of the Forestry Division of the Department of Agriculture of the United States. A graduate of a Forestry Academy of his own country, Germany, where, as he himself said, the preservation of forests is traditional, Mr. Fernow is astonished at the careless—in many cases, indeed, deliberate—wastefulness with which the New World utilizes its treasures of timber, and he looks to the Government to remedy the evil. "As far as the forest yields material for the arts," he said, "it is an object of private industry; but when, by its position on a watershed, the forest becomes an influential factor in the water conditions of the plain, it may still serve the purposes of gain and wealth, which are the objects of private industry, but its indirect significance for society at large exceeds the private interest, and this class of resources, being in the direction of a social gain or gain for a larger number, must become an object of public economy by the State or community."

The following passage from Mr. Fernow's paper is worthy of quotation, showing as it does his perspicacious views on this difficult problem of forest conservation:—

"Whatever tends to stimulate private activity is to be promoted. Whatever retards development of intensive methods is to be removed by Government. Industrial education, cultural surveys, organization of national irrigation systems, fish commissions, bureaus of information, experimental stations and other aids to private enterprise will constitute the chief methods of expressing State interest with regard to these resources. The three great sources upon which mankind is most dependent, which demand first the attention of the State, are the soil, as food producer, the water, and climatic conditions. A rational management of the water capital of the world in connection with the agricultural use of the soil will become the economic problem of the highest importance, as the necessity for increased food production calls for intensive methods. In the United States the action of the Government on economic and cultural questions is apt to be fitful and the result of personal influence rather than a logical analysis of conditions and principles. While our Government is ready to go to war in order to protect its fisheries, it has never even known the value as food supply of the game which has been killed. Whole races of animals have been extirpated before there were population enough to require the meat. While with one hand we pay exorbitant prices in land and wasted energy to get the plains re-forested, and that with poor success, with the other hand we offer a premium for forest destruction in mountains by leaving them without proper administration. And now we propose to establish irrigation systems, neglecting to provide first for those conditions which assure a regulated water supply—namely, by forest preservation."

This paper led to the adoption by the Association of three resolutions: one, that Congress be memorialized on behalf of a proper administration of the forests of the western mountain ranges; a second, that legislative enactments were necessary for the development of natural resources; and a third, appointing a committee to urge the importance of these matters on the President and Congress of the United States and on the Premier and Parliament of Canada.

Section of Chemistry.

The Vice-Presidential address in this Section was read by Prof. William L. Dudley, of Vanderbilt University, who gave a *résumé* of the more important researches on the nature of amalgams, to which was appended a very complete index to the literature on the subject. Prof. Dudley confined himself almost wholly to the historic aspect of his theme, taking occasion only to remark that the results of previous experiments seem to prove that amalgams are chemical compounds more or less unstable.

Mr. Charles Munro spoke on the explosiveness of the celluloids. He gave the results of experiments for testing their stability, flashing-point, &c., and maintained that the opaque varieties were insensitive to detonation at ordinary temperatures, but that the translucent readily exploded.

Mr. John W. Langley, of Pittsburg, read a paper on "International Standards for the Analysis of Iron and Steel." He stated that a system of international standards had been arranged for between England, France, Germany, Sweden, and the United States. He gave a description of the system, and asked the Section to name one chemist to act with six others to conduct the analysis on behalf of the American Committee on the International Standards, and to co-operate regarding the same with European analysts. The meeting appointed Mr. Thomas M. Brown, of Boston, with Prof. F. A. Gooch, of Yale College, New Haven, Conn., as alternative.

Section of Mathematics and Astronomy.

In the Section of Mathematics a paper—which resulted in an important resolution being adopted by the Association at large—was read on the Peruvian arc. The two meridional arcs, the one in Peru and the other in Lapland, measured a century and a half ago, were examined by Mr. E. D. Preston, of the United States Coast and Geodetic Survey, with reference to the degree of accuracy attained, and a comparison was made between the uncertainties of these measures and those resulting from work with modern instruments, and following more recent methods. It was shown that the probable errors were much larger than would be indicated by the agreement of the published results, and that therefore the concordance of this arc with those in other parts of the world is no proof of its accuracy. By far the most significant errors came from the astronomical observations, and the unavoidable uncertainties here, either from the imperfection of the instruments, or the attraction of the high mountains, were shown to affect perceptibly the present value of the earth's axis.

The resolution touching this matter, which was unanimously adopted at a general session of the Association, reads as follows:—

"Whereas the history of geodesy includes no more important page than that relating to the measurement in 1739 of the so-called Peruvian arc, which work was conducted by the French Government with the co-operation of Spanish officers, and in magnitude of plan and difficulty of a most serious character it was in its time unexcelled; whereas recent improvements in all the processes incidental to such an undertaking have been so very great, rendering possible a vastly more accurate execution of the work; whereas it is and has been for several years a matter of deep regret that the one great contribution which the American continent has made to the solution of the problem of the figure of the earth should fall so short of what it should and might: be it therefore resolved by the American Association for the Advancement of Science, that the Congress of the Three Americas about to assemble in Washington is earnestly requested to consider the desirability of undertaking the measurement of this Peruvian arc, to be accomplished by a union of the Republics represented. This result is not likely to be reached except through international effort, and this recommendation by the Congress would be a fitting and proper act of this first conference of representatives of the New World."

Section of Physics.

The President of the Association, Mr. T. C. Mendenhall, read before the members of this Section a short paper on globular lightning. He adduced no new theory as to its source or character, but submitted an interesting account of several authentic records of its occurrence, many of them abstracted from the reports sent in to the United States Hydrographic Office. He showed that there was abundant trustworthy proof that atmospheric electricity took on the form of globular lightning, but conceded that the evidence was in details discordant. He hoped that some day opportunity might be given to obtain a photograph of the phenomenon.

Mr. Thomas Gray read a paper on the relative values of the magnetic and the electrodynamic methods of measuring electric currents in absolute measures.

In the subsequent discussion on the paper, Prof. Nichols, of Cornell University, stated that he had compared the constants of one of Sir William Thomson's balances as certified by him, with the constants as determined by the large standard galvanometer in Cornell University, and found them to agree perfectly through the entire range—a result with which he was greatly pleased.

Prof. H. S. Carhart, of the University of Michigan, read two papers before this Section, one on magnetic leakage in dynamos, the other on an improved standard cell with low temperature coefficient. The following abstracts of these papers will show their gist and purport:—

The first paper gives an account of some experiments to determine the magnetic leakage of two dynamos of the Mather and Edison type respectively; the former was a small machine of 500 watts capacity, built by a student in the laboratory, the latter an Edison of 5000 watts capacity.

In the small machine the leakage was due to some projecting machine steel studs which carried the armature yokes. The number of magnetic lines cut by the armature when the machine was coupled as a self-exciting shunt dynamo was determined, and then the steel studs were replaced by brass and the determinations were repeated. The result was 190,000 and 252,000 lines of force respectively, or a gain due to removing the steel studs of 32·6 per cent. This was partly due, however, to increase in the field when the leakage was stopped. Hence the machine was independently excited by a storage battery, and the number of lines determined in the two cases as before. The result was 164,600 and 184,100 lines cut by the armature with and without steel studs, a gain of 11·2 per cent. This measured the true leakage due to the assigned cause.

The leakage in the Edison machine was due to the iron bed-plate. A plank base was made, and the number of magnetic lines cut by the armature was determined first with the iron base and then with the plank, the machine being self-exciting and running at the same speed in the two cases. The number of lines was 1,510,000 and 1,605,000, a gain of 6·25 per cent. due to removal of the cause of leakage.

In his second paper, on an improved Clark standard cell with low temperature coefficient, Prof. H. S. Carhart said:—"The objections to the Clark cell, as described by Lord Rayleigh, are high and variable temperature coefficient, objectionable mechanical construction, and serious local chemical action. These I have, at least in large measure, overcome. The cell which I now make is so constructed that the mercury cannot reach the zinc during transportation. The temperature coefficient is represented by the equation

$$E^1 - E[1 - \cdot000387(t - 15) + \cdot0000005(t - 15)^2].$$

Per degree the coefficient is

$$- \cdot000386 + \cdot000001(t - 15).$$

At 0° C. this coefficient becomes − ·000401; at 25°, − ·000376; and at the highest temperature observed, 52°·7, it is − ·000348. It will be observed that this coefficient diminishes with rise of temperature, while that of Lord Rayleigh's cells increases. In cells of the old form local action is due to zinc replacing mercury when in contact with the solid mercury salt. The zinc is thus amalgamated, and the amalgam creeps up. This I prevent by keeping the zinc out of contact with the mercury salt. The same device has the effect of raising the E.M.F. about 0·4 per cent. The polarization of these cells amounts to only one ten-thousandth part in five minutes with an external resistance of 10,000 ohms. It recovers in a few minutes. The different cells show great uniformity of E.M.F. All comparisons are made by Lord Rayleigh's method slightly modified. A charge or difference of E.M.F. of one ten-thousandth part is very readily detected."

In this Section Messrs. W. A. Rogers and R. T. Woodward, in a paper on mercurial thermometers, held the following theses:—(1) The movements of a mercurial column are in all cases by pulsation; (2) these pulsations have a regular recurrence; (3) the period of recurrence is constant in the same thermometer; (4) every pulsation has the same harmonic relation; (5) the amplitude of the curve which represents the harmonic is inconstant; (6) as the period is constant and the time required for the completion of the cycle variable, it follows that the danger of error in random readings of the thermometer is greater for slow than for rapid variations of temperature.

Section of Biology.

In the Biological Section, Mr. A. J. Cook read an interesting paper on the alimentary apparatus of the bee, in which he embodied the results of a long series of personally conducted experiments. He differed, he said, widely in many particulars from the author of the article on the anatomy of the bee in the "Encyclopædia Britannica," notably as regards the conformation of the tongue. This organ, Mr. Cook strongly maintained, was a hollow cylinder furnished on the under side with a slit throughout its entire length. He explained that suction could be performed in three ways: (1) through the terminal aperture of the internal tube, when the nectar could be reached only by the end of the tongue; (2) through the slit opening into this tube, when the fluid to be sucked in was shallow and placed on a flat surface; (3) by the aid of the labial *palpæ* when the fluid was abundant. The author also expressed his incredulity as to the possibility of a trustworthy analysis of honey, arguing that in many cases more nectar was taken into the honey-stomach by the bee than the glands had time or secretion sufficient to digest. Especially, he thought, did this happen when the linden was in bloom, when a single hive of bees would sometimes store up 15 pounds of honey in the day. The queen bees and the drones, he held, were fed with digested food only, and to this fact he traced the extraordinary fecundity of the queen bee.

Prof. Burrill read a paper on fermentation of ensilage. He stated that all fermentation of organic matter is now universally admitted to be due to the action of micro-organisms, and he described the phenomena presented in recently stored green fodder, used for cattle food. This material is now placed in bins of large size, where it soon becomes very hot, reaching a temperature of 60° C. (140° F.). This temperature was sufficiently high to kill or at least prevent the growth of nearly all animal and vegetable species, 50° C. being the upper limit. Upon the proper examination of this hot material one soon finds that a single species of Bacteria (*Bacillus butyricum*) is associated with the fermentation and subsequent rise in temperature. Further tests prove that it is the cause of these changes. Secondary changes are very liable to occur as the heat decreases, and lactic and acetic acid, the latter often in large amounts, are produced. Possibly alcohol is sometimes, but never as a first product of the hot material.

On the whole, this the thirty-eighth annual meeting of the American Association for the Advancement of Science may be considered to have been a successful one. Close upon two hundred papers were actually read in the various Sections, some of these of course not reflecting that "dry light" which is supposed to beat upon all scientific investigation, yet the majority of them evincing real and enthusiastic work on proper lines. One thing, however, might have been noticeable to an English ear, many of the writers seemed to possess a greater mastery over abstruseness of subject than over elegance of diction.

Many eminent men, some famous in both hemispheres, were present. The total number of persons in attendance on the meetings, and actually belonging to the Association, either as Fellows, Members, or Associates, was between four and five hundred.

Financially, the Association is declared to be in a better position to-day than ever it has been before. The annual income is at present about $6000. It has also the sum of $4500 invested at 5 per cent., the interest of which is devoted to the furtherance of original research. For the ensuing year this sum has been apportioned thus: $150 to Prof. Moseley to continue his researches on the velocity of light in the magnetic field; and $50 to Prof. Attwater for the purpose of investigating the heats of combustion of certain mineral and vegetable compounds.

Indianapolis and the third Wednesday in August were chosen as the place and time of meeting for 1890. Mr. G. L. Goodale, of Cambridge, Massachusetts, was elected President for the coming year.

The meeting was closed by a public gathering, at which many complimentary speeches were made both by hosts and guests.

ARNOLD HAULTAIN.

THE IRON AND STEEL INSTITUTE.

THE autumn meeting of the Iron and Steel Institute was held last week in Paris under the presidency of Sir James Kitson. The meeting was held in the rooms of the Société d'Encouragement, and was addressed, in the first instance, by M. Eiffel, President of the Société des Ingénieurs Civils, and by M. H. de la Goupillière, President of the Société d'Encouragement. The President of the Institute, after thanking M. Eiffel and M. de la Goupillière for their kind hospitality, announced that the Council had awarded the Bessemer Medal to M. Henri Schneider, of Creusot, for his services to the iron and steel trade of France, to whom it was presented on Friday by Sir Lowthian Bell. Sir James Kitson made a brief address, referring to their last visit to Paris in 1878, under the distinguished presidency of the late Sir William Siemens, to the increase in the roll register of the Institute which had taken place since that date. He drew attention to the improvements which had taken place during the last decade in the metallurgy of steel and iron; the commercial development of the Siemens-Martin and Thomas-Gilchrist steel processes; the increased development in the manufacture of steel owing to the extension which had taken place in its applications. The Eiffel Tower was an elegant example of the scientific power and imaginative genius of French engineering, whilst the French chemical study of the processes of metallurgy had rendered great service, not only to their own industry, but to that of the world at large. The names of many eminent French metallurgists were mentioned, and the work they had done was briefly referred to.

The business of the meeting was then proceeded with, viz. the reading and discussion of the various papers which are referred to below.

Prof. S. Jordan's paper, "Notes on Iron and Steel Manufacture in France in 1887, and as illustrated by the French exhibits at Paris," the first paper read, was of a statistical character, and compared the present production of these metals with what it was ten years ago.

The Channel Bridge.—This was a paper by Messrs. Schneider and Co., of Creusot, and M. H. Hersent, Past-President of the Société des Ingénieurs Civils, descriptive of a bridge for connecting England with the Continent. The paper consists of three parts, an introductory notice, a general description of the bridge, and of the superstructure, being preliminary projects of M. Hersent and Messrs. Schneider respectively. From the introductory notice it would appear that projects have been submitted by Messrs. Fowler and Baker, but these are not published in the paper.

It is proposed that the bridge should span the Channel at about its narrowest portion—namely, between Folkestone and Cape Griznez, a distance of 25 miles, by which means also the sand-banks of Varne and Colbart can be taken advantage of, thereby diminishing the height of the piers necessary to be erected. These banks are in mid-Channel, about 3¾ miles apart, and are separated by a depression of between 80 and 90 feet deep; this is also about the depth between the bank and the British coast, whilst on the French side, between the Colbart Bank and the Cran-aux-Œufs, the bottom sinks somewhat abruptly down to 132 feet, attaining 180 feet about midway across, when it gradually rises again. In these parts the chief difficulties would be encountered in laying the foundations. As the result of frequent experiments, it is found that the blue and white chalk which forms the Channel bottom is capable of supporting a load of from 140 to 170 pounds to the square inch, and the surface of the bases of the piers has been so calculated that the foundations should not have a greater load on them than the smaller of these amounts. This would imply that no factor of safety has been allowed, which is hardly likely to be the case, as in masonry structures with a live load a factor of safety of 8 is generally recommended; on the other hand, the ordinary kinds of chalk are capable of resisting a crushing pressure of 330 pounds per square inch. The masonry piers are 190 feet in length at the base, and 140 feet above, the width depending on the columns which they have to support. The distance between the piers is fixed at 1650 and 990 feet, 1155 and 660 feet, and 825 and 330 feet, the largest spans corresponding to the greatest depths, and the smaller ones to smaller depths and the parts near the shore. Each supporting pier will consist of a block of masonry of best material, set with Portland cement, and laid on the sea bottom; the masonry will be built inside metal caissons similar to those used for ordinary bridge piers, and forced by compressed air down to the solid ground. Their surface above high-water level will form the foundation for the metal columns, which are cylindrical in shape, and vary in height between 132 and 140 feet, and on them are placed the main girders of the bridge. These girders are 200 feet above low-, and 178 feet above high-water level. This height is amply sufficient for the passage of the largest ships. The system of girders proposed to be employed is simple, unlatticed, trussed, so as to insure the proper distribution of all the stresses. After consideration it has been found advisable, instead of forming the 990 and 1650 feet spans of girders extending over the whole length of 990 feet, and extending on either side in the form of cantilevers of 825 feet, so that the junction of the two cantilevers should constitute a span of 1650 feet in all, not completely to cover the spans by means of cantilevers, but to connect these by an ordinary independent span, a saving of 17 per cent. being thus realized in each overhanging portion of the cantilever. In this manner the 1650-feet span comprises two cantilevers of 619 feet each, and an independent span of 412 feet. The metal flooring on the central span and cantilever is formed of two girders resting upon two piers 990 feet apart, and lengthened on either side to the extent of 619 feet. These girders are 36 feet high at the ends of the overhanging portions, and 214 feet high almost throughout the span of 990 feet. Each girder consists of two chords connected by bracings forming isosceles triangles. The lower ribs of the two girders have a distance of 82 feet between their axes in the central span of 990 feet, and an interval of 33 feet at the ends. The level of the permanent way is 237 feet above low water; a double set of rails is proposed, and the width of flooring proper will be 26 feet.

The paper further gives a detailed description of the foundation work, comprising the situation and dimensions of the piers, the construction, conveyance, and fitting into position of the supporting columns, and the materials and machinery required for the completion of the work; also the construction, transport, and putting into position of the metal spans, with estimates of weight, and calculations of the resistances throughout the structure. The metal required for this bridge would amount to a million tons, of which about three-quarters would be steel; the cost is estimated at £35,000,000, and the period requisite to complete the work ten years. This interesting pamphlet of nearly 100 pages will be referred to on account of the careful manner in which the subject has been brought forward, even should the building of the bridge not take place, on account either of political objections or constructive difficulties. As stated in the paper itself, each pier comprises a small lighthouse, and as about 150 of these small lighthouses will have to be erected, an injury to any one of which would close the bridge for a lengthy period, one thinks of the Eddystone Lighthouse, built by Smeaton 100 years ago, which has had to be replaced, not on account of any fault in its design or construction, but because the sea had made inroads on its foundation of rock.

On Gaseous Fuel, by Sir Lowthian Bell. The author assumes a certain quality of coal, and then compares the work that can be performed with it according as it is used in the solid state or in the condition of producer gas or in that of water gas. Producer gas is that supplied to the Siemens regenerative gas furnace; the specimen of coal used for comparison is assumed to consist of 70 per cent. fixed carbon, 16 coal gas, and 14 ash, oxygen and nitrogen, and the producer gas obtained from it of 16 parts of coal gas, 163·3 of carbonic oxide, and 222 of nitrogen, the producer gas being supplied cold at the foot of the regenerators; the calorific value of the coal is 7200 calories. 100 parts of this coal are equal to 720,000 calories, and by the combustion of the producer gas 551,920 calories are produced, showing a loss of 168,080, equal to 23·3 per cent. The method of manufacture of water gas is next explained. The fuel recommended to be employed is coke, which is placed in a cylinder of iron lined with fire-brick; the coke is rendered incandescent by an air blast. When in this state the blast is stopped, and a jet of steam passed through it. The steam is decomposed; its oxygen burns the carbon into carbonic oxide, setting free the hydrogen, the mixture constituting so-called water gas, comprising equal volumes of carbonic oxide and hydrogen. The change in producing water gas is expressed chemically by $H_2O + C = H_2 + CO$, and the heat required to tear hydrogen away from its associated oxygen is not less than that evolved when the two gases unite, or 2 × 34,200 = 68,400 calories. The weight of the combining equivalent of carbon required to effect the change is twelve times that of the two units of hydrogen, and the heat generated by this quantity of carbon being burnt to carbonic oxide is 12 × 2400 = 28,800, so that something over 14½ units weight of carbon will be required to generate a unit weight of hydrogen. But as only 6 units of carbon are being burnt per unit of hydrogen, the incandescent carbon is soon cooled down below the temperature of decomposition. When this point is arrived at, the steam is shut off, and the blast is again turned on. Using the data given in the water gas publications, water gas produces per 100 parts of carbon 682,520 calories out of a possible total of 800,000, there being a loss of 14·68 per cent.; as the coke used is produced from coal, the actual loss rises to 37 per cent. The author sums up as follows:—

(1) Coal as burnt in an ordinary furnace—

		Calories.
100 parts, yielding 7200 calories per unit	=	720,000
Chimney gases, estimated after making the necessary allowance for oxygen in the coals, 1129 units × 427° C. × ·24 specific heat	=	115,700

the loss in this case by chimney gases being equal to 16·07 per cent.

(2) Producer gas from same coal, as used in the Siemens furnaces, without the addition of steam—

		Calories.
70 of carbon or 133·33 of CO × 2400	=	391,992
16 of coal gas × 10,000	=	160,000
Sensible heat transmitted to furnace		62,411
		614,403
Heat in chimney gases, 1129 × 377° C. × ·24 specific heat	=	102,151

Loss of chimney equal to 16·61 per cent.

(3) Water gas and its accompanying producer gas—

		Calories.
Water gas, 17°·5 C. = 40·83 CO × 2400	=	97,992
Hydrogen from steam, 2·926 × 29,400	=	86,024
		184,016
Producer gas, 52°·5 C. = 122·5 CO × 2400... ...	=	294,000
Coal gas, 16 × 10,000	=	160,000
Sum of heating-power of water gas and producer gas...		638,016

Heat in a chimney gas assumed at same temperature as ordinary producer gas—

779·7 × 377° × ·24 sp. heat = 70,547 calories = 11·05 per cent.

These figures intimate that each 100 units of the three kinds of fuel burnt there is afforded by: coal, 83·93; producer gas, 71·14; water gas and its producer gas, 78·80.

To these figures of Sir Lowthian Bell the supporters of gaseous fuel will object that, if with the use of gaseous fuel there are 1129 units of waste gases passing up the chimney, with solid fuel there must be considerably more; whilst the employers of the regenerative gas-furnace, whilst accepting 377° C. as the temperature of their chimneys, will not allow the same for water gas, where regenerators are not used.

Another interesting paper presented to the meeting was one by Mr. W. C. Fish, on the Thomson electric welding process. The *rationale* of the process may be thus shortly described. If an inclosed circuit of inappreciable resistance be completed by the insertion and abutment of short lengths of the pieces to be welded, the passage of an electric current through the circuit will produce a transformation of electric into heat energy, and the production of this heat will take place almost entirely at the point of abutment of the metal pieces where the cross-section of the conductor is virtually of least area, and the resistance is proportionately great. If the current is of sufficient strength, a welding heat is produced at the point of abutment, and, with the aid of suitable pressure forcing together the heated extremities of the pieces, a weld is made. Various applications are given in the paper, the employment of an alternating current dynamo and a transformer being found the most effective method of working.

Mr. Alexander Siemens, in the discussion of this paper, said he was able to confirm the general results given, for in making one of the Atlantic cables twelve years ago, it was found that welding could be done more quickly by electricity than by ordinary means. An electrical machine was placed alongside of the cable machine, and they made all the joints for the sheathing of the wire by electricity. They would find that the subject had been mentioned by Sir William Siemens in his address to the Mechanical Section of the British Association at Newcastle in 1877.

Papers were also presented to the meeting on the Robert-Bessemer steel process, by Mr. F. L. Garrison, of Philadelphia; on alloys of iron and silicon, by Mr. R. A. Hadfield, of Sheffield, both being papers of a technical character. A new form of Siemens furnace, arranged to recover waste gases as well as waste heat, was described by Mr. John Head, and M. P. Pouff, of Nevers. In this furnace, instead of two air and two gas regenerators being employed, only a pair of air regenerators are used, the gas being supplied hot to the furnace. Instead of the whole of the products of combustion being passed through the regenerators, a portion is directed through a regenerator to the chimney, and the remainder through a converter producer, there to be reconverted into combustible gases, and to do the work of distilling hydrocarbons from the coal; in fact, the gas producer or converter in this furnace absorbs or utilizes the heat formerly deposited in the gas regenerators, and in doing this transforms spent gases into combustible gases. It had to be ascertained whether the products of combustion from the heating chamber would contain a sufficient amount of heat to insure their conversion into combustible gases; this has been found to be the case in practice with furnaces working for the past six months. Assuming that the producer contains only coke in the incandescent state, this coke if fed with oxygen will produce carbonic acid in the lower, and will be converted into carbonic oxide in the upper zone of the producer; if fed with hot carbonic acid instead of oxygen, one-half the fuel, comprising the lower zone, may be dispensed with, and an economy in weight of fuel to the same extent realized. In actual practice finished rolled iron has been heated in this furnace with a consumption of fuel as low as 2 cwt. per ton of iron.

SCIENTIFIC SERIALS.

American Journal of Science, September.—From experiments here described, Messrs. A. A. Michelson and E. W. Morley infer the possibility of establishing a material standard a metre long, whose length in light-waves is known to within one part in one million, and perhaps one in ten millions.—Mr. H. Crew has measured spectroscopically the solar rotation for a zone some 60° wider than any before observed, getting the equatorial value 26·23 days, and finding no certain variation of period with latitude by this method. A comparison of the results from various methods appears to suggest a decrease of angular velocity outwards.—Stretching suddenly soft annealed wires by descent of weights through a trap door, and measuring thermo-electrically the heat evolved, Mr. C. Barus finds that as much as one-half the work done in stretching up to the limit of rupture may be stored up permanently. The work thermally dissipated varies (*e.g.* 75 per cent. for copper, 60 for brass, and 50 for iron); and with a given metal, there is large potentializing in the first stages of strain, and large dissipation in the final stages.—Mr. J. Trowbridge shows reason for thinking that short waves of electrical energy are not absorbed by an approximately perfect dielectric.—A determination of the value of the B.A. unit of resistance in absolute measure by the method of Lorenz, by Messrs. Duncan, Wilkes, and Hutchinson, yields the value 0·9863 ohms.—The Carboniferous Echinodermata of the Mississippi basin are studied by Mr. C. R. Keyes. Crinoidea greatly predominated in the first part, and Blastoidea in the later part, of the period. Abrupt differentiation and extinction of genera towards the end of the Keokuk formation, point to decided changes in the environment.—Mr. M. Carey Lea continues his interesting account of the properties of allotropic silver. No other metal seems capable of such a variety of appearances. *Inter alia*, he notes the remarkable beauty of colouring in rings produced by a small crystal of iodine placed on paper that has been coated with allotropic silver in its moist and plastic state.—There are also papers on the "Grand Gulf" formation of the United States (Mr. L. C. Johnson); paragenesis of allanite and epidote as rock-forming minerals (Mr. W. H. Hobbs); a fossil spider (Mr. C. E. Beecher), &c.

Revue d'Anthropologie, troisième série, tome iv., quatrième fasc. (Paris, 1889).—Scientific anthropometry and artistic proportions, by Colonel Duhousset. In treating of the origin of anthropometric canons of proportion, the writer considers that while there is no doubt of the influence exerted by the Egyptians on Hellenic art, the beauty of their own people must early have led Greek artists to adopt, as typical models for the representations of their divinities, the most highly developed specimens of the human form, as it was manifested in their immediate neighbourhood. It would appear that the most ancient canon of beauty recognized by the Greeks was derived from Polycletus (452-412 B.C.), whose celebrated statue, "Doryphorus," the spear-bearer, was long known as "canon" from its perfect embodiment of the ideal of the male figure. A century later this type gave place to the more idealized representation of Lysippus, who in his statues of the gods raised the height of his figures from the ordinary proportion of 7½ to 8 heads. Under Vitruvius the proportions of Lysippus received greater precision, and became the type that has essentially served through later ages as the true canon for the perfect human form. The purpose of the writer is to compare this artistic type with a scientific canon, for the establishment of which our recent progress in anthropology now for the first time supplies the necessary materials.—In a subsequent article, M. Topinard, following up the relations between these two canons of proportion, treats of the differences between the methods followed by the artist and the anthropologist. He considers that the establishment of a scientific canon demands a careful study of the skeleton and the body immediately after death, as well as of the living subject, and his observations, elucidated by numerous tables, will be found of great value to the artist. He suggests, *e.g.*, that the decimal system of measurement should be used in determining the proportions of the several parts of the body to the whole body, while racial and sexual differences should be taken into account before the height of the figure is determined. This preliminary step is of importance, for while all races have a general similarity in the proportion of the height of the head to the whole body, the yellow races have comparatively "high" heads. Women, moreover, in all races, other things being equal, have higher heads than men. M. Topinard concludes that there is no fixed relation between variations in the height of the head and those of other parts of the body, and that, consequently, the artistic method of taking the head as a standard for the relative proportions of the rest of the body is erroneous. Hence there is no absolute type of beauty, the canons of proportion varying with sex, age, race, and individuals.—On vestiges of pagan practices among the Provençals of our own days, by Dr. B. Férand. The Provençals, who from their origin were powerfully influenced by the Greeks and Romans, still retain in their modes of worship, and their social and domestic habits, numerous traces of paganism. Curious instances of this are supplied by the practice of libations, still followed by the peasants of Provence, who, after having concluded some unusual transaction, or an agreement of importance, commemorate the event by pledging those present, after which they invariably extend the right arm and turn their glass down, so as to let the last drop fall to the ground. Similarly, at the festival of Christmas, which is locally known as "Leis Festos de Caleno" (the Calends), a solemn repast is partaken of, known as "Lou gros Soupar," at which the eldest and the youngest member of the assembled family perform, amid a profound silence, the ceremony known as the "benediction of the fire." This act is performed by pouring wine three times upon the burning log, which must be of oak or olive wood. This is accompanied by the singing of some verses, in which the excellence of fire is praised, and God is thanked for having given man beneficent heat. These verses vary in different localities, but everywhere the ceremony of the silent libations precedes the supper of which the combined household partake.—On lacustrine and other pile-structures in Northern Italy, by M. P. Castelfranco. The writer gives an interesting summary of the various works which have appeared in Italy in recent years, regarding the different forms of pile-structures discovered in the Parmese and neighbouring lowlands. In Italy such explorations date back only to 1861, when MM. Pigorini and Strobel discovered extensive remains of prehistoric pile-dwellings at Castione. Since then other explorers, more especially Dr. Chierici, have followed up these researches in the province of Reggio, where the latter discovered traces of a *chaussée* raised above the level of the ground on closely adjusted piles. The remains of some of the pile-dwellings showed, moreover, that there had been in course of time as many as three distinct structures raised the one upon the substructures of the others. The animal remains and the flint implements found in the *débris* belonged to the Bronze Age. M. Castelfranco's summary is worthy of the careful attention of our most distinguished palæontologists, while the important facts which he adduces appear to warrant the interesting conclusion that in these palustrine habitations of Northern Italy we have the most ancient Italian stations of the tribes, from whom descended those prehistoric peoples whose occupation of the country is attested by the celebrated cemeteries at Villanova, Bologna, &c., which belong to the earliest period of the Iron Age. M. Pigorini believes that the civilization of the palustrine and land-pile dwellings—the *terremare* of Northern Italy—is identical with that of prehistoric Hungary, which gradually penetrated to Central Europe by the Danube and its great affluents, the Drave and the Save, but never advanced to the western districts of France, or to Britain, where there is no trace of any but lacustrine pile habitations.

SOCIETIES AND ACADEMIES.

LONDON.

Entomological Society, September 4.—Captain H. J. Elwes, Vice-President, in the chair.—Prof. C. H. Fernald and Mr. C. J. Fryer were elected Fellows; and Prof. C. V. Riley and Dr. A. S. Packard were admitted into the Society.—Mr. G. T. Baker exhibited two remarkably dark specimens of *Acronycta ligustri* taken near Llangollen.—Dr. P. B. Mason exhibited and remarked on a collection of Lepidoptera which he had recently made in Iceland. The following species, amongst others, were represented, viz.:—*Crymodes exulis*, *Triphæna pronuba*, *Noctua conflua*, *Plusia gamma*, *Larentia cæsiata*, *Eupithecia scoriata*, *Melanippe sociata*, *Coremia munitata*, *Phycis fusca*, and *Crambus pascuellus*.—The Rev. Dr. Walker also exhibited a number of Lepidoptera, Diptera, and Hymenoptera, recently collected by himself in Iceland.—Mr. W. White exhibited, on behalf of Mr. G. C. Griffiths, a specimen of *Nephronia hippia*, Fab., var. *gæa*, Feld., which he believed to be hermaphrodite. He also exhibited, for comparison, a female of the same species. A discussion on hermaphroditism ensued, in which Mr. Distant, Captain Elwes, Mr. McLachlan, and Mr. Baker took part.—Dr. Sharp exhibited specimens of *Cychramus luteus* and *fungicola*, Auct., and stated that they are the sexes of one species, *C. luteus* being the male, *C. fungicola* the female. In working through the Central American *Cychramini*, he had found that in some genera the males differed greatly from the females in size and sculpture; but this was not a constant character, for in some species, while certain males scarcely differed from the females in these respects, others were so different that they would scarcely be recognized as belonging to the same species.—Mr. E. A. Butler exhibited specimens of *Platymetopius undatus*, from Ewhurst, Surrey. He remarked that the species was recorded as having been once previously taken near Plymouth by the late Mr. J. Scott.—Mr. G. T. Baker read a paper entitled "On the distribution of the Charlonia group of the genus *Anthocharis*." Mr. Baker stated that the species of this small division of the genus Anthocharis formed a very natural and closely allied group, presenting many points of interest, both in their relationship to each other, and in their geographical distribution, which extended from the Canaries on the west to the valley of the Indus on the east. The author's theories as to the causes of the present distribution of the group, which were based on geological data, were discussed by Captain Elwes, Mr. McLachlan, Mr. Distant, and Mr. Stainton.—The Chairman read a paper entitled "On the genus *Argynnis*," which gave rise to a discussion in which Mr. Distant, Mr. Jenner-Weir, and Prof. Riley took part.

SYDNEY.

Royal Society of New South Wales, August 7.—Sir Alfred Roberts, Vice-President, in the chair.—The Chairman announced that the Council had awarded the Society's bronze medal and a money prize of £25 to the Rev. John Mathew, Coburg, Victoria, for his paper upon the aborigines of Australia: also that the Clarke Memorial Lectures would be delivered to the members of the Society by Mr. C. S. Wilkinson, Government Geologist, as follows: (1) on the geological researches of the late Rev. W. B. Clarke, F.R.S., S. Stutchbury, and other early Australian geologists, November 13; (2) on the geology and ancient life-history of Australia, November 20; (3) on the economic geology of Australia, November 27.—The following papers were read:—On the source of the underground water in the western districts, by H. C. Russell, F.R.S.; on the eruptive rocks of New Zealand, by Capt. F. W. Hutton; on the application of prismatic lenses for making normal-sight magnifying spectacles, by Mr. P. J. Edmunds; flying-machine memoranda, by Lawrence Hargrave.

PARIS.

Academy of Sciences, September 23.—M. Des Cloizeaux, President, in the chair.—International Congress of Chronometry; International Congress of Applied Mechanics, by Mr. Phillips. The former, at his instance, expressed the desirability of thorough experiments, at Government expense, to determine how compensation is affected by the nature of metals and alloys used for springs and balance wheels, and the various types of the latter. The other Congress expressed a similar wish for the formation of testing laboratories for materials and machines, and for an International Commission to fix units and uniformize methods; it also proposed definitions of the terms used in mechanics. M. Mascart called attention to the fact, that, while the proposed unit of power, the *poncelet*, was 100 kgm. per second, the electricians' *kilowatt* was 102 kgm. per second. M. Berthelot objected to proper names being used for abstract units.—On analysis of the light diffused by the sky, by M. Crova. He made observations on the top of Mont Ventoux, with a modified form of his spectro-photometer, which could be directed to any part of the sky. The curves for zenithal light (alone examined) show a predominance of the more refrangible radiations at sunrise, diminishing towards midday, then increasing towards sunset; but not reaching, in homologous hours after noon, the same values as in the morning. The curves vary notably from day to day, with the state of the atmosphere. His figures show to what extent the light is bluer than the direct sunlight, and the light of the sky at Montpellier.—The Emperor of Brazil announced, by telegram, an observation of globular lightning on September 16.—Observations of Davidson's comet, with the bent equatorial (0·35 m.) of Lyons Observatory, by M. Le Cadet.—Observations of Brooks's comet and its companion, by the same. The nebulosity of the companion was elongated in the line of junction, and, at times, seemed to join the other.—On the determination of integrals of certain equations with partial derivatives by their values on a contour, by M. E. Picard.—Physiological researches on hydrocyanic acid, by M. N. Gréhant. Diminishing the force of the poison by dilution, &c., he found (in dogs and frogs), the heart-beats persist after the respiratory movements (gradually) stopped.—On the phosphorescent infection of *Talitrus* and other Crustacea, by M. A. Giard. On examining microscopically a brightly phosphorescent *Talitrus* he found walking slowly on the beach (instead of leaping like its companions), he traced the light to bacteria in its muscles, which were greatly altered. He inoculated other individuals (both *Talitrus* and *Orchestia*) with blood containing these microbes, and produced the disease with entire success. The laboratory cellar had quite a "fairy-like" aspect in the evening. The inoculations were continued to the sixth (luminous) generation, without attenuation, apparently, of the microbes' action. The disease follows a regular course; and the animal dies in three or four days, the phosphorescence lingering some hours after death. M. Giard also inoculated crabs successfully, and will describe results later.—On the metamorphosis and the migration of a free Nematode (*Rhabditis oxyuris*, Cls.), by M. R. Moniez. This animal is common in cow's dung. Young individuals fix themselves to the carapace of an Acarian (sometimes as many as sixty on one), by a chitinous plate (secreted from the anterior part) and short stem; then the tissues and organs shrink together from the transparent skin, forming a smaller ovoid body. When the dung dries, the Acarian, with these new larvæ on it, attaches itself to some insect, and is conveyed to fresh dung, where new transformations doubtless take place (not followed by the author). This was observed in August.—On the probable cause of the frondal bifurcations of ferns, by Dom B. Rimelin. When one of these anomalies is met with, others may generally be found quite near. The author thinks they must be due to fungi, *e.g.* of the family of Uredineæ; basing this induction on the diseased look where they are numerous, reproduction of the anomalies from sori of those divided ferns (considered with the fact that some parasitic fungi specially affect the organs of reproduction), &c.—Recent eruptive rocks of the Western Pyrenees, by MM. Seunes and Beaugey.

THURSDAY, OCTOBER 10, 1889.

THE SCIENCE COLLECTIONS AT SOUTH KENSINGTON.

THE English, like their American cousins, are a remarkable people, and in nothing more remarkable than in their toleration of incongruities.

They are gradually amassing at South Kensington an art collection which has but few rivals in the world, and the approach to it is shadowed by architectural monstrosities which, if regard is had to their position, are absolutely unrivalled. Within, they visit with apparent pleasure a hall decorated by the hand of Sir Frederick Leighton, and filled with the most exquisite masterpieces of Oriental art. Without, they are satisfied with the "Brompton boilers."

They concentrate, during a quarter of a century, collections to illustrate natural history, the physical sciences, and art, on one spot. They make it the head-quarters of State-aided education in science and art. Under the highest auspices a building is growing there, in which the products of the colonies are to be displayed to view. Close to it stands the Central Institute of the City and Guilds of London for Technical Education. Thus, in their own peculiar way, by apparently disconnected steps, and under the management of half-a-dozen independent, authorities, they evolve the noble idea of a great centre in which collections of all that is interesting, beautiful, and useful in the history and present applications of science and art shall illustrate, and be illustrated by, the researches and teaching of men like Profs. Huxley and Flower. They arrange a scheme by which the benefits are not confined to the metropolis only. The collections are circulated through the provinces, and provincial teachers are brought to the collections. Having done all this, they leave it in the power of one of the authorities—a set of irresponsible Commissioners—to cut into the heart of the site thus dedicated to science and art, with rows of stucco "mansions."

They house their natural history collections in a palace, and place its management in hands which have made it a palace of delight. They store invaluable collections to illustrate the progress of science and technology in sheds which are barely water-tight, and liable to burn like a tinder-box. They rely for their arrangement upon the "good-nature" of Professors of whose formal duties it forms no part, and upon the patriotism of men like Mr. E. A. Cowper, who, rather than see a good thing left undone, are willing, at great personal sacrifice, to do it themselves. Lastly, they leave questions as to the success of this haphazard system to be raised, not by some recognized scientific authority, but by the Treasury clerks.

Fortunately, as is so often the case in England, the results are better than the system. The suggestion that a great collection of scientific apparatus should be formed at South Kensington was made by the Duke of Devonshire's Commission. The ideal to be aimed at was defined by Commissioners appointed by the Science and Art Department, under the Chairmanship of Sir Frederick Bramwell. The Treasury, however, alarmed by "complaints of want of space in the galleries," recently determined to reconsider the matter for themselves, and appointed another Commission, which was, as it was doubtless intended to be, a very strong one. Had the Report, signed by the Treasurer of the Royal Society—Dr. Evans—as Chairman, by Lords Rayleigh and Francis Hervey, by Mr. Bernhard Samuelson, by Sir Douglas Galton and Sir Henry Roscoe, been adverse to the practical results attained by the collections, apart from the system under which they have been achieved, their opinion would doubtless have been regarded as conclusive. As it is, the Treasury will now have to bear in mind the following, which it will perhaps regard as inconvenient, facts.

The Commissioners were asked "whether there are any duplicates or other objects no longer essential to the value and representative character of the collections, which might be removed in order to provide additional accommodation for new objects of greater importance." They reply that "little, if any, space can be gained by weeding the existing collections."

They were requested to "investigate the existing practice of circulating scientific objects on loan to museums and schools so far as it affects the question of accommodation for storage or exhibition purposes at South Kensington." They reply that the space used for such purposes "has no practical bearing as to the housing of the collections."

They were not explicitly asked as to whether the existing museum accommodation is or is not adequate, but they assert that the question cannot be separated from those which were referred to them, and they recommend that, instead of the 60,000 square feet at present occupied, "an exhibition space of about 90,000 square feet should be provided without delay" in order to secure "a creditable Science Museum."

They also assume that this space will be covered with buildings "well arranged, well lighted, and of a durable character," a series of conditions which, as is evident to the casual visitor no less than to the Commissioners, is not fulfilled by some of those at present in use.

In short, the South Kensington Museum contains only objects which ought to be exhibited, in buildings *not* suited for their preservation and exhibition, and in space so cramped that it ought *without delay* to be increased by 50 per cent.

The Report was very well received by the daily press, and is certainly justified by the facts. It now only remains for public opinion to urge the Treasury to carry out the recommendations of its own Commission.

The Museum appears to be appreciated by the general public, and even to compete with the Natural History Museum on more equal terms than could have been expected. During the last four years there has been a steady increase in the number of visitors. In 1888 the Science Museum was inspected by 259,588, and the Natural History Museum by 372,802 persons.

Teachers under the Department are allowed, with certain reasonable restrictions, to bring their classes to the galleries, and to have the apparatus taken out of the cases for their inspection. The number of visitors who have thus had the cases opened for them, or in other ways have received special assistance in the galleries, has risen from 174 in 1880 to 1687 in 1888. The number of classes which have had the advantage of instruction illustrated by the apparatus which their teachers have been allowed to handle and to demonstrate, has increased from 7 in 1880 to 81 last year.

Every year 600 science teachers apply to be allowed to attend the summer courses held in the Normal School of Science. From these 200 are selected, and not only are the lectures which they attend illustrated by means of objects contained in the Museum, but they are able to inspect typical collections of apparatus, ready set up and arranged for the performance of the experiments which they are recommended in the Directory of the Science and Art Department to show to their classes.

It appears, then, that the full use of the galleries is not hampered by unnecessary restrictions. Permission to handle the apparatus is a privilege which does not suggest red-tape. Every effort is made to enable provincial teachers to share the advantages which may be reaped from the Museum, and it is casting no discredit upon the admirable provincial colleges which are springing up in our large towns to say that even a country like England could not gather more than one such collection as that which is being formed at South Kensington. Let us hope that the Report of the Commission has made it certain that, to the benefit of both town and country, the development of the collection will be promoted, and that before long it will be properly housed.

Although, however, the management of the Museum seems to have been satisfactory in practice, the Commissioners again travel outside the exact terms of reference to them, to express an opinion that the organization of the staff in charge of it requires revision. One of the Professors was specially examined on this point, and his opinion appears to be closely in accordance with the terms of the Report.

At present the responsibility for the collections lies primarily with the Lord President, and next to him with the Vice-President and the Secretary to the Science and Art Department. It is but one of the many proofs—which are often overlooked or ignored—of the ability with which the Department has been administered, that the Commissioners find no fault with the present state or future aims of the Museum. It is, however, impossible that collections so varied should be controlled without the help of experts, and, as matters stand, this assistance is sought in a more or less informal way from consultative Committees who have no real authority and no official responsibility. The results attained in some sections have been, for the most part, due to volunteers like Mr. Cowper, who has acted on several Committees of advice, and done the lion's share of the work, so that he "has been"—to quote his own words—"familiar with every one of the machines in the Department." The collections of scientific instruments are supervised by the Professors of the Normal School, whose advice is given subject to the limitations just described.

It would be premature to discuss the details of a scheme by which these arrangements might with advantage be superseded. A hearty admiration for the work which has been accomplished and for the ability of the officers of the Department under whose authority it has been carried out is, however, compatible with a no less hearty assent to the opinion of the Commissioners that "the system is defective in principle, apart from the personal qualities of those working under it," and that "the responsibility for the formation and supervision of these collections should certainly be of a more definite kind."

DARWINISM.

Darwinism. By Alfred Russel Wallace, LL.D., F.R.S. (London: Macmillan and Co., 1889.)

THE object of Mr. Wallace in writing the admirable work which he has published with the title of "Darwinism" has been "to give such an account of the theory of natural selection as may enable any intelligent reader to obtain a clear conception of Darwin's work, and to understand something of the power and range of his great principle." No one has so strong a claim as Mr. Wallace to be heard as an exponent of the theory of the origin of species, of which he is—with Darwin—the joint author. He has produced a thoroughly readable book, condensing into an octavo volume much of the speculation and description of important facts which are contained in the numerous volumes published by Darwin himself, and in the essays and occasional contributions of subsequent writers. Besides this, Mr. Wallace's book contains an exposition of highly important and interesting views of his own on subsidiary matters, which have either not been published previously or have appeared in a scattered and more or less inaccessible form. Consequently, the book is one which has interest not only for the general reader, to whom it is primarily addressed, but also for the more special student of natural history. The latter will find in its pages an abundance of new facts and arguments which, whether they prove convincing or not, are of extreme value and full of interest. If we attempt here to point out some of the shortcomings of Mr. Wallace's treatise, it is not from any desire to minimize its value and interest, but rather an acknowledgment of the weight and significance of a work on so important a subject by so specially competent an author.

Mr. Wallace's book necessarily suffers, in comparison with the works of Darwin himself, by the limitation of space. It is in consequence of this compression that we miss in the new statement by Mr. Wallace that extraordinary cogency or power of convincing which so distinguished the writings of Darwin. With Darwin one becomes accustomed to see no speculation put forward, no step of an argument advanced, unless there is an overwhelming weight of testimony in its favour: facts are cited in astonishing abundance, and at the same time the conviction establishes itself that the author has reserves of fact as rich as those of which he makes use, and further that he is so scrupulous and so modest that he will never ask his reader to accept a conclusion, however trivial, without stating fairly the amount of evidence for and against such conclusion. Mr. Wallace is prevented by the scope of his work from such treatment of his subject. As a result, his conclusions often appear to be (when they may not be so) based on very insufficient evidence, and his statement meagre. "Darwinism" can never take the place of the "Origin of Species," but may well serve as an introduction to the study of that and the other works of Darwin—the value of which, not only as storehouses of fact and suggestion, but as classical models of scientific discussion, cannot be over-estimated, and will probably never be surpassed.

In his preface, Mr. Wallace, through a misconception which is perhaps explained by the retired life which he enjoys—makes an attack upon what he calls "the modern school of laboratory naturalists." He states that these persons seek to minimize the agency of natural selection and to subordinate it to laws of variation, of use and disuse, of intelligence and heredity. He commends, as leading to truer views, the study of the external and vital relations of species to species in a state of nature—a study which Semper has called "the physiology of organisms," and I have proposed in the article "Zoology" in the "Encyclopædia Britannica" to call "bionomics." Now though there is no doubt an increasing number of younger students who have little or no interest in natural history beyond what is derived from the contemplation of ribbons of sections dyed like Joseph's coat, yet it is going too far to say that they have in any sense formed a school. And further, if we endeavour to estimate the influence on naturalists of a considerable devotion of time to the study in the laboratory of histology and embryology, physiology and morphology, we shall be led to the conclusion that this study has been associated with exactly opposite results from those attributed to it by Mr. Wallace. Who are they who seek to minimize natural selection and to set up the false gods of variation, use and disuse, &c.? Certainly not laboratory men. Is the Duke of Argyll a laboratory naturalist? Is Dr. George Romanes? Is Prof. Cope? Are Mr. Herbert Spencer and Prof. Patrick Geddes? I venture to say they are not; yet they are the authors with whom Mr. Wallace has subsequently to contend when he maintains that the selection of congenital variations by natural selection is an adequate theory of the origin of species, and requires no aid from Lamarckism, Copism, or other interlopers. Who are they who agree with Mr. Wallace in this contention? Precisely "laboratory men," who are, however, by no means *only* laboratory men, but, like Darwin himself, search for their material in the garden, the field, the seashore, or the sea-bottom; and as a part—but only a part—of their study of it eventually bring it to the laboratory. Such a "laboratory naturalist" is Weismann, whose essays and memoirs in favour of the identical view maintained by Mr. Wallace, appear to have escaped his attention until very recently. I presume also that I may claim to be a laboratory naturalist; and yet four years ago I found it necessary, in lectures delivered at the London Institution, to discard even that tincture of Lamarckism which Darwin had admitted, and to advocate "pure Darwinism," on the ground that the Lamarckian hypothesis is still devoid of experimental basis, and in view of the logical principal *Entia non sunt multiplicanda præter necessitatem*. It is true, as I have elsewhere insisted, that there are not at present such facilities for the study of bionomics as are provided in our laboratories for the study of histology, embryology, morphography, and the physics and chemistry of living bodies. But it is not right to identify the class of speculations, to which Mr. Wallace is opposed, with laboratory training. This, indeed, in virtue of its tending to bring speculation to the test of fact, is favourable, and often directly conducive, to the study of "the external and vital relations of species to species in a state of nature," or in one word "bionomics." I will only cite as instances Bateson's researches in Tartary, Caldwell's in Australia, Poulton's experiments on insects, and Moseley's "Notes of a Naturalist on the *Challenger*."

Mr. Wallace's plan of treatment of his subject is an excellent one. After a brief statement of what naturalists have understood by the word "species," and a lucid exposition of the views of the earlier transmutationists, he enunciates Darwin's theory. He then proceeds to show, by citing a wide and comprehensive array of facts, that the foundations of the theory are secure. In one chapter he describes the rapid multiplication of organisms and the consequent struggle for existence; in further chapters the fact of variability is shown, by an appeal to instances, to be one of the widest and most general character; in another chapter the facts of heredity and selection are brought forward. Then follow discussions of "difficulties and objections," hybridity, the origin and use of colour in animals and in plants, geographical distribution, the geological evidences of evolution, the fundamental problems of variation and heredity, and, lastly, Darwinism applied to man.

The chapter on "Variability of Species in a State of Nature" is one on which considerable pains has been expended. It presents some of the facts of variation in a very striking manner, and provides us with a number of well-studied instances which have not before been accessible to naturalists. A method followed by Mr. Wallace is to take any large collection of a single species and to measure various parts, such as length of head, tail, limb, &c. As he observes, it is very important to convince ourselves that variation does occur in a state of nature, so that natural selection has the material to act upon. He considers that the instances which he brings forward show that the range of variation is larger and more general in a state of nature than is usually assumed, and that "it is clear that Mr. Darwin himself did not fully recognize the enormous amount of variability that actually exists." Whilst admitting the interest of Mr. Wallace's present contribution to this subject, I think it is clear that he has failed to make a distinction which is desirable and important, viz. that between *variations* exhibited by adult specimens and the *variability* presented by the young of any given species. After all, the specimens of lizards and birds, of which the measurements are given to us by Mr. Wallace, only comprise such individuals as were *not too widely divergent* from the parent form to survive to maturity under conditions which select more or less closely a given specific set of characters. What one would like to know is the actual range of variability as shown by the artificial rearing of *all* the offspring of a single pair. With plants such a study of variation is practicable, but less so with animals. Variation includes those extreme cases which are called "monstrosities," and it is by no means certain that natural selection would *always* exclude these extreme cases from survival. The facts of variation under domestication are more to the point, in so far as the range of congenital variability is concerned, since in regard to a limited number of animals and plants we have removed the primary sifting of young forms. This sifting must occur under natural conditions, so as to allow only a limited range of variations to reach the collector in his museum. Clearly enough, this primary sifting, and all later operations of the same kind due to natural conditions, may under new circumstances be vastly modified in their nature, and variations may be allowed to pass the sieve which at another time are excluded. The range of variation, therefore, in even a very large museum series of a wild species, can afford but an inadequate notion of the variability of animals. We may, however, justly conclude that, if the former is so large as Mr. Wallace shows it to be, the congenital variations which occur, but never in given conditions reach maturity, must comprise instances which are very much more marked, and would furnish abundant material for natural selection were the natural conditions of the species to change. An attempt to determine by experimental rearing, the range of congenital variation (that is, of *possible* adult variation) in such animals and plants as are fitted for the inquiry, seems to be well worth making.

Mr. Wallace, who must have watched the early criticism of Darwin's theory with special keenness, makes a good point when he insists that the objection that it is difficult "to imagine a reason why variations tending in an infinitesimal degree in any special direction should be preserved" is a quibble. Darwin never used the word "infinitesimal," but spoke of variations being "slight" or of "small amount," and we agree with Mr. Wallace that even those terms are open to the objection that they may seem to imply that congenital variation is of less range and frequency than it really is.

Naturally enough, Mr. Wallace is not equally thorough in his treatment of each of the various "difficulties and objections" which he discusses, but the chapter thus headed gives an interesting summary of the present state of opinion. Among the matters discussed are the supposed smallness of variations, the doubt as to the right variations occurring when required, the beginnings of important organs, useless or non-adaptive characters, the instability of non-adaptive characters, the swamping effects of intercrossing, and the effects of isolation. In some of these instances Mr. Wallace's reasoning is very clear and forcible; in other cases it is much less so. Mr. Cunningham has already pointed out, in a letter to NATURE (July 25, p. 297) a curious slip on Mr. Wallace's part in his explanation of the gradual development of the twisted condition of the head and eyes of flat-fish. Mr. Wallace declines to admit the transmission of acquired characters as a cause of variation and progressive development; yet, apparently without being conscious of it, he attributes the movement of the eye of flat-fish from one side of the head to the other, to the transmission of a series of slight shiftings of the eye acquired in successive generations by the muscular effort of the ancestors of our present flat-fish, which is (to use an expression already known to the readers of NATURE) "flat Lamarckism." In relation to this, I may mention that the asymmetry of the Gastropod Mollusca, the forward position of the anus, and the twisted condition of the nerve-loop in the Streptoneurous division of that class, had been similarly attributed by myself to the cumulative effect of a mechanical cause—the one-sided lopping of the shell—operating in successive generations. Like Mr. Wallace, I had failed to notice that the explanation adopted was an admission of Lamarckism. It seems to me possible to explain the position of the flat-fish's eye by the selection of congenital variations, since there is no doubt of the advantage to the animal of having its two eyes on the one side of the body. But I confess that the Gastropods at present have not been satisfactorily explained. I have not been able at present (and I say at present advisedly) to find any evidence of advantage to the Gastropod in the torsion of its visceral hump, such as would justify the supposition that a monstrosity presenting this condition in full development was favoured by natural selection; still less does it appear how the steps of a gradual torsion—that is, a series of approximations to complete torsion—could be advantageous. It does not follow that we must admit Lamarckism; but merely that we must further examine Gastropod habits, structure, and development with this problem in mind.

Mr. Wallace does not, in my judgment, give sufficien grounds for rejecting the proposition which he indicate as the main point of Mr. Gulick's valuable essay o "Divergent Evolution through Cumulative Segregation." By the bye, Mr. Gulick is one of the heretics who attribut some part in the production of species to other cause than natural selection, yet he is not a laboratory naturalist but one who, substituting land-shells for butterflies, ha precisely the same foundations and training as M Wallace himself. Mr. Gulick's idea is that there is an in herent tendency to variation in certain divergent lines, an that when one portion of a species is isolated, even thoug under identical conditions, that tendency sets up a dive gence, which carries that portion further and further awa from the original species; or, in other words, no tw portions of a species possess exactly the same averag character, and the initial differences will, if the individua of the two groups are kept from intercrossing, asse themselves continuously by heredity in such a way as t insure an increasing divergence of the forms belongir to the two groups, amounting to what is recognized a specific distinction. Mr. Gulick's idea is simply the recog nition of a permanence or persistency in heredity, whicl *cæteris paribus*, gives a twist or direction to the variatio of the descendants of one individual as compared wi the descendants of another. Ireland is cited by M Wallace as an evidence that isolation has not been effe tive in modifying specific character of plants and anima If, however, unlike Mr. Wallace, we may look upon ma kind as subject to the same developmental causes, a only to the same causes, as animals, then Ireland wo seem to be a very interesting case of the production divergent character by isolation. All parties are agre that, whatever value is to be assigned to the fact, t human inhabitants of Ireland, whether of Celtic or Teuto ancestry, exhibit characters which are "divergent" fr those of the inhabitants of Great Britain, and, with going into details, we may say that the isolation a persistence of an original tendency seem to be the o explanation of the divergence.

The subject of "correlated variations" is but ligh touched on by Mr. Wallace, and its immense importa in relation to the whole question of "useless organs" useless characters of growth and structure is not sufficie put forward, as it was by Mr. Darwin. It is true that we know little about the physical basis of correlated variation, and are therefore open to hostile criticism when we take refuge in an appeal to it as an explanation of phenomena. The truth is that correlated variation is as important a property of living matter as heredity and variability themselves. It may be formulated thus: "Every departure from the parental form of any given part of an animal or plant is accompanied by a definitely correlated and often a commensurate departure in other parts remote from it." The possibilities thus introduced are simply gigantic—a new factor is brought in which extends the results of simple variation and selection indefinitely. In the future the laws and limitations of correlated variation will no doubt be determined. At present our knowledge of them rests where Mr. Darwin himself placed it. Both Mr. Gulick's doctrine of persistent hereditary tendency, and that of the immense capacities of correlation in variation, commend themselves to the mind of a laboratory naturalist who is accustomed to conceive of vital phenomena as mechanico-physical affections of a living substance, viz. protoplasm. They are, on the other hand, less valued—perhaps insufficiently—by Mr. Wallace.

In his chapter on the infertility of crosses, Mr. Wallace treats at length and with admirable effect a very important subject, as to which he is full of ingenious novel suggestions and apposite facts. His criticism of Mr. Romanes's essay, entitled "Physiological Selection," appears to me to be entirely destructive of what was novel in that laborious attack upon Darwin's theory of the origin of species.

The chapter on the origin and uses of colour in animals is that which will be most interesting to the general reader, and is indeed a charming essay, illustrated by numerous woodcuts. Here Mr. Wallace sets forth at length his convincing argument as to the use of colour as a means of recognition among animals, giving many examples—amongst others, that of the white patch on the rabbit's tail. In conjunction with his theory of the importance of the principle "like to like" in the segregation of varieties and the consequent development of new species, great significance must be attached both to the nervous organization, which makes recognition possible, and to the markings or other characters which are recognized. A very interesting discussion of Mr. Darwin's theory of sexual selection occurs in a subsequent chapter. Mr. Wallace, whilst admitting some of the effects of sexual selection recognized by Darwin, is not able to follow him in attributing to it the brilliant colours of birds and butterflies. Mr. Wallace attributes the deeper or more intense colouring of the male, which often occurs, to his "greater vigour and excitability." The female in many groups retains the primitive and more sober colours of the group for purposes of protection. The occurrence of colour itself in patches and lines is attributed by Mr. Wallace (following the late Mr. Alfred Tylor) to the distribution of subjacent nerves and blood-vessels, which follow, like the colour-patches, in the main, certain lines determined by the general structure. Mr. Wallace seems scarcely to have succeeded in showing that Darwin's theory of sexual selection is inapplicable to the explanation of special developments of colour and ornament, although he has suggested additional causes which influence the primary distribution and development of colour.

We have not space to speak of subsequent chapters on colour in plants and on geographical distribution, concerning the latter of which subjects Mr. Wallace speaks with every title to respect, and suggests some novel views. On the "Geological Evidences of Evolution" as well as on the "Fundamental Problems" of variation and heredity, he is less satisfactory. In regard to the latter, one chapter is altogether an inadequate space in which to deal with such an array of antagonists as Mr. Herbert Spencer, Dr. Cope, Dr. Karl Semper, and Mr. Patrick Geddes. Mr. Wallace has barely space to do more than state his opponents' views, and to give a rapid summary of reasons for his dissent, without sufficiently establishing those reasons. This will be especially regretted by those who, like myself, agree with Mr. Wallace in his rejection of Spencer's and Semper's Lamarckism, and are unable to attach any serious value to the speculations put forward on this matter by Dr. Cope and Mr. Geddes. The translation of Weismann's "Essays," which appeared coincidently with Mr. Wallace's book—although many of the essays have been for some years familiar to readers of German—supplies that more solid treatment of the subject which is desirable. It is satisfactory to find that justice is done by Mr. Wallace to Mr. Francis Galton, whose views on heredity, arrived at by a special method of inquiry, are closely similar to those arrived at on other grounds by Weismann.

Prof. Semper's work "On the Natural Conditions of Existence as they affect Animal Life" is duly mentioned by Mr. Wallace, and he does not fail to notice the striking fact that in this interesting volume the author entirely fails—as I pointed out in NATURE when it appeared—to adduce a single fact in proof of the Lamarckian theory which he sets out to champion.

Of the American evolutionists Mr. Wallace justly says: "In place of the well-established and admitted laws to which Mr. Darwin appeals, they have introduced theoretical conceptions which have not yet been tested by experiments or facts, as well as metaphysical conceptions which are incapable of proof." They have, in fact, conspicuously abandoned the "scientific method."

The words which Mr. Wallace has applied to the American evolutionists are, in the opinion of many, strangely applicable to portions of his own concluding chapter on "Darwinism applied to Man." He here introduces us to a "spiritual world" and to "different degrees of spiritual influx." Mr. Wallace is in the peculiar position of one who believes that he has experimental evidence of the remarkable theoretical and metaphysical conceptions which he introduces. He boldly takes up this position, and we may be sure that he would not wish attention to be diverted from it. It remains an interesting problem for the future student of human faculty to reconcile Mr. Wallace's wonderful ingenuity and skill as a reasoner and observer concerning animal life, with his views as to the so-called "manifestations" of spiritualists.

Mr. Wallace's contention that the mathematical, musical, and artistic faculties of man have not been developed under the law of natural selection must in large part be conceded. Whilst the earlier development of these faculties may be explained as due to natural selection since some amount of each may well have been an advantage to the primitive man in his struggle for existence, it is yet true that their sudden and rapid development to a very much higher level in civilized communities cannot be traced to the struggle between man and man. It does not, however, follow that, because natural selection will not account for these extraordinary developments of the human brain, therefore we must have recourse to the assumption of supernatural agencies. Mr. Wallace seems so much convinced of the importance and capability of the principle of natural selection, that when it breaks down as an explanation he loses faith in all natural cause, and has recourse to metaphysical assumption. On the other hand, it must be contended that we know very little of the development, either in the individual or in various races, of these and other faculties of the mind. The formation of civilized communities has had the result of withdrawing the individual man almost entirely from the operation of natural selection. Such selection as still obtains operates by the struggle of communities rather than by that of individuals. Accordingly there is a possibility of the most useless "sports" making their appearance, and even establishing themselves in human communities as hereditary qualities. Mr. Gulick's notion that an initial tendency due to accidental variation can increase and develop in succeeding generations, without reference to the advantage or disadvantage of the species, would assuredly be applicable, if anywhere, to the human mind in communities where individuals are no longer subject to natural selection, or only to a minimal extent, and in relation to a few points of structure. Does the luxuriant development of some Professor's mathematical faculty, as compared with the poor numerical conceptions of an Australian black, offer really any greater difficulty of transition than do the 9-feet-long tail feathers of some Japanese barn-door fowls, as compared with the shorter feathers of other varieties? That is a question which can only be answered by a more elaborate analysis of the nature of the qualities compared than has, so far as I know, been hitherto accomplished.

E. Ray Lankester.

GALTON'S AFRICAN TRAVELS.

Narrative of an Explorer in Tropical South Africa; being an Account of a Visit to Damara Land in 1851. By F. Galton. With *Vacation Tours in* 1860 *and* 1861, by Sir George Grove, F. Galton, and W. G. Clark. (London: Ward, Lock, and Co., 1889)

THE editor of the Minerva Library has added Mr. Francis Galton's "Narrative of an Explorer in Tropical South Africa" to a library consisting only of "works of the most widely-spread and lasting popularity, which have proved themselves worthy of a permanent place in literature." Had the stamp of popularity not been so precisely insisted upon as a title to admission into this particular series, it might have been his gracious task, now and then, to have rescued from oblivion a stray work which had failed to obtain recognition from causes in no way affecting its intrinsic merits. Books of travel, for instance, have often suffered from inopportune publication, and, being out of season, have fallen flat and unheeded; whereas, if introduced a quarter of a century later, they would have been welcomed by an expectant public, educated for the occasion. But the condition, as it now stands, relieves the editor from a difficult and somewhat delicate responsibility, the adequate discharge of which might well need the exercise of more than one man's judgment and experience. Fortunately for the book under notice, it fulfils all the professed requirements of Mr. Bettany's prospectus. It presents quite a model in respect of style, and is essentially the production of a master mind. The writer lucidly recounts his experiences for the instruction as well as entertainment of his readers, and the outcome of his labour is a success to himself and a benefit to his fellows. His narrative is interesting and well sustained; his descriptive powers are manifestly considerable; his appreciation of men and things, the animate and inanimate, is admirable; and he is realistic to the legitimate extent of insuring credence for a record of personal adventure not untinged with romance.

Independently of these considerations, however, there is another reason why the reproduction of Mr. Galton's book at the present hour is practically useful. He treats of a particular section of Africa which has hardly received its fair amount of attention from the politicians and geographers of Europe, when discussing the great partition question of the day. The Congo has had the lion's share of solicitude as regards the western coast-line; while the spirited and intelligent action of the British East African Company, and movements of rival or contemporary Companies, have resulted in throwing, as it were, a broad bright light upon the whole length of eastern sea-board from Guardafui to the Zambesi. Names such as Mombasa and Vitu are becoming familiar as Zanzibar and Mozambique, and the practical effect of Messrs. Johnston and Thomson's successful journeys has been to introduce into our school teaching the true stories of Kilimanjaro and the Masai Land. Below the Congo there has been little demand for information, and consequently little supply. The knowledge that Portugal is owner of the coast-line from the much-coveted mouth of that river to that of the Kunene, has appeared sufficient to render Benguela and Mossamedes, with their inland territories and contiguous tracts, matters of secondary interest; and below Mossamedes nothing but a political embroglio has caused Walfisch Bay and Angra Pequena to emerge from out the haziness of quasi-mythical places. Mr. Galton's narrative will not only be found instructive in itself, but it cannot fail to lead the uninitiated reader into references and inquiries also full of enlightenment; and even those who are well up in African geography, and may have read the book on its first appearance, will most probably derive advantage in reverting to its pages. The part of the Dark Continent comprehended in its treatment is from somewhere near the mouth of the Kunene to the mouth of the Orange River, and may be roughly indicated by a figure to which the parallels 17° and 27° S. latitude give a northern and southern boundary, and the meridians 12° and 20° longitude western and eastern limits. In the appendix much of the exploration of later years is reviewed, and the names of Messrs. Anderson and Coates Palgrave, Lord Mayo, and Père Duparquet of the Huilla Mission are honourably mentioned. Those of Drs. Höpfner and Stapff might have been added, bringing up to May 1886 the roll of authorities whose labours need only some new political complication to become of palpable value. Moreover, it may here be parenthetically stated that the West African Telegraph Company have recently prolonged their cable south of St. Paul de Loanda, opened as a station in 1886—a proceeding which should facilitate the acquisition of much new geographical information in connection with the region specified. Already has a contribution from one of its officers appeared in the Proceedings of the Royal Geographical Society, from which we learn that the harbour of Mossamedes is only second to that of Loanda among the harbours of Western Africa, and that the latter, possessing less depth of water, and being smaller, suffers in the comparison. Benguela is described as the more important commercial port, the total amount of its annual imports and exports (£268,398) being nearly four times more than those of Mossamedes.

Now that thirty-nine years have passed since this exploration was undertaken it may be well to recall its extent and character. As apparent from the map illustrative of his labours, Mr. Galton moved in a north-easterly direction from Walfisch Bay to Barmen, journeying a distance of nearly 200 miles. After an excursion from that place—called "the head seat of intelligence as regards Damara and Hottentot movements"—he struck off to Ovampo Land in the north by a route involving a slight detour to the east. But before making a fair start from Schmelen's Hope (a point somewhat further inland than Barmen), he was led by circumstances to Eikhams and Rehoboth in the south; and part of the return road from Ondongo, the *ultima Thule* of his northerly journey, was by a track other than that he had at first pursued. From the date that his waggons left Schmelen's Hope to that of their return, a period of exactly five months elapsed. Of these, we are told that "ninety days were employed in journeying onwards, independently of such excursions as were made from time to time to look out for roads." The return distance is reckoned at about 462 miles, the average rate of travelling being nine and a half miles a day—fair indeed with a more or less improvised carriage, barbarous retinue, and tired or hungry and thirsty bullocks.

Some notion of the privations endured may be gathered from our traveller's statement that, on his leaving Schmelen's Hope for Ovampoland, his "biscuit and every kind of vegetable food had been eaten up"; or, as later expressed, he had "no biscuit, no flour, or anything of the sort." He and his party had to live on the oxen and sheep they possessed, and the game they contrived to shoot on the way, so that grain-food was a special luxury. Milk, though used in profusion by the Damaras, could rarely be purchased from them, owing to some impeditive superstition. Their ordinary *pabulum*, pig-nuts, was "worthless and indigestible," inasmuch as it should be "eaten in excessive quantities to afford enough nourishment to sustain life." As to water, this was a more serious matter still. On some days it utterly failed; on others it was brackish, or barely drinkable—as may be inferred from the following description of a *vley*, or watering-place:—

"Fancy a shallow pool, from 10 to 20 yards across, and from 6 to 12 inches deep, in which a herd of wild animals, say fifty zebras, have been splashing and rolling themselves all night, and which they have left in every respect like the water pumped out of a farmyard; and, where wild animals are wanting, the oxen, in spite of every precaution, will do the same."

The sporting adventures of the book are especially remarkable. It is not improbable that more than one tender-minded reader will accord sympathy to a wounded giraffe hunted to the death, or a dog slain for the sake of its skin—both occasions illustrating an act perpetrated to satisfy the pressing wants of man. Few, however, can fail to appreciate the manly qualities of a traveller whose career in Africa brings him into frequent and willing contact with the lion, rhinoceros, hippopotamus, elephant, and those larger and more formidable animals contention with which is risk of limb and life. The same stout-heartedness is exhibited in his intercourse with the savage inhabitants of the tracts through which he moves, and in the fearless but efficient diplomacy which characterizes his dealings with Bushman and Hottentot, Namaqua, Damara, Ovampo, or whatever the designation of those with whom he has to do.

Not the least exciting part of Mr. Galton's narrative will be found in the penultimate chapter. At this time he had retraced his steps from Ovampo Land to Barmen. Instead, however, of continuing his return journey to the coast, he resolved to devote three and a half out of the four months which would necessarily intervene before the arrival of an expected schooner in Walfisch Bay, to an expedition to the eastward, for the double purpose of seeing something of the Hottentot inhabitants, and ascertaining how far correct was the statement that the Karrikarri Desert was "interposed as an impracticable barrier between the sea-coast countries and Lake 'Ngami." The following extract from this particular chapter (pp. 168–69) furnishes a good specimen of the writer's descriptive powers. He and his associates had just repaired some circular walls of loose stones intended to serve as shooting-screens:—

"It is one of the most strangely exciting positions that a sportsman can find himself in, to lie behind one of these screens or holes by the side of a path leading to a watering-place so thronged with game as 'Tounobis. Herds of gnus glide along the neighbouring paths in almost endless files; here standing out in bold relief against the sky, there a moving line just visible in the deep shades; and all as noiseless as a dream. Now and then a slight pattering over the stones makes you start; it jars painfully on the strained ear, and a troop of zebras pass frolicking by. All at once you observe, 20 or 30 yards off, two huge ears pricked up high above the brushwood; another few seconds, and a sharp solid horn indicates the cautious and noiseless approach of the great rhinoceros. Then the rifle or gun is poked slowly over the wall, which has before been covered with a plaid, or something soft, to muffle all grating sounds; and you keep a sharp and anxious look-out through some cranny in your screen. The beast moves nearer and nearer; you crouch close up under the wall, lest he should see over it and perceive you. Nearer, nearer still; yet somehow his shape is indistinct, and perhaps his position unfavourable to warrant a shot. Another moment, and he is within 10 yards, and walking steadily on. There lies a stone, on which you had laid your caross and other things, when making ready to enter your shooting-screen; the beast has come to it, he sniffs the taint of them, tosses his head up wind, and turns his huge bulk full broadside on to you. Not a second is to be lost. Bang! and the bullet lies well home under his shoulder. Then follows a plunge and a rush, and the animal charges madly about, making wide sweeps to right and left with his huge horn, as you crouch down still and almost breathless, and with every nerve on the stretch.

"He is off; you hear his deep blowing in the calm night; now his gallop ceases. The occasional rattling of a stone alone indicates that he is yet a-foot; for a moment all is still, and then a scarcely audible 'sough' informs you that the great beast has sunk to the ground, and that his pains of death are over."

The author has long since been so well known as a gold medallist and leading member of the Royal Geographical Society, and for his important contributions to anthropology and other departments of science, that it would be superfluous at this time to dwell on the value of his explorations, compared with those of the ordinary and less-gifted traveller. His exceptional aptitude for what may be called professional travel is well exemplified at pp. 180–82 of the volume now republished, in which, among other useful hints, he gives plain and practical instructions for selecting the best sort of travelling compass and checking distances and directions. His manual on the "Art of Travel" has for many years been a standard work of reference; while no one who reads, in the "Narrative of an Explorer," his amusing record of "a series of observations" taken by sextant upon the figure of a Hottentot lady—with results worked out "by trigonometry and logarithms"—can affirm that his sense of humour has been blunted by scientific pursuits.

A republication of "Vacation Tours in 1860 and 1861" —papers by Sir George Grove and the late Mr. W. G. Clark, added to one by Mr. Galton—enhances the value of this new accession to the Minerva Library.

OUR BOOK SHELF.

Practical Photometry: a Guide to the Study of the Measurement of Light. By W. J. Dibdin. (London: Walter King, 1889.)

THIS work forms a good practical text-book on the art of photometry, which, both scientifically and commercially, is becoming more and more important. It contains a comprehensive account of the various methods in daily use, so that the student, when he finds that he is dealing with instruments and methods unfamiliar to him, may turn to this book as a guide to the many precautions necessary to insure accurate results. The first few chapters deal with the history and principles of photometry, together with horizontal, radial, and jet photometers, and diagrams are given of the determinations of the quantity of light afforded in all directions horizontally by three classes of flames tested at every 10°, and also of Dr. Pole's method of expressing the illuminating power and rates of consumption per hour of fifteen-candle gas. In chapters vi. and vii. we have a discussion on the various standards of light which have been and are still in use, followed by the numerous proposed substitutes, such as Harcourt's pentane, Sugg's sixteen-candle argand, Methuen's screen, &c. The apparatus necessary to check and measure the flow of gas to the standard burner is given in chapter viii., with detailed descriptions. Chapters ix. and x. treat of "The Examination and Adjustment of a Gas-testing Photometer" and "Colour Photometry," the latter dealing with methods of estimating the colour and intensity of the illumination of fabrics, &c. Lastly, in chapter xi., on "Stellar Photometry," the author gives an account of the methods employed by Sir John Herschel, Zöllner, and others, concluding with a description of a method proposed by himself.

The appendix contains some useful pieces of miscellaneous information, and tables of illuminating power of sperm candles, candle corrections, &c. The work is well illustrated with numerous woodcuts of the various instruments employed.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Testing of Colour-Blindness.

THE important article in NATURE of September 5 (p. 438) will have been read by all friends of education with deep and melancholy interest.

I desire to point out that the real remedy ought not to be dealt with by an Act of Parliament, partly because this is a makeshift, and partly because the sudden dismissal of a trained seaman for a constitutional defect is so cruel that human nature would get very much in the way of such an Act of Parliament.

What is wanted is that the colour sight and other measurable faculties of youths should be tested before they go out into life. It is a detail of practical anthropometry. Just as no parent would think of encouraging his son to become a barrister when he knew that he stammered or was deaf, so no parent would waste money in training his son to be an engine-driver or a sailor when he knew—as he ought to know—that the lad was colour-blind.

I protest against a defect of our educational system being treated as a defect of legislation or of administration, and I trust that the friends who seek that scientific education should have its due place will move in this direction, and thus prevent the cruelty to seamen and their families as well as the deaths of their fellow-creatures which are at present possible from the causes indicated in your article.

I desire to ask if some of your readers will kindly furnish information, through your columns, as to where the colour-tests can be obtained, their cost, and the literature respecting them.

9 King Street, Oxford, September 19. J. F. HEYES.

Mites.

IN the grounds of the Leicester Museum there are some half-dozen young lime trees, about fifteen years old, of which the trunks and under sides of the main branches are covered with an extremely thin glistening film. It seems to consist of a similar material to that of which spider's web is made, but spread out into a film instead of being spun into thread. When rubbed up it has all the appearance of spider's web similarly treated. But there are no spiders visible, except here and there an Epeira, who has fixed his geometric web to some protuberances on the trunk.

The bark, however, is thickly dotted over with small yellowish mites, very similar to cheese mites in size, form, and colour. Some of these mites are creeping on the outside of the film also, and a few of them are captured in the webs of the Epeira. No other trees appear to be affected except the limes, and only one particular row of these. I have found a few of the mites, but no film, on other limes in the grounds, but none on horse-chestnuts or laburnums which stand nearer to the affected trees.

How has this film been produced? and are the mites connected with it as cause or effect? F. T. MOTT.

Leicester, September 23.

Sailing Flight of Large Birds over Land.

THE explanation of this, in NATURE (p. 518), seems inadequate.

If a large body of air be moving uniformly both in respect of direction and of velocity, no matter at what rate, it might as well be perfectly motionless, in respect of its ability to aid the flight of a bird that is simply floating in it. But in fact the air never is motionless: it moves with the earth, from west to east, at the rate, let us assume, of 500 miles an hour. To a bird floating in the air, whether the earth beneath it moves exactly as the air moves, or not, must be a matter of perfect indifference. The earth's relative motion does not affect it. I must myself adhere to the explanation which I gave in a former number of NATURE (vol. xxviii. p. 28), that the birds avail themselves of differences of the movement of the air, in respect of velocity, or of direction, or of both. Mr. S. E. Peal has noticed that "flocks which drift over the hills recover their position on the plains by descending to windward." This is simple enough. The wind is flowing from the plains towards the hills. It rises then as it flows, and has many inequalities in its direction and rate. On entering a gorge a narrow current of air would be thrown upwards with very rapid ascent. Of all the inequalities the birds know how to avail themselves. R. COURTENAY.

Tean Vicarage, September 28.

A Remarkable Meteor.

ON Sunday, September 29, at 7.30 p.m., I observed a very brilliant meteor falling nearly perpendicular a little to the west of north. Its progress towards the earth appeared to be much slower than is usually the case with such bodies, the heavens being illuminated for several seconds. The meteor was of a bright sapphire hue; preceding it were a few drops of bright fiery red, whilst following it came a brilliant trail of light. It seems to have been pretty generally observed throughout Ireland, and letters to the Press from counties Roscommon, Galway, Kilkenny, and Kildare, testify to the interest it has awakened in the country. RICHARD CLARK.

113 Upper Leeson Street, Dublin, October 7.

THE METHOD OF QUARTER SQUARES.[1]

THE method of quarter squares consists in the use of the formula

$$ab = \tfrac{1}{4}(a + b)^2 - \tfrac{1}{4}(a - b)^2$$

to effect the multiplication of two numbers, a and b. If we are provided with a table giving the values of $\frac{1}{4}n^2$ up to a given value of n, we may obtain, by the aid of this formula, without performing any multiplication, the product of any two numbers whose sum does not exceed the limit of the table.

The method is specially interesting on account of the great simplicity of the formula, by means of which a table of double entry may be replaced by one of single entry. How great a transformation is effected by such a change is evident, if we consider that the largest existing multiplication table of double entry reaches only to 1000 × 1000, and forms a closely-printed folio of 900 pages, but that a table of quarter squares of the same extent (*i.e.* of $\frac{1}{4}n^2$ up to $n = 2000$) need only occupy 4 octavo pages. The disparity becomes even more conspicuous as the limit of the table is extended, for a table of double entry extending to 10,000 × 10,000, would require nearly 100 folio volumes; and one extending to 100,000 × 100,000, would require nearly 10,000 volumes; whereas the corresponding quarter-square tables need only occupy 40 and 400 octavo pages respectively.

The use of a table of squares in effecting multiplications was recognized as far back as 1690, when Ludolff published his large table of squares, extending to 100,000. In the introduction to the table Ludolff explained how it could be employed in multiplications. In order to multiply a and b the table is to be entered with $a + b$ and $a - b$ as arguments, and the difference of the corresponding squares divided by 4. If a and b are both even, or both uneven, their sum and difference will both be even numbers, so that $\frac{1}{2}(a + b)$ and $\frac{1}{2}(a - b)$ will be integers. In either of these two cases we may therefore enter the table with the semi-sum and semi-difference of the numbers as arguments, the product being the simple difference of the corresponding squares.

It was not, however, till 1817 that a table of *quarter* squares (*i.e.* of $\frac{1}{4}n^2$ for argument n) was published, for the purpose of facilitating multiplications. If n be uneven, $\frac{1}{4}n^2$ consists of an integer and the fraction $\frac{1}{4}$. This fraction $\frac{1}{4}$ may be ignored in the use of the table, for if either $a + b$ or $a - b$ is uneven, the other is so too; the fraction $\frac{1}{4}$ therefore occurs in both squares, and disappears from their difference. It may therefore be omitted from the table.

The table of 1817, which contained the first practical application of the method, was published by Antoine Voisin, at Paris, under the title "Tables des Multiplications; ou, Logarithmes des Nombres entiers depuis 1 jusqu'à 20,000." It is curious that Voisin should have called a quarter square a logarithm: he called a the root, and $\frac{1}{4}a^2$ its logarithm. His table extended to 20,000, and was thus available for multiplications up to 10,000 × 10,000. On the title-page Voisin described it as effecting multiplications up to 20,000 by 20,000. This statement is justified by the formula

$$ab = 2\{\tfrac{1}{4}a^2 + \tfrac{1}{4}b^2 - \tfrac{1}{4}(a - b)^2\},$$

by which the product was to be obtained if the sum of the numbers exceeded 20,000, the method of quarter squares being then no longer available. It is to be observed, however, that this formula requires three entries besides the final duplication.

Almost simultaneously (1817) a similar table, of the same extent, was published independently by A. P. Bürger at Carlsruhe. The method was rediscovered by J. J. Centnerschwer, who published a table of the same extent in 1825 at Berlin. In 1832, J. M. Merpaut published, at Vannes, a table of quarter squares extending to 40,000. In 1852, Kulik (well known for his large table of squares and cubes to 100,000), who had again rediscovered the method, published a table extending to 30,000. In 1856, Mr. S. L. Laundy published, at London, the largest table of quarter squares which had appeared previous to the publication of the present table. Laundy's table extends to 100,000. It was intended that the multiplications should be effected by means of quarter squares if the sum of the numbers did not exceed 100,000, but other five-figure numbers were to be multiplied by means of Voisin's three-entry formula referred to above.

It is this change of method that has detracted so greatly from the value of Laundy's fine table. It is evident that the table should have been carried to double its actual extent, *i.e.* to 200,000, so that any two five-figure numbers could be multiplied together by means of the two-entry formula. The late General Shortrede constructed such a table, but it was never printed. In the work under notice Mr. Blater carries the table as far as 200,000; so that, more than sixty years after the publication of the first table effecting the multiplication of two four-figure numbers, the extension to five figures has at last been completed.

The method of quarter squares has had no opportunity of a fair trial in the absence of a table extending to 200,000. Considering the many purposes to which Crelle's tables (which give the product of any two three-figure numbers by a single entry) are continually applied, it is perhaps surprising that no general use should ever have been made of a table which in a very small compass gives, by only two entries, the product of two four-figure numbers. Still it is clear that the full power of the method

[1] "Table of Quarter Squares of all Whole Numbers from 1 to 200,000 for simplifying Multiplication, Squaring, and Extraction of the Square Root, and to render the Results of these Operations more certain." Calculated and published by Joseph Blater. (London: Trübner and Co., 1888.)

is not felt till we are provided with such a table giving the product of two five-figure numbers. As already stated, the fact that the limit of Laundy's table was only 100,000 has deprived it of most of its value, for it is obvious that, unless all five-figure numbers can be treated by a uniform method, the table could not be conveniently employed in practice.

Mr. Blater's work consists of the principal table (giving quarter squares up to 200,000), which occupies 200 pages; a small table of four pages, called the index, to facilitate the use of the table in the extraction of square roots; and an introduction, &c., of fourteen pages.

The arrangement of the table (in which the author has followed the plan adopted by Kulik in his table of 1852, already referred to) is somewhat peculiar. The table is first entered (*i.e.* the required page of the table is found) by means of the *last* three figures of the number: the table is then entered on this page (or, more correctly, double page), by means of the preceding figures. For example, the quarter square corresponding to 126,993 is found by turning to the double page headed 990. In one of the four columns headed 993 we enter the table at the line 126: from this line we obtain, in the first column, the first four figures of the result, 4031; in the column under 993, the next three, 805; from the bottom of the column we take the last three figures, 512. The result is therefore given in three parts A, B, C; A being common to ten numbers (in the same line) beginning with 126, C being common to fifty numbers (in the same column) ending with 993, and B being special to the combination 126,993.

The table is beautifully printed in large antique figures on thick and excellent paper, and is a handsome piece of typography. The author mentions that it was entirely set up by a single compositor at the printing-office of Mr. Falk, at Mayence, and that it occupied his whole time for eleven months. Besides being admirably printed, the table is no doubt very correct, as a triple calculation was made, and no pains seem to have been spared by Mr. Blater for insuring accuracy.

The book is dedicated to Mr. Anthony Steinhauser, of Vienna, who has contributed a short historical preface. Mr. Steinhauser, who is himself the author of several logarithmic tables, encouraged Mr. Blater in his work, and rendered him great assistance throughout. The actual calculation occupied eighteen months.

With respect to the general employment of Mr. Blater's table for the performance of multiplications, it is to be feared that its utility has been jeopardized by the size of page adopted. Anyone who has had occasion to make constant use of tables knows the enormous advantage of the octavo form over the quarto. The book is placed to the left of the computer, and the effort of carrying by the eye a series of figures from the left-hand page of a quarto table to the paper—a distance of 18 inches to 2 feet—is but ill compensated for by larger figures or fewer pages. Handsome as the book is to look at, it seems to us that the table would have had much more chance of bringing the method into general use if it had been of octavo form. It is greatly to be regretted that it was not printed on 400 octavo instead of 200 quarto pages, which would have been quite possible with the existing arrangement of the table. If this had been done, and if the type had been somewhat smaller, a neat and handy volume might have been produced.

The mode of entering the table is very insufficiently explained in the introduction. This is unfortunate, as the mode of entry (by the last figures) is so unusual in tables that it should have been explicitly mentioned. Also the translation into English is so very unsatisfactory as to be obscure in places. These, however, are minor blemishes which would have but slight influence on the general utility of the table, if only the form were convenient.

The question of how far the method of quarter squares is likely to come into use is of some interest. Hitherto the method has been very little known, and, so far as we know, it has never been used in practice on any extended scale. The mere fact that it has been so constantly discovered anew is sufficient evidence of the slight attention that it has received. Still, there ought to be room for a table that gives, to the last figure, the products of any two five-figure numbers with only two entries. A seven-figure table of logarithms is inadequate for this purpose, for, besides requiring three entries, it only gives the first seven figures of the result. On the other hand, it may be said that in ordinary calculations seven figures are as many as are required, and that logarithms possess the advantage of being equally convenient for divisions and multiplications. It must be admitted that a five-figure quarter-square table is appropriate to only a limited class of calculations: it applies only to multiplications, and the number of figures in each of the two numbers must not be greater than five. These conditions are of a somewhat special kind. In recent years when heavy multiplications have been required it has become the custom to make use of Thomas de Colmar's arithmometer; and probably, at the present time, nearly all systematic work of this character is carried out either by Crelle's tables or by the arithmometer.

Passing now to the general question of multiplication by means of a table of single entry, we have the two methods of quarter squares and logarithms, each possessing its special advantages. There is also an older method which passed out of notice with the invention of logarithms. This method was called "prosthaphæresis," and depended on the formula

$$\sin a \sin b = \tfrac{1}{2}[\sin\{90^\circ - (a - b)\} - \sin\{90^\circ - (a + b)\}].$$

A table of natural sines could therefore be used as a multiplication table, four entries being required. This method is due to Wittich, of Breslau, who was assistant for a short time to Tycho Brahé, and it was used by them in their calculations in 1582. It is referred to by Raymarus Ursus, Clavius, and Longomontanus; and it seems to have been used for performing multiplications not only when the numbers occurred as sines but also in the case of ordinary numbers.

The method of quarter squares depends upon so simple a formula, that it is strange that the first table should not have appeared until 1817. There seems no reason why it should not have been employed before the invention of logarithms, when it would have been a most valuable aid to calculation. The geometrical theorem, which is equivalent to the algebraical identity $(a + b)^2 - (a - b)^2 = 4ab$, on which the method depends, forms Prop. viii. of the second book of Euclid; and one would think that the application of the geometrical or algebraical theorem to arithmetic might have been noticed at any time. The actual history of mathematical tables is, however, entirely different from what we might expect it to have been, owing to the wonderfully early invention of logarithms: and it was, in fact, only just about that time that the importance of tables as an aid to general calculation was beginning to be felt. The date of Herwart ab Hohenburg's great double-entry multiplication table, extending to 1000 × 1000 (the same limit as Crelle's table, and which has never been exceeded) is only four years earlier (1610) than that of Napier's "Canon Mirificus" (1614).

It is interesting to notice that the method of quarter squares is more closely connected mathematically with the method of prosthaphæresis than with that of logarithms; in fact, from the formula

$$\sin a \sin b = \tfrac{1}{2}\{\cos(a - b) - \cos(a + b)\},$$

we readily deduce

$$ab = \tfrac{1}{4}\{(a + b)^2 - (a - b)^2\},$$

by expanding the sines and cosines in ascending powers of their arguments and equating the terms of two dimensions.

The method of quarter squares enables us to multiply together two numbers of n figures each if we have a table extending to 2×10^n. If the latter only extends to 10^n three entries are required, and the final result has to be doubled whenever the sum of the numbers exceeds $10n$ (as in Laundy's table). If we consider the question of the multiplication of two numbers of n figures each by means of a table extending only to 10^n, the same process being employed in all cases, it appears that three entries are necessary, and that it would be better to tabulate half squares, using the formula

$$ab = \tfrac{1}{2}a^2 + \tfrac{1}{2}b^2 - \tfrac{1}{2}(a-b)^2,$$

In tabulating the half squares the fraction $\frac{1}{2}$ would be thrown off, so that if a and b were both uneven, unity would have to be added to the result.

It would, however, we think, if the table is not to go beyond 10^n, be more convenient to employ a table of triangular numbers. The nth triangular number is $\frac{1}{2}n(n \times 1)$, and if we are provided with a table extending to 10^n we may multiply any two numbers not exceeding 10^n by means of the formula

$$ab = \tfrac{1}{2}(a-1)a + \tfrac{1}{2}b(b+1) - \tfrac{1}{2}(a-b-1)(a-b);$$

or, as we may write it

$$ab = \mathrm{T}(a-1) + \mathrm{T}(b) - \mathrm{T}(a-1-b),$$

$\mathrm{T}(n)$ denoting the nth triangular number.[1]

Thus, to multiply two numbers we subtract unity from the larger number, and enter the table with the larger number so diminished, with the smaller number, and with the difference of these two numbers. For example, to multiply 5289 and 2156, we add the tabular results corresponding to 5288 and 2156, and subtract from this sum the tabular result corresponding to 3132.

The mode of construction of a table of triangular numbers is almost the simplest possible, the numbers being formed by adding to zero the natural numbers 1, 2, 3, ... *e.g.*,

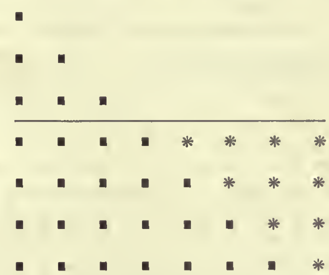
$$0+1=1,\ 1+2=3,\ 3+3=6,\ 6+4=10,\ 10+5=15,$$

and so on. It may be noticed also that any two consecutive triangular numbers are the most nearly equal parts into which a square of points can be divided by a line parallel to the diagonal. For example, in the square of 16 points, the two most nearly equal triangular parts are, $1+2+3=6$, and $1+2+3+4=10$. This is shown in the following diagram:—

Whether the square contains an even or an uneven number of points, the diagonal, which is in the middle, has to be given to one of the two parts, which therefore necessarily differ by the number of points it contains. In the square n^2, the two consecutive triangular numbers which form it are $\frac{1}{2}n(n-1)$ and $\frac{1}{2}n(n+1)$, differing, as they should, by n, the number of points in the diagonal. Viewing the same matter from a slightly different point of view, we see that any two consecutive triangular numbers always make a square, *e.g.*,

$$1+3=4,\ \ 3+6=9,\ \ 6+10=16,\ \ \&c.$$

It is interesting to exhibit by means of a diagram the manner in which the rectangle representing the product ab is derived from the three triangular numbers corresponding to $a-1$, b, $a-1-b$. As an example, the mode of formation of the product 8×4 is shown below, the triangular number corresponding to 7 being represented by dots and the triangular number corresponding to 4 by stars:—



The dots above the line form the triangular number corresponding to $7-4=3$.[1]

It is not suggested that the method just described by means of triangular numbers is comparable to that of quarter squares. It is certainly better to double the extent of the table and have but two entries. Still, it is interesting to note how readily a table of triangular numbers extending only to 10^n is available for the performance of multiplications of two n-figure numbers. So far as we know, only one extended table of triangular numbers has ever been published. This table, which gives the value of $\frac{1}{2}n(n+1)$ from $n=1$ to $n=20{,}000$, was published at the Hague, by E. de Joncourt, in 1762, under the title "De Natura et Præclaro Usu Simplicissimæ Speciei Numerorum Trigonalium." The book is a small and handsomely printed volume of 267 pages, 224 of which are occupied by the table.

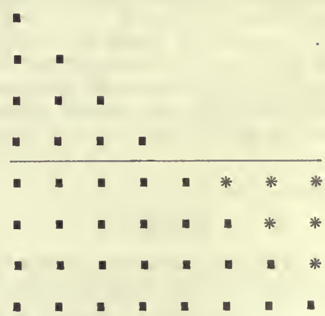
In tabulating quarter squares, the fraction $\frac{1}{4}$ which occurs when the square is uneven is omitted. If we denote by $\mathrm{qsq}\,n$ the tabulated quarter square of n, we have, therefore—

$$\mathrm{qsq}\,(2n) \quad = n^2,$$
$$\mathrm{qsq}\,(2n+1) = n^2 + n.$$

A table of quarter squares may be formed by adding to zero the numbers 1, 1, 2, 2, 3, 3, ... *e.g.* $0+1=1$, $1+1=2$, $2+2=4$, $4+2=6$, $6+3=9$, $9+3=12$, and so on. Its construction, therefore, is

[1] It is interesting to compare the two formulæ which involve half squares and triangular numbers respectively. In the former case we tabulate a discontinuous function, and in the use of the formula a unit has sometimes to be arbitrarily added. In the latter case we tabulate a continuous function, and the formula always holds good (the larger of the arguments being always reduced by unity). One formula depends on squares, n^2; the other on factorials of the second order, $n(n-1)$.

[1] We might of course also perform the multiplication thus:—



corresponding to the formula

$$ab = \mathrm{T}(a) + \mathrm{T}(b-1) - \mathrm{T}(a-b).$$

But if unity is subtracted from the smaller, instead of from the larger, number, slightly higher numbers are involved in the process.

very similar to that of a table of triangular numbers, the only difference being that the added numbers 1, 2, 3, ... are each twice repeated. We may also regard the tabulated quarter squares as defined by this rule: The quarter square of n is equal, if n be even, to the sum of all the uneven numbers less than n, and, if n be uneven, to the sum of all the even numbers less than n. For evidently the series $1 + 3 + 5 + \ldots\ldots + (2n - 1) = n^2$, and the series $2 + 4 + 6 + \ldots\ldots + 2n = n^2 + n$.

By means of this definition of a quarter square we may exhibit the method of quarter squares diagrammatically as follows.

Taking as examples the products 8×3 and 7×4, we have

$$\text{qsq } 11 - \text{qsq } 5 = 8 \times 3,$$

which may be represented by—

and

$$\text{qsq } 11 - \text{qsq } 3 = 7 \times 4,$$

which may be represented by—

The number of points in the extreme left-hand column of the difference of the quarter squares is always equal to the smaller of the numbers to be multiplied. If this number is uneven, there will be one middle line containing a number of points equal to the greater of the two numbers; the points in excess of this number are to be transferred from the line below the middle one to the line next above it, the excess from two lines below is to be transferred to make up the deficiency two lines above, and so on. If the smaller number is even, as in the second diagram, there are two middle lines differing from each other by two points; one point from the lower of these lines is to be transferred to the upper, three points from the line below the lower middle line to the line above the upper middle line, and so on.

It will be noticed that the tabulated quarter squares are, as it were, a species of triangular number in which the succeeding lines of points differ by two, instead of by one, as in ordinary triangular numbers (*i.e.* viewing the matter arithmetically, the quarter squares are derived alternately from the series $1 + 3 + 5 + \ldots$ and $2 + 4 + 6 + \ldots$, and the triangular numbers from the series $1 + 2 + 3 + \ldots$). It is the fact of the lines differing by two which enables us in all cases to adjust the points in the difference of two quarter squares so as to form a rectangle in the manner indicated above.

J. W. L. GLAISHER.

NOTES.

THE American Philosophical Society at Philadelphia is about to celebrate the centennial anniversary of the first occupation of its present hall. The celebration will be held on November 21. The Hon. Frederick Fraley, the President of the Society, will deliver an address in the afternoon of that day, and in the evening a banquet will be given at the Bellevue. The Society was founded in 1743 "for promoting useful knowledge."

ON November 16, the Naturwissenschaftlicher Verein of Bremen will celebrate the twenty-fifth anniversary of its foundation by an evening gathering and a banquet.

THE International Medical Congress will meet next year in Berlin, from August 4 to 10. Inquiries by intending visitors should be addressed to the General Secretary, Dr. Lassar, Karl Strasse, Berlin. The Congress will be divided into eighteen Sections, and the official languages will be German, English, and French.

THE Congress of the International Geodesic Association was opened in Paris, at the Foreign Office, on October 3. M. Spuller welcomed the delegates, who represented Austria, Belgium, Denmark, Spain, France, Greece, Hamburg, Hesse-Darmstadt, Italy, Holland, Prussia, Roumania, Servia, and Switzerland. M. Faye presided.

THE Ethnographic Congress, which held meetings of its various Sections every day last week in Paris, brought its proceedings to a close on Monday afternoon in one of the large halls of the College of France. It was decided that the Congress should hold its next meeting at Bucharest in the autumn of 1890.

THE next annual meeting of the Mineralogical Society will be held in the apartments of the Geological Society, Burlington House, London, on Tuesday, November 5, at 8 p.m.

THE Committee of the Sunday Lecture Society have decided that twenty-one lectures shall be given, during the winter, in St. George's Hall, Langham Place, on Sunday afternoons at 4 p.m., as in former years. The first lecture, on "The Origin and Uses of the Colours of Animals," with oxy-hydrogen lantern illustrations, will be delivered by Dr. Alfred Russel Wallace on October 20. This will be followed by lectures by Mr. John M. Robertson, Mr. Arthur Nicols, Mr. Chas. Cassal, Dr. Andrew Wilson, Prof. Percy Frankland, and Sir R. S. Ball.

ON Monday afternoon, about a quarter to 2 o'clock, a shock of earthquake was felt in Cornwall. It was accompanied by a loud underground noise like thunder, and was felt distinctly at Doubleborough, Boscastle, and Camelford. The earthquake is said to have been severe enough to shake houses, but no harm was done either to person or property.

THE death is announced from Georgetown, British Guiana, of Mr. E. E. H. Francis, Professor of Chemistry in Queen's College, Georgetown, and Analytical Chemist to the Government, at the early age of thirty-nine. Mr. Francis entered the service of British Guiana in 1875, having formerly been Professor of Chemistry and official analytical chemist in Trinidad. The two posts now vacant in Georgetown are said to be worth more than £700 per annum. Mr. Francis was a member of various learned Societies in this country.

AT the recent meeting of the Iron and Steel Institute, Mr. Frederick Siemens made some remarks during the discussion of Sir Lowthian Bell's paper on gaseous fuel, of which we gave an abstract last week. We draw attention to these remarks on account of the important influence Mr. Siemens's experiments and inventions have had on the application of gas for the heating of furnaces. Mr. Samson Fox had stated that he did not propose to use water gas alone for furnace purposes, but mixed with producer gas or other carburetted gas. Mr. Siemens said that a gas would thus be produced similar to that formed in the Siemens gas producer, which he had applied for a considerable time to furnace purposes. He had lately been experimenting with various gases for furnace use, and had come to the conclusion to divide gases generally into two classes, luminous and non-luminous. The latter, the class to which water gas belonged, could be advantageously used for heating by contact; as, for instance, in incandescent gas-lamps, for heating up refractory material to the temperature of incandescence, as the flame struck upon the material which had to give the light. But it would never do to heat high-temperature furnaces with a non-luminous gas, because it radiated very little light or heat, and, as he had proved some years ago, large furnaces must be heated by radiation to work economically and efficiently. Although it was proposed to mix water gas and producer gas, he thought that this would not be very easily effected, the one being supplied at a pressure, and the other without pressure. He had no doubt, however, that, if so mixed, they could be advantageously employed.

THE Report of the Manchester Technical School, presented at the annual meeting of the life members last week, is a very satisfactory document, and as a record of the year's work it is highly encouraging to all who are interested in the extension of technical instruction. The number of students has increased during the year from 2371 to 3328, and the amount paid in students' fees from £2970 to £3711, and the financial position is otherwise hopeful. The details of the work carried on in the school and in the recently-established spinning and weaving department, afford abundant evidence that the Council take a very comprehensive view of the sphere of technical education. The opening of this new department was the most important extension made during last year, and though at present the number of day students enrolled is small, there can be no doubt that, as the advantages it offers become better known, it will be more and more resorted to by those who wish to gain practical instruction in the chief textile industries in combination with the study of the scientific laws which regulate them. A considerable number of students are already attending the evening classes in the department. The Report refers to the proposal to establish a technical school in connection with the Whitworth Institute, and the prospects are considered promising by the Council. The negotiations between the Council and the Governors of the new institution will probably result in the foundation of a technical college on the scale, and with all the appliances, of the best schools of the kind in Germany and Switzerland. The growth of the school during the past six years is well shown in the following short table:—

Year ending July 31.	Individual students.	Tickets issued.	Fees. £ s. d.
1884	1429	2046	1259 12 5
1885	1995	2783	2010 10 5
1886	2299	3091	2241 11 8
1887	2529	3406	2931 10 4
1888	2871	3918	2970 1 8
1889	3328	4383	3711 15 0

THE grotto lately discovered near the caves of Adelsberg was said to be superior to these famous caverns. According to the Burgomaster of Adelsberg, who has written on the subject to the Vienna Correspondent of the *Times*, this is a mistake. The new grotto, he says, is very far from equalling the Adelsberg caves. It is a little more than a kilometre in length, and is believed to be a continuation of the Adelsberg caves. Its en-entrance is half an hour's walk from the latter, between the villages of Gressotak and Zagon. It is rich in stalactites, but most of these have the appearance of being covered with white chalk.

THE Boston Society of Natural History is at present much interested in a scheme for the establishment of natural history gardens in that city, and it has authorized its Council to proceed with the work as soon as the sum of 200,000 dollars shall have been raised for the purpose. Mr. A. Hyatt, Curator of the Society's Museum, is sanguine enough to write, in his latest Annual Report, that "it is perfectly feasible to establish a series of natural history gardens which shall co-operate with the Museum and other public work of the Society, and to form, perhaps, the most effective apparatus for public culture in natural history that has ever been planned before for any city in the world."

LAST week we noticed (p. 549) the work done, under the supervision of Prof. Giglioli, at the stations established in Italy for ornithological observations. Similar stations were created in Saxony, in accordance with the decisions of the Ornithological Congress held at Vienna in 1884, and we have now received the fourth annual Report relating to the results achieved by the observers. The Report, which is accompanied by a map, is by Dr. A. B. Meyer and Dr. F. Helm, and presents a great mass of information, clearly arranged. The first Report, issued in 1885, contained the facts noted in Saxony by 43 observers, at 35 stations, regarding 180 species of birds. In the present Report there is a record of what 122 observers at 111 stations have to tell about 213 species of birds.

A FULL report of the Apple and Pear Conference held at Chiswick from October 16–20, 1888, is presented in the tenth volume to the Journal of the Royal Horticultural Society. The report opens with the address delivered by the President, Sir Trevor Lawrence, after which come the following papers: apples for profit, by Mr. GeorgeBunyard; fruit culture for profit in the open air, by Mr. W. Paul; dessert pears, by Mr. W. Wildsmith; on pruning, by Mr. Shirley Hibberd; canker in fruit trees, by Mr. Edmund Tonks; canker, its cause and cure, by Mr. James Douglas; enemies of the apple and pear, by Mr. J. Fraser; apples for Sussex, by Mr. J. Cheal; orchards in the West Midlands, by Mr. W. Coleman; apples and pears for Scotland, by Mr. Malcolm Dunn; cultivation in Jersey, by Mr. C. B. Saunders; production and distribution, by Mr. F. J. Baillie; compensation for orchard planting, by Mr. W. F. Bear; the railway difficulty, by Mr. D. Tallerman. The volume includes statistical and other information, compiled by Mr. A. F. Barron, as to the cultivation of apples in Great Britain and Ireland; and a descriptive catalogue, also by Mr. Barron, of apples exhibited in 1883 and 1888.

A SECOND edition of Prof. Lloyd Morgan's "Animal Biology" (Rivingtons) has been issued. The author has revised the text, substituted in several cases improved woodcuts, and added a brief classification of the types, and a glossary.

THE Royal Geographical Society has issued the sixth edition of the well-known "Hints to Travellers," edited for the Society by Mr. Douglas W. Freshfield and Captain W. J. L. Wharton, R.N. The work has been revised and enlarged.

M. A. VAYSSIÈRE has just completed the publication of his "Atlas d'Anatomie comparée des Invertébrés," in 60 quarto plates. This atlas, accompanied by concise and clear explanations, has been received with much favour in the zoological laboratories.

M. R. BLONDEL has published a pamphlet of 150 pages, with plates, on the odorous properties of the rose, and the methods used in industry for the extraction of its perfume.

MR. WILLIAM JORDAN has issued a pamphlet entitled "Instructions to Inventors as to obtaining Letters Patent and registering Trade Marks and Designs." Reference is made to the latest patent laws of Great Britain, our colonies, and foreign countries.

MR. R. H. PORTER has sent us his October catalogue of new and secondhand books. It includes many works of scientific interest.

PROF. G. POUCHET, Director of the Laboratory of Concarneau, has published, in a large quarto volume of eighty-one pages, with plates, an account of experiments made by him under the auspices of the Municipal Council of Paris, on the currents of the North Atlantic. The work deals more particularly with the Gulf Stream, and with the details of the experiments made on board the *Hirondelle* with the assistance of the Prince of Monaco, but also takes into consideration the results of investigators from the earliest times. The experiments refute the idea that the French coast is warmed by the Gulf Stream; M. Pouchet states that they show clearly that, at least in summer, no surface-current reaches France from the south-west, but that, on the contrary, there is a current from the west and north-west.

THE following details about the Tomsk University have been published. The buildings constitute the finest edifice in the town, and are situated in the middle of a magnificent park. When the staff is complete there will be twenty-five Chairs—thirteen ordinary, eleven extraordinary, and one for orthodox theology. There will also be librarians, teachers of music, and surgeons and assistant-surgeons. There are already seventy-two students, who pay about 12 or 13 roubles a month for lodging, books, and attendance, and it is expected that this number will be largely increased before the end of the year.

THE Pilot Chart of the North Atlantic Ocean for the month of September shows that the most important storm during the month of August was one first reported about San Domingo on the 19th, whence it moved north-westward over the Bahamas and afterwards recurved and followed the course of the Gulf Stream. During the first half of the month the pressure along the Atlantic States was persistently high, and the tracks of all storms from the continent lay well to the northward of this area of high barometer, moving mostly beyond the region of observation. No storm can be traced all the way from the American continent to the British Isles, although several originated in mid-ocean and moved in an east-north-east direction. A severe tornado was reported off Cienfuegos, Cuba, on August 4. Ice was reported in great quantities about the Straits of Belle Isle, but very little off the Grand Banks.

METEOROLOGICAL science will be much enriched by the recent contributions of the Danish observers in Greenland during 1882-83 ("Expédition Danoise," vol. ii., part 2, Copenhagen, 1889). The principal station was at Godthaab, on the west coast of Greenland, in latitude about 64°, where the observations were made under the direction of M. Adam Paulsen. A large series of observations of temperature was made and the results are given in tables, as well as represented by curves. The temperature was taken every hour during twelve months, and the mean temperatures at each hour for each month are given in the tables. As might be expected, the greatest variation occurs in August—namely, from + 3°·5 C. at 3 a.m. to + 7°·2 at 2 p.m. The minimum variation is in February, from − 15°·4 to − 15°·7. During the summer months the maximum occurs about 1 p.m., and in winter about 2 p.m. Similar results are recorded for the stations at Reykjavik, in lat. 64° and Stykkisholm, in lat. 65°. The maximum monthly mean temperature occurs in July, and the minimum in February. Observations were also made of the direction, force, and velocity of the wind, form and direction of clouds, temperature of the soil, &c., full details of which are given in the report. An appendix contains the results of various meteorological observations in the Kara Sea in 1882-83, and at Nanortalik and D'Angmagsalik. Observations of auroræ at the two latter stations and at Godthaab also form part of the appendix. It is greatly to be regretted that the spectroscope was not employed in the auroral observations.

THE additions to the Zoological Society's Gardens during the past week include a Mealy Amazon (*Chrysotis farinosa*) from South America, presented by the Hon. and Rev. F. G. Dutton; two Cape Crowned Cranes (*Balearica chrysopelargus*) from South Africa, presented by the Hon. Mrs. Barker; seven Common Slowworms (*Anguis fragilis*), British, presented by Miss Alice Leonora Selly; a Common Chameleon (*Chamæleon vulgaris*) from North Africa, presented by Mr. J. Watkins; a Long-nosed Crocodile (*Crocodilus cataphractus*) from West Africa, presented by Mr. John R. Holmes; a Royal Python (*Python regius*) from West Africa, deposited; four Common Rheas (*Rhea americana*) from Holland, purchased.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1889 *OCTOBER* 13–19.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on October 13

Sun rises, 6h. 23m.; souths, 11h. 46m. 11·5s.; daily decrease of southing, 14·0s.; sets, 17h. 10m.: right asc. on meridian, 13h. 15·1m.; decl. 7° 57′ S. Sidereal Time at Sunset, 18b. 40m.

THE LIFE-WORK OF A CHEMIST.[1]

IN asking myself what subject I could bring before you on the present occasion, I thought I could not do better than point out by one example what a chemist may do for mankind. And in choosing this theme for my discourse I found myself in no want of material, for amongst the various aspects of scientific activity there is surely none which, whether in its most recondite forms or in those most easily understood, have done more to benefit humanity than those which have their origin in my own special study of chemistry. I desired to show what one chemist may accomplish, a man devoted heart and soul to the investigation of Nature, a type of the ideal man of science—whose example

[1] An Address delivered to the members of the Birmingham and Midland Institute, in the Town Hall, Birmingham, on October 7, 1889, by Sir Henry E. Roscoe, M.P., D.C.L., LL.D., F.R.S., President.

may stimulate even the feeblest amongst us to walk in his footsteps if only for a short distance, whose life is a consistent endeavour to seek after truth if haply he may find it, whose watchwords are simplicity, faithfulness, and industry, and whose sole ambition is to succeed in widening the pathway of knowledge so that following generations of wayfarers may find their journeys lightened and their dangers lessened.

Such men are not uncommon amongst the ranks of distinguished chemists. I might have chosen as an example the life and labours of your sometime townsman, Joseph Priestley, had not this theme been already treated by Prof. Huxley, in a manner I cannot approach, on the occasion of the inauguration of the statue which stands hard by. To-day, however, I will select another name, that of a man still living, the great French chemist—Pasteur.

As a chemist Pasteur began life, as a chemist he is ending it. For although, as I shall hope to point out, his most important researches have entered upon fields hitherto tilled, with but scanty success, by the biologist, yet in his hands, by the application of chemical methods, they have yielded a most bountiful harvest of new facts of essential service to the well-being and progress of the human race.

And after all the first and obvious endeavour of every cultivator of science ought to be to render service of this kind. For although it is foolish and shortsighted to decry the pursuit of any form of scientific study because it may be as yet far removed from practical application to the wants of man, and although such studies may be of great value as an incentive to intellectual activity, yet the statement is so evident as to almost amount to a truism, that discoveries which give us the power of rescuing a population from starvation, or which tend to diminish the ills that flesh, whether of man or beast, is heir to, must deservedly attract more attention and create a more general interest than others having so far no direct bearing on the welfare of the race.

"There is no greater charm," says Pasteur himself, "for the investigator than to make new discoveries, but his pleasure is more than doubled when he sees that they find direct application in practical life." To make discoveries capable of such an application has been the good fortune—by which I mean the just reward—of Pasteur. How he made them is the lesson which I desire this evening to teach. I wish to show that these discoveries, culminating as the latest and perhaps the most remarkable of all, in that of a cure for the dreaded and most fearful of all fearful maladies, hydrophobia, have not been, in the words of Priestley, "lucky haphazardings," but the outcome of patient and long-continued investigation. This latest result is, as I shall prove to you, not an isolated case of a happy chance, but simply the last link in a long chain of discoveries, each one of which has followed the other in logical sequence, each one bound to the other by ties which exhibit the life-work of the discoverer as one consequent whole. In order, however, to understand the end we must begin at the beginning, and ask ourselves what was the nature of the training of hand, eye, and brain which enabled Pasteur to wrest from Nature secret processes of disease the discovery of which had hitherto baffled all the efforts of biologists. What was the power by virtue of which he succeeded when all others had failed, how was he able to trace the causes and point out remedies for the hitherto unaccountable changes and sicknesses which beer and wine undergo? What means did he adopt to cure the fatal silkworm disease, the existence of which in the south of France in one year cost that country more than one hundred millions of francs? Or how did he arrive at a method for exterminating a plague known as fowl cholera, or that of the deadly cattle disease, anthrax, or splenic fever, which has killed millions of cattle, and is the fatal woolsorters' disease in man? And last but not least how did he gain an insight into the working of that most mysterious of all poisons, the virus of hydrophobia?

To do more than point out the spirit which has guided Pasteur in all his work, and to give an idea of the nature of that work in a few examples, I cannot attempt in the time at my disposal. Of the magnitude and far-reaching character of that work we may form a notion, when we remember that it is to Pasteur that we owe the foundation of the science of bacteriology, a science treating of the ways and means of those minute organisms called microbes, upon whose behaviour the very life, not only of the animal, but perhaps also of the vegetable, world depends—a science which bids fair to revolutionize both the theory and practice of medicine, a science which has already, in the hands of Sir Joseph Lister, given rise to a new and beneficent application in the discovery of antiseptic surgery

The whole secret of Pasteur's success may be summed up in a few words. It consisted in the application of the exact methods of physical and chemical research to problems which had hitherto been attacked by other less precise and less systematic methods. His early researches were of a purely chemical nature. It is now nearly forty years ago since he published his first investigation. But this pointed out the character of the man, and indicated the lines upon which all his subsequent work was laid.

Of all the marvellous and far-reaching discoveries of modern chemistry, perhaps the most interesting and important is that of the existence of compounds which, whilst possessing an identical composition—that is, made up of the same elements in the same proportions—are absolutely different substances judged of by their properties. The first instance made known to us of such isomeric bodies, as they are termed by the chemist, was that pointed out by the great Swedish chemist Berzelius. He showed that the tartaric acid of wine-lees possesses precisely the same composition as a rare acid having quite different properties and occasionally found in the tartar deposited from wine grown in certain districts in the Vosges. Berzelius simply noted this singular fact, and did not attempt to explain it. Later on, Biot observed that not only do these two acids differ in their chemical behaviour, but likewise in their physical properties, inasmuch as the one (the common acid) possessed the power of deviating the plane of a polarized ray of light to the right, whereas the rare acid has no such rotatory power. It was reserved, however, for Pasteur to give the explanation of this singular and at that time unique phenomenon, for he proved that the optically inactive acid is made up of two compounds, each possessing the same composition, but differing in optical properties. The one turned out to be the ordinary dextro-rotatory tartaric acid; the other a new acid which rotates the plane of polarization to the left to an equal degree. As indicating the germ of his subsequent researches, it is interesting here to note that Pasteur proved that these two acids can be separated from one another by a process of fermentation, started by a mere trace of a special form of mould. The common acid is thus first decomposed, so that if the process be carried on for a certain time only the rarer lævo-rotatory acid remains.

Investigations on the connection between crystalline form, chemical composition, and optical properties, occupied Pasteur for the next seven years, and their results—which seem simple enough when viewed from the vantage-ground of accomplished fact—were attainable solely by dint of self-sacrificing labours such as only perhaps those who have themselves walked in these enticing and yet often bewildering paths can fully appreciate, and by attention to minute detail as well as to broad principles to an extent which none can surpass and few can equal. A knowledge of the action of the mould in the changes it effects on tartaric acid led Pasteur to investigate that *bête noire* of chemists, the process of fermentation. The researches thus inaugurated in 1857 not only threw a new and vivid light on these most complicated of chemical changes, and pointed the way to scientific improvements in brewing and wine-making of the greatest possible value, but were the stepping-stones to those higher generalizations which lie at the foundation of the science of bacteriology, carrying in their train the revolutions in modern medicine and surgery to which I have referred.

The history of the various theories from early times until our own day which have been proposed to account for the fact of the change of sugar into alcohol, or that of alcohol into vinegar, under certain conditions, a fact known to the oldest and even the most uncivilized of races, is one of the most interesting chapters in the whole range of chemical literature, but, however enticing, is one into which I cannot now enter. Suffice it here to say that it was Pasteur who brought light out of darkness by explaining conflicting facts and by overturning false hypotheses. And this was done by careful experiment, and by bringing to bear on the subject an intelligence trained in exact methods and in unerring observation, coupled with the employment of the microscope and the other aids of modern research.

What now did Pasteur accomplish? In the first place he proved that the changes occurring in each of the various processes of fermentation are due to the presence and growth of a minute organism called the ferment. Exclude all traces of these ferments, and no change occurs. Brewers' wort thus preserved remains for years unaltered. Milk and other complex liquids do not turn sour even on exposure to pure air, provided these infinitely small organisms are excluded. But introduce even the smallest trace of these microscopic beings, and the peculiar changes which they alone can bring about at once begin. A few cells of the yeast plant set up the vinous fermentation in a sugar solution. This is clearly stated by Pasteur as follows:—"My decided opinion," he says, "on the nature of alcoholic fermentation is the following. The chemical act of fermentation is essentially a correlative phenomenon of a vital act beginning and ending with it. I think that there is never any alcoholic fermentation without there being at the same time organization, development, multiplication of globules, or the continued consecutive life of globules already formed."

Add on a needle's point a trace of the peculiar growth which accompanies the acetous fermentation, and the sound beer or wine in a short time becomes vinegar. Place ever so small a quantity of the organism of the lactic fermentation in your sweet milk, which may have been preserved fresh for years in absence of such organisms, and your milk turns sour. But still more, the organism (yeast) which brings about the alcoholic fermentation will not give rise to the acetous, and *vice versâ*, so that each peculiar chemical change is brought about by the vital action of a peculiar organism. In its absence the change cannot occur; in its presence only that change can take place.

Here again we may ask, as Pasteur did, Why does beer or wine become sour when exposed to ordinary air? And the answer to this question was given by him in no uncertain tone in one of the most remarkable and most important of modern experimental researches. Milk and beer which have become sour on standing in the air contain living micro-organisms which did not exist in the original sound fluids. Where did these organisms originate? Are they or their germs contained in the air, or are these minute beings formed by a process of spontaneous generation from material not endowed with life?

A controversy as to the truth or falsity of the theory of spontaneous generation was waged with spirit on both sides, but in the end Pasteur came off victorious, for by a series of the most delicate and convincing of experiments he proved the existence of micro-organic forms and their spores—or seeds—in the air, and showed that whilst unpurified air was capable of setting up fermentative changes of various kinds, the same air freed from germs could not give rise to these changes. Keep away the special germ which is the incentive to the pathological change, and that change cannot occur. In the interior of the grape, in the healthy blood, no such organisms, no such germs exist; puncture the grape or wound the animal body, and the germs floating in the air settle on the grape-juice or on the wounded tissue, and the processes of change, whether fermentative or putrefactive, set in with all their attendant symptoms. But crush the grape or wound the animal under conditions which either preclude the presence or destroy the life of the floating germ, and again no such change occurs; the grape-juice remains sweet, the wound clean.

I have said that every peculiar fermentative change is accompanied by the presence of a special ferment. This most important conclusion has only been arrived at as the result of careful experimental inquiry. How was this effected? By the artificial cultivation of these organisms. Just as the botanist or gardener picks out from a multitude of wild plants the special one which he wishes to propagate, and planting it in ground favourable to its growth, obtains fresh crops of the special plant he has chosen, so the bacteriologist can by a careful process of selection obtain what is termed a pure cultivation of any desired organism. Having obtained such a pure cultivation, the next step is to ascertain what are the distinctive properties of that special organism; what characteristic changes does it bring about in material suitable for its growth. This having been determined, and a foundation for the science having thus been laid, it is not difficult to apply these principles to practice, and the first application made by Pasteur was to the study of the diseases of beer and wine.

In September 1871, Pasteur visited one of the large London breweries, in which the use of the microscope was then unknown. A single glance at the condition of the yeast instantly told its tale, and enabled him to explain to the brewers the cause of the serious state of things by which frequently as much as 20 per cent. of their product was returned on their hands as unsaleable—this being that this yeast contained foreign or unhealthy organisms. And just as pure yeast is the cause of the necessary conversion of wort into beer, so these strange forms which differ morphologically from yeast, and whose presence can therefore be distinctly ascertained, are the cause of acidity, ropiness, turbidity, and other diseases which render the beer undrinkable. It is no exaggeration to say that, whereas before Pasteur's researches the microscope was practically unknown in the brewhouse, it has now become as common as the thermometer or the saccharimeter, and by its help and by the interpretations we can place upon its revelations through Pasteur's teaching, yeast—of all brewers' materials the least open to rough and ready practical discernment—becomes easy of valuation as to its purity or impurity, its vigour or weakness, and, therefore, its behaviour during fermentation. Thus, while in former days the most costly materials were ever liable to be ruined by disease organisms unconsciously introduced into them with the yeast, at the present day the possibilities of any such vast pecuniary disasters become easily avertable.

Of all industries, brewing is perhaps the one which demands the most stringent care in regard to complete and absolute cleanliness. The brewers' materials, products, and by-products, are so putrescible, there is always so vast an abundance of disease-organisms in the brewery air, that the minutest amounts of these waste products lying about in vessels or pipes transform these places into perfect nests for the propagation of these micro-organisms, whence, transferred into the brewings, they inevitably ruin them, however carefully and scientifically prepared in other respects. Without the microscope, any breach of discipline in the way of the supreme cleanliness necessary is impossible of detection; with it we can track down the micro-organisms to their source, whether it be in uncleanly plant, in impurity of materials, or in carelessness of manipulation.

Among the more direct applications of Pasteur's researches, the so-called Pasteurization of beer claims a place. Pasteur showed that temperatures well below the boiling-point sufficed for destroying the disease organisms in alcoholic fluids, and, based on these results, enormous quantities of low-fermentation beers are annually submitted to these temperatures, and thus escape the changes otherwise incident to the micro-organisms which have succumbed to the treatment. This process is, however, for several intricate reasons, not suited for English beers, but if we cannot keep our beers by submitting them to high temperatures, we can foretell to a nicety how they will keep by artificially forcing on those changes which would occur more slowly during storage. The application of a suitable temperature, the exclusion of outside contamination, a microscopic examination of the "forced" beer, and the knowledge which we owe to Pasteur of what the microscopic aspect means, suffice to make each brewing foretell its own future history, and thus suffice to avert the otherwise inevitable risks incident to the storage and export of beer, the stability of which is unknown.

Brewing has thus become a series of precise and definite operations, capable of control at every point. Instead of depending—as it had to depend—on intuition and experience handed down in secrecy from father to son, it now depends upon care, forethought, and the soundness of the brewer's scientific training. This change in the nature of the brewer's operations, and in the persons who govern them, is primarily due to Pasteur. Other men have done much to carry on his work, but it is to his example of ceaseless patience, and to his example of freely publishing to the world all the results of his work, that the brewers of all countries are indebted for the connection of each phenomenon with a controllable cause, and for thus emancipating their industry from empiricism and quackery.

Much the same story has to be told about Pasteur's investigation of wine and its diseases. As with the brewer, so with the wine-grower Pasteur has pointed out the causes of his troubles, and, the causes having been ascertained, the remedies soon followed, and the practical value of these researches to the trade of France and other wine-producing countries has been enormous.

The next labour of our scientific Hercules was of a different kind, but of a no less interesting or important character. The south of France is a great silk-producing district. In 1853 the value of the raw silk was represented by a sum of some five millions sterling, and up to that date the revenue from this source had been greatly augmenting. Suddenly this tide of prosperity turned, a terrible plague broke out amongst the silkworms, and in 1865 so general had the disease become that the total production of French silk did not reach one million, and the consequent poverty and suffering endured in these provinces became appalling. Every conceivable means was tried to overcome the disease, but all in vain. The population and the Government of France—for the evil was a national one—were at their wits' end, and a complete collapse of one of the most important French industries seemed inevitable. Under these circumstances the great chemist Dumas, who was born at Alais, in the centre of one of the districts most seriously affected, urged his friend Pasteur to undertake an investigation of the subject. Pasteur, who at this time had never seen a silkworm, naturally felt diffident about attempting so difficult a task, but at last, at Dumas' renewed entreaty, he consented, and in June 1865 betook himself to the south for the purpose of studying the disease on the spot. His previous training here again stood him in good stead, and in September 1865 he was able to communicate to the Academy of Sciences results of observation and experiment which, striking at the root of the evil, pointed the way to the means of securing immunity from the dreaded plague. This paper was freely criticized. Here, it was said, was a chemist who, quitting his proper sphere, had the hardihood to lay down rules for the guidance of the physician and biologist in fields specially their own. Why should his proposals be more successful than all the other nostrums which had already so egregiously failed?

In order to appreciate the difficulties which met Pasteur in this inquiry, and to understand how wonderfully he overcame them, I must very shortly describe the nature of this disease, which is termed *pébrine*, from the black spots which cover the silkworm. It declares itself by the stunted and unequal growth of the worms, by their torpidity, and by their fastidiousness as to food, and by their premature death.

Before Pasteur went to Alais the presence of certain microscopic corpuscles had been noticed in the blood and in all the tissues of the diseased caterpillar, and even in the eggs from which such worms were hatched. These micro-organisms often fill the whole of the silk organs of the insect, which in a healthy condition contain the clear viscous liquid from which the silk is made. Such worms are of course valueless. Still this knowledge did not suffice, for eggs apparently healthy gave rise to stricken worms incapable of producing silk, whilst again other worms distinctly diseased yielded normal cocoons. These difficulties, which had proved too much for previous observers, were fully explained by Pasteur. "The germs of these organisms," said he, "which are so minute, may be present in the egg and even in the young worms, and yet baffle the most careful search. They develop with the growth of the worm, and in the chrysalis they are more easily seen. The moth derived from a diseased worm invariably contains these corpuscles, and is incapable of breeding healthy progeny."

This moth-test is the one adopted by Pasteur, and it is an infallible one. If the female moth is stricken, then her eggs—even though they show no visible sign of disease—will produce sick worms. If in the moth no micrococci are seen, then her immediate progeny at any rate will be sound and free from inherited taint, and will always produce the normal quantity of silk. But this is not all. Pasteur found that healthy worms can be readily infected by contact with diseased ones, or through germs contained in the dust of the rooms in which the worms are fed. Worms thus infected, but free from inherited taint, can, however, as stated, spin normal cocoons, but—and this is the important point—the moths which such chrysalides yield invariably produce diseased eggs. This explains the anomalies previously noticed. The silkworms which die without spinning are those in which the disease is hereditary, viz. those born from a diseased mother. Worms from sound eggs which contract the disease during their life-time always spin their silk, but they give rise to a stricken moth, the worms from which do not reach maturity and furnish no silk.

As I have said, these results were but coldly received. It was hard to make those engaged in rearing the worms believe in the efficacy of the proposed cure. Then, seeing this state of things, Pasteur determined to take upon himself the *rôle* of a prophet. Having in 1866 carefully examined a considerable number of the moths which had laid eggs intended for incubation, he wrote down a prediction of what would happen in the following year with respect to the worms hatched from these eggs. In due course, after the worms from a mixed batch of healthy and unhealthy eggs had spun, the sealed letter was opened and read, and the prediction compared with the actual result, when it was found that in twelve out of fourteen cases there was absolute conformity between the prediction and the observation, for twelve hatchings were predicted to turn out diseased, and this proved to be the case. Now all these "educations" were believed to be healthy by the cultivators, but Pasteur foretold that they would turn out to be diseased by the application of the moth-test in the previous year. The other parcels of eggs were pronounced by Pasteur to be sound, because they were laid by healthy moths containing none of the micrococci, and both these yielded a healthy crop. So successful a prophecy could not but gain the belief of the most obtuse of cultivators, and we are not surprised to learn that Pasteur's test was soon generally applied, and that the consequence has been a return of prosperity to districts in which thousands of homes had been desolated by a terrible scourge.

I must now ask you to accompany me to another and a new field of Pasteur's labours, which, perhaps more than his others, claims your sympathy and will enlist your admiration, because they have opened out to us the confident hope of at least obtaining an insight into some of the hidden causes and therefore to the possible prevention of disease.

In the first place, I must recall to your remembrance that most infectious diseases seldom if ever recur, and that even a slight attack renders the subject of it proof against a second one. Hence inoculation from a mild case of small-pox was for a time practiced, but this too often brought about a serious if not fatal attack of the malady, and the step taken by Jenner of vaccinating, that is of replacing for the serious disease a slight one which nevertheless is sufficient protection against small-pox infection, was one of the highest importance. But Jenner's great discovery has up to recent years remained an isolated one, for it led to no general method for the preventive treatment of other maladies, nor had any explanation been offered of its mode of action. It is to Pasteur that science is indebted for the generalization of Jenner's method, and for an explanation which bids fair to render possible the preventive treatment of many—if not of all—infectious diseases. It was his experience, based upon his researches on fermentation, that led to a knowledge of the nature of the poison of such diseases, and showed the possibility of so attenuating or weakening the virus as to furnish a general method of protective or preventive inoculation.

I have already pointed out how a pure cultivation of a microbe can be effected. Just as the production of pure alcohol depends on the presence of the pure yeast, so special diseases are dependent on the presence of certain definite organisms which can be artificially cultivated, and which give rise to the special malady. Can we now by any system of artificial cultivation so modify or weaken the virus of a given microbe as to render it possible to inoculate a modified virus which, whilst it is without danger to life, is still capable of acting as a preventive to further attack? This is the question which Pasteur set himself to solve, nor was the task by any means an apparently hopeless one. He had not only the case of Jennerian vaccination before him, but also the well-known modifications which cultivation can bring about in plants. The first instance in which Pasteur succeeded in effecting this weakening of the poison was in that of a fatal disease to which poultry in France are very liable, called chicken cholera. Like many other maladies, this is caused by the presence of a micro-organism found in the blood and tissues of the stricken fowl. One drop of this blood brought under the skin of a healthy chicken kills it, and the same microbe is found throughout its body. And if a pure culture of these microbes be made, that culture—even after a series of generations—is as deadly a poison as the original blood. Now comes the discovery. If these cultures be kept at a suitable temperature for some weeks exposed to pure air, and the poisonous properties tested from time to time, the poison is found gradually to become less powerful, so that after the lapse of two months a dose which had formerly proved fatal now does not disturb in the slightest the apparent health of the fowl. But now let us inoculate a chicken with this weakened virus. It suffers a slight illness, but soon recovers. Next let us give it a dose of the undiluted poison, and, as a control, let us try the action of the same on an unprotected bird. What is the result? Why, that the first chicken remains unaffected, whilst the second bird dies. The inoculation has rendered it exempt from the disease, and this has been proved by Pasteur to be true in thousands of cases, so that, whereas the death-rate in certain districts amongst fowls before the adoption of Pasteur's inoculation method was 10 per cent., after its general adoption it has diminished to less than 1 per cent.

We can scarcely value too highly this discovery, for it proves that the poisonous nature of the microbe is not unalterable, but that it can be artificially modified and reduced, and thus an explanation is given of the fact that in an epidemic the virus may either be preserved or become exhausted according to the conditions to which it is subjected. We have here to do with a case similar to that of Jenner's vaccine, except that here the relation between the weak and the strong poison has become known to us, whilst in Jenner's case it has lain concealed. This, then, is the first triumph of experimental inquiry into the cause and prevention of microbic disease, and this method of attenuation is of great importance, because, as we shall see, it is not confined to the case of chicken cholera, but is applicable to other diseases.

And next I will speak of one which is a fatal scourge to cattle, and is not unfrequently transmitted to man. It is called anthrax, splenic fever, or woolsorters' disease. This plague, which has proved fatal to millions of cattle, is also due to a microbe, which can be cultivated like the rest, and the virus of which can also be weakened or attenuated by a distinct treatment which I will not here further specify. Now, what is the effect of inoculating cattle or sheep with this weakened poison? Does it act as a preventive? That the answer is in the affirmative was proved by Pasteur by a convincing experiment. Five-and-twenty sheep, chosen promiscuously out of a flock of fifty, were thus inoculated with the weak virus, then after a time all the fifty were treated with the strong poison. The first half remained healthy, all the others died of anthrax. Since the discovery of this method, no fewer than 1,700,000 sheep and about 90,000 oxen have thus been inoculated, and last year 269,599 sheep and 34,464 oxen were treated. The mortality which, before the introduction of the preventive treatment, was in the case of sheep 10 per cent., was, after the adoption of the method, reduced to less than 1 per cent. So that now the farmers in the stricken districts have all adopted the process, and agricultural insurance societies make the preventive inoculation a *sine quâ non* for insuring cattle in those districts. This is, however, not the end of this part of my story, for Pasteur can not only thus render the anthrax poison harmless, but he has taught us how to bring the highly virulent poison back again from the harmless form. This may go to explain the varying strength of an attack of infectious disease, one case being severe and another but slight, due to the weakening or otherwise of the virus of the active microbe.

Last, but not least, I must refer to the most remarkable of all Pasteur's researches, that on rabies and hydrophobia. Previous to the year 1880, when Pasteur began his study of this disease, next to nothing was known about its nature. It was invested with the mysterious horror which often accompanies the working of secret poisons, and the horror was rendered greater owing to the fact that the development of the poison brought in by the bite or by the lick of a mad dog might be deferred for months, and that, if after that length of time the symptoms once make their appearance, a painful death was inevitable. We knew indeed that the virus was contained in the dog's saliva, but experiments made upon the inoculation of the saliva had led to no definite results, and we were entirely in the dark as to the action of the poison until Pasteur's investigation. To begin with, he came to the conclusion that the disease was one localized in the nerve-centres, and to the nerve-centres he therefore looked as the seat of the virus or of the microbe. And he proved by experiment that this is the case, for a portion of the matter of the spinal column of a rabid dog, when injected into a healthy one, causes rabies with a much greater degree of certainty and rapidity than does the injection of the saliva. Here, then, we have one step in advance. The disease is one of the nerve-centres, and, therefore, it only exhibits itself when the nerve-centres are attacked. And this goes to explain the varying times of incubation which the attack exhibits. The virus has to travel up the spinal cord before the symptoms can manifest themselves, and the length of time taken over that journey depends on many circumstances. If this be so, the period of incubation must be lessened if the virus is at once introduced into the nerve-centres. This was also proved to be the case, for dogs inoculated under the *dura mater* invariably became rabid within a period rarely exceeding eighteen days.

Next came the question, Can this virus be weakened, as has been proved possible with the former poisons? The difficulty in this case was greater, inasmuch as all attempts to isolate or to cultivate the special microbe of rabies outside the animal body had failed. But Pasteur's energy and foresight overcame this difficulty, and a method was discovered by which this terrible poison can so far be weakened as to lose its virulent character, but yet remain potent enough, like the cases already quoted, to act as a preventive; and dogs which had thus been inoculated were proved to be so perfectly protected, that they might be bitten with impunity by mad dogs, or inoculated harmlessly with the most powerful rabic virus.

But yet another step. Would the preventive action of the weakened virus hold good when it is inoculated even after the bite? If so, it might be thus possible to save the lives of persons bitten by mad dogs. Well, experiment has also proved this to be true, for a number of dogs were bitten by mad ones, or were inoculated under the sk with rabic virus; of these some were subjected to the preventive cure and others not thus treated. Of the first or protected series not one became mad, of the other, or unprotected dogs, a large number died with all the characteristic symptoms of the disease. But it was one thing to thus experiment upon dogs, and quite another thing, as you may well imagine, to subject human beings to so novel and perhaps dangerous a treatment. Nevertheless, Pasteur was bold enough to take this necessary step, and by so doing has earned the gratitude of the human race.

In front of the Pasteur Institute in Paris stands a statue worked with consummate skill in bronze. It represents a French shepherd boy engaged in a death struggle with a mad dog which had been worrying his sheep. With his bare hands, and with no weapon save his wooden *sabot*, the boy was successful in the combat. He killed the dog, but was horribly bitten in the fight. The group represents no mythical struggle; the actual event took place in October 1885; and this boy, Jupille, was the second person to undergo the anti-rabic treatment, which proved perfectly successful, for he remained perfectly healthy, and his heroic deed and its consequences have become historic. "*C'est le premier pas qui coute*," and as soon as the first man had been successfully treated, others similarly situated gladly availed themselves of Pasteur's generous offer to treat them gratuitously. And as soon as this cure became generally known, crowds of persons of all ages, stations, and countries, all bitten by rabid animals, visited every day Pasteur's laboratory in the Rue d'Ulm, which, from being one in which quiet scientific researches were carried on, came to resemble the out-patient department of a great hospital. There I saw the French peasant, the Russian *moujik* (suffering from the terrible bites of rabid wolves), the swarthy Arab, the English policeman, with women too and children of every age, in all perhaps a hundred patients. All were there undergoing the careful and kindly treatment, which was to insure them against a horrible death. Such a sight will not be easily forgotten. By degrees this wonderful cure for so deadly a disease attracted the attention of men of science throughout the civilized world. The French nation raised a monument to the discoverer better than any statue, in the shape of the "Pasteur Institute"—an institution devoted to carrying out in practice this anti-rabic treatment, with laboratories and every other convenience for extending by research our knowledge of the preventive treatment of infectious disease.

For, be it remembered, we are only at the beginning of these things, and what has been done is only an inkling of what is to come. Since 1885, twenty anti-rabic institutions have been established in various parts of the world, including Naples, Palermo, Odessa, St. Petersburg, Constantinople, Rio Janeiro, Buenos Ayres, and Havannah.

We in England have also taken our share, though a small one, in this work. In 1885 I moved in the House of Commons for a Committee to investigate and report on Pasteur's anti-rabic method of treatment. This Committee consisted of trusted and well-known English men of science and physicians—Sir James Paget, Sir Joseph Lister, Drs. Burdon Sanderson, Lauder Brunton, Quain, Fleming, and myself, with Prof. Victor Horsley as secretary. We examined the whole subject, investigated the details of a number of cases, repeated Pasteur's experiments on animals, discussed the published statistics, and arrived unanimously at the opinion that Pasteur was justified in his conclusions, and that his anti-rabic treatment had conferred a great and lasting benefit on mankind. Since then His Royal Highness the Prince of Wales, who always takes a vivid interest in questions affecting the well-being of the people, has visited the Pasteur Institute, and has expressed himself strongly in favour of a movement, started by the present Lord Mayor of London, for showing to Pasteur, by a substantial grant to his Institute, our gratitude for what he has done to relieve upwards of 250 of our countrymen who have undergone treatment at his hands, and likewise to enable poor persons who have been bitten, to undertake the journey to Paris, and the sojourn there necessary for their treatment. This lasts about a fortnight, it is nearly painless, and no single case of illness, much less of hydrophobia—due to the preventive treatment—has occurred amongst the 7000 persons who have so far undergone the cure.

Now let me put before you the answer to the question, Is this treatment a real cure? For this has been doubted by persons, some of whom will I fear still doubt or profess to doubt, and still abuse Pasteur whatever is said or done! From all that can be learnt about the matter, it appears pretty certain that about from fifteen to twenty persons out of every hundred bitten by mad dogs or cats, and not treated by Pasteur's method, develop the disease, for I need scarcely add that all other methods of treatment have proved fallacious; but bites on the face are much more dangerous, the proportion of fatal cases reaching 80 per cent. Now of 2164 persons treated in the Pasteur Institute, from November 1885 to January 1887, only thirty-two died, showing a mortality of 1·4 per cent. instead of fifteen to twenty, and amongst these upwards of 2000 persons, 214 had been bitten on the face, a class of wounds in which, as I have said, when untreated, the mortality is very high; so that the reduction in the death-rate seems more remarkable, especially when we learn that in all these cases the animal inflicting the wound had been proved to be rabid. The same thing occurs even in a more marked degree in 1887 and 1888. In 1887, 1778 cases were treated, with a mortality of 1·3 per cent., whilst last year 1626 cases were treated, with a mortality of 1·16 per cent.[1]

Statistics of the anti-rabic treatment in other countries show similar results, proving beyond a doubt that the death-rate from hydrophobia is greatly reduced. Indeed, it may truly be said that in no case of dangerous disease, treated either by medicine or surgery, is a cure so probable. Moreover, in spite of assertions to the contrary, no proof can be given that in any single case did death arise from the treatment itself. And as showing the safety of the inoculation, I may add that all Pasteur's assistants and laboratory workers have undergone the treatment, and no case of hydrophobia has occurred amongst them.

You are no doubt aware that Pasteur's anti-rabic treatment has been strongly opposed by certain persons, some of whom have not scrupled to descend to personal abuse of a virulent character of those who in any way encouraged or supported Pasteur's views, and all of whom persistently deny that anything good has come or can come from investigations of the kind. Such persons we need neither fear nor hate. Their opposition is as powerless to arrest the march of science as was King Canute's order to stop the rising tide. Only let us rest upon the sure basis of exactly ascertained fact, and we may safely defy alike the vapourings of the sentimentalist and the wrath of the opponent of scientific progress. But opposition of a much fairer character has likewise to be met, and it has with propriety been asked—How comes it that Pasteur is not uniformly successful? Why, if what you tell us is true, do any deaths at all follow the anti-rabic treatment? The answer is not far to seek. In the first place, just as it is not every vaccination which protects against small-pox, so Pasteur's vaccination against rabies occasionally fails. Then, again, Pasteur's treatment is really a race between a strong and an attenuated virus. In cases in which the bite occurs near a nerve-centre, the fatal malady may outstrip the treatment in this race between life and death. If the weakened virus can act in time, it means life. If the strong virus acts first, prevention comes too late—it means death. So that the treatment is not doubtful in all cases, but only doubtful in those which are under well-known unfavourable conditions. This, it seems to me, is a complete reply to those who ignorantly fancy that, because Pasteur's treatment has not cured every case, it must be unreliable and worthless.

One word more. I have said that Pasteur is still—as he has always been—a chemist. How does this fit in with the fact that his recent researches seem to be entirely of a biological character? This is true. They seem, but they really are not. Let me in a few sentences explain what I mean. You know that yeast produces a peculiar chemical substance—alcohol. How it does so we cannot yet explain, but the fact remains. Gradually, through Pasteur's researches, we are coming to understand that this is not an isolated case, but that the growth of every micro-organism is productive of some special chemical substance, and that the true pathogenic virus—or the poison causing the disease—is not the microbe itself, but the chemical compound which its growth creates. Here once more "to the solid ground of nature trusts the man that builds for aye," and it is only by experiment that these things can be learnt.

[1] For further details, see Dr. Ruffer, *Brit. Med. Journ.*, Sept. 21, 1889.

Let me illustrate this by the most recent and perhaps the most striking example we know of. The disease of diphtheria is accompanied by a peculiar microbe, which, however, only grows outside, as it were, of the body, but death often takes place with frightful rapidity. This takes place not by any action of the microbe itself, but by simple poisoning due to the products of the growing organism, which penetrate into the system, although the microbe does not. This diphtheritic *Bacillus* can be cultivated, and the chemical poison which it produces can be completely separated by filtration from the microbe itself, just as alcohol can be separated from the yeast granules. If this be done, and one drop of this pellucid liquid given to an animal, that animal dies with all the well-known symptoms of the disease. This, and similar experiments made with the microbes of other diseases, lead to the conclusion that in infectious maladies the cause of death is poisoning by a distinct chemical compound, the microbe being not only the means of spreading the infection, but also the manufacturer of the poison. But more than this, it has lately been proved that a small dose of these soluble chemical poisons confers immunity. If the poison be administered in such a manner as to avoid speedy poisoning, but so as gradually to accustom the animal to its presence, the creature becomes not only refractory to toxic doses of the poison, but also even to the microbe itself. So that instead of introducing the micro-organism itself into the body, it may now only be necessary to vaccinate with a chemical substance which in large doses brings about the disease, but in small ones confers immunity from it, reminding one of Hahnemann's dictum of "Similia similibus curantur."

Here then we are once more on chemical ground. True, on ground which is full of unexplained wonders, which, however, depend on laws we are at least in part acquainted with, so that we may in good heart undertake their investigation, and look forward to the time when knowledge will take the place of wonder.

In conclusion, I feel that some sort of apology is needed in thus bringing a rather serious piece of business before you on this occasion. Still I hope for your forgiveness, as my motive has been to explain to you as clearly as I could the life-work of a chemist who has in my opinion conferred benefits as yet untold and perhaps unexampled on mankind, and I may be allowed to close my discourse with the noble words of our hero spoken at the opening of the Pasteur Institute in the presence of the President of the French Republic:—

"Two adverse laws seem to me now in contest. One law of blood and death, opening out each day new modes of destruction, forces nations to be always ready for the battlefield. The other a law of peace, of work, of safety, whose only study is to deliver man from the calamities which beset him.

"The one seeks only violent conquests. The other only the relief of humanity. The one places a single life above all victories. The other sacrifices the lives of hundreds of thousands to the ambition of a single individual. The law of which we are the instruments, strives even through the carnage to cure the bloody wounds caused by this law of war. Treatment by our antiseptic methods may preserve thousands of soldiers.

"Which of these two laws will prevail over the other? God only knows. But of this we may be sure, that science in obeying this law of humanity will always labour to enlarge the frontiers of life."

THE PHYSICAL PAPERS AT THE BRITISH ASSOCIATION.

PROF. A. W. RÜCKER, F.R.S., read a paper on cometic nebulæ. Prof. Lockyer has suggested that comet-like nebulæ may be caused by the passage of a very dense swarm through a stream of meteorites, the relative velocity of the two being very considerable. The author has, therefore, attempted to calculate the increase in the number of collisions which takes place in the rear of an attracting mass which passes through a swarm of meteorites so sparsely scattered through space that the main effects of the attraction are produced in a distance which is small compared with the length of the mean free path. Assuming, with Clausius, that the particles have equal velocities equally distributed in all directions, and which are small compared with the relative velocity of approach, the collisions will be most numerous within a cone the apex of which is the attracting body or nucleus, and which contains the lines which are parallel to the relative velocities of the individual meteorites and the nucleus when at an infinite distance apart. The collisions will increase enormously when the nebulæ come nearer the sun, and will take place about every second at points, in round numbers, 100 miles apart.

Prof. C. Piazzi Smyth, late Astronomer-Royal for Scotland, read a paper entitled "Re-examination of the Spectra of Twenty-three Gas-vacuum, End-on Tubes, after six to ten years of existence and use." This inquiry began in an attempt to ascertain, by refined mensurations, whether there was any sensible difference of spectral place for hydrogen lines, when they appeared adventitiously and scantily in tubes of other and very different gases, or in tubes of nothing but pure and abundant hydrogen by original intention. But, after having obtained a negative in every case, the inquirer became more taken up with the *changes* that had occurred in certain of the tubes subsequent to 1880, when he published upon them in the Transactions of the Royal Society of Edinburgh. Thus, a chlorine tube, of which it was printed in 1880 that it was then still showing its chlorine lines, though fainter, after two years' use; while carbon bands and hydrogen lines had begun to appear; yet now, in 1889, it has nothing but hydrogen lines, and in great brilliance, to show. Again, an iodine tube which had a comparatively large quantity of solid iodine granules introduced into, and sealed up in, its interior eleven years ago; and showed then a splendid spectrum of 148 measured iodine lines, extending discontinously from red to violet, and had nothing else, *save* three very faint puny images of the three principal lines of hydrogen—this tube, in 1889, has not a single iodine line now left; but its spectrum, which is brighter than ever, is composed of nothing but hydrogen lines, so that the once solid iodine granules would seem to be partly changed into hydrogen, and partly deposited on the inside of the tube as yellow haze, besides leaving a trifle of loose dust. The author also mentions with much satisfaction that a London maker, Mr. Charles Casella, transcended all others by supplying him with one tube of CO, two of N, and two of O, which have, through six years of existence and work, shown their respective spectra without a trace of hydrogen.

Lord Rayleigh, Sec. R.S., in a paper on the tones of bells, said that observations were made on a considerable number of bells of the usual church pattern. The pitch of the various tones, usually five for each bell, was fixed by comparison with a harmonium and with the aid of resonators. The nominal pitch of the bells appears to depend on the *highest* of the tones recorded. From a musical point of view it would seem that all the bells are far removed from perfection; while the differences of relative pitch in the various cases recorded indicates that it may be possible to effect an improvement even to the extent of bringing all the five tones into harmonious relations. The quality of the sound is, however, very difficult to estimate, and even the imperfect octaves, of which several examples occur, give much less of a dissonant effect than might have been expected.

Captain Abney, F.R.S., read a paper on the quantity of deposit of silver produced by the development on a photographic plate in terms of the intensity of light acting. The author concludes from his experiments that the deposit of silver made by different intensities of light varies directly as the intensity of light acting—this, of course, within such limits that reversal of the image is not commenced, and that the film is not at any part exhausted of the silver salt which can be reduced.

Lord Rayleigh, Sec. R.S., read a paper on pin-hole photography. It was shown, in the *Philosophical Magazine* for 1880, that a simple aperture was as effective as the best possible lens in forming an image, provided only that the focal length (f) was sufficiently great. Conversely, if f be given, the aperture may be made so small that the use of a lens will give no advantage; but if the focal length was such as was usually afforded by a camera, the admissible aperture, being very much less than that of the pupil of the eye, is insufficient for reasonably good definition. In some recent experiments the focal length was about 9 feet, and the aperture $\frac{1}{10}$ inch. The specimens exhibited were taken upon gelatine plates, and represented a weathercock seen against the sky. The amount of detail was not materially less than that observable by direct vision in the case of ordinary eyes, but modern plates are so sensitive that there would be no difficulty in working with an aperture equal to that of the pupil, other than that incurred in providing a focal length of 66 feet, with the necessary exclusion of foreign light.

Prof. O. J. Lodge, F.R.S., and Mr. R. T. Glazebrook, F.R.S., read a paper on the determination of v by means of electric oscillations. The authors have recently made a determination of v, using the oscillatory discharge of a condenser. The period of the discharge, which passed between two terminals connected through a circuit of measured self-induction to a condenser of known capacity, was determined by forming an image of the spark on the edge of a rapidly revolving circular photographic plate, the rate of revolution being accurately ascertained.

Prof. A. W. Rücker, F.R.S., read a paper on the instruments used in the recent magnetic survey of France. A magnetic survey of France has recently been completed by M. Mourceaux, who has determined the magnetic elements at some seventy stations. Prof. Rücker exhibited a set of instruments recently made under the supervision of M. Moureaux for the Science Museum at South Kensington. The point aimed at in their construction was to secure accuracy combined with dimensions and weight much less than those of the Kew pattern instruments. The main points in the construction are (1) that the needles used are much smaller than those used in the Kew pattern instruments; (2) the end of the declination needle forms a concave mirror, and a reading is taken when the image of a linear mark formed by the mirror is in the prolongation of another line which is exactly opposite to the first on a thin piece of metal; (3) the geographical meridian is determined by a theodolite, which forms part of the apparatus, instead of by using—as in the Kew—a plane mirror to reflect the image of the sun into a horizontal telescope; (4) extremely fine silk threads are able to support the small magnets used; (5) in the dip circle the graduated arc rotates in its own plane about a horizontal axis, and a reading is taken when the end of the needle and its image, formed by a concave mirror attached to the graduated circle, coincide when viewed through a microscope.

Prof. J. A. Ewing, F.R.S., in a paper on the magnetic viscosity of iron, described experiments showing that in certain circumstances the process is gradual by which iron assumes magnetization after the imposition of magnetizing force. The experiments are given in detail in Proc. Roy. Soc., June 20, 1889.

Prof. Everett, F.R.S., read a paper on the relation between brachistochrones and ray-paths, in which he pointed out an application of well-known laws of optics to the comparison of the law of force for a free path with the law of force for a path of least time, the path itself being supposed given; and to the closely allied problems of deducing the form of the path of least time from the form of the free path when the law of force is given. Most of his results, he stated, have previously been obtained by means of the principle of least action, but the optical method will be available for many students who have not mastered that principle.

Prof. Cayley, F.R.S., addressed the Section on curves in space.

Prof. J. A. Ewing, F.R.S., read a paper on hysteresis in the relation of strain to stress. It is now well known that when an iron wire is subjected to the alternate application and removal of tensile stress, many times repeated, certain of its qualities which are affected by the changes of stress exhibit hysteresis with regard to the changes of stress. If the load is cyclically varied between definite limits, these qualities do not have the same values at corresponding intermediate points during the application and removal of load; there is hysteresis or lagging in the change of quality, and in some cases this appears to be of a static character—that is to say, independent of the time-rate of variation of stress. Conspicuous instances of this action are seen in the change of magnetic and thermo-electric qualities under change of stress, some of which have been described by the author in former papers. It is natural to look for an effect of the same kind in the extension and retraction which the wire undergoes. We should expect that, after the change of loads has been frequently repeated so that a cyclic *régime* is established, the wire will, for any value of load intermediate between the two extremes, be longer during unloading than during loading. Evidently, if such an effect exist, it must be small, as it is well known that the proportionality of strain to stress which is expressed by Hooke's law is at least approximately exact. Sir W. Thomson's experiments on the damping of torsional vibrators have long ago shown that an action of the kind spoken of occurs in quickly-performed cycles of torsional strain. But it does not appear to have been looked for in slow cycles of longitudinal pull. The author has, with the assistance of one of his students, Mr. D. Low, looked for the effect in question, and has found it, not only in iron, but in steel, brass, and copper wires. He has not yet examined other metals. The experiment consisted in observing, with much optical magnification, the extension of a very long piece of wire, directly loaded with lead weights. The wire was hung from a rigid support in a testing flue or recess, built in the wall of the laboratory, and extending up through four stories. At a distance of 806 cms. below the top a small clamp was fixed on the wire, and this formed the support of the back foot of a little tripod, the feet of which consisted of three needle points about an inch apart. The two front feet rested in a slot and hole in a fixed shelf which stood in front of the long wire. The tripod carried a plane mirror which became tilted forward or backward as the wire extended or retracted. Readings were taken by a telescope of the reflected scale of a levelling staff placed vertically at a distance of some 5 metres from the mirror. The staff was graduated to 1/100 of a foot, and it was easy to read by estimation to 1/1000 of a foot, which corresponded to 0·000000102 of the length of the wire. At first a fixed shelf was used to support the two front feet of the mirror, but the effects of temperature were found to be excessive, although the greatest care was taken to shield the wire from draughts; and the plan was resorted to of hanging the shelf from two adjacent wires of the same material, suspended from the same support as the wire which was to be stretched. In this form the arrangement for optical multiplication was nearly the same as one used by Mr. Bottomley in recent experiments on the extension of loaded wires by heat.

Prof. Henry Stroud, in a paper on the E.M.F. produced by an abrupt variation of temperature at the point of contact of two portions of the same metal, gave the results of experiments on the E.M.F. produced when two portions of the same metal are in contact, and one portion is *kept* at a high temperature and the other at a low temperature. The precautions necessary in the performance of such experiments are discussed in the paper, and the results obtained are given in the case of copper and iron. The E.M.F. established in the case of copper is from hot to cold across the junction, while in the case of iron it is from cold to hot, and of far greater magnitude. These experiments are being continued with a view to obtaining the relation between the E.M.F. and the difference of temperature.

Prof. McLeod, F.R.S., in a paper on the black-bulk thermometer *in vacuo*, concludes the black bulbs should be as small as possible, and very little of the stem blackened, and also that the case should be as thin as is consistent with strength.

Sir W. Thomson, F.R.S., communicated a paper, by Magnus Maclean and Makita Goto, on electrification of air by combustion. A series of experiments was made, under the instructions of Sir William Thomson, for the purpose of endeavouring to find: (1) the state of the air inside a room as regards electrification; (2) the relation between electrification of air within a building and the atmospheric potential in its neighbourhood outside; and (3) the causes which produce or change the electrification of any given mass of air. It was found that an inclosed mass of air is electrified negatively by the burning of a paraffin lamp, of coal gas, of sulphur, of magnesium, and of several other substances; and, on the other hand, the burning of charcoal electrified a room positively.

Prof. C. Michie Smith read some notes on atmospheric electricity and the use of Sir W. Thomson's portable electrometer. Recent observations fully confirm the author's previous conclusions that, with a dry west wind, the potential of the air for some distance above the ground is usually negative. This seems always to be associated with dusty air. In using the portable electrometer in hot moist climates, special precautions have to be taken in drying it. As much sulphuric acid must be used as the pumice can absorb, and the pumice should be dried at least once a fortnight. The charging-rod itself must be very carefully dried, and, after charging, should be lifted out with a piece of warm silk.

Mr. A. W. Clayden read a paper on dark flashes of lightning. The author exhibited a negative taken on June 6 last, which shows several reversed images of lightning-flashes. He described a series of experiments which he had carried out with the object of discovering whether the phenomenon could be imitated in the laboratory. The steps in the investigation were illustrated by a series of negatives showing photographs of electric sparks. The conclusions arrived at are, that photographic images of electric sparks can be reversed by the action of diffused light. Reversal is only produced when the exposure to diffused light is subsequent to (or possibly simultaneous with) exposure to the image of the spark. If the plate is first acted upon by diffused light, the sparks give a direct image unless the action has been considerable, in which case they seem to make no impression.

Prof. Cleveland Abbe, in a paper on the determination of the amount of rainfall, gave a *résumé* of the general results of investigations on this subject. The deficit in catch by a gauge due to the eddies of wind is shown, on general reasoning, to be proportional to the velocity of the wind and to the relative percentage of small and slowly-falling drops.

Prof. C. Piazzi Smyth, late Astronomer-Royal for Scotland, read a paper entitled "Hygrometry in the *Meteorological Journal*." After noting the superior value officially attached to determinations of the mean temperature by observations of self-registering thermometers, recording its maximum and minimum every twenty-four hours, the author inquires why the still more difficult problem of ascertaining the mean daily moisture of the atmosphere is thrown over to a different principle of observing, long since condemned for simple temperature. Believing that the want of good self-registering dry- and wet-bulb thermometers for the purpose was the chief obstacle, and having alighted on some recent makes of Sixe's thermometers with several very recommendable qualities, he invested two out of four of them with the peculiar fittings for wet-bulb hygrometers, after having made a table of index corrections for them all, as compared with standard thermometers. But as soon as hygrometric observations began, the depression of the wet, below the dry, bulb always came out at only two-thirds of what a standard but non-registering Glaisher arrangement gave out, for the horizontal form of Sixe, and no more than half for a vertical form. These differences of hygrometric statement, though rather puzzling for a time, were traced up to the wet bulbs of the Sixe's thermometers being in contact on one side with the scale-plate. For when that plate in the horizontal Sixe form was cut entirely away from the bulb, and a new vertical form of Sixe was made (*per* Mr. James Bryson, Edinburgh) with its long thin bulb wholly outside the rest of the instrument, the indications of all three varieties of wet-bulb hygrometers became practically the same; and hygrometry was relieved of the old drawback on its registrations of maximum and minimum quantities of moisture in every twenty-four hours.

Mr. F. T. Trouton read a paper on some experiments on radiation with Prof. Hertz's mirrors. These experiments were described in NATURE, vol. xxxix. p. 391, and vol. xl. p. 398. Certain of them were repeated by Mr. Trouton in the Physical Laboratory of the Durham College of Science.

Profs. A. W. Rücker, F.R.S., and T. E. Thorpe, F.R.S., read a paper, on the relation between the geological constitution and the magnetic state of the United Kingdom, before a joint meeting of Sections A and C. The authors have, during the last five summers, determined the magnetic elements at 200 stations, distributed over the whole of the United Kingdom, and have employed the results of their observations in a study of the disturbing magnetic forces in play in various districts. If all disturbing causes were removed, an observer travelling due west from London would find that the declination increased by about half a degree for each degree of longitude. In fact, the rate of increase, though equal on an average to this amount, is irregular. Between London and Windsor it is considerably larger, and between Windsor and Reading smaller than the mean. The forces which produce these abnormal variations depend upon the geological character of the district. Two principal theories have been proposed to account for these disturbances: (1) the theory of direct action of magnetic rocks; (2) the other explanation associates the deflection of the needle with disturbances of the earth currents of electricity produced by irregularities in the geological constitution of the country, and especially with geological faults. On the whole, the authors think that the theory of the direct action of magnetic rocks agrees best with the observed facts, and they have shown that the kingdom can be divided into a small number of magnetic districts in which the directions of the disturbing forces are evidently closely connected with the geological constitution.

In a paper on the passage of electricity through gases, Prof. Arthur Schuster, F.R.S., gave an acccount of his investigations during the last two years on the distribution of potential in the neighbourhood of the negative pole of discharge of electricity through rarefied gases. Knowing the rate of fall of potential, it can be determined whether there is any bodily electrification in any part of the negative glow. It was found that the kathode is surrounded by an atmosphere of positively electrified gaseous particles extending to the outer edge of the so-called dark space. According to the author's views, this atmosphere corresponds to the polarized layer adjoining the negative electrode in an electrolyte. The cause of the sudden difference in luminosity between the dark space and the negative glow has also been investigated, and it has been found that negative particles projected from the kathode pass unhindered through the dark space, while their velocity is quickly reduced in the glow proper, the translatory energy being thus changed into energy of vibration.

Prof. Oliver J. Lodge, F.R.S., read a paper on the failure of metal sheets to screen off the electrostatic effect of *moving* or *varying* charges. Experiments have been made on the screening effect of a very thin film of silver chemically deposited, the thickness of the deposit being different in the different experiments. The silver screens are only found to protect so long as they are opaque; they no longer do so when the deposit is so thin as to be transparent.

Prof. James Blyth described a new form of current-weigher. In the construction of balances for the measurement of electric currents, a greater or less difficulty has always been experienced in leading the current into the movable parts of the instrument without seriously interfering with its sensibility. Several methods have been adopted to overcome this difficulty. In some balances the current is led in by mercury cups; in others, flexible leads, made of thin wire spirals or thin metal strips, are employed; while, in the recent balances by Sir William Thomson, the difficulty has been overcome by means of his well-known ligature suspension. Some time ago it occurred to the author that still another form of balance might be employed for this purpose, and the present paper is a short description of one which he has made. The balance referred to is of the ordinary Roberval type, with the pivot connections all replaced by tightly-stretched torsion wires. It is constructed as follows:—On a flat base-board are placed two vertical uprights of wood or other insulating material, about 6 inches apart. Between these are stretched two parallel wires in the same vertical plane about 3 inches apart. To the middle points of these wires are soldered the two horizontal metal bars of the Roberval. These are about 9 inches long. Both horizontal bars terminate at each end either in forks or rings, placed in a horizontal plane, and wires are tightly stretched between the prongs of the forks, or across a diameter of the rings. To the middle points of these last wires are attached, also by soldering, the vertical bars of the balance, thus completing what takes the place of the ordinary jointed parallelogram of the Roberval. The vertical bars have metal terminals, insulated from each other, and carry the circular disks, on the rims of which the movable coils of wire are wound. The bars pass at right angles through the centres of the disks, and are fixed to them at their middle points. The middle coils, which are of exactly the same diameter as the movable ones, are supported from the base-board, and are placed so that one is about half an inch above one movable coil, while the other is as much below the other movable coil. From this it will be seen that, when the balance is in equilibrium, the fixed and movable coils are all horizontal, with a space of about half an inch between each pair. The stretched wires may be either of steel or phosphor-bronze, and before being finally soldered are placed under considerable tension. The current flows through the instrument thus:—Entering, say, by the upper wire connecting the fixed supports, it passes to the upper horizontal bar. There it splits into two, one half (supposing the resistances equal) passing to each end of the bar, and, by means of the corresponding fork-wires, passing through the movable coils. From the movable coils each half returns along the lower horizontal bar, and together pass out by the lower wire connecting the two main supports. From this the whole current passes first through the one fixed coil, and then through the other, and in such a direction as to produce a repulsion between each pair of coils. In the constructing, care is taken that the suspended coils are both made of equal weight, and that when the balance is in equilibrium no torsion is in any of the wires. Small scale-pans are attached to each vertical bar, and a bob for raising or lowering the centre of gravity of the whole is placed on a rod springing at right angles from the middle of one of the horizontal bars. The current strength is estimated by the weight needed to restore the balance to equilibrium when disturbed by the passage of the current. A sliding weight may also be used, as in a steelyard. It will be readily seen that, as in all forms of current-weigher, the weights are proportional to the square of the current strength.

Prof. S. P. Thompson described a phenomenon in the electro-chemical solution of metals—originally discovered by Planté—which occurs when a current is passed between two copper wires immersed in dilute sulphuric acid in a cell. The solution takes place in two stages, the metal first oxidizing, and then the oxide dissolving in the acid. This was projected on the screen, the audience being able to observe that the bubbles evolved when the current was turned on ceased as the current died down, choked by the formation of oxide, but almost immediately re-commenced when the oxide began to dissolve. The author has tried other metals and other acids—silver, zinc, and iron showing similar effects in sulphuric acid, but not in nitric, acetic, or hydrochloric acids.

Mr. J. Wilson Swan read a paper on chromic acid as a depolarizer in Bunsen's battery. When chromic acid became an article of commerce at a moderate price, it occurred to the author to see if he could not obtain a substitute for the nitric acid of the Bunsen battery. As the results of his experiments he finds that a solution, of the composition nitric acid 1 part, chromic acid 2 parts, sulphuric acid 5 parts, and water 5 parts, gives results equal to that obtained with nitric acid.

Prof. Perry, F.R.S., described a variable standard of self-induction. An instrument like that hitherto used as a variable standard by Prof. Ayrton and the author, was used by Prof. Hughes. It is a fixed coil of wire, inside which a movable coil is placed; the coils are in series one with another. When their planes are parallel there is either a minimum or a maximum co-efficient. When the movable coil is rotated so that its plane makes various angles with the plane of the fixed coil, a pointer shows on a scale the coefficient for that particular position.

In another paper on a hot twisted strip voltmeter, Prof. Perry described the behaviour of twisted strips subjected to axial pull. A small elongation is accompanied by a great rotation, so that these strips may be employed in measuring-instruments such as weighing-machines, aneroid barometers, testing-machines, &c. For the Ayrton and Perry voltmeter a double twisted strip of platinum silver with its ends insulated is initially in tension inside a tube or frame two-thirds brass and one-third iron, a pointer at the middle of the strip being visible above a dial and capable of a motion of nearly 360°. When the current passes the pointer rotates because of the heating of the strip. By continuous making and breaking of a large current through the strip during seventy-two hours all zero and other errors seem to be eliminated. The highest reading of the exhibited instrument was 2½ volts, so that it is particularly useful in accumulator-work. The author gave the law of transformers generally, and found that a small transformer on the base of the instrument converted it into a voltmeter of any range whatsoever for alternating currents, the readings being independent of the frequency of alternation. The author exhibited twisted strips of carbon made by Messrs. Woodhouse and Rawson, which he intends to use for voltmeters of higher range.

Mr. W. H. Preece, F.R.S., read a paper on the relative effects of steady and alternate currents on different conductors. Sir W. Thomson, at the Bath meeting of the British Association, stated that alternating currents entered a distance of only about 3 millimetres into the heart of a thick round copper conductor, when the frequency was 150. This "diffusion law," as he called it, is dependent on the coefficient of self-induction and on the frequency, *i.e.* on the number of complete alternations of positive and negative currents transmitted per second. As this law has a most important bearing on the commercial value of systems of distribution dependent on alternating currents, it becomes most desirable to study the question practically. The verification of this law is almost beyond the reach of experiment. It occurred to the author, however, that if conductors of different materials are taken, such as iron, copper, lead, and platinoid, of easily measurable lengths and of convenient sectional areas, and if measurable and variable currents, both alternating and direct, approximately similar to those used in practice, are transmitted through them, the question could be studied by observing any difference, if such existed, in the total expenditure of energy in the conductors under these different circumstances. The general conclusion to be drawn from the experiments is that practically no serious error has been made in the form of conductors so much used for alternating current systems, and that nothing cheaper or better has been devised than a simple stranded conductor coated with a suitable insulating coating. The experiments do not solve the question of the distribution of current density through the section of the conductor, but they do show that within the range of practice the total flow of energy is the same in copper conductors, whether it be urged by alternate or by steady currents.

Prof. G. Forbes, F.R.S., and Mr. W. H. Preece, F.R.S., in a paper on a new thermometric scale, suggest the joule as the thermal unit instead of the therm or the calorie. 4·2 joules will raise the temperature of 1 gramme of water at 4° one degree, hence to raise 1 gramme of water from freezing-point to boiling-point requires 420 joules; and it is suggested that the difference of temperature between freezing- and boiling-points should be represented by 420 units of temperature.

Mr. J. T. Bottomley, F.R.S., exhibited some large Leyden jars, broken during the testing of a large Wimshurst machine which was being constructed by Sir Archibald Campbell, Bart., of Blythswood. They were excellent examples of multiple fracture.

Prof. S. P. Thompson, in a paper on sparkless electro-magnets, discussed the various means of suppressing the sparks in the circuits of electro-magnets. The most effective means, he finds, is to surround the core of the magnet with a substantial shield of copper. The author illustrated his method by experiments before the Section.

Mr. W. W. Haldane Gee and Dr. Arthur Harden read a paper on stereometry. This communication relates to the methods used for the determination of the volumes of bodies to which the hydrostatic method is not applicable. The authors have devised a convenient form of instrument, first proposed by Say, and afterwards modified by Leslie, Kopp, Regnault, and Miller. They have also shown that the following method for ascertaining volumes is very generally applicable, and likely to be of considerable service in physico-chemical researches. The body whose volume is desired is inclosed within a vessel of known volume, and then carbon dioxide (or other dry soluble gas) is passed into it for some time. The gas is then displaced by dry air (or other gas), and the volume of the carbon dioxide driven out is ascertained *gravimetrically* by absorption in bulbs containing caustic potash solution. By first filling the vessel with dry air and then driving it out with carbon dioxide, the volume of the air, and hence that of the body, may also be ascertained *volumetrically*, but with less accuracy. The gravimetric method is especially applicable for accurately ascertaining the density of soluble gases. For this purpose it is far more convenient than the process of direct weighing as used by Regnault.

In a paper on the specific heat of caoutchouc, Mr. W. W. Haldane Gee and Mr. Hubert L. Terry described a number of determinations which had been made of the specific heat of Para india-rubber which had been masticated, hydraulically compressed, and then cut into sheets from 0·22 millimetre to 1·40 millimetre thick. The rubber was alternated with sheets of tin-foil, and heated for two hours in a steam-jacket at 100° C. A modification of Regnault's method of mixtures was employed to find the specific heat of the hot rubber. Owing to the non-conducting nature of the substance the time of the calorimeter attaining its maximum temperature is as long as ten minutes; hence it has been necessary to apply special formulæ for the correction due to cooling. Those proposed by Pfaundler, Pape, and Schuster have been used, and the results calculated in accordance with them. The mean of the best-conducted experiments gives for the Para rubber the number 0·486. The investigation is being extended to allied bodies, especially the different forms of vulcanized rubber and gutta-percha.

Mr. F. T. Trouton read a paper on the temporary thermo-currents in iron. If a portion of an iron wire connected up to a galvanometer be heated red hot, and the heated portion be caused to travel along the wire by moving the flame, a current is produced, which is due to the fact that when iron changes its molecular state at the temperature of recalescence this change does not take place at the same temperature on heating as on cooling, so that when a flame is moved along an iron wire so as to continuously heat it above the temperature of recalescence the junction of the altered with the unaltered metal in front is at a higher temperature than of the junction behind the flame.

Prof. Barrett read a paper on recalescence of iron.

THE CHEMICAL PAPERS AT THE BRITISH ASSOCIATION.

OWING, doubtless, to the numerous chemical industries of the district, many of the papers read in Section B at Newcastle were of special interest to the technical student.

The President's Address on "The Metallurgy of Iron" was followed by the Report of the Committee for Investigating the Influence of Silicon on the Properties of Steel. From the results of Mr. Hadfield's experiments, it appears that silicon by itself does not produce a steel that will harden by water-quenching. The brittleness noticed in ordinary so-called silicon steel is due, not to silicon alone, but to the combined presence of the two hardeners, silicon and carbon. Silicon, up to 6 per cent., does not destroy the malleability of iron, nor are the magnetic properties greatly affected by increasing percentages of silicon, as is the case with manganese steel.

The Committee for Establishing an International Standard for the Analysis of Iron and Steel reported that they had made good progress with the work, and hoped before long to have the necessary analyses completed.

Some curious experiments were described by Mr. J. W. Hogg, on the volatilisation of lead oxide and its action upon glass at low temperatures. If some writing is placed upon a glass plate or platinum-foil, using lead oxide as a pigment, if a polished plate of glass be placed over this as closely as possible and prevented from actual contact by suitable means, upon now heating up to scarcely visible redness, a distinct reverse of the design will appear upon the upper glass. The quantity of lead oxide which will produce this effect is not shown by the most delicate balance.

Photographers were interested in Prof. Liveing's account of a new developer, "Eikonogen," which appears to give greater detail than most of those now in use. The tone of the negative is also excellent. Eikonogen is the sodium salt of amido-β-naphthol-β-sulphonic acid.

Mr. C. T. Heycock and Mr. F. H. Neville read a paper on Raoult's method applied to alloys. Alloys of a number of metals with sodium and tin were studied. The "atomic fall" of the freezing-point for aluminium was about half that of most other metals—pointing to twice the present number as the atomic weight of aluminium. Antimony produces a rise in the freezing-point of the alloy, for some unexplained reason. Contrary to Raoult's so-called second law, it was found that the nature of the solvent is of influence; 1 atomic weight of metal in 100 atomic weights of sodium not giving the same fall as 1 in 100 of tin. The method would seem to give a means for correcting and verifying atomic weights; though it does not give much information as to the molecular weight. It was shown that, in accordance with Van 't Hoff's theories on the nature of solution, each metal produces its own lowering of the freezing-point in presence of others.

On the Friday morning, Prof. Dunstan read the Report on the present methods of teaching chemistry.

Prof. Bedson afterwards gave an interesting description of Dr. Netto's process, at work on the Tyne, for the manufacture of aluminium from cryolite. The cryolite is first fused with salt in a reverberatory furnace; then run out into converters in which sodium is gradually added—about five pounds at a time. Sodium fluoride and metallic aluminium are formed. The sodium is obtained by allowing molten caustic soda to flow gradually onto charcoal contained in a cast-iron retort heated to dull redness. The sodium carbonate formed in the reaction sinks to the bottom of the retort. The greater concentration of the caustic soda thus produced enables the temperature to be kept lower than in the Castner process.

An account was afterwards given, by Mr. J. H. I. Dagger, of the Cowles method for manufacturing aluminium alloys.

On Monday, numerous Reports of Committees were handed in, the most interesting being that read by Dr. Richardson on the action of light on the hydracids. Dr. Richardson has found that, if white light is allowed to act upon water in presence of oxygen, a considerable quantity of hydrogen peroxide is produced. This accounts for the fact mentioned in previous Reports, that a mixture of dry oxygen with dry hydrogen chloride, or bromide, is unaffected by light.

Dr. Richardson also exhibited and described a new self-registering actinometer, based on the fact, discovered by Budde, that chlorine expands in the actinic rays, contracting again in the dark.

Prof. H. B. Dixon gave an account of experiments made by himself and Mr. J. A. Harker, on the explosion of a mixture of hydrogen, chlorine, and oxygen. It was found, in contradiction to previous statements, that steam is produced by the explosion even when chlorine is in excess. It was noted that hydrogen and chlorine, when exploded alone, give a sensible contraction.

In another paper the same workers show that hydrogen and chlorine do not explode when dry, unless exposed to very intense light.

Dr. A. P. Laurie gave some results of his researches on artists' colours. He is comparing the recipes given in the manuscripts of the old masters with those in modern use.

A new ferment was described on Tuesday, in a paper by Prof. P. F. Frankland, Miss Grace F. Frankland, and Mr. J. J. Fox. From the products of its activity, ethyl alcohol and acetic acid, it is termed *Bacillus ethaceticus*. It will cause a solution of mannite to ferment, while dulcite is unaffected by it.

In his paper on the Constitution of the Aromatic Nucleus, Mr. S. A. Sworn gave preference to the octahedral formula of Thomsen. A further development of Thomsen's formula, he believes, affords a full explanation of the laws of para- and meta-substitution.

Dr. Isaac Ashe read a paper entitled "Dimidium: an Attempt to represent the Chemical Elements by Physical Forms." He put forward the view that the primordial basis is to be found in an element having half the combining weight of hydrogen. This hypothetical element is named dimidium. The relations of attraction and repulsion under the influence of polar force suggest a linear form for such a body. A series of vortex-rings, superposed one on the other, would yield a form elongated in one direction and limited in the other two. Having shown that the primordial element may have a bar-like form of definite length, the author proceeds to construct models of the different elements, conforming in each case to the combining weight, valency, crystalline form, &c.

SOCIETIES AND ACADEMIES.

Paris.

Academy of Sciences, September 30.—M. Des Cloizeaux, President, in the chair.—Presentation of the fourth sheet of the Bulletin of the International Committee for preparation of a map of the heavens; meeting of Committee at Paris Observatory, by M. E. Mouchez. Five other Observatories (Vienna, Catania, Mexico, Manilla, and the Vatican) have been added to the original sixteen. Each Observatory will have to take about 700 photographs in the zone alloted to it, and it is hoped to finish the work in three or four years. A central office for utilizing the results will be necessary.—Addition to the theory of thin weirs extending throughout the breadth of the bed of a water-course; calculation of variations in the contraction of the outflowing sheet at its lower face, by M. J. Boussinesq.—On the last communication of Halphen to the Academy, by M. F. Brioschi.—On the denomination of the industrial unit of work, by M. H. Resal. He advocates the unit of 100 kilogrammetres, to be called the *quintalmetre*.—On the application of high temperatures in observing the spectrum of hydrogen, by MM. L. Thomas and Ch. Trépied. The electric arc is found a sure and comparatively easy way of making hydrogen sufficiently luminous for spectroscopic observation, even with large dispersions; (four jets of the gas were made to converge conically towards an axis coinciding with that of the carbons).—On concatenation (*enchainement*) of the atomic weights of the elements, by M. Delauney. He shows that the atomic weights may be joined together by addition in each case of the square root of a whole number, which is variable, but always *harmonic* (not containing any other prime factors than 1, 2, 3, and 5).—Combinations of cupric oxide with amylaceous matters, sugars, and mannites; new reagents for proximate analysis, by M. Ch.-Er. Guignet. Solutions of cellulose, also dry starch, or inuline, give well-defined combinations with oxide of copper, when put in contact with its solution in ammonia. Some sugars (pure glucose from honey, galactose, &c.) quickly precipitate copper ammonio-sulphate (but not the oxide); and while inverted sugar does not precipitate the sulphate, a previous addition of glucose produces a deposit of the glucosic combination (which does not retain ammonia). Mannite and dulcite, &c., yield at once blue precipitates in an ammoniacal sulphate of copper solution, which reagent is useful with decoctions of vegetable matters, as most substances in these are not precipitated by it.—On the number and calibre of nerve-fibres in the common oculomotor nerve, in the new-born and in the adult cat, by M. H. Schiller. The number does not increase during life (or increases very little); average 2942 in the kitten, 3035 in the cat. The calibre is increased six or eight times.—On the preceding investigation, by M. Aug. Forel. Various researches point to the stability of the nervous elements during life, and this he regards as very important for explanation of the phenomena of memory.—On the vitality of trichinæ, by M. Paul Gibier. He submitted small pieces of fresh pork with numerous trichinæ (which were much more lively when brought out of their cysts into a water-heated vessel than those of the salt meat) to a temperature of 20° to 25° below zero, for about two hours, and found the animals, on reheating, as lively as before.—The innervation of the osphradium of mollusks, by M. Paul Pelseneer. Like the other sensorial organs of mollusks, the osphradium proves to be innervated by the cerebral ganglion.—On the *Spongeliomorpha Saportai*, a new Parisian species, by M. S. Menier.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

On the Causes, Treatment, and Cure of Stammering: A. G. Bernard (Churchill).—A Text-book of Physiology, 5th Edition, Part 2: M. Foster (Macmillan).—A Contribution to the Flora of Derbyshire: Rev. W. H. Painter (Bell).—Notes on the Pinks of Western Europe: F. N. Williams (West).—Watts' Dictionary of Chemistry, vol. ii.: M. M. P. Muir and H. F. Morley (Longmans).—The Microscope in the Brewery and Malthouse: C. G. Matthews and F. E. Lott (Bemrose).—An Epitome of the Synthetic Philosophy: F. H. Collins; Preface by H. Spencer (Williams and Norgate).—Watts' Manual of Chemistry, vol. i. 2nd edition: W. A. Tilden (Churchill)—Nature Stories, Myths, and Phantasies (Hamilton).—Prodromus of the Zoology of Victoria, Decade xviii.: F McCoy (Trübner).—Service Chemistry: V. B. Lewes (Whittingham).—Chemical Technology; vol. i. Fuel and its Applications: E. J. Mills and F. J. Rowan (Churchill).—The Cradle of the Aryans: G. H. Rendall (Macmillan).—Mount Vesuvius: J. L. Lobley (Roper and Drowley).—Thermodynamics of the Steam-Engine: C. H. Peabody (Macmillan)—A Manual of Forestry, vol. i. The Utility of Forests and Fundamental Principles of Sylviculture: W. Schlich (Bradbury).—Sixth Annual Report of the Bureau of Ethnology, 1884–85: J. W. Powell (Washington).—Hydrostatics for Beginners: F. W. Sanderson (Macmillan). Differential Equations: W. W. Johnson (Macmillan).—Manures and their Uses: A. B. Griffiths (Bell).—A Text-book of Physiology; vol. ii. Special Physiology: J. G. Dall (Washington).—Aus dem Archiv der Deutschen Seewarte, xi. Jahrg., 1888 (Hamburg).—Mind, September (Williams and Norgate).—Bulletin of the United States National Museum, No. 35: H. Edwards (Washington).

CONTENTS.

THURSDAY, OCTOBER 17, 1889.

THE ELEMENTARY TEACHING OF SCIENCE.

PERHAPS the most important event in the Chemical Section at Newcastle was the presentation of a second Report (the first part of which we print elsewhere) by the Committee[1] appointed "to inquire into and report upon the present methods of teaching chemistry." It is a remarkable fact that the daily Press in general has made only the barest possible reference to the Report or to the animated discussion which followed its reading; although, as the *Times* points out, "there is a Committee attached to Section B, the professed purpose of which is to inquire into and report upon the teaching of chemistry; the truth is, however, that it involves the wide question of science teaching in general. The national importance of such an inquiry is evident, and it behoves all the Sections to take an interest in it."

At the Bath meeting the Committee reported on the condition of chemical teaching in the principal public schools of Great Britain and Ireland, their Report being founded upon information obtained from the principals, head masters, and science masters of these schools. This Report demonstrated the existence of a most unsatisfactory state of things. It proved unquestionably that physical science still occupies a very subordinate position in most of our public schools, and it appears that this is the result, in no small measure, of the manner in which it is taught. The attempt to cram the minds of boys with a conglomeration of chemical facts under the name of "science" has reached a crisis; and head masters, and even some parents, are beginning to feel, and to say in so many words, that science teaching, which has been on its trial for so many years, has failed to produce the educational effect which was expected from it. The teachers, while complaining of the various difficulties which surround their attempts to teach chemistry, *e.g.* insufficient time and laboratory accommodation, frankly admit that the methods at present employed in teaching the science are for the most part ineffective, and that to this circumstance may be attributed, in the majority of instances, the inferior position which is assigned to the subject in the school curriculum. Partly in self-justification, and partly as an explanation of the continued existence of these abortive methods, teachers have drawn attention to the requirements of the various examining bodies by which their hands are tied. It is rare to find the science master who is free to break away from conventional lines, and to use chemistry in illustration of the scientific method of questioning Nature, instead of relating to his boys the properties of all the elements from hydrogen to uranium, and by a system of laboratory drill instructing them how to "test" rare compounds or absurdly complex mixtures. Of the few examinational schedules which are likely to assist the teacher in making his elementary instruction in science most useful as an educational instrument, special mention may here be made of the syllabus of physiography issued by the Science and Art Department, having been drawn up by Mr. Norman Lockyer, and of the syllabus issued by the same Department for the "Alternative First Stage in Chemistry" (why should not this be made *the* "First Stage in Chemistry"?), which was compiled by two members of the present Committee, Sir Henry Roscoe and Dr. Russell.

The Committee thought that they might be able to do something towards a reorganization of elementary instruction in science; in fact several teachers had pointed out that the Committee were most favourably constituted for taking such action, and that they would doubtless be able to induce examining Boards to reconsider their present regulations.

About the middle of the present century two schools of educational authorities were actively engaged in propagating their views. The one school contended that the object of primary education should be to teach those subjects which can be practically applied in after life, while the other asserted that its main object should be to develop the faculties and not merely to store the mind with knowledge. Chemistry, no doubt, was introduced into the school curriculum chiefly to satisfy the demands of the first theory, but nevertheless it may equally well serve the purposes of the second. The mental discipline afforded by chemical investigation in developing the powers of observation and inference, and in teaching the correct use of hypothesis, is not less conspicuous than the many applications of which the science is susceptible both in industrial and "common" life. Happily, of late years, a fusion of these two theories has taken place, and agreement has very generally been reached on two important points. First, that the main purpose of elementary education should be to train the intelligence. In this sense "education is a high word—it is nothing less than the formation of mind." Secondly, it is admitted that before a man can apply science to practice he must be familiar with its methods, his mind must be able habitually to perform those logical processes which accurate thought demands. We are now fairly unanimous in the opinion that it should be the endeavour of elementary education to develop habits of correct observation and reasoning, so that in later life the more advanced knowledge of science, which will subsequently have been acquired, may be intelligently applied to the solution of social and industrial problems.

In the opinion of the Committee, this training of the intelligence can be readily effected by a properly arranged course of elementary instruction in physical science. This fact is, however, not recognized by the majority of educational authorities, since chemical teaching, which represents physical science in most schools, has hitherto been chiefly directed to the acquisition of a vast number of chemical facts. But the "learning of true propositions, dogmatically delivered, is not science," and does not produce any mental effect that cannot as well be reached by many other paths, *e.g.* the multiplication table and the facts of English history. So far, the public in this country have had very few opportunities of judging of the educational value of physical science, and it is to be feared that they have not yet sufficiently recognized the truth and significance of Herbert Spencer's definition of

[1] Consisting of Prof. H. E. Armstrong, F.R.S., Prof. W. R. Dunstan (Secretary), Dr. J. H. Gladstone, F.R.S., Mr. A. G. Vernon Harcourt, F.R.S., Prof. McLeod, F.R.S., Prof. Meldola, F.R.S., Mr. M. M. Pattison Muir, Sir Henry E. Roscoe, F.R.S., Dr. W. J. Russell, F.R.S. (Chairman), Mr. W. A. Shenstone, Prof. Smithells, and Mr. G. Stallard.

science as "trained and organized common-sense," which implies that those same mental processes whose use has led to great scientific discoveries are also applicable to even the commonest affairs of life with equally successful results. In order to make chemistry subservient to the needs of mental education, it is necessary to depart almost entirely from the usual method of teaching it, which is better adapted for the subsequent training of those comparatively few students who intend to follow chemistry as a profession. Instead of attempting to traverse the greater part of the science, the teaching must be restricted to those portions of it which best exemplify the scientific method of investigation; and it should, as far as possible, have reference to objects which are more or less familiar to the pupils, or which can be readily understood by them.

The Committee having agreed as to the principles on which a scheme of elementary instruction should depend, Prof. Armstrong undertook to prepare a series of suggestions for an actual course of instruction in sufficient detail to serve as a general guide to teachers. These suggestions form a part of the Committee's Report, and are of very considerable importance. The course is divided into six "stages." Stage I. deals with lessons on common and familiar objects; the classification of these according to their uses and origin; elementary physiography and *Naturkunde*. Stage II., with lessons in measurement. Stage III., with studies of heat on things in general; of their behaviour when burnt. Stage IV., the problem stage—to determine what happens when iron rusts; to determine the nature of the changes which take place when substances are burnt in air; to separate the active from the inactive constituent of air; to determine the composition of chalk; to determine what happens when organic substances are burnt; to determine what happens when sulphur is burnt; to determine what happens when metals are heated with acids; to determine what happens when oxides are treated with acids; to determine what happens when the gas obtained by dissolving iron and zinc in sulphuric acid or muriatic acid is burnt; to determine what happens when hydrogen and other combustible substances are heated with oxides; to determine whether oxides, such as water and chalk gas, may be deprived of oxygen by means of metals; to determine the composition of salt-gas and the manner in which it acts on metals and oxides; to determine the composition of washing-soda. Stage V., the quantitative stage: study of the quantitative composition of some of the substances which have already been qualitatively examined. Stage VI., studies of the physical properties of gases in comparison with those of liquids and solids; the molecular and atomic theories, and their application.

Without pledging themselves to accept every detail, many of which would naturally be modified by teachers to suit their own special cirumstances, the Committee state that Prof. Armstrong's suggestions are typical of the kind of instruction which they wish to see generally introduced into schools. They prefer to speak of it as a course of elementary instruction in "physical science," since, although it is mainly chemical, physical problems are largely introduced, and the course, as a whole, may be looked upon as a suitable introduction to the study of any of the physical sciences.

In bringing this scheme under the notice of teachers, the Committee make several recommendations as to the manner in which it should be carried out, but these can only be briefly alluded to here. They insist that the instruction should be commenced with young children, and that every pupil in the school should receive it. In order that it may be successful, a fair share of the school time must be devoted to the subject, and a larger number of teachers must be employed than is now usually the case. While this may lead to some extra expense, on the other hand it is pointed out that the simplest laboratory fittings and apparatus are all that will actually be needed. Thus the expenditure attending the adoption of the new course need not be greater than it is now in those schools where science teaching occupies a prominent place among the subjects of study.

Space does not allow of more than a passing mention of the series of statistics in reference to the teaching of chemistry in public elementary schools which have been admirably collected and commented upon by Prof. Smithells, and which form the second part of the Report. As in the higher public schools, the teaching of elementary science in these institutions is shown to be far from satisfactory, and here also a scheme of the kind suggested by the Committee might be introduced with very great advantage.

In the discussion which followed the reading of the Report the Committee had the satisfaction of learning that their recommendations receive the approval of several teachers of experience. A representative of Section E stated that those interested in the efficient teaching of geography felt strongly that the course of work advocated by the Committee was on the proper lines. The head master of a large elementary school complained of the present methods of teaching chemistry, and stated that they tended so strongly towards making those who followed them into professional and technical chemists, that he had been obliged to substitute for chemistry instruction in some other branch of science. A useful contribution to the discussion was made by a former assistant science master in one of the largest public schools in London, who gave a graphic account of the hardships which were suffered by the solitary science master and his assistant in their efforts to teach "practical chemistry" to large classes of boys. If the comparison he instituted between the methods respectively adopted in this school in teaching classics and science be true, and if his statistics are correct as to the number of boys who are "taught" science, and the number of masters employed to teach them, they reveal a scandalous state of affairs, which no City Company ought to tolerate in a school which it endows. Finally, Prof. Armstrong read letters which he had received from Prof. Huxley, the head master of Rugby, Sir Philip Magnus, and other authorities, in which they spoke with approval of the scheme for science teaching which the Committee advocate in their Report.

It seems likely, then, that through the action of this Committee a considerable impetus in a new direction will be given to the elementary teaching of science in this country. The words which Mark Pattison wrote more than twenty years ago are as true now as they were then, and may appropriately bring these remarks to a conclusion. "The dispute between science *versus* classics in education will not be settled on paper or by discussion. It will be settled, in fact, by the establishment somewhere or other, and in some form or other, of a system of scientific education, the results of which will vindicate themselves. We may argue, and vested interests may resist, but the tendency of things is unmistakable—the sciences will end by conquering their place."

W. R. D.

CORRESPONDENCE OF CHRISTIAN HUYGENS.

Œuvres Complètes de Christiaan Huygens. Publiées par la Société Hollandaise des Sciences. Tome Deuxième: Correspondance, 1657–59. (La Haye: Martinus Nijhoff, 1889.)

THE second volume of the great edition of Huygens's works, the first volume of which was noticed last year in these pages (NATURE, vol. xxxviii. p. 193), has made its appearance with creditable promptitude. The letters included in it range from 1657 to 1659. That they are numerous and elaborate is sufficiently shown by the bulk of their receptacle; their value might be taken on trust from the names of the writers, and can be ascertained by the somewhat laborious process of perusal. This, however, may be curtailed at pleasure by having recourse to a series of admirably-constructed indexes, aided by which, readers, exempted from the ignominious necessity for "skipping," are enabled to find what they want, and neglect what less immediately concerns them.

Scientific correspondence was in those days of far greater importance than it is now. It, in fact, to a great extent, took the place of scientific journalism. There was then no recognized channel of public criticism. The first numbers of the *Philosophical Transactions* and the *Journal des Savans* appeared within a few months of each other in 1665; the *Acta Eruditorum* began to be published at Leipzig only in 1682. The learned formed a cosmopolitan caste, using a cosmopolitan language. They made an audience "fit and few" for each other's communications, and cared little, in general, to address a wider public. Epistolary intercourse assumed, accordingly, proportions and a significance which we find it difficult to realize. From one end of the Continent to the other, workers were, by means of letters nominally private, kept *au courant* of the progress of invention, readers of the course of publication; ideas and criticisms were interchanged; authors were informed of the impression produced by their works; controversies were conducted or commented upon.

In the correspondence now before us, indeed, there is small trace of the *odium scientificum.* Although often obliged to stand on the defensive against unjust attacks upon his originality, Huygens never lost self-control. The *scelerata insania belli* had no place in his calm and reasonable mind. His reticence is strikingly illustrated by the incident of the feigned anagram, left unfinished and mysterious by the earlier letters, but brought to a satisfactory conclusion in the present collection. The bogus claim put forward by Dr. Wallis to the detection of Saturn's first-known satellite, proves, in accordance with the conjecture emitted by Mr. Maunder in the *Observatory* for last March, to have been an infelicitous practical joke. It enforced, however, a designed moral by rendering palpable the protective inefficacy of crytographical announcements; and no more was heard (that we are aware) of the entrenchment of discoveries or inventions behind logogryphs. Huygens continued in a state of mystification on the point for above three years, the Savilian Professor's first explanatory letter having miscarried; but he allowed his natural irritation only the vent of a few jottings of a strictly private character.

The publication of Huygens's "Systema Saturnium" was the leading event of the period now under consideration. The book was long and eagerly expected, and was received—so far as letters acknowledging the receipt of "complimentary copies" enable us to judge—with a chorus of approbation. Its author, at the age of thirty—Galileo being already dead, and Newton as yet unknown—found himself pre-eminent among the astronomers of Europe. "*Ora ha Giotto il grido.*" Yet the flattering assurances with which he was overwhelmed did not wholly exclude some expressions of misgiving. The physical and mechanical difficulties attending the existence of such a Saturnian system as he described were very great. The hypothesis of a ring was no doubt beautifully ingenious, and accounted for observed phenomena with the utmost neatness and sufficiency; but was it true? Was such an incredible structure, in point of actual and undeniable fact, to be found in the heavens? Such questionings could not but arise, and were only finally set at rest by the predicted complete disappearance of the anomalous appendages as the earth got to the unilluminated side of them towards the end of 1671.

Saturn's ring-system has now so long held a place in astronomical consciousness that it costs an effort of the imagination to conceive the audacity of the first attempt to establish it there. Its author himself did not look for immediate and unqualified assent. All he hoped for was that his mode of accounting for the "bizarre appearances" of the "triple planet" should get an unprejudiced trial. Writing to Slusius in September 1659, he congratulated himself that his hypothesis had not struck him as absurd; and he met the scruples of objectors with a quiet appeal to time. It has not failed to justify his confidence.

An incidental paragraph in the "Systema Saturnium" (p. 9), announcing the virtual discovery of the great Orion nebula, appears to have excited little attention. Huygens's correspondents passed it over in silence; he took no trouble to invite their opinions on the subject; nor is there evidence that any of his subsequent observations were directed towards that "gap" (as it were) in the crystalline vault through which the glimmering of empyreal fire was discernible. Still more singularly, Hevelius, although he catalogued the stars, and enumerated fourteen nebulæ, did not include among them the Orion "portent," upon which, indeed, he seems never to have had the curiosity to direct his telescope (H. Schultz, *Astr. Nach.*, No. 1585). The first intelligent observer of nebulæ was Halley.

A sidereal phenomenon of another sort, however, attracted considerable attention in the learned *côteries* of Paris and the Hague. Janson's "new star," *in collo Cygni*, was again visible in 1658–59. First seen in 1600 as of the third magnitude, it disappeared from view in 1621, but was re-detected, in its pristine brightness, by Domenico Cassini at Bologna in 1655. The news seems to have taken no less than three years to filter to the Low Countries. Golius, of Leyden, was one of the first to get hold of it, and he transmitted it to Boulliau, of Paris, who thereupon perceived, plainly enough, a brilliant star shining in the place of a usually telescopic one. As an example of mental inertia comparable to that afforded by Hevelius with regard to the Orion nebula, it is worth noting that the object had caught his eye twelve days previously, but without rousing his attention. He imparted to Huygens his conviction that the Milky Way "provided the material for such generations," among which he included comets; and judiciously wound up his speculations by urging the necessity for continued observation.

His correspondent had anticipated the recommendation. His interest in the "renaissante of the Swan" (as he termed it) is shown by various remarks; but a more formal essay on the subject, alluded to in a letter to the Sicilian astronomer Hodierna, has not been preserved. Huygens considered the star, on November 20, 1659, to have lost none of its lately-acquired brilliancy. Boulliau, however, had already noticed a diminution in *size*, though not in *lustre* (a distinction to which he evidently attached some importance), and on December 12 saw further symptoms of fading in its pale and languid aspect. From the decline which then set in, it has never completely recovered, but has remained, since the abortive maximum of 1665, undistinguished by conspicuous vicissitudes. "P Cygni," as Janson's star is called in modern nomenclature, now betrays peculiarity of constitution only by the bright hydrogen lines photographically discovered by Prof. Pickering in its spectrum.

Huygens's invention of the pendulum clock is a prominent topic in the correspondence before us. He was not without hope of solving, by its means, the ever-recurring problem of longitudes, "if only it would bear transport by sea"—a prudent qualification. Of curves and quadratures, telescopes and lenses, chronometry, meteorology, mechanics, the theory of numbers, much is said, showing the working of thought along these various lines of research. There is scarcely, in fact, a branch of scientific history which is not usefully illustrated by these valuable letters.

A. M. CLERKE.

THE ANATOMY OF THE HUMPBACK WHALE.

The Anatomy of the Humpback Whale (*Megaptera longimana*). By John Struthers, M.D. (Edinburgh: 1889.)

THERE is probably no order of Mammals which during the last twenty-five years has been more worked at than the Cetacea. The result has been that we now possess a valuable body of information on both the classification and anatomy of this most interesting group of animals. On the continent of Europe, the names of Eschricht, Reinhardt, Lilljeborg, Van Beneden, and Gervais stand out most prominently as authorities; whilst in this country Sir Richard Owen, Profs. Flower, Struthers, and Turner, Dr. Murie, and Prof. Macalister, have all written valuable memoirs which have added largely to our knowledge of the whales. Through the combined labours of these anatomists the order has been rescued from the state of confusion into which it had been thrown by some systematic writers, who, by regarding almost every specimen stranded on our coasts as a new species, had introduced a complexity of nomenclature which was most puzzling.

The humpbacked whale, the anatomy of which forms the subject of Prof. Struthers's memoir, is, from its form and structure, one of the most interesting of the occasional visitors to our coasts. The number of specimens the capture of which has been recorded in British waters, prior to that of the specimen dissected by Dr. Struthers, was only three: viz. a female cast ashore near Newcastle in September 1829, and described by the late Dr. George Johnston; another female taken in 1863 in the estuary of the Dee, the skeleton of which is in the Derby Museum, Liverpool; and an adult towed into Wick Bay in March 1871, the skeleton of which was not preserved. This whale is, however, not uncommon in the North Atlantic, more especially off the coasts of Norway and Finmark, and in the seas of Iceland and Spitzbergen.

The specimen described in Prof. Struthers's memoir was seen in the Firth of Tay, in the month of December 1883. It was harpooned, but broke away from its captors, was ultimately found floating dead off Bervie, and was towed into Stonehaven Harbour on January 8, 1884. It is fortunate that it fell into the hands of so competent an anatomist and so enthusiastic a cetologist as the Aberdeen Professor. Thanks to his untiring energy and industry, he has furnished us with a monograph on the external characters, the skeletal anatomy, the muscular anatomy of the pectoral limbs, and the connections of the pelvic bones and rudimentary hind limbs of this animal, far more precise and detailed than had been given by any previous anatomist. He has added also greatly to the value of his description by instituting a comparison between the skeleton of Megaptera and that of *Balænoptera musculus*. The memoir will have to be studied by all cetologists who wish to have an exact knowledge of the anatomy of this great baleen whale.

OUR BOOK SHELF.

First Mathematical Course. Blackie's "Science Text-Books." (London: Blackie and Son, 1889.)

THIS little work, comprising arithmetic, algebra (as far as simple equations), and the first book of Euclid, is adapted to the requirements of the examinations of the Science and Art Department in mathematics (Subject V.), first stage. The more elementary parts of arithmetic have been briefly treated, as the pupil will have most probably reached fractions, but great attention has been paid to the examples, which are both numerous and judiciously chosen. The algebraical part is completed up to and includes simultaneous equations, and here, as in the arithmetical part, we have a great number of well-arranged examples, including those set for this stage in previous examinations. Part III. consists of the first book of Euclid with exercises on the various propositions. Preceding the answers to the examples is an appendix containing specimen examination papers set by the above-named Department. Teachers, who require a great number of easy examples on these three branches of mathematics, will find this book very useful.

Key to Todhunter's Integral Calculus. By H. St. J. Hunter, M.A. (London: Macmillan and Co., 1889.)

ALL the examples in Todhunter's "Integral Calculus" are fully worked out in this volume. In the earlier chapters, the solutions are exhibited with considerable detail, so that the "Key" will be a valuable aid to those who are beginning the subject without the help of a teacher. Throughout the work many references are made to the text, the edition referred to being that of 1886.

The Hand-book of Jamaica for 1889-90. By A. C. Sinclair. (London: Edward Stanford. Jamaica: Government Printing Establishment.)

THIS is the ninth annual issue of Mr. Sinclair's "Handbook," and to those who have already had occasion to consult the work we need hardly say that it contains all the information, clearly and compactly presented, that is likely to be wanted by its readers. The writer provides a good description and historical sketch of Jamaica, and full details are given with regard to all the leading institutions of the island. The volume is published by authority, and has been compiled from official and other trustworthy records.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Method of Quarter-Squares.

MAY I point out, by way of note to Mr. Glaisher's article (October 10, p. 573) on the method of quarter-squares, that the method is indicated in the second edition of Sir John Leslie's "Philosophy of Arithmetic" (Edinburgh, 1820; see pp. 246–57). Leslie gives what he calls a "specimen" table, extending as far as 2000, whereby any two numbers containing not more than three digits each can be multiplied; and he also points out the application of the table for any two numbers less than 2000 by using the formula—

$$ab = 2\left\{\frac{a^2}{4} + \frac{b^2}{4} - \frac{(a-b)^2}{4}\right\}.$$

Apparently, Leslie was an independent discoverer of the method; at least this seems to be implied in the remarks which follow his table in the work cited above:—"This application of a table of quarter-squares, as it is derived from the simplest principles, might have readily occurred to a mathematician; yet I have nowhere seen it brought into practical use till, last summer, I met with, at Paris, a small book by Antoine Voisin, printed in 1817. It contains a table of quarter squares for the multiplication of whole numbers from 1 to 20,000, with an explanation of the mode of employing them." G. CAREY FOSTER.

University College, London, October 13.

Marine Biological Association.

THE British Association, at the recent meeting at Newcastle placed a grant of money in the hands of a Committee, consisting of Prof. W. H. Flower, Prof. M. Foster, Prof. E. Ray Lankester, Prof. S. H. Vines, and myself (Secretary), "for the purpose of nominating students to work at the Laboratory of the Marine Biological Association at Plymouth." Arrangements are being made with the Council of the Marine Biological Association, by which the Committee hope to obtain the use of a table at the Laboratory at Plymouth for twelve months.

May I ask you to assist, through the medium of NATURE, in making this information public? Persons who wish to take advantage of the opportunity, afforded by the British Association, of working at the Plymouth Laboratory should address their applications to me at the earliest possible date. The application should contain full particulars as to the nature of the investigation which it is proposed to carry on, together with a statement of the period of time during which the applicant would be able to work at Plymouth. S. F. HARMER.

King's College, Cambridge, October 15.

Section Work at the British Association.

THE recent meeting at Newcastle has emphasized what has been frequently noticed before, that the British Association week undoes the benefit of previous holiday, and that the conditions under which the work of the Sections is carried on are prejudicial to health, and have this time resulted in a considerable list of sick and wounded. I speak especially of Section A, but have no reason to suppose it different from others.

The principal difficulty is the elementary one of food. A satisfactory midday meal is at present practically unattainable, unless one is willing to sacrifice everything else to it. The time of meeting (from 11 to 3, or, for those more intimately connected with the business of the Sections, from 10 to 5) and the practice of non-adjournment for lunch are to blame for this; and I write to raise the question, whether it may not be wise to reconsider the time-honoured meeting-hours both of Sections and of Committees. Several proposals can be made, but the one I wish to bring forward is, to postpone the Sectional Committee meetings till after the Section has sat, and to begin the Section work at 10 a.m. The work should begin then more freshly than it does now after an occasionally tedious, though occasionally interesting, Committee meeting; and it may go on steadily till 1.30, when it will usually stop for the day. At 2.30, or possibly, but less advantageously, at 2, the Sectional Committees can meet and transact their business comfortably. It will be easier to arrange the papers for next day when it is known how many stand over from the recent meeting; and as the Secretaries usually have things pretty well arranged beforehand, there need be no difficulty or delay in getting the list to the printer in good time. The important business of appointing Committees and such-like can be discussed very rationally after the Committee or individual has just reported to the Section, instead of, as at present, before such report. At 3.30 the General Committee and the Committee of Recommendations can meet, instead of at 3. This apparent lengthening of the day's work by half an hour will be more than compensated by a comfortable sit-down lunch, and one useful function of the Association, viz. the interchange of ideas in conversation, will be much assisted. It may be objected that, if all the Sections rise at 1.30, the luncheon-room will be inconveniently crowded, but there are usually many clubs and private houses available; and if a midday meal became a feature, there is no lack of hospitality. The usual difficulty is how to fit anything social into the crowd of engagements and evening lectures.

My proposal curtails the Section time by half an hour. Whether this is regrettable or not, I am not sure: there are ways of avoiding it if it is. If any hard-pressed Section chooses, it might meet again at 3.30 on every day but Monday, and sit, concurrently with the Committee of Recommendations, for an hour or two without essential hardship. What I feel sure ought to be reconsidered, is the present health-destroying practice of continuous session. OLIVER J. LODGE.

Anthropometric Measurements at Cambridge.

I QUITE agree with your correspondent "F. M. T." that the head measurements are not sufficiently accurate to warrant their use as data for coming to any conclusion as to increased cranial capacity, much less as the foundation for the theories of Mr. Francis Galton. On a comparison of the head measurements of any one individual, they are found to be so variant that one is forced to conclude that the errors of observation are far greater than the maximum error which could exist without completely vitiating the trustworthiness of the data. The following measurements of my head during the last two years are sufficient to render this obvious—

	Breadth.	Length.	Above line from brow to ear-lobe.	Total.
May 28, 1887	5·7	7·4	5·3	223·55
November 19, 1887	5·6	7·3	5·5	224·84
June 14, 1888	5·8	7·4	5·5	236·06
February 4, 1889	5·7	7·3	5·2	216·37
August 23, 1889	5·8	7·5	5·4	234·90
August 30, 1889	5·8	7·4	5·6	240·35

I would particularly call attention to the third and fourth measurements, as also to the last two, and venture to think that no one could entertain the trustworthiness of data that involve such great changes in cranial capacity in such short spaces of time. To what, then, are these differences due? Partly, of course, to unavoidable errors of observation. This, however, I think is only a small portion of the differences. The main difference is, I believe, due to other causes. Anyone who has seen the instruments will recognize that they are far too rough and imperfect to measure small differences with any degree of accuracy, and yet it is on differences as small as one-tenth of an inch that Mr. Galton's calculations are based.

I admit it is quite possible that, even after elimination of the errors due to experimental causes and to the imperfection of the instrument, the figures would still be somewhat variable. These variations may, however, be readily explained, without the assumption of any improbable head-growth. The amount of hair on the head must considerably influence the measurements, and, according as it is long or short at the time of measurement, so will the figures show an increase or a decrease. I have tested this, and proved it to be the case. On August 30 (my hair not being very long, having been cut two and a half weeks previously) my head was measured, the figures being as follows:—

$$5\cdot8,\ 7\cdot4,\ 5\cdot6 = 240\cdot35.$$

I then had my hair cut fairly short, and was measured again; the figures then read—

$$5\cdot7,\ 7\cdot4,\ 5\cdot5 = 231\cdot99.$$

Again, the scalp being, as is well known, very vascular, any change in the fulness of its vessels must materially affect the thickness of the scalp, and so influence the measurements, and so any cause producing either increased blood-flow or hindering the return of blood from the scalp, will have some effect on the measurements.

Several other similar explanations of supposed head-growth might be given, but I think the measurements I have given will suffice to show the uselessness of the measurements for calculating head-growth, and, further, that such differences as actually do exist can be readily explained without having recourse to any such improbable assumption as the further growth of the head after nineteen years of age, and without involving the unintelligible statement that the head of a "poll" man grows more than the head of an honour man. This would necessitate the supposition that a "poll" man, by his three years' study (?) at Cambridge, profits more than an honour man! Such an hypothesis would need more scientific proof than has been given.

Trinity College, Cambridge, September 3. H. J. P.

Glories.

COLOURED rings are often seen surrounding the shadow of the spectator's head when the sun is shining on a fog of water particles. They are known by various names, such as glories, anthelia, Ulloa's rings, &c. Can any of your readers inform me if they can also be seen when the fog is frozen? I should also be glad of accurate accounts of their colour and angular dimensions. I have read those given by Scoresby (Kaemtz, "Meteorology," translated by Walker); Flammarion (Glaisher's "Travels in the Air"); Abercromby (*Phil. Mag.*, January 1887); and Mohn (NATURE, February 1888).

JAMES C. MCCONNEL.

Hotel Buol, Davos, Switzerland.

Fine Slow-moving Meteor.

ON September 25, at 8h. 5m., I saw a bright first-magnitude meteor amongst the stars of Aquarius. It moved very slowly to the east, and, after a duration of about 13 seconds, disappeared at the point R.A. 11°, Decl. + 8°. Its place of first appearance was near R.A. 332°, Decl. $-7\frac{1}{2}°$, so that the length of its observed path was about 42°. The nucleus was followed by a thick train of sparks, and at the end it divided into two parts. This meteor was observed at Oxford by Mr. W. H. Robinson, of the Radcliffe Observatory. He writes:—"This evening a fine meteor was seen slowly moving between the constellations Aquarius and Pegasus, at 8h. $5\frac{1}{2}$m. G.M.T. It was first seen at R.A. 330°, N.P.D. 88°, disappearing near R.A. 352°, N.P.D. 82°; duration, 3 or 4 seconds." A comparison of these observations shows that the radiant point was probably in R.A. 244°, Decl. − 22°, and that the meteor, when first seen, was at a height of 46 miles over a point in the English Channel 20 miles south of the Isle of Wight. It disappeared near Staplehurst, in Kent, at the same height. Length of path, 100 miles. At Oxford, the early part of the meteor's flight was not seen. The Bristol observer watched the meteor through 91 miles of its course, and the duration of 13 seconds would give a velocity of 7 miles per second. At Oxford, 35 miles of the terminal section of the flight was seen in 3 or 4 seconds, which gives a velocity of 10 miles per second.

Further observations of this body would be valuable to corroborate these results. The meteor was an exceptional one, both as regards its slow speed and the position of its radiant point. No meteor-shower has hitherto been recognized at this epoch in the region of Scorpio. Isolated slow-moving meteors of this description are of great value as giving us indications of feeble systems not otherwise discoverable, and as allowing good determinations to be made of their heights and velocities.

Bristol, October 4. W. F. DENNING.

A Brilliant Meteor.

AT 7h. 6m. ± p.m. G.M.T., on October 10, a brilliant meteor was observed here, about 10° south-west of α Pegasi, and travelling from thence to near Jupiter, being apparently three times the size and brilliancy of that planet. Its colour was of a bluish-white, and it possessed a fine train, disappearing after six seconds, having burst into a number of pieces. W. HUGO.

Kew Observatory, Richmond.

The Shining Night-Clouds—An Appeal for Observations.

THE following is the substance of an appeal for observations made by Herr O. Jesse in the spring. The time of year in which the clouds appear in these latitudes has now elapsed; I have seen no sign of them this summer, either in this country or while travelling in the Alps. But as Mr. D. J. Rowan saw them (see NATURE, June 13, p. 151) it is very desirable that they should be looked for in all parts of the world. I see Mr. Le Conte assumes (October 3, p. 544) that Mr. Rowan is correct in calling these clouds self-luminous—which conclusion I agree with Herr Jesse in considering highly improbable.

Sunderland, October 12. T. W. BACKHOUSE.

The time of year has again arrived when the lustrous silvery clouds, which have appeared annually in June and July from 1885 to 1888, may be expected to again become visible to observers throughout Europe.

These clouds are not only of high meteorological interest, but may be of an almost greater astronomical one, for, from their so decidedly pronounced periodicity, joined to their extraordinary height, it may perhaps be inferred that they are of extra-terrestrial origin.

As there is entire lack of previous record of these clouds, and they may disappear soon for an indefinite period, I would earnestly ask for such early observations as may be likely to determine their origin, nature, and periodic motion. Spectroscopic examination of their light would be valuable. Prof. Galle and others have considered that the clouds in question are phosphorescent, but this is very improbable, and I hold they are scarcely, if at all, visible unless the sun shines directly upon their substance. On this assumption, their height in 1885 was found to be from 49 to 54 kilometres; but, by photographic observations in 1888, it came out as great as 75 kilometres.

Prof. Kohlrausch advances the opinion that these clouds have in some way been formed by the eruption of Krakatão, although they were not generally seen until nearly two years after that event. From this hypothesis I suggest that they may be caused by the condensation of gases from that volcano, and that the process of condensation occupied the intervening time. One observer, however, states that he saw them in 1884.

NOTES.

WE deeply regret to have to record the death of James Prescott Joule, one of the greatest men of the age. He died on Friday last at his residence at Sale, near Manchester.

PROF. H. G. SEELEY, who has recently returned from an expedition to South Africa, has obtained from the Karroo, among a large number of other treasures, a complete specimen of the much-discussed *Parieasaurus*.

THE ordinary general meeting of the Institution of Mechanical Engineers will be held on Wednesday, October 30, and Thursday, October 31, at 25 Great George Street, Wesminster. The chair will be taken at half-past seven p.m., on each evening, by the President, Mr. Charles Cochrane. The following papers will be read and discussed, as far as time permits:—On the results of blast-furnace practice with lime instead of limestone as flux, by the President; description of a rotary machine for making block-bottomed paper bags, by Mr. Job Duerden, of Burnley, communicated through Mr. Henry Chapman; further experiments on condensation and re-evaporation of steam in a jacketed cylinder, by Major Thomas English, R.E., Superintendent, Royal Carriage Department, Woolwich.

THE Government of Victoria has definitely deputed Mr. James Stirling, Assistant Geological Surveyor in the service of the Government, to make a thorough and systematic survey and mapping of the coal districts in the colony. This step has been taken in consequence of the suggestions of Sir James Hector, the Director of the Geological Survey of New Zealand, who, during a recent visit to Victoria, examined the supposed coal-bearing seams, and reported favourably on them. The great drawback to Victorian prosperity so far has been the absence of coal deposits.

THE *Civil and Military Gazette* of Lahore says that Mr. Dauvergne has succeeded in erecting a monument to the memory of Mr. Dalgleish, where the latter was murdered at the foot of the Karakoram Pass two years ago.

DR. A. ALCOCK, of the Indian Marine, has been deputed to examine and classify the collections which the Indian Marine Survey has made over to the Imperial Museum, Calcutta, during the past few years.

THE cultivation of the Egyptian date-palm in India is to be tried on a large scale, and an order for over 700 off-sets and three maunds of seed has been sent to Egypt. It is intended that the consignment shall be distributed in the Punjab, Bombay, Madras, Rajputana, and Coorg, for experiment.

THE *Kew Bulletin* for October opens with a paper on a valuable fibre, largely used in this country under the name of Bahia piassava. This fibre is obtained from the leaf-stalks of a Brazilian palm known as *Attalea funifera*, Mart., and is used in the making of brushes and brooms. Some interesting remarks on the condition of the industry in Brazil, by Mr. W. S. Booth, are presented in the paper. In another paper there is a letter, addressed by Mr. D. Morris to the Colonial Office, on the treatment of seedling sugar-canes at Barbados, and of any that may be found in other sugar-producing colonies in the West Indies. The remaining subjects dealt with are cinchona in Jamaica; the commercial product called gambier, used by tanners; and the fibre industry at the Bahamas.

THE *Photographic Quarterly*, if we may judge from the first number, is likely to be of great service to all who interest themselves in the study of photographic methods. It opens with a series of hints, by the Rev. T. Perkins, on the production of pictures by photography. Among the other articles are "Chemistry and Photography," by C. H. Bothamley; "The Influence of Photography on Art, and its Consequences," by A. M. Rossi; "A Plea for Photogravure," by Major J. F. Nott; "Photo-micrography," by J. Hall-Edwards; and "New Method of Printing in Clouds in Lantern Slides," by Lionel Clark. A portrait of Mr. James Glaisher, F.R.S., President of the Photographic Society of Great Britain, accompanies the first number. There is also a view of Salisbury Cathedral from the Bishop's garden.

THE Pilot Chart of the North Atlantic Ocean for the month of October shows that September was very stormy, especially off the American coast and in the West Indies. Low barometer, accompanied by gales, prevailed along the transatlantic routes from the 4th to the 15th inclusive. The most notable disturbance was the West India hurricane, which seems to have originated east of the Windward Islands at the end of August, reaching Antigua and Martinique on September 2, and continuing with unabated force in a west-north-west direction until the 12th. The large area and the severity of this hurricane make it one of the most notable on record, and it is the subject of a special appendix, with charts, showing its behaviour over the ocean during each of ten days. The rapidity with which these charts have been published is, we believe, unequalled in maritime meteorology, and indicates, as stated in the remarks, the cordial support that the Washington Office receives from masters of vessels in its efforts to collect and utilize maritime data. There was a marked diminution of fog during the month, and an unusually large amount of ice as far as the 49th meridian, and even south of the 50th parallel.

THE appendix to the Bulletin of the New England Meteorological Society for the year 1888, shows that the number of stations constituting that weather service amounts to 172. The year was, on the whole, cool and wet, and some of the cyclones, of which 88 are classified according to the direction of their paths, were of great violence. Thunderstorms were very numerous, and in some cases destructive. A marked peculiarity of the year was the heavy rainfalls which occurred in the last six months. In the five months August to December the excess was nearly 11 inches. The greatest and least movements of the wind, as shown by anemometrical records, were in March and June respectively; the largest totals for the year were at Blue Hill Observatory.

AT the meeting of the Linnean Society of New South Wales on August 20, Mr. J. H. Maiden read an interesting paper on spinifex resin. The resin examined was a sample obtained by Mr. W. Froggatt near Derby, North-West Australia, last year, and presented by Sir William Macleay to Mr. Maiden. It is in flat cakes, about 3 inches in diameter, has a dirty bronze-green appearance, and a persistent disagreeable odour not easily described. It consists of vegetable *débris* (which may prove to belong to a grass) cemented with a yellowish-brown resin, and containing about 3 per cent. of fat. Mr. Froggatt states that it is employed by the natives as a cement for spear-heads, &c.; and the consistent testimony of the natives, as well as of the Europeans, is that it is obtained from the roots of spinifex grass (*Triodia irritans*, R.Br.). As far as the author knows, the extraction of resin from a grass has never previously been recorded. The resin isolated bears no resemblance to any other Australian resin known to the author.

A SCHEME is now being matured to establish regular training schools for surveyors in the Straits Settlements. The demand for surveyors is very great on the part both of the Government and of private individuals, and this demand is sure to increase with the rapid development of the Malay Peninsula.

TECHNICAL instruction is receiving a good deal of attention in the Central Provinces of India. Under the new scholarship rules, high school scholarships are tenable in the engineering and agricultural classes which were opened last year at Nagpore, and College scholarships have also been reserved for engineering students who desire to study in some Engineering College, or in any superior School of Forestry. At present, the classes at Nagpore are not well attended. In the engineering class, thirty students entered, but only eleven passed the first year's course. It is, however, expected that a large number will enter during the coming session. There was an average of twenty-five students in the agricultural class. In connection with the latter class, the students are compelled to work with their own hands at all the ordinary agricultural processes, and each receives a plot of land, which he is expected to till as directed. Besides practical agriculture, the students are taught mechanical and chemical analyses of soils and practical field-surveying. Gardening and carpentry are also taught. One of the greatest hindrances to the progress of this and similar institutions in India is the dislike of the Brahmins to any manual labour; but the authorities do not despair of overcoming this difficulty.

SOME Italian observers have been recently testing the senses of criminals; and they find these duller than in the average of people. Signor Ottolenghi, in Turin, found, last year, a less acute sense of smell in criminals; and he now affirms the same for taste, which he tested by applying bitter and sweet substances (strychnine and saccharine) in dilute solution to the tongue. He finds also the taste of the habitual criminal less acute than that of the casual offender, and a slightly more acute taste in male than in female criminals. Experiments with regard to hearing were made by Signor Gradenigo (also in Turin); and of 82 criminals he found 55 (or 67·3 per cent.) to have less than the normal acuteness, the greatest inferiority being in the oldest. In female criminals the relations were somewhat better: 15 out of 28 had hearing under the average. The limits of variations in acuteness also appeared to be much wider in criminals than in normal persons. Ear disease was common. Signor Gradenigo attributes these things to bad hygienic conditions of life, and vicious habits.

MESSRS. MACMILLAN AND CO. have issued Part 2, comprising Book II., of the fifth edition of Prof. M. Foster's "Text-book of Physiology." The work has been largely revised.

THE sixth edition of the well-known "Treatise on Dynamics of a Particle," by Prof. Tait and the late Mr. W. J. Steele (Macmillan), has been issued. The work was begun by Prof. Tait and Mr. Steele towards the end of 1852, and first appeared in 1856. "At Mr. Steele's early death," says Prof. Tait in the preface, "his allotted share of the work was uncompleted, and I had to undertake the final arrangement of the whole. In the subsequent editions it has derived much benefit from revision: first by Mr. Stirling of Trinity in 1865, then by Mr. W. D. Niven of Trinity in 1871, and by Prof. Greenhill of Emmanuel in 1878. It last appeared after a general revision by myself, with the assistance of Dr. C. G. Knott and of my colleague Prof. Chrystal. The present edition has been prepared by me, with the assistance of Dr. W. Peddie."

THE second volume of the "Geological Record" for 1880-84 (inclusive) has been issued. It is edited by Mr. W. Topley, F.R.S., and Mr. C. D. Sherborn. The subjects to which the lists of publications relate are physical and applied geology, petrology, meteorites, mineralogy, mineral waters, and palæontology. There is also a division entitled "General," and another deals with maps and sections. A carefully compiled index adds to the value of the work. Mr. Topley and Mr. Sherborn appeal to editors, publishers, and authors to aid them in future labours by forwarding copies of their publications, especially pamphlets separately published, and new series.

MESSRS. DULAU AND CO. will publish, in December, a "Catalogue of British Fossil Vertebrata," by Arthur Smith Woodward and Charles Davies Sherborn. The volume will consist of about 350 pages, and will tabulate the results of researches upon the British fossil Vertebrata since the time of Linnæus. The nature of the type specimen in each case is stated, and, whenever traceable, the museum or collection in which it is now preserved is mentioned. Special attention has been given to the distribution of the Pleistocene Mammalia.

WE have received from Napier, New Zealand, a copy of a pamphlet containing some papers on Maori folk-lore read before the Hawke's Bay Philosophical Institute by Mr. William Colenso. The first is entitled "Ancient Tide-lore and Tales of the Sea," and gives the Maori lore on the cause of the tides, on the sounding, or, as it is styled in Cornwall, the "calling," of the sea. These are followed by other Maori stories from the east coast of New Zealand, translated with explanatory notes. The whole forms one of the most charming contributions to folk-lore that have ever come under our notice.

IN his last Report to the Foreign Office on the agricultural condition of Colombia, the British Consul at Bogota says that the potato is the chief food of the people of the cold part of that country. Two principal varieties are known—namely, the criollas, which are red-skinned and orange-coloured inside, and the ordinary white potatoes. In 1865 the potato disease, which was unknown till that year, attacked the crops, and they have decreased very much in quantity since then. It is worthy of remark that the greater the altitude at which potatoes are planted (they are sometimes planted at a height of above 9000 feet on the mountains) the less tendency is there for the disease to break out, and at the greatest altitudes the disease is almost, if not quite, unknown. With regard to the cinchona industry, the Consul reports that in 1884 the Government of the Republic passed a law for the purpose of promoting the plantation of cinchona, india-rubber, and eucalyptus trees, and the President was authorized to award valuable prizes to the most successful growers of cinchona trees. The trees to be planted were to be of four species, *C. ledgeriana*, *C. officinalis*, *C. lancifolia*, and *C. pitayensis*, but, though the distribution of trees was free, the law has remained a dead letter; no new plantations have been made under its provisions.

A NEW series of experiments upon the vapour-density of aluminium chloride have been made by Profs. Nilson and Pettersson, with the view of deciding the somewhat vexed question of the valency of aluminium. Former experiments of the Swedish chemists led them to the conclusion that aluminium chloride does not become completely vaporized until a temperature of about 800° C. is attained, when the density of the vapour corresponds to the formula $AlCl_3$, this value (4·6) remaining constant until over 1000° C. On the other hand, Messrs. Friedel and Crafts, employing the method of Dumas, found that between 218° and 433° C. the density remains constant at a value (9·2) corresponding to the formula Al_2Cl_6. In order to render their experiments as unimpeachable as possible, Profs. Nilson and Pettersson have made their redeterminations at the lower temperatures by Pettersson and Ekstrand's modification of Dumas method, and have also been enabled by taking advantage of recent improvements in the construction of the Perrot furnace, to extend their observations to a white heat of 1600° C. Taking the higher temperature determinations by Victor Meyer's method first, the platinum apparatus used in the former experiments was discarded for glass and porcelain, as it has been shown that heated platinum has a slightly injurious effect upon the stability of aluminium chloride. Using glass apparatus heated in sulphur vapour (440° C.) the density was found to be 7·5. Heated still further in vapour of phosphorus pentasulphide (518°) the density diminished to 7·16. In stannous chloride vapour at 606° it became reduced to 5·34. The former results with the platinum apparatus at temperatures from 800° to 1000° showed that the density remains constant at about 4·6, corresponding to $AlCl_3$. Using the new Perrot furnace and a porcelain apparatus at 1400°, the density is still found to be not much reduced, 4·26; and at

1600°, the highest temperature attained, the value 4·08 was obtained. It therefore appears that for 600° over 1000° a very small amount of dissociation occurs, probably owing to the influence of a small platinum tube in which the chloride was introduced, as a minute quantity of an alloy of aluminium and platinum was afterwards found. Hence the molecules of $AlCl_3$ must be remarkably stable. The first of the experiments by the method of Dumas was conducted at the temperature of boiling nitrobenzene, 209°; at this temperature the density was 9·9. At the temperature of boiling eugenol, 250°, 9·62. At 301°, in vapour of diphenylamine, 9·55. In mercury vapour, at 357°, 9·34. In volatilized antimony tri-iodide, at 401°, 9·02; while at the temperature of boiling sulphur, the density, according to this method, had diminished to 8·79. From these results the Swedish experimenters conclude that the vapour-density of aluminium chloride decreases continuously and almost regularly up to 800°, when it becomes practically constant for four or five hundred degrees of temperature, and that although the value 9·2 is found somewhere between 200° and 400°, yet this value does not remain constant for a sufficient interval of temperature to enable us to assert the existence of molecules of the composition Al_2Cl_6.

THE additions to the Zoological Society's Gardens during the past week include two Common Marmosets (*Hapale jacchus*) from South-East Brazil, presented by Mr. Stanley Gibson; a Canadian Beaver (*Castor canadensis*) from North America, presented by Mr. J. R. Politzer; a Palm Squirrel (*Sciurus palmarum*) from India, presented by Mr. W. Tweedie; a Green Monkey (*Cercopithecus callitrichus*) from West Africa, presented by Mrs. E. Reeves; a Centipede, presented by Dr. C. H. Bousfield; a Rhesus Monkey (*Macacus rhesus*) from India, two Black-headed Lemurs (*Lemur brunneus*) from Madagascar, two Spur-winged Geese (*Plectropterus gambensis*) from West Africa, a Red and Yellow Macaw (*Ara chloroptera*) from South America, deposited; two Black Storks (*Ciconia nigra*), European, two Mantchurian Crossoptilons (*Crossoptilon mantchuricum*) from Northern China, purchased; a Puma (*Felis concolor*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OBSERVATORIES.—A list of the astronomical observatories of the world, by George H. Boehmer, has just been reprinted from the Smithsonian Report for 1886 (Government Printing Office, Washington, 1889). The work is the outcome of the preliminary account published by Prof. Holden, in 1879, a large amount of material having since been collected by correspondence. The various observatories are arranged under two heads—(1) American, (2) foreign—an alphabetical arrangement being adopted in each case. References are made to 78 American and upwards of 200 foreign observatories, including private observatories. In many cases the particulars are incomplete, but it is hoped that the publication will induce the directors of observatories to communicate to the author any further accounts and corrections which they may deem desirable. Latitudes and longitudes are given in nearly every case, and also a list of past and present directors. Descriptions of the more important observatories and their instrumental equipments are given.

A SPECTROSCOPIC SURVEY OF SOUTHERN STARS.—In a private letter, Mr. R. L. J. Ellery, F.R.S., writes:—"We have been making a spectroscopic *reconnaissance* of southern stars with a 'Maclean' spectroscope on our 8-inch refractor as a kind of 'jackal' list for the great reflector, with which we intend to make a systematic spectroscopic survey of stars between 40° S. and the South Pole. I am sending to the Royal Astronomical Society the first list of 100 stars." This is a most important step, and fills a gap which has been a disgrace to southern science.

THE ASTRO-PHOTOGRAPHIC CONFERENCE.—The *Comptes rendus*, containing the full proceedings of the above Congress, which met at Paris during the past month, have not yet been received. The following, however, are some of the points decided by the Permanent Committee:—

The centre of the plate is to be pointed not more than 5″ distant from the selected point in the heavens, the size of the plate to be 160 millimetres square. The size of the field adopted was 2° square, whilst the *réseau* is to be 130 millimetres square, with lines 5 millimetres apart.

The amount of overlapping decided upon was 5′. Vogel has undertaken the construction and verification of the *réseau*. The distribution of the work among the co-operating Observatories has been completed, and to Greenwich is allotted that from Declination +48 to +40.

Plate glass only must be used for the plates; the chemical formula, however, is left open. The sensitiveness for the Chart and for the Catalogue is to be the same. *Réseau* to be used in both series.

A series of standard plates will be prepared by the Paris Observatory, and the time of exposure must be adjusted so as to compare properly with these standards. There will be one or more *bureaus* established for such Observatories as cannot measure their own plates.

INTERNATIONAL CONGRESS ON CELESTIAL PHOTOGRAPHY.—There was a preliminary meeting of this Congress at Meudon on September 20, to consider the programme that had been drawn up by the Provisional Committee. A few slight alterations were made in the original scheme, but the details of the work were not entered into. It was, however, decided that the greatest latitude should be allowed in the choice of instruments, and that each observer should employ that instrument to which he was accustomed, having no regard to uniformity.

In order to indicate the spectroscopic work included in the programme, a change in the style of the Congress was agreed to. It is henceforth to be the "International Congress on Celestial Photography and Spectroscopy."

A LARGE detailed drawing of the Milky Way—the result of five years' labour—is now on view at the rooms of the Royal Astronomical Society, Burlington House. An explanatory note will be read at the next (November) meeting of the Society.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1889 OCTOBER 20–26.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on October 20

Sun rises, 6h. 35m.; souths, 11h. 44m. 47·5s.; daily decrease of southing, 9·8s.; sets, 16h. 55m.: right asc. on meridian, 13h. 41·3m.; decl. 10° 31′ S. Sidereal Time at Sunset, 18h. 52m.

Moon (New on October 24, 14h.) rises, 1h. 3m.; souths, 8h. 35m.; sets, 15h. 52m.: right asc. on meridian, 10h. 31·5m.; decl. 13° 56′ N.

GEOGRAPHICAL NOTES.

DR. MOHN contributes to the *Scottish Geographical Magazine* a useful summary of our knowledge of the Barents Sea, between Spitzbergen and Novaya Zemlya. The depths of the Barents Sea contrast in a marked degree with those of the Norwegian and Greenland Seas. Between Jan Mayen and Norway, and between Greenland and Spitzbergen, there are depths of upwards of 2000 fathoms, but the bottom of the Barents Sea is found at depths under 300 fathoms. The transition from the great depths in the western part of the Northern Ocean to the shallows of the Barents Sea is marked by an imaginary line drawn between Western Spitzbergen and Tromsö. Here is a submarine plateau, having on its western wall a steep declivity towards the depths of the Northern Ocean, and on its eastern wall a relatively flat sea-bottom rising slowly towards the coasts of Norway, Russia, Novaya Zemlya, and Spitzbergen, and continuing towards the north-east, with only 100 fathoms of water, to between Spitzbergen and Novaya Zemlya. The adjacent Siberian Sea is also characterized by slight depths. The Barents Sea is therefore deepest in its western part. A depreesion of upwards of 200 fathoms in depth projects from here into the middle of the sea eastwards as far as the longitude of Vardö, the part of the bottom lying further east having depths varying between 200 and 100 fathoms, but more generally averaging the latter. The 100-fathom line runs very near the Norwegian coast; here the bottom consequently descends rather quickly from the coast-line. But from Kola, on the Murman coast, the 100-fathom line stretches direct to Novaya Zenlya, and continues in a sinuous direction to the north of this twin island. Further on we find it again in higher latitudes. It incloses Bear Island, and reaches the banks of Western Spitzbergen. On the eastern plain of the Barents Sea, where the depths are mostly a little over 100 fathoms, are found some slight elevations and depressions; the form of the sea-bottom is slightly undulating. As regards the material deposited on the bottom of the Barents Sea, we have acquired some knowledge from the researches of the Norwegian North Atlantic Expedition. The specimens consist of a peculiar sort of clay, different in description from that lying on the bottom of the deep Northern Ocean. Its chief constituent is silica (quartz); it is very poor in carbonate of lime, and is characterized by the existence in it of the shells of a small animal belonging to the Foraminifera, from which our zoologists have given it the name of the Rhabdammina clay. Its colour is dark green. It is probable that this material is derived from the quartz rocks of the surrounding countries, which, by means of the rivers, tides, currents, and drift-ice, have been spread over the sea-bottom. The salinity of the water of Barents Sea is slightly lower than that of the Norwegian Sea, particularly at the surface. The temperature of the water in the Barents Sea exhibits some contrast in its southern and its northern part. The mean annual temperature of the surface is 5° C. at the North Cape, 4° on the Murman coast, from 2° to 1° C. on the west coast of Novaya Zemlya, and 1° C. at Bear Island. In the month of August—the warmest for surface temperatures—the normal temperature of the sea is 9° C. at Söröen (Hammerfest), 8° to 6° and lower on the Murman coast, 5° to 1° at Novaya Zemlya, 2° at Bear Island, and 1° at the South Cape of Spitzhergen. In March—the coldest month for surface temperatures—the temperature of the sea is 2°·4 C. at the North Cape, 1°·4 at Vardö, 0° to − 2° at Novaya Zemlya, a little above 0° at Bear Island, and 1° at the South Cape of Spitzbergen. For the whole year as well as for the warmest and the coldest months, the surface water is consequently warmest at the coast of Finmarken, and coldest in the sea between Novaya Zemlya and Spitzbergen. At the depth of 100 fathoms we have 4° C. off Hammerfest, 3° off the Tana Fjord, 2° off the Fisher Peninsula (Rybatschi Ostrow), 1° off Kola, and 0° along a line running south to north from the 70th to the 75th parallels of latitude, and east to west along the last-named parallel. Similar curves show the other isotherms for 1° to 4°. In the above-named bay, bordered by the 200-fathom line, are found temperatures of from 1° to 3° above zero. At the sea-bottom, irrespective of its depth, the temperature is distributed in the following degrees. Off and near the coast of Finmarken it is upwards of 4° from Vardö to off Hammerfest, and 5° further west. From here the temperature decreases towards the east and towards the north. The current runs in the Barents Sea as a rule along the coast of Finmarken and the Murman coast eastwards, in the eastern part of the sea northwards, and in the northern part, between Novaya Zemlya and Spitzbergen, westward. Along the east coast of Spitzbergen the current sets southwards. The warm Atlantic current, a branch of the Gulf Stream (this name being taken in its widest sense) runs along the coast of Finmarken, curves on leaving the Murman coast towards the north, and turns then to the west towards Bear Island. It fills the sea down to the bottom with its temperate water. This is warmest in the southern branch running eastwards; and it becomes by and by, further on, cooled down by the neighbouring ice-cold water with which it mixes, and which from the northern regions is driven southwards and westwards. The surface of the sea between Spitzbergen and Novaya Zemlya is always covered with drifting ice. The larger animals in the sea being the objects of capture, live on smaller animals. The development and presence of these small organisms is greatly dependent on the temperature of the water. But their presence in a certain place, and to a certain time, depends upon the oceanic currents, these being as a rule so strong, and the locomotive powers of the small animals so small, that these must follow the movements of the currents. The animals living at or on the bottom get their food brought to them by means of the currents.

DR. JULIUS RÖLL, of Darmstadt, in the course of a mission of botanical exploration in the north-west of America, made an ascent in June 1888 of a summit in the Cascade Mountains, hitherto unnamed on our maps. The peak in question is situated under long. 121° 15′ W., and lat. 47° 22′ N., between two small lakes, and about 20 miles north of Easton on the Northern Pacific Railroad. The following is taken from a short account of his excursion contributed by Dr. Röll to the current number of *Petermann's Mitteilungen*. On June 19, in company with Herr Purpus, he made his way through the primæval forest, and over rising ground to the foot of the mountain, pitching his tent at an altitude of 5500 feet. The next morning the actual summit was ascended. It is composed of melaphyr, and many pieces of agate and rock crystal were found. The steep slopes are overgrown with ceanothus bushes, maples, and pines, between which bloom yellowish-red lilies (*Lilium philadelphicum*), and species of dark-red pentstemons. Three successive summits were climbed. The highest was estimated at 7500 feet; unfortunately the exact altitude could not be ascertained, as the traveller's barometer had become useless. The rocky crest of the mountain is covered with the *Selaginella rupestris*, pentstemons, phlox, pedicularis, several saxifrages, and some low umbelliferous plants, &c. Traces of bears, mooses, and mountain sheep were observed. The following day another ascent was made, and a magnificent view of the snow-covered Mount Tacoma obtained. Some weeks later, finding that the peak he had ascended was unnamed, Dr. Röll designated it "Mount Rigi," from the resemblance to the Swiss mountain of that name.

THE question of the influence of wind and rain in valley formation is discussed by Herr Rucktäschel in a short memoir contributed to the current number of *Petermann's Mitteilungen*, abstracted in the Proceedings of the Royal Geographical Society. The author, who has been pursuing his studies in Saxony and elsewhere, ascribes the "one-sidedness" which is observable in so many of the river valleys of Saxony to the action of rainy winds, in the absence of considerations arising from the configuration or composition of the soil. It has been observed that, in the case of most streams in this region flowing through soft sandstone, conglomerate, and diluvial soils, the east, north-east, or south-east bank presents a steep slope, while the opposite shore is flat. The cause is, according to Herr Rucktäschel, to be found in the action of the prevailing south-west, west, and north-west winds, which, heavily charged with rain, precipitate themselves almost at right angles upon the eastern sloping bank of a stream, washing away the soil in much greater quantity than from the western bank, and thus producing the one-sidedness referred to. Similar phenomena have been observed in some of the river valleys of Prussia and Bavaria. The author lays down the following conditions as necessary for the production of these effects by the westerly rain winds:- (1) the soil must be composed of some loose or soft substance, (2) the valley must be eroded to a certain depth, (3) the volume of water in the stream must not be too great in proportion to that washed down the banks. For these reasons the phenomena can occur, as a rule, only along the smaller rivers, a large river; by the force of its own current, shapes its banks, and the influence of the prevailing rain winds is not so noticeable. Herr Rucktäschel visited England last summer to carry out researches there, but was unable to find any river-valleys suited for his purpose.

IT is reported from Hong Kong that the expedition of Mr. Rosset in the as yet unexplored districts of Annam, Cochin China, Cambodia, Siam, and the Laos States has been concluded. Much danger and many difficulties were encountered, but the result has been excellent, and Mr. Rosset will take back with him to Europe a valuable collection illustrative of the ethnology of the regions he has traversed. The journey was divided into three sections. The first comprised the Mekong River, the Chane and Bang-Came Rivers, to Stung-treng, in Siam, 104° to 106° long. and 13° to 14° lat. In this section the tribes of the Brouns or Bruns, the Kongs, and the Bennongs, were visited and studied. The second section of the journey as projected was from the mouth of the River Dongnai in Cochin China up to the frontier, covering the country between 104° and 106° long., and 11° and 12° lat., the special object of study being the ethnology of the Mois tribes. It was found, however, that the route was impracticable, the heavy rains and thickness of the jungle preventing the progress of the caravan, and the expedition was obliged to make a detour into the mountains of Binthuan. The third section of the journey again followed the Mekong River to Kratse, from thence branching east and north-east to the coast of Annam. Approaching Bung U the expedition followed a north-easterly direction to 13° lat. About 25 kilometres south-east of Kratse the River Pree Sé was passed, and the same river was crossed three times in the journey north-east to the coast; also a tributary river called the Sala. In this section the tribes of the Bennongs, Sliengs, Nhongs, and Ahongs were studied.

THE TEACHING OF SCIENCE.[1]

IN a Report presented to the Bath meeting the Committee gave an account of the replies they had received to a letter addressed to the head masters of schools in which elementary chemistry is taught. In this letter the Committee had asked for a report on the chemical teaching, and also for a statement as to the methods which had been found to render the teaching most effective as mental training. In commenting on these replies the Committee pointed out that the evidence which had been collected was conclusive in showing that much of the teaching of elementary chemistry is far from satisfactory, and needs to be considerably modified if it is to effect that valuable mental discipline which science teaching can afford.

[1] Report of the Committee, consisting of Prof. H. E. Armstrong, Prof. W. R. Dunstan (Secretary), Dr. J. H. Gladstone, Mr. A. G. Vernon Harcourt, Prof. H. McLeod, Prof. Meldola, Mr. Pattison Muir, Sir Henry E. Roscoe, Dr. W. J. Russell (Chairman), Mr. W. A. Shenstone, Prof. Smithells, and Mr. Stallard, appointed for the purpose of inquiring into and reporting upon the present methods of teaching Chemistry.

The Committee are convinced that the high educational value of instruction in physical science has never been exhibited to its full advantage in most of our educational institutions. Nevertheless there exists already a considerable body of experience which proves that there is no more effective and attractive method of training the logical faculties than that which is afforded by a properly arranged course of instruction in physical science; by no other means are the powers of accurately ascertaining facts, and of drawing correct inferences from them, so surely developed as they are by the study of this subject.

Since the last meeting the Committee have been actively engaged in discussing the lines which a course of elementary instruction in chemistry should follow. The Committee were the more inclined to offer suggestions of their own, since they had learnt from the replies made to their letter of last year, by teachers in many of our well-known schools, that not only is the necessity for the adoption of improved methods fully recognized, but that teachers are anxious to receive advice and assistance in introducing them.

It cannot be too strongly insisted that elementary physical science should be taught from the first as a branch of mental education, and not mainly as useful knowledge. It is a subject, which when taught with this object in view, is capable of developing mental qualities that are not aroused, and indeed are frequently deadened, by the exclusive study of languages, history, and mathematics. In order that the study of physical science may effect this mental education, it is necessary that it should be employed to illustrate the scientific method of investigating Nature, by means of observation, experiment, and reasoning with the aid of hypothesis; the learners should be put in the attitude of discoverers, and should themselves be made to perform many of the experiments. The lessons ought to have reference to subjects which can be readily understood by children, and illustrations should be selected from objects and operations that are familiar to them in every-day life. Chemistry is particularly well adapted for affording this kind of instruction, and the Committee are of opinion that a course which is mainly chemical will be most useful in developing logical habits of thought.

Chemical inquiry involves, however, the use of various physical processes, and these are themselves of great value from the point of view from which the instruction is being given. It is also of great importance that the learners should become acquainted with the characteristic instrument of physical science, viz. measurement, and therefore quantitative processes should be largely made use of.

Having agreed as to the general principles on which a scheme of elementary instruction in chemistry should depend, the Committee gladly accepted the offer of Prof. Armstrong to draw up an account of such a scheme in sufficient detail to serve as a guide to those who have to provide such teaching. Without pledging themselves to accept all its details, the Committee consider that the scheme which Prof. Armstrong has prepared is in general accordance with their views as to what should constitute a course of elementary instruction in physical science.

With regard to the manner in which the scheme should be carried out, the Committee wish to lay stress on the following points. In order that the plan shall produce its full educational effect, the instruction should be commenced at an early age, and be extended to every child in the school. They do not desire to bring forward physical science as a substitute for any of the other principal subjects of study, but they ask that like these subjects it should be looked upon everywhere as a necessary part of education, and that it should receive a due share of the time devoted to school work. It is well known that at present science-teaching does not generally receive as much time and attention as is given to other studies. This was made clear in the Report of the Committee last year. It will be necessary to allot more time to the subject, and to employ a greater number of teachers. A teacher should not be required to give practical instruction to more than from fifteen to twenty pupils at one time, although the classes at lectures and demonstrations might be somewhat larger.

While the scheme now proposed may involve the employment of a larger number of teachers of natural science, on the other hand fittings and apparatus of the simplest description are all that will be absolutely needed, and the cost of maintenance will be relatively small.

The Committee are aware that the course of instruction now suggested is not in conformity with the present requirements of examining bodies. Its general adoption must therefore depend on their co-operation.

Suggestions for a Course of Elementary Instruction in Physical Science, drawn up by Prof. Armstrong.

Although the Committee is ostensibly charged to report as to methods of teaching *chemistry*, chemistry pure and simple is not what is required in schools generally, and therefore the Committee must be prepared to take into consideration and make recommendations as to a course of instruction preliminary to the natural science course proper, which in their opinion affords the most suitable and efficient preparation for later natural science studies.

After the most careful consideration of the question during at least ten years past, and after long holding the opinion that chemistry as usually understood is not the most suitable science subject for school purposes, I am now of opinion that a course which is mainly chemical is not only the best but also the only one possible if we are to secure all the objects aimed at in introducing science teaching into schools. Those objects are essentially: to train boys and girls to use their brains; to train their intelligence; to make them observing and reasoning beings, accurate observers, and accurate thinkers; to teach them to experiment, and that, too, always with an object—more frequently than not with what may be termed a logical object—not for mere descriptive purposes; to gradually inculcate the power of "doing," on which Charles Kingsley has laid so much stress, and which undoubtedly is the main factor of success in life. It can scarcely be gainsaid that through chemistry more than through any other branch of natural science it is possible to give precisely that kind of "practical" training so requisite at the present day, because the student is able to ascertain *by experiment* what are the exact facts, and thus to arrive independently at an explanation, whereas in the case of other sciences more often than not the explanation of necessity has to be given by the teacher.

Chemistry as usually taught loses greatly in educational value because pupils are told, more often than not, that "so and so is the case," instead of being taught *how it has been found out* that such is the case; indeed, that which has to be proved is usually taken for granted. Practical chemistry has hitherto, as a rule, been interpreted to mean the preparation of a few gases, &c., and the analysis of simple salts. Much useful information may be and is occasionally imparted during the performance of exercises of this kind, but the tendency undoubtedly is for analysis to degenerate into a mechanical drill, and, looking at the question from the practical point of view, and considering what is the general outcome of such teaching, probably we are bound to agree that the results thus far obtained are usually unsatisfactory. The difficulty, however, is to devise a course sufficiently simple both in conception and when carried into practice the cost of which is not too great; but with respect to this item of cost the Committee has to make clear to parents and teachers the claim of natural science to a fair and proportionate share of the total expenditure, which certainly has never yet been granted to it. By the introduction of such studies into the school course, a set of faculties are trained which it is all-important to develop, but which hitherto have been allowed to remain dormant, if not to atrophy, through neglect, and which, it is admitted by all competent authorities, cannot possibly be developed by any amount of attention paid to literary and mathematical studies. It is often not sufficiently clearly stated or understood that the advocates of natural science studies have no desire to displace any of the traditional subjects from the school course, and that all that they ask for is a fair share of the child's time, attention, and brains—a share proportionate to the effect which such studies can demonstrably produce in developing the mental faculties of the individual: that, in fact, natural science claims to co-operate and in no sense puts in an appearance as a rival.

STAGE I.—*Lessons on common and familiar objects.*

The first stage of instruction must be one of simple object-lessons, but these should have an intimate relation to the child's surroundings, and should be made the pegs on which to hang many a tale. Probably the most satisfactory and practical mode of commencing is to get children to draw up lists of familiar and common objects under various heads, such as

Natural objects.

Things used in building construction.

Things from which household furniture is made or which are in daily use.

Things used as clothing.

Food materials.

The children should be induced to describe these from observation as far as possible; to classify them according to their origin into mineral and animal and vegetable or organic; and occasion should be taken at this stage to give by means of reading lessons and demonstrations as much information as possible about the different things, their origin, how made, and their uses. It is obvious that in this way a great deal of geography and natural history (*Naturkunde*) might be taught in an attractive manner. Geikie's "Science Primer on Physical Geography" is the type of book which may be worked through with great advantage at this stage.

STAGE II.—*Lessons in measurement.*

This stage should be entered upon as soon as children have learnt the simple rules of arithmetic, and are able to add, subtract, multiply, and divide, and to use decimals.

Lineal measurements may be first made, using both an English foot-rule with the inch subdivided in various ways and a metric rule subdivided into millimetres. In this way the relation of the two scales is soon insensibly learnt.

Measurements of rectangular figures and the calculation of their areas may then be made.

After this the use of the balance may be taught, and the relation between the English and French systems may be learnt by weighing the same objects with the two kinds of weights. Use may then be made of the balance in determining the areas of irregular figures by cutting out rectangular and irregular figures from the same cardboard or thin sheet metal, and weighing these, &c.

Solid figures are next studied: a number of cubes made from the same wood having been measured, their volumes are then calculated, and the results thus obtained are compared with those which are obtained on weighing the cubes. The dimensions and weights of cubes made from different woods or other materials are then ascertained, and thus it is observed that different materials differ in *density*. The study of the *relative density* of things generally is then entered upon. The ordinary method is easily learnt and used by children, a suitable bottle being provided by filing a nick down the stopper of a common two-ounce narrow-mouth bottle; it may then be shown that the same results are obtained by the hydrostatic method of weighing in air and water, and it is not difficult to lead children to understand this latter method after they have determined the heights of balancing columns of liquids, such as turpentine, water and saturated brine, of which they have previously ascertained the relative density. These hydrostatic experiments are of value at a later stage in considering the effects of atmospheric pressure.

By determining the dimensions of a cube and the weight of the water which it will displace, an opportunity is afforded to point out that if the results are expressed in cubic centimetres and grammes respectively there is a practical agreement between the numbers, and hence, to explain the origin of the metric system of weights and the relationship between its measures and weights; the irrationality of the Ehglish system may then be explained.

The relative densities of a large number of common substances having being ascertained, the results may be tabulated and then the value of the data as criteria may be insisted on; as an illustration of their value, quartz, flint, sand, and gravel pebbles may be selected. The children having determined their relative densities, the agreement between the results may be pointed out and the identity of the material explained. By drawing perpendiculars corresponding in height to the densities of various substances, a graphic representation is obtained which serves to bring out the value of the graphic method of representation.

A very valuable exercise to introduce at this stage is based on the well-known fact that in certain conditions of the atmosphere things appear moist; a muslin bag full of seaweed may be hung up under cover but freely exposed, and may then be weighed daily at a given time; simultaneously the state of the weather, direction of the wind, the height of the barometer, and the wet and dry bulb thermometer may be noted; on tabulating the results, and especially if the graphic method be employed, the variations and their relationship will be noticeable.

The thermometer, having thus become a familiar instrument, may be used to examine melting ice and boiling water; the construction of both the Centigrade and Fahrenheit thermometer may then be explained, and the effect of heat on bodies made clear. The density of ice and of water at various temperatures may then be determined, a Sprengel tube—which is easily made—being used for warm water; the bursting of pipes in winter, the formation of ice on the surface of water, &c., may then be explained. Afterwards simple determinations of the heat capacity of a few metals, &c., and of the latent heat of water and steam, may be made in accordance with the directions given in a book such as Worthington's "Practical Physics."

STAGE III.—*Studies of the effect of heat on things generally; of their behaviour when burnt.*

As it is a matter of common observation that heat alters most things, the effects of heat on things generally should be studied; in the first instance qualitatively, but subsequently, and as early as possible, quantitatively. Bits of the common metals may be heated in the bowl of an ordinary clay pipe plunged into a clear place in any ordinary fire, or in such a pipe or a small iron spoon over a gas flame. The difference in fusibility is at once apparent, and in the case of metals like iron and copper it is noticeable that although fusion does not take place, a superficial change is produced; the gradual formation of a skin on the surface of fused lead and tin is also easily perceived. Observations like this become of great importance at a later stage, and indeed serve to suggest further experiments: this is a point of special importance, and from the beginning of this stage great attention should be paid to inculcating habits of correct observation; the effect should first be recorded by the pupil, the notes should then be discussed and their incompleteness pointed out, and they should afterwards be re-written. The fusibility of substances which are not affected when heated in the tobacco pipe may be tested by heating them with a Fletcher gas blow-pipe on charcoal; and by heating little bits of wire or foil in such a flame it is easy for children to discover the changes which metals undergo when burnt, especially in cases such as that of zinc or copper or iron.

The further study of the effects of heat should be quantitative, and may well commence with water. It being observed that water disappears on heating, water may be put into a clock glass or glass dish placed on a water bath (small saucepan); it evaporates, and it is then observed that something is left. A known quantity of water by weight or volume is therefore evaporated and the residue weighed. This leads to the discovery that water contains something in solution. The question then naturally arises, What about the water that escapes? so the steam is condensed and the distilled water evaporated. The conception of pure water is thus acquired. An experiment or two on dissolution—using salt and sugar—may then be introduced, a water oven or even an air oven (a small Fletcher oven) kept at a known temperature being used, and the residue dried until the weight is constant. Rain and sea-water may next be examined; the results afford an opportunity of explaining the origin of rain and of accounting for the presence of such a large quantity of dissolved matter in sea-water. Then the various common food materials may be systematically studied, commencing with milk; they should first be dried in the oven, then carbonized and the amount of char determined, then burnt and the percentage of ashes determined. A small platinum dish, 15 to 20 grammes in weight, is required for these experiments, and a gas muffle furnace is of the greatest use in burning the char and in oxidizing metals. In addition to the discipline afforded by such experiments a large amount of valuable information is acquired, and the all-important fact is established that food materials generally are combustible substances. Afterwards mineral substances are examined in a similar manner, such as sand, clay, chalk, sulphur, &c., and then metals such as lead, copper, tin, and iron may be studied; their increase in weight is in striking contrast to the inalterability of substances like sand and salt, and the destruction of vegetable and animal substances. Chalk, from which lime is made by burning, is found to occupy a middle position, losing somewhat in weight when strongly heated. The exceptional behaviour of coal among mineral substances, and of salt among food materials, is shown to be capable of explanation, inasmuch as coal is in reality a vegetable and salt a mineral substance; but sulphur remains an instane of exceptional behaviour requiring explanation. It is not exceptional in being combustible, as metals like magnesium and zinc are combustible, but in affording no visible product. The smell of burning sulphur, however, serves to suggest that perhaps, after all, there is a something formed which is an invisible substance possessed of an odour, and then follows quite naturally the suggestion that perhaps in other cases where no visible or perceptible product is obtained—as on burning charcoal, for instance—there may nevertheless be a product. Whereas, therefore, in Stage I. the pupil will have learnt to appreciate the existence of a great variety of substances, and will have gained the power of describing their outward appearance more or less fully; and in Stage II. having learnt how to measure and weigh, will acquire the habit of determining by measurement certain properties of substances, and will thus be in a position to express in exact terms the kind of differences observed; in Stage III. the pupil will be led to see that profound changes take place on burning substances, and that these changes involve something more than the destruction of the things burnt. The foundation is thus laid for the study of change, *i.e.* chemical studies proper.

STAGE IV.—*The problem stage.*

Many of the changes observed in the course of the experiments made in Stage III. might be examined and their nature determined, but the best to take first is a very familiar case, that of the rusting of iron.

PROBLEM I. *To determine what happens when iron rusts.*—The pupil *must* be led in the first instance to realize that a problem is to be solved, and that the detective's method must be adopted and a *clue* sought for. It is a familiar observation that iron rusts, especially when wet; what happens to the iron, why does it rust, is the iron alone concerned in the change? No information can be gained by looking at it—perhaps the balance which has brought to light so much in Stage III. may be of service, so the iron is allowed to rust in such a manner that any change in weight can be observed. A few grammes of iron filings or borings are put on to a weighed saucer or clock glass along with a bit of stiff brass or copper wire to be used as a stirrer; the iron is weighed, then moistened and exposed under a paper cover to keep off dust, preferably in a warm place; it is kept moist and occasionally stirred. After a few days it is dried in the oven and then weighed. The weight is greater. *Something from somewhere has been added to the iron.* Thus the clue is gained. Where did this something come from? The fact that when a tumbler, for instance, is plunged mouth downwards into water the water does not enter, and that on gradually tilting the tumbler to one side something escapes—viz. air—at once affords a demonstration of the presence of air in the space around us. The iron rusted in this air, but was kept moist, so it may have taken up the something from either the air or the water. To ascertain whether the air takes part in the rusting, some iron borings are tied up in a bit of muslin and the bag is hung from a wire stand placed in a (jam) pot full of water and a so-called empty (pickle) bottle, which in reality is full of air, is inverted over the iron; in the course of a few hours, as the iron rusts, the water is observed to rise until it occupies about one-fifth of the jar (determined by measuring or weighing the water); the something added to the iron during rusting appears therefore to come from the air, and the all-important fact is thus discovered that the rusting is a change in which not the iron alone, but also the air, is concerned. The experiment is several times repeated, fresh iron being used with the same air and the same iron put in succession into fresh portions of air, but the same result is always obtained: whence it follows that whatever it is in the air which takes part in the rusting, the air as a whole is not active. The changes previously observed to take place when iron, copper, lead, zinc, &c., were heated in air, are then recalled; as the metals were found to increase in weight, it would appear probable that in these cases of change also the air was concerned.

These results at once suggest the question, What is air? So much having been learnt by studying the change which iron undergoes in rusting, other changes which happen in air therefore are next studied.

PROBLEM II. *To determine the nature of the changes which take place on burning substances in air.*—The use of phosphorus is introduced by reference to a match. Phosphorus is then burnt under a bell jar over water and the result noted: the disappearance of some of the air again shows that the air is concerned. The fact that phosphorus smokes when taken out of the water in which it is always kept suggests that some change is going on, so a stick of phosphorus is exposed in air as in the previous experiment with iron: soon one-fifth has disappeared, and the phosphorus then ceases to smoke. The *quantitative* similarity of the two results suggests that iron and phosphorus behave alike towards air, and *vice versâ*, and serves to confirm the idea that some constituent of the air present only to the extent of about one-fifth is active. But nothing is to be taken for granted, so iron is exposed in the phosphorus-air residue and phosphorus in the iron-air residue: as no change occurs, there is no room left for doubt. Recalling the experiments in which various metals were burnt in air, in order to determine whether in these cases the same constituent of the air was concerned in the change, air from which the active constituent has been removed by means of phosphorus is passed through a heated tube containing bits of the metals: no change is observed, so it is evident that as a rule, if not always, one and the same constituent of air is concerned. The experiments with iron and phosphorus, although they show that the air is concerned in the changes which are observed to take place, do not afford any information whether or no the water which is also present is concerned in the change. Phosphorus is therefore burnt in a "Florence" flask closed with a rubber stopper: on removing the stopper under water some water enters, and by measuring this and the amount of water which will fill the flask the same result is obtained as in the previous cases. To be certain whether in this case anything enters or escapes from the flask it is weighed before and after the phosphorus is burnt. There is no change in weight. But does nothing escape? Yes, much heat; whence it follows that heat is not material—that, although some of the air disappears, it is merely because it has become affixed to or absorbed by something else. This has been proved in the case of the rusting iron and the burnt metals. To obtain indisputable evidence in the case of the phosphorus this is burnt in a current of air in a tube loosely filled with asbestos to retain the smoke: the weight is found to increase. The observation that the phosphorus ceases to burn after a time suggests the introduction of a burning taper into the residue left by iron, &c.; it is found to be extinguished. Then a candle and subsequently a gas flame may be burnt in a bell jar full of air over water. Reversed combustion may then be demonstrated in order to fully illustrate the reciprocal character of the phenomena. Thus it is ascertained that all ordinary cases of combustion are changes in which the air, and not the air as a whole but a particular constituent, is concerned, and no doubt remains that the same constituent is always active, but active under different conditions; it is realized also that the production of heat is the consequence of the union of the substance burnt with the active substance in air. The experiment of exposing phosphorus in air affords the opportunity of demonstrating the evolution of heat even in a case where no visible combustion occurs, as the phosphorus is always observed to melt. At this stage careful note should be taken of the appearance of the different products of combustion, and of a change such as that which occurs when the product from phosphorus is exposed to the air.

PROBLEM III. *To separate the active from the inactive constituent of air.*—It now has become of importance to get this active constituent of the air by itself, and the question arises whether it cannot be separated from one of the metals or other substances with which it has been found to combine. The pupil is therefore told to collect information about the different substances formed by burning metals, &c.,—whether they can be obtained in sufficient quantity to work with, &c. Iron rust and iron scale are easily obtainable, and so is copper scale; zinc is burnt to produce zinc white, which is used as paint; lead is also burnt on a large scale, and in this case it appears that one or other of two substances is formed—litharge at a high temperature, red lead at a lower temperature. This peculiarity of lead suggests the study of the two products in the hope of discovering the clue to a method. Weighed quantities of the litharge and red lead are heated; it is observed that only the latter changes in appearance and that it loses weight. But what does it lose? It was formed by merely roasting lead in the air, and the something which it loses must therefore have been derived from the air. If the red lead is heated in a tube a gas is given off which is collected and tested—how? With a taper or glowing splinter as it is to be supposed that the gas will support combustion if, as is to be expected, it is the active constituent of air. The *discovery* of the active constituent of air is thus made! If air consist of this gas and that which remains after exposing phosphorus or iron in air, then by adding to such residual air as much of the gas from red lead as was withdrawn, air should be re-obtained; this is found to be the case. The names of the two gases are now *for the first time* stated, and an easy method of preparing oxygen is demonstrated, such as that of heating chlorate, but without any explanation. The conclusion previously arrived at, that probably in all the cases previously studied of changes occurring in air, the oxygen is the active substance, may now be verified by burning or heating in oxygen the substances which had been burnt in air.

So much having been learnt of the chemistry of air, the study of the pressure exercised by air may next be taken up, and the common pump, the force pump, the barometer, and air currents may be discussed and explained. Nowadays the charts given in the daily papers, and the Ben Nevis and glycerine barometer readings quoted in the *Times* make it particularly easy to explain the barometer. The pupils should be led to make barometer curves.

PROBLEM IV. *To determine the composition of chalk.*—The discovery of the *composition* of the air in the course of experiments made with the object of determining the nature of certain changes naturally suggests that the attempt be made to ascertain the composition of other things by studying the changes which they undergo. Chalk is known to give lime when burnt, and experiments made in Stage III. have indicated that chalk loses something when burnt—the idea that an invisible something is given off is especially probable after the experiments with red lead have been made; so it is decided to heat chalk strongly, but before doing this chalk and lime are examined comparatively. Chalk is not observed to be altered by water; on shaking it up with distilled water and evaporating some of the filtered liquid in a weighed dish, very little residue is obtained—so it is established that it is but very slightly soluble in water. Lime is slaked, weighed quantities of lime and water being used; the retention of a considerable amount of water, even after exposing the slaked lime in a drying oven, shows that the slaking involves a definite change in composition—that slaked lime is lime and water. The solubility of the lime is next determined, and found to be considerably greater than that of the chalk. It is found that chalk is but very slightly altered in weight when heated over a gas flame, and that it is only when it is strongly heated that it is converted into lime: so the chalk is strongly heated in an iron tube in a Fletcher blow-pipe furnace, when gas is freely given off. This is tested with a taper, which it extinguishes, so it cannot be oxygen, but may be nitrogen; if it be nitrogen, when mixed with oxygen in the proportion of 1 to 4, it should give air, but this is found not to be the case; so evidently it is a peculiar gas, and may be called chalk gas. If chalk consist of this gas and lime it should be possible to reproduce chalk from them; so the gas is passed through a small weighed tube containing lime, and the tube is found to get heavier. But lime and chalk are so much alike that it is difficult to say that chalk is formed; perhaps dissolved lime will act similarly; the gas is therefore passed into or shaken up with lime water. The precipitate which forms looks like chalk and probably is, but this remains to be decided. The discovery of this behaviour of chalk gas, however, is important as affording a means of again comparing the gas from chalk with nitrogen. In working with lime water it is scarcely possible to avoid noticing that a film forms on its surface; by exposing a quantity of the lime water a considerable amount of the precipitate is obtained; its resemblance to chalk is noted, and the possible presence of chalk gas in air is thus suggested; but in view of the absence of proof of the identity of the precipitates with chalk a decision is reserved. The discovery is made, however, that air contains something besides oxygen and nitrogen.

It being thus established that chalk consists of two things, lime and chalk gas, at this stage it is pointed out how firmly these two constituents hold to each other in the chalk. The absorption of the gas by the lime—its entire disappearance in fact—is commented on. Accurate determinations of the loss of weight on heating crystallized chalk (calc-spar) should at this stage be carried out before the class, if not by the pupils, so that the numbers may be quoted and that it may become impressed on them that the proportions in which the lime and chalk gas are present is constant. Their attention may be recalled to the oxides previously studied, it being pointed out that on inspection these afford no indication that they contain oxygen; that here again the gas entirely loses its individuality on entering into union or combining. That oxides contain their constituents in fixed proportions may be demonstrated experimentally by oxidizing finely-divided copper and determining the increase in weight, lime being used as drying agent. In this way the characteristics of *compounds* are elucidated. Then the comparison may be made with air, and the fact made clear that it behaves as a mere mixture. Still no reference should be made to elements.

PROBLEM V. *To determine what happens when organic substances are burnt.*—The experiments thus far made have shown that phosphorus and a number of metals burn in the air because they combine with the oxygen, forming oxides, heat being given out *as a consequence;* but that chalk when burnt is split up or decomposed into lime and chalk gas, this result being a consequence of the heating alone, the air having nothing to do with it. It remains to ascertain what happens when organic substances are burnt, as these give no visible product beyond a little ashes. As in all cases when vegetable or animal substances are burnt a certain amount of "char" is obtained, which then gradually burns away, charcoal or coke is first studied. It having been discovered that the oxygen in air is the active cause of burning in many cases, it appears probable that the air is concerned in the burning of charcoal, coal, &c. As when once set fire to, these continue to burn, the charcoal is at once heated in oxygen: it burns, but no visible product is formed; it therefore follows that if the charcoal is oxidized the oxide must be an invisible gas. How is this to be tested for? What gases are already known to the pupil? How are these distinguished? Oxygen is excluded. Is it perhaps nitrogen, and is not perhaps the nitrogen in air merely used-up oxygen as it were, produced by the burning of organic substances? Or is it perhaps that gas which was found in the air along with oxygen and nitrogen, and which turned lime water turbid? This last being an easy test to apply is at once tried; the lime water is rendered turbid, and so to leave no doubt a sufficient amount of the gas is prepared and passed into lime water, the precipitate is collected, and the loss it suffers on heating is determined and found to agree with that suffered by the precipitate prepared from chalk gas. Finally, to ascertain whether the product is really heavier than the charcoal burnt, as in the case of the metals previously studied, the charcoal is burnt in oxygen in a tube connected to a flask containing milk of lime with a lime-drying tube attached to it; the tube is weighed before and after burning. Thus the discovery is made that chalk gas is an oxide of carbon, and that chalk consists of at least three things.

It may be objected that to make the experiment in this manner takes too much time; but to this it may be answered that such experiments are precisely of the kind of those made in actual practice, and that they exercise a most important influence in teaching the pupils to take nothing for granted, never to jump at conclusions, and to rest satisfied if they progress surely, however slow the advance may be.

A number of organic substances may now be burnt, and the gas passed into lime water; chalk gas is found in every case to be a product, and hence the presence of a common constituent—carbon—in all is established. In making these experiments the formation of a liquid product is observed, so it is evident that chalk gas is not the only product, or carbon their only constituent.

Food materials generally having been found to contain "carbon," as they are obviously in some way destroyed within the body, and it is known that air is necessary for life, the question arises, what becomes of food, and why is air necessary for life? Is the food, perhaps, in large part "burnt up" within the body, thus accounting for the fact that our bodies are always warm? The characteristic product of combustion of carbonaceous substances is therefore tested for by breathing into lime water. The discovery thus made affords an opportunity for a digression and for explaining how plants derive their carbon from the air.

PROBLEM VI. *To determine what happens when sulphur is burnt.*—From the results of the experiments with carbon, it appears probable that the disappearance of sulphur when burnt is also really due to its conversion into a gaseous oxide, so it is kindled and introduced into oxygen: if it be burnt over water in a bell jar in a spoon passing through the stopper (a rubber cork), the water is seen to rise; if, on the other hand, it be burnt in a dry flask closed by a rubber cork carrying a gauge-tube, as suggested by Hofmann,[1] the volume is seen to be almost unchanged after combustion. It follows, therefore, that the sulphur and oxygen unite and form a soluble product. Sulphur is next burnt in a tube in a current of oxygen, and the gas is passed into water; a solution is thus obtained having the odour of the gas and sour (acid) to the taste. The fact that carbon and sulphur—both non-metals—behave alike in yielding gaseous oxides suggests that a comparison be made of their oxides; so the acid solution is added to lime water; a precipitate is formed, which redissolves on adding more of the sulphur gas solution; on the other hand, on adding the lime water to the acid liquid, this latter after a time loses its characteristic smell. There can be no doubt, therefore, that the sulphur gas does in some way act upon the lime. The experiment is then made of burning the sulphur in a weighed tube containing lime; the weight increases, so that no doubt remains that sulphur, like carbon, forms an oxide when burnt. The discovery that the addition of more of the sulphur oxide leads to the dissolution of the precipitate which it first forms in lime water, suggests trying the effect of excess of the carbon oxide on the lime water precipitate; this is done, and the discovery is made that the precipitate gradually dissolves. The solubility of the new substance may then be determined by passing the gas into water containing chalk in suspension, filtering, and evaporating. This leads to the observation that a precipitate is formed on heating the liquid, and this is soon found to be chalk. An opportunity is thus afforded of explaining the presence of so much "chalk" in water; of demonstrating its removal by boiling and by lime water; and the effect it has on soap.

The observation that the oxides of both carbon and sulphur combine with lime suggests trying whether the one will turn out the other; so the solution of the sulphur oxide is poured on to chalk: effervescence is observed, and on passing the gas into lime water a precipitate is obtained. The production of this effect by the *acid* solution suggests trying common vinegar—a well-known *acid* substance. This also is found to liberate chalk gas, and the discovery of an easy method of preparing chalk gas is thus made. The oxide formed on burning phosphorus, having previously been found to give an acid solution, is tried, and it is found that it also liberates chalk gas. As a good deal of vinegar is found to give very little chalk gas, the question arises, Are there not acids to be bought which will have the same effect and are stronger and cheaper? On inquiry it is found that sulphuric acid or oil of vitriol, muriatic acid or spirits of salts, and nitric acid or aquafortis may be bought, and that these all act on chalk. The behaviour of chalk with acids affords a means of testing the lime water precipitate obtained in working out Problems IV. and V. In this manner the pupil is led to realize that certain agents may very readily produce effects which are only with difficulty produced by heating—that the *chemical agent* may produce very powerful effects. The ready expulsion of the carbon oxide of chalk suggests that other substances not yet studied, such as the metals, when treated with acids may behave in a special manner which will afford information as to their nature. At this point, prior to making the experiments with the acids, an explanation may be given of the names *oil of vitriol, spirits of salts*, and *aquafortis;* the processes by which they are made may be described and illustrated, without, however, any attempt being made to explain them from the chemical point of view. The sulphuric acid should be made from green vitriol, and its behaviour on dilution should be demonstrated as well as its use as a drying agent.

PROBLEM VII. *To determine what happens when metals are heated with acids.*—Iron, zinc, lead, tin, copper, and silver may be taken. On pouring diluted oil of vitriol on to iron or zinc, the metal dissolves with effervescence; the gas is collected, and when tested is found to burn. Thus a new gas is discovered, differing from all which have previously been studied, inasmuch as it is combustible; in order not to interrupt the study of the action of acids on metals, however, its further examination is postponed for a while. Resuming the experiments with metals, lead, tin, copper, and silver are found not to be acted upon by diluted oil of vitriol.

Muriatic acid, in like manner, dissolves iron and zinc and also tin with effervescence, and the gas which is given off in each case exhibits the same behaviour as that obtained from iron or zinc and diluted oil of vitriol. Lead, copper, and silver are not appreciably affected.

Aquafortis is found to dissolve not only iron and zinc but also copper, lead, and silver, and to convert tin into a white substance—to attack all the metals in fact, thus justifying its name. The gas which is given off as the metal dissolves is observed to be coloured; when it is collected over water, however, it is seen to

[1] By burning carbon also in this way a most effective demonstration is given of the fact that no loss or gain of matter attends the change, and that only heat escapes; the results in the case of carbon and sulphur are particularly striking, as the products are gaseous and invisible.

be colourless, and to become coloured on coming into contact with air—oxygen and nitrogen are, therefore, added to portions of the gas over water. In this manner, not only is a new gas discovered, but also a test for oxygen; and opportunity is afforded of here calling attention to the fact that air behaves exactly as oxygen, that the oxygen in air appears to be unaffected by its association with nitrogen—that, in fact, it is uncombined. From these experiments it is obvious that metals and acids interact in a variety of ways. Finally, the dissolution of gold and platinum by aqua regia may be demonstrated.

PROBLEM VIII. *To determine what happens when oxides are treated with acids.*—In the course of the previous experiments a number of oxides have been prepared by burning various metals in air; these are found to be unchanged by water. The discovery that acids act on metals suggests a trial of the effect which acids will have on their oxides; so the oxides of zinc, iron, copper, and lead are submitted to the action of the three acids previously used. Sulphuric acid is found to dissolve zinc oxide, iron rust, and copper oxide, but no gas is evolved; excess of the oxide may be used, and the filtered liquid concentrated; the crystals which separate may be examined and compared with those obtained by dissolving the metal in sulphuric acid, &c. Litharge apparently is not changed by sulphuric acid, but red lead is, although not dissolved. Muriatic acid being used, all the oxides are found to dissolve, and in the case of red lead a greenish-yellow gas is given off possessing a most disagreeable smell: this is noted as a case for study. The product from the lead oxides is observed to crystallize out from the hot liquid on standing, so the undissolved original product is boiled up with water, and the solution is filtered, &c. Attention is thus directed to the difference in solubility of the products. Next, aquafortis is used; again all are dissolved, except the red lead, which, however, is obviously altered. In the case of the lead oxides the product is again less soluble than those afforded by the other oxides, but more soluble than the product obtained on using muriatic acid. The pupil has already been led to realize that of two substances capable of acting on a third, such as chalk gas and sulphur gas, which both combine with lime, one may be the stronger, and may turn out the other, sulphur gas turning out chalk gas from chalk. A comparison of the three acids with the object of ascertaining which is the strongest is therefore suggested: the metal or oxide is dissolved in one of the acids, and the others are then added. No positive result is obtained in case of zinc, iron, or copper, but the solution of lead in nitric acid is precipitated by muriatic and by sulphuric acid; the former precipitate is found to dissolve in boiling water and to crystallize out in exactly the same way as the substance obtained from lead oxide and muriatic acid. The sulphuric acid product is found to be almost insoluble in water, and also in muriatic and nitric acids: these observations make it possible, by examining the behaviour towards muriatic and nitric acids of the products of the action of sulphuric acid on the lead oxides, to establish the fact that the product is the same whether lead be dissolved in nitric acid and sulphuric acid be then added, or whether either of the oxides be treated with sulphuric acid. It is further evident that those acids which give difficultly soluble or insoluble products act with difficulty if at all on the metal. Other metals besides those mentioned may be now studied, and, a solvent being found, the acids which do not dissolve the metal may be added to the solution. In this way, for example, the chloride test for silver is discovered.

In experimenting with acids the pupils can hardly fail to stain their clothes and their fingers. The observation that acids alter colours serves to suggest experiments on the action of acids on colours, especially those of leaves and flowers. The use of litmus, methyl-orange, cochineal, &c., may then be explained. As various oxides have been found to "neutralize" acids, the study of their effect on the colours altered by acids is suggested. Lastly, a few experiments with vegetable and animal substances, sugar, &c., may be made, which demonstrate the corrosive action of oil of vitriol and aquafortis.

PROBLEM IX. *To determine what happens when the gas obtained by dissolving iron or zinc in sulphuric or muriatic acid is burnt.*—The gas has been observed to burn with a smokeless, odourless flame. To ascertain whether, as in all other cases of combustion previously studied, the oxygen of the air is concerned in the combustion, a burning jet of the gas is plunged into a dry cylinder full of oxygen, in which it is not only seen to continue burning, but it is also noticed that drops of liquid condense on the cylinder above the flame; this immediately suggests that the product is a liquid. The jet is found to be extinguished in nitrogen, so evidently when the gas burns it forms an oxide. The experiment is repeated, and the gas burnt in a bell jar full of oxygen over water: the water rises as the combustion proceeds, proving that the oxygen is used up. To collect a sufficient quantity of the product for examination, the dried[1] gas is burnt at a jet underneath a Florence flask through which a stream of cold water is allowed to circulate: the neck of the flask is passed through the neck of a bell jar and the flask and bell jar are clamped up in an inclined position, so that the liquid which condenses may drop into a small beaker placed below the rim of the jar. What is the liquid? It looks very like water, and is without taste or smell. Is it water? How is this to be ascertained? What are the properties of water? The knowledge previously gained here becomes of importance. It has been observed that frozen water melts at 0° C., that water boils at 100°, and that one cubic centimetre weighs one gramme at 4° C.; so the liquid is frozen by the ice-maker's mixture of ice and salt, a thermometer being plunged into it so that the solid ice forms on the bulb: the melting-point is then observed. Subsequently the boiling-point is determined, a little cotton-wool being wrapped around the bulb of the thermometer. Lastly, the density of the liquid may be determined. It is thus established that the gas yields water when burnt, and the name of the gas may now *for the first time* be mentioned and explained. The results thus obtained leave little doubt that water is an oxide of hydrogen; but in order to place this beyond doubt it is necessary to exclude nitrogen altogether. How is this to be done? Red lead is known to consist of lead and oxygen only, and readily parts with a portion at least of its oxygen; so dried oxygen is passed over red lead, which is then gently heated. Again a liquid is obtained which behaves as water, so there can be no doubt that water is an oxide of hydrogen. Water is not obtained on merely mixing oxygen and hydrogen; it is only produced when combustion takes place. To start the combustion a flame is applied to a small quantity of a mixture of the two gases: a violent explosion takes place. An opportunity is here again afforded of calling attention to the entire change in properties which takes place when the compound is formed. On heating red lead in hydrogen, lead is obtained, although on heating it alone it loses only a portion of its oxygen, and the "reduction" takes place very readily; evidently, therefore, hydrogen is a powerful agent. This observation suggests further experiments. Will it not be possible to remove oxygen by means of hydrogen from other oxides which are not altered on heating? and will not other combustible substances besides hydrogen remove oxygen from oxides?

PROBLEM X. *To determine what happens when hydrogen and other combustible substances are heated with oxides.*—Zinc oxide, iron rust, and copper oxide are now heated in a current of hydrogen: the first remains unaltered, the other two are seen to change, a liquid being formed which it cannot be doubted is water; the copper oxide evidently becomes reduced to copper. Is the iron rust similarly reduced to the metallic state? How is iron to be tested for? Iron is attracted by the magnet, and dissolves in diluted oil of vitriol with evolution of hydrogen. Applying these tests, no doubt remains that the iron rust is deprived of its oxygen.

Litharge and copper oxide may then be mixed with soot or finely powdered charcoal and heated in tubes; gas is given off which renders lime water turbid, and metallic lead or copper is obviously obtained. It is thus established that some but not all oxides may be deprived of their oxygen by means either of hydrogen or carbon. Opportunity is here afforded of explaining the manufacture of iron.

Several dried combustible organic substances, sugar, bread, and meat, may now be burnt with copper oxide in a tube the fore part of which is clean and is kept cool: liquid is seen to condense, while "chalk gas" is given off; the liquid has the appearance of water, and sufficient may easily be obtained to ascertain whether it is water. The presence of hydrogen in organic substances is thus discovered; its origin from water may now be explained, and the double function of water in the plant and animal economy may be referred to—viz. that it both enters into the composition of the animal and plant structure and also acts as a solvent. The combustion of ordinary coal gas, of alcohol, of petroleum, of oil and of candles, may then be

[1] The importance of drying the gas is realized without difficulty, as previous observations have shown that the air is moist, and as the gas is given off in presence of water, lime may be used.

studied, and the presence of hydrogen in all of these noted.

PROBLEM XI. *To determine whether oxides such as water and chalk gas may be deprived of oxygen by means of metals.*—It being found that hydrogen and carbon withdraw the oxygen from some but not from all metals, it follows that some metals have a stronger, others a weaker, hold upon or "affinity" to oxygen than has either hydrogen or carbon; the question arises whether any and which metals have so much greater an affinity to oxygen that they will withdraw it from hydrogen and carbon. Copper and iron have been found to part with oxygen, but zinc and magnesium did not, so these four metals may be studied comparatively. Steam is passed through a red-hot copper tube full of copper tacks: no change is observed. The experiment is repeated with an iron tube charged with bright iron nails: a gas is obtained which is soon recognized to be hydrogen, and on emptying out the nails they are found to be coated with black scale. Zinc and then magnesium are tried, and, like iron, are found to liberate hydrogen. Chalk gas is next passed over red-hot copper, and is found to remain unchanged, but on passing it over red-hot iron or zinc a gas is obtained which burns with a clear blue smokeless flame: this gas is not absorbed by milk of lime, but on combustion yields chalk gas, so it evidently contains carbon, and is a new combustible gas. Like hydrogen, it is found to afford an explosive mixture with oxygen. Finally, magnesium is heated in chalk gas: it is observed to burn, and the magnesium to become converted into a blackish substance unlike the white oxide formed on burning it in air. But it is to be expected that this oxide is produced, and to remove it, as it is known from previous experiments to be soluble in muriatic acid, this acid is added: a black residue is obtained. What is this? Is it not probable that it is carbon? If so, it will burn in oxygen yielding chalk gas. So the experiment is made. These experiments in which hydrogen is obtained from water and carbon from chalk gas afford the most complete "analytic" proof of the correctness of the conclusions previously arrived at regarding water and chalk gas, and which were based on "synthetic" evidence; taken together, they illustrate very clearly the two methods by which chemists determine composition.

As hydrogen and carbon form oxides from which oxygen may be removed by means of some metals but not by all, the question arises, Which has the greater hold upon or affinity to oxygen—carbon or hydrogen? As it is the easiest experiment to perform, steam is passed over red-hot charcoal: a combustible gas is obtained which yields water and chalk gas when burnt, so evidently the hydrogen is deprived of its oxygen, and this latter combines with the carbon, forming the combustible oxide of carbon. Will not carbon partly deprive chalk gas of its oxygen? The experiment is made and it is found that it will. These results afford an opportunity of calling attention to and explaining the changes which go on in ordinary fires and in a furnace.

PROBLEM XII. *To determine the composition of salt gas, and the manner in which it acts on metals and oxides.*—It has previously been demonstrated that spirits of salt or muriatic acid is prepared by acting on salt with oil of vitriol and passing the gas which is given off into water; the solution has been found capable of dissolving various metals and oxides, chalk, lime, &c., and as water alone does not dissolve these substances the effect is apparently attributable to the dissolved gas, so it becomes of interest to learn more of this gas in order that its action may be understood. It is first prepared; its extreme solubility in water is observed, and also the fact that as it dissolves much heat is given out; and it is noted that although colourless and transparent it fumes in the air. How is its composition to be determined? Is there any clue which can be followed up? Reference is made to the previous observations, and it is noted that its solution dissolves various metals with evolution of hydrogen; water alone has no such effect. Is this hydrogen derived from the water or from the dissolved gas? The gas alone is passed over heated iron turnings, and the escaping gas is collected over water: it proves to be hydrogen, so evidently salt gas is a compound of hydrogen with something else. How is this something else to be separated from the hydrogen? Do not previous experiments suggest a method? Yes, they have proved that hydrogen has a marked affinity to oxygen, and now it is recollected that on treating muriatic acid with red lead—a substance rich in oxygen—a greenish-yellow gas is obtained. The experiment is repeated on a larger scale and the gas is examined. If it is contained together with hydrogen in salt gas, perhaps salt gas will be obtained on applying a flame to a mixture of the two gases just as water is from a mixture of oxygen and hydrogen: the mixture is made and fired, and the result leaves little doubt that salt gas does consist of hydrogen in combination with the greenish-yellow gas—chlorine. Whence is this chlorine derived—from the salt or the sulphuric acid?

The notes are again consulted, and it is seen that a solution of silver in nitric acid gave a characteristic precipitate with muriatic acid but not with sulphuric, so salt solution is added to the silver solution, and a precisely similar precipitate is obtained, leaving little doubt that the chlorine is derived from the salt. It is now easily realized that the iron and zinc displace the hydrogen of the dissolved hydrogen chloride. What happens when the oxides are acted on? In addition to the metal they contain oxygen, which is known to combine readily with hydrogen, forming water; is water formed? Lime oxide is therefore heated in hydrogen chloride; a liquid is obtained which behaves exactly as a solution of hydrogen chloride in water. When the action is complete, after driving off all that is volatile, a solid remains very like fused common salt—doubtless zinc chloride, as it is to be supposed that as the hydrogen has taken the place of the zinc the chlorine has taken the place of the oxygen. What, then, is the action of hydrogen chloride on chalk? It evidently not only separates the chalk gas from the lime, but also dissolves this latter. What is formed? Dry (unslaked) lime is therefore heated in a current of hydrogen chloride. It behaves just as zinc oxide, yielding a liquid product—evidently a solution of hydrogen chloride in water, as it dissolves zinc with evolution of hydrogen, and the residue is like that of zinc chloride. The important discovery is thus made that lime also is an oxide—that chalk, in fact, is a compound of two oxides; the resemblance of lime to zinc oxide and magnesium oxide is so striking that the conclusion is almost self-evident that lime is probably a metallic oxide, and it may be here pointed out that this actually is the case. The gradual discovery of the composition of chalk in the manner indicated is an especially valuable illustration of chemical method, and serves to show how chemists are often obliged to pause in their discoveries and to await the discovery of new facts and methods of attack before they are able to completely solve many of the problems which are submitted to them. The solids obtained on dissolving zinc oxide and lime in muriatic acid and boiling down the solution, when all the water is driven off, are white solids like fused salt, but on exposure they gradually become liquid. In so doing they increase in weight, and evidently behave like sulphuric acid. Probably water is absorbed from the air: no change takes place when they are kept over sulphuric acid or dry lime. In this way two new desiccating agents are incidentally discovered.

PROBLEM XIII. *To determine the composition of washing-soda.*—The study of this substance is of importance as introducing the conception of an alkali. The preparation from salt is first described. On heating the crystals they melt and give off "steam"; the experiment is made in such a way that a quantity of the liquid is obtained sufficient to place beyond doubt that it is water. The water is found to be easily driven off on heating the crystals in the oven, and to constitute a very large proportion of the weight of the crystals. The conception of water of crystallization is thus gained. On heating the dried substance to full redness in the platinum dish, no loss occurs. The residue dissolves in water, and "soda crystals" may again be obtained from the solution, so that heat does not affect it. Perhaps acids which have been found to act so powerfully in other cases will afford some clue. On trial this is found to be the case: a colourless, odourless gas is given off, which extinguishes a burning taper. Is this perhaps nitrogen or chalk gas? The lime water test at once decides that it is the latter. So it is determined that washing-soda, like chalk, is a compound of chalk gas—but with what? With an oxide? The dried substance is heated in hydrogen chloride: chalk gas is given off as before, and a liquid which is soon recognized as water saturated with hydrogen chloride. The residue dissolves in water, and separates from the concentrated solution in crystals exactly like salt, and, in fact, is soon recognized to be salt; evidently, therefore, that which is present in salt along with chlorine is present in soda crystals along with oxygen, chalk gas, and water. The preparation of the metal sodium from soda is then explained. Acquaintance being thus made with compounds of chalk gas with two different oxides, the question arises, which oxide has the greater affinity to the chalk gas? Will lime displace sodium oxide from soda or *vice versâ?* On adding lime water to soda solution, a precipitate of chalk is formed. What does the solution contain? Lime water contains lime in combination with water; is the sodium oxide present in combination with water? Soda is boiled with milk of lime (in an iron saucepan to avoid breakage) until it no longer affects lime water; afterwards the liquid is poured off and boiled down. The product is very unlike soda: it is very caustic, and when exposed to the air becomes liquid. If it is an analogous substance to slaked lime, it should combine with chalk gas and be reconverted into soda; this is found to be the case. Caustic soda is thus discovered. Chalk and lime are known to neutralize acids; both soda and caustic soda are found to do so, and their effect on vegetable colours is found to be the reverse of that of acids. At this stage the origin of the name alkali is explained, and it is pointed out that the oxides which have been studied may be arranged in two groups of alkali-like or *alkylic* and acid-forming or *acidic* oxides, the former being derived from metals, the latter from non-metals. The production of *salts* by the union of an oxide of the one class with the oxide of the other class is then illustrated by reference to earlier experiments.

The point is now reached at which the results thus far obtained may be reconsidered. The student has been led in many cases to make discoveries precisely in the manner in which they were originally made; and it is desirable that at this stage, if not earlier, the history of the discovery of the composition of air and water, &c., should be briefly recited. It is then pointed out that a variety of substances have been analyzed and resolved into simpler substances—air into oxygen and nitrogen, water into oxygen and hydrogen, &c.; and that these simpler substances thus far have resisted all attempts to further simplify them, and are hence regarded as elements. A list of the known elements having been given, the diverse properties of the elements may be illustrated from the knowledge gained in the course of the experiments. The fact that when elements combine compounds altogether different in properties from the constituents are formed also meets with manifold illustration. Too little has been ascertained to admit of any general conclusion being arrived at with regard to the proportions in which elements combine, but it is clear that they may combine in more than one proportion since two oxides of carbon have been discovered, and in the only cases studied—viz. copper oxide and chalk—the composition has been found not to vary. The existence of various types of compounds has been recognized, and a good deal has been learnt with reference to the nature of chemical change. But, above all, the method of arriving at a knowledge of facts has been illustrated time after time in such a manner as to influence in a most important degree the habit of mind of the careful student. New facts have been discovered by the logical application of previously discovered facts: the logical use of facts, and the habit of using facts have been inculcated. This is all-important. It has become so customary to teach the facts without teaching how they have been discovered that the great majority of chemical students never truly learn the use of facts; they consequently pursue their daily avocations in a perfunctory manner, and only in exceptional cases manifest those qualities which are required of the investigator; their enthusiasm is not awakened, and they have little desire or inclination to add to the stock of facts. It must not for one moment be supposed that the object of teaching chemistry in schools is to make all chemists. Habits of regulated inquisitiveness, such as must gradually be acquired by all who intelligently follow a course such as has been sketched out, are, however, of value in every walk of life; and certainly the desire to understand all that comes under observation should as far as possible be implanted in everyone.

STAGE V.—*The quantitative stage.*

The *quantitative* composition of many of the substances which have previously been studied qualitatively should now be determined—in some cases by the teacher in face of the pupils, so that every detail may be observed and all the results recorded; in other cases by the pupils.

The composition of water is first determined by Dumas' method; this may easily be done, and fairly accurate results may be obtained in the course of a couple of hours. The results obtained by Dumas and subsequent workers should then all be cited, and, attention having been drawn to the extent to which such experiments are necessarily subject to error, the evidence which the results afford that hydrogen and oxygen combine in certain *fixed and invariable proportions* to form water is especially insisted upon.

The composition of chalk gas is next determined; this also is easily done, as impure carbon (lampblack) may be burnt and the hydrogen allowed for. Again, attention is directed to the results obtained by skilled workers, and the evidence which they afford that chalk gas never varies in composition.

The composition of copper oxide has already been ascertained; it may be re-determined by reducing the oxide in hydrogen: in fact, in determining the composition of water.

The lead oxides may be reduced in a similar manner, the oxide obtained by igniting white lead as well as red lead and the brown oxide obtained by treating red lead with nitric acid being used. In this way it is ascertained that the brown oxide is the highest oxide; the loss in weight which this oxide suffers when ignited may then be determined.

Tabulating the results thus obtained, after calculating with what amount of the particular element that quantity of oxygen is associated which in water is combined with one part by weight (*unit weight*) of hydrogen, numbers such as the following are obtained:—

1 part of hydrogen is combined with 8 parts of oxygen in water.

3 parts of carbon are combined with 8 parts of oxygen in chalk gas.

31·5 parts of copper are combined with 8 parts of oxygen in copper oxide.

103·5 parts of lead is combined with 8 parts of oxygen in lead oxide (litharge).

51·8 parts of lead are combined with 8 parts of oxygen in lead oxide (brown).

These clearly illustrate the fact that elements combine in very different proportions, and the results obtained with the lead oxides afford also an illustration of combination in multiple proportion.

The amounts of silver and lead nitrates formed on dissolving silver and lead in nitric acid are next determined by evaporating the solutions of known weights of the metals in porcelain crucibles on the water-bath, and then drying until the weight is constant; accurate results may be easily obtained, and these two exercises afford most valuable training. The nitrates are subsequently evaporated with muriatic acid and the weights of the products determined. What are these products? Does the metal simply take the place of the hydrogen in hydrogen chloride as zinc does when it dissolves in muriatic acid? If so, the products are silver and lead chlorides, and it may be expected that the same substances will be obtained—that the same increase in weight will be observed, when, say, silver is combined directly with chlorine as when it is dissolved in nitric acid and the solution is precipitated with muriatic acid or salt. Silver is, therefore, heated in chlorine, and is found to increase in weight to the same extent as when it is dissolved in nitric acid, &c.; a given weight of silver precipitated by salt is also found to increase to the same extent as when it is directly combined with chlorine. The composition of silver chloride having thus been ascertained, the amount of chlorine in salt is determined. The composition of salt being ascertained, purified dried washing-soda is converted into salt, and also the amount of chalk gas which it contains is determined: from the data, the composition of sodium oxide may be calculated. In like manner the composition of lime may be ascertained by converting chalk into chloride by igniting it in hydrogen chloride, and then determining the chlorine in the chloride; the same method may be applied to the determination of the composition of the oxides and chlorides of zinc, magnesium, and copper.

Discussing these various results, and comparing the quantities of oxygen and of chlorine which combine with any one of the metals examined, it is seen that in every case about 35·4 parts of chlorine take the place of 8 parts of oxygen. Combination in *reciprocal proportions* is thus illustrated, and by considering the composition of chalk and washing-soda it may be shown that this applies equally to compounds of two and to compounds of three elements. As 35·4 parts of chlorine are found in every case to correspond to 8 parts of oxygen, it is to be expected that hydrogen chloride contains one part of hydrogen in combination with 35·4 parts of chlorine; a solution containing a known weight of hydrogen chloride is, therefore, prepared by passing the gas into a tared flask containing water and the chlorine is then determined.

It being thus clearly established what are *equivalent* weights of elements, the conception of equivalents may be further developed by exercises in acidimetry carried out by the pupils themselves. The proportions in which washing-soda and hydrogen chloride interact may be determined by mixing solutions of known strength until neutralization is effected; if the solution be evaporated and the chloride weighed, the results may be used in calculating the composition of hydrogen chloride; they serve, in fact, as a check on the conclusions previously arrived at as to the composition of washing-soda and hydrogen chloride. Solutions of sulphuric and nitric acid may be similarly neutralized, and, the amounts of sulphate and nitrate formed having been ascertained, the equivalents of the acids may be calculated on the assumption that the action is of the same kind as takes place in the case of hydrogen chloride. Determinations of the strengths of acids, &c., may then be made. In a similar manner the volumetric estimation of silver may be taught, and the percentage of silver in coinage and other alloys determined.

Such a series of quantitative exercises as the foregoing, when carried out *before* and to a considerable extent *by* the pupils, undoubtedly affords mental discipline of the very highest order, and is effective of good in so many ways that the value of such teaching cannot be over-estimated. The failure to grasp quantitative relationships which examiners have so frequently to deplore is without question largely, if not alone, due to students' entire ignorance of the manner in which such relationships have been determined. Moreover, the appreciation by the general public of the principles on which quantitative analysis is founded would undoubtedly be directly productive of good in a multiplicity of cases.

STAGE VI.—*Studies of the physical properties of gases in comparison with those of liquids and solids. The molecular and atomic theories and their application.*

A series of quantitative experiments on the effect of heat on solids, liquids, and gases should now be made, and these should be followed by similar experiments on the effect of pressure; the similar behaviour of gases, and the dissimilar behaviour of liquids and solids, is thus made clear. The condensation of gases is then demonstrated and explained, and also the conversion of solids and liquids into gases, and the dependence of boiling-point on pressure and temperature. Regnault's method of determining gaseous densities is studied, and the method of determining vapour densities is illustrated. The molecular constitution of a gas is now discussed; the phenomena of gaseous and liquid diffusion are studied, and a brief reference is made to the kinetic theory of gases; then Avogadro's theorem is expounded and applied to the determination of molecular weights; and eventually the atomic theory is explained, and the manner in which atomic weights are ascertained is brought home to the pupils. The use of symbols must then be taught. Finally, the classification of the elements in accordance with the periodic law should be explained.

It is all-important that at least a large proportion of the experiments in each of the stages should be made by the pupils; but even if this were not done, and the lessons took the form of demonstrations, much valuable instruction might still be given.

The majority of pupils probably would not proceed to the fifth and sixth stages; but those who perforce must terminate their studies without gaining any knowledge of chemical philosophy should unfailingly be led to make a few simple quantitative experiments: for example, to determine silver volumetrically, and the method of determining the composition of water and chalk gas should be demonstrated in their presence: and it may be added that, if only the examples in Stages I. and II. and Problems I. to V. of Stage III. were thoroughly worked out, most important educational training would be given, and much valuable information as to the nature of common phenomena would be gained.

The complete course would undoubtedly take up considerable time, but so does a satisfactory mathematical or classical course of study, and it is absurd to suppose that useful training in science is to be imparted in a few months. If instruction be given in the manner suggested at all generally, it will be necessary, however, to modify the present system of testing results. Pupils could not be expected to pass at an early age examinations such as are at present held, and awards would have to be based chiefly on an inspection of the classes at work and of note-books and on *vivâ voce* questioning. But all are agreed that the present system of payment on results tested by a terminal examination is a most unhealthy one, and that a more rational system *must* be substituted for it. I may suggest that if members of the staff of science colleges, such as are now established in so many towns, could be appointed *supervising inspectors*, whose duty it would be to advise teachers in schools and *occasionally* to inspect the teaching in company with the permanent inspector, it would be possible to secure the assistance of a body of men who are in touch with scientific progress and conversant with the improvements which are being effected. A man who "once an inspector is always an inspector" of necessity must get into a rut, and will escape from the wholesome leavening and rousing influence which is always more or less felt by those whose office it is to follow the march of scientific progress.

It should also here be pointed out that the great majority of the experiments and exercises described may be carried out with very simple apparatus, and with slight provision in the way of special laboratory accommodation. In but very few cases is there any production of unpleasant smells or noxious fumes. It is, in fact, a mistake to suppose that an elaborately fitted laboratory is in every case essential for successful teaching: much might be done in an ordinary schoolroom provided with a demonstration bench for the use of the teacher, a draught closet over the fire-place, a sink, a raised table for balances (raised so that the teacher might see what was going on), a cupboard for apparatus, and a long narrow bench provided with gas-burners at which, say, twenty pupils might stand, ten a-side. At present the Science and Art Department will not recognize "practical chemistry" unless it be taught in a laboratory fitted up in a certain specified manner, and their regulations are such as to enforce the provision of expensive laboratories in all cases where it is desired to obtain the grant. If greater latitude in fittings were allowed, more attention being paid to the character of the work done and less to the tools with which it is accomplished, probably much less money would be wasted by inexperienced school authorities in providing special laboratories, and there would be much greater readiness displayed to enter on the teaching of experimental science. The course which has been sketched out is one which doubtless might well be modified in a variety of ways according to circumstances. Thus many simple exercises in mechanics, in addition to those directly mentioned, might be introduced into Stage II., and the mechanical properties of common materials might be somewhat fully studied at this stage in districts where engineering trades are largely established, and where such knowledge would be specially valuable. In like manner the physical effects of heat on substsnces might be studied in Stage III. instead of Stage VI. And there are other chemical problems and simple exercises besides those described which might be substituted for some of them, or included in the course.

Probably, however, it would be found undesirable, if not impossible, as a rule, to continue the teaching of chemistry proper much, if at all, beyond the stage indicated in this scheme. Other subjects will have a prior claim should it ever be deemed essential to include in a comprehensive scheme of school education the elements of the chief physical and physiological sciences; it certainly is of primary importance to introduce at as early a period as possible the conception of energy, and to explain the mechanical theory of heat, so that later on it may be possible to discuss the efficiency of heat and other engines; and, until the laws of the electric current are understood, the subject of chemical change can never be properly considered.

In many cases, where it is convenient or desirable to continue the chemical studies, it probably will be advantageous as a rule that they have reference to specific (local) requirements—*e.g.* to agriculture in schools in agricultural districts; to food materials and physiology in the case of girls especially, &c. But in any case more consideration must be paid in the future in schools where chemistry is taught to educational requirements—the teaching must have reference to the requirements of the general public; and it must be remembered that the college, not the school, is the place for the complete study of a subject.

With the object of presenting in an available form information as to the position occupied by chemistry in Board and other public elementary schools, which are controlled either by the Education Department, Whitehall, or the Science and Art Department, South Kensington, the Committee now present a report on the subject which has been prepared by Prof. Smithells. A consideration of this statement will show that, as in the higher grade public schools, with which the Report of the Committee last year was chiefly concerned, the condition of the teaching in public elementary schools is far from satisfactory. As a rule chemistry is not taught on the proper lines. The pupils frequently receive the same kind of instruction in chemistry as they would at a later stage if they were preparing for a professional or technical career; consequently the subject has failed to provide that mental education which it should be the main object of elementary teaching to develop. It appears, too, that in many of these schools physical science has not hitherto been regarded as a necessary part of the educational scheme. It is essential that this state of affairs should be altered, and that physical science should occupy a more favourable position in the Education Code, and that its teaching should be more thoroughly controlled.

It is to be hoped also that the Education Department, as well at the Science and Art Department, South Kensington, will take steps to arrange a more efficient mode of inspecting science teaching than that at present in vogue, which can only be regarded as satisfactory from a purely statistical standpoint. Under the present system little or no control can be exercised over the science teaching, since the Whitehall inspectors are, as a rule, not qualified to form an opinion as to its value. There would seem to be no difficulty in obtaining the services of properly qualified persons to act as additional inspectors for the purpose of reporting on the character of the science teaching. It is probable that many of the professors and lecturers in University Colleges, and other educational institutions, might be willing to take part in such inspection, and it would thus become possible to maintain a high standard of excellence in the teaching.

THE GEOLOGICAL PAPERS AT THE BRITISH ASSOCIATION.

ON Thursday morning the first business of Section C was to hear Prof. Milne's ninth Report on the earthquake and volcanic phenomena of Japan, in which a list of seventy-nine earthquakes occurring between June 1888 and March 1889 is given. After a paper by Dr. Naumann, which will be referred to later on, Mr. T. P. Barkas read a paper on footprints of four-, three-, and two-toed animals, discovered in Lower Carboniferous sandstones near Otterburn, of which he exhibited specimens. A paper by Mr. Mellard Reade reviewed the chief theories advanced to account for the Lower Triassic rocks, and advocates their formation by tidal action in straits, seas, and bays from the denudation of the rocks of the Channel, Mendips, Belgian coal-field, Pennine, and the Old Red of Herefordshire.

Friday's sitting opened with Dr. A. Geikie's paper on the age and origin of the crystalline schists of Norway. In the Trondhjem region ordinary sedimentary rocks, much disturbed, contain Lower and Upper Silurian fossils, and are underlain by basic lavas and tuffs, succeeded by grits, slates, and schists with black pyritous and carbonaceous beds. Traced southwards, the whole series becomes progressively more crumpled and crystalline until it passes into a group of twisted mica schists, in which, however, the pyritous shales, although converted into mica schists, are still recognizable. Specimens were exhibited to show every step of metamorphism from an amorphous igneous rock to a perfect schist, the change being sometimes visible in a hand specimen In Bergen the author confirmed the discovery of fossils by Dr. Reusch in a frilled mica schist or phyllite, proving that the regonial metamorphism in this area was of post-Silurian date. Mr. Marr followed with a description of the Skiddaw slates on the east side of Brownber, where quartz veins have been intruded between the bedding planes, the rock has been contorted, and converted into a rock composed largely of mica and secondary quartz, and exhibiting *ausweichungsclivage*, in fact a mica schist. Prof. Bonney contributed a paper showing that the limestones associated with crystalline rocks were coarsely crystalline as a rule, but that pressure often obliterated this coarse texture by crushing, and thus could only be appealed to as a minor agent in producing crystallization; a further paper by the same author dealt with the fossils obtained amongst the crystalline schists in the Val Canaria, Val Piora, Nufenen Pass, and Lukmanier Pass; he concluded that in the first two localities the relations of the rocks had been misunderstood, while in the last two the fossils were in a rock whose minerals were in a very different state from those in the older crystalline schists. Mr. Watts exhibited a collection of Belemnites from the rocks of the Lukmanier Pass. Dr. Hatch described potash and soda felsites from the Lower Silurian of Ireland, which were ancient equivalents of the rhyolites and pantellerites of to-day; and Mr. A. R. Hunt brought forward a view that the granites of Dartmoor and of the Channel were of pre-Devonian and probably Archæan age. Mr. Teall sent an interesting communication on the amygdaloids of the Tynemouth dyke, in which he summarized the history of the rock as follows: (1) development of granular aggregates of felspar allied to anorthite under plutonic conditions; (2) addition of new felspar substance to these, giving them outward crystalline form; (3) formation of lath-shaped felspars; (4) separation of augite; (5) formation of vesicles probably due to relief of pressure when the magma rose into a fissure; (6) filling of some of these vesicles with interstitial matter which probably oozed into them from the surrounding liquid magma, as they are seen in all stages of filling; (7) consolidation of interstitial matter; (8) filling up of the rest of the vesicles with carbonates. Mr. Swan exhibited specimens of marble from Paros, and described the new and old quarries; and then the Section listened to an account from Dr. Fridtjof Nansen of the geological bearings of his journey across Greenland.

Greenland is covered by a shield of ice rising to a height of 9000 or 10,000 feet in the centre, where it probably covers an area of mountains and valleys, and not a table-land, reduced to a gently sloping surface, and even polished, by the wind. The only evidence of ice melting on the surface in the interior consists of thin ice crusts at varying depths. The enormous pressure of the ice mass forces it out partly as ice and partly as water melted by friction, thus giving rise to the rivers, which flow even in winter. The great rate at which the ice flows out into the fjords makes the author an advocate for the agency of ice in forming these features.

On Saturday, Prof. W. C. Williamson read a paper in which he acknowledged the help he had received from all parts of the world in acquiring specimens and slides of coal and mineral charcoal from many English, Welsh, and Scotch localities, as well as from Japan, New Zealand, America, Europe, Asia, and Australia. The inquiry was still proceeding, with a view to ascertain the nature and origin of this mineral charcoal, and to estimate the extent to which cryptogamic spores contributed to coal formation. Prof. Williamson further stated that in *Lyginodendron Oldhamium*, he added a fern to the other cryptogams in which exogenous growth took place, and announced what he termed another botanical heresy, that in the Carboniferous Lycopods the vascular bundle enlarged into a ring inclosing a medulla which enlarged *pari passu* with the ring. Prof. T. R. Jones reviewed the advancement made by himself and others to our knowledge of the Palæozoic Phyllopoda; and Dr. Johnston-Lavis's Report on Vesuvius was presented. This Report announces that Messrs. Philip and Son will shortly publish the map of Vesuvius; it further gives a diagram of the cone in 1887 and 1886 (? 1888), and three taken in January, May, and August, 1889, so as to show the changes resultant on overflows of lava, formation of fissures, and building of new cones. The Report concludes with a further account of the new railway tunnels in the Phlegræan Fields.

Further specimens of the peculiar coral-like structures from the limestone of Culdaff have been obtained by the Geological Survey, and some of these, with photographs, were exhibited to the Section by Prof. Hull. Some foreign palæontologists, judging from the photographs, regarded them as organic, and referred them to Favistella, but English palæontologists give only a hesitating assent to this view. Mr. Cameron described Kellaway's sand and doggers from exposures near Bedford, and Mr. Vine described sixteen species of Stomatopora and Proboscina from the Hunstanton Red Chalk.

On Monday, Mr. Ussher's paper on the Devonian rocks of Britain was presented. He divided the rocks into three typical areas, in each of which they presented peculiar characters. In North Devon there are arenaceous deposits indicating shoal water; in South Devon the rocks are variable, with sporadic volcanic and coral deposits; while in Cornwall and Devon, west of Dartmoor, the succession, though much disturbed and faulted, consists chiefly of mud and slates. A table is given, correlating the principal divisions in these three areas with their Franco-Belgian and German equivalents. An important paper by Prof. Lebour and Mr. Marley, on the South Durham salt industry and the extension of the Durham coal-field, followed. The area of proved salt amounted to at least twenty square miles, and although it had been found not to extend to Seaton Carew, there was no doubt that the eastern and northern borings at South Bank and North Ormesby did not mark the limits of the salt in those directions. The thin coals found in the Seaton boring were regarded by Prof. Lebour as being of gannister or millstone-grit age, and hence of little value except in giving an idea of the structure of the Carboniferous rocks below their red-rock covering. Mr. De Rance's Underground-water Report gave the details of some of these borings, as well as others from Devon, Worcester, Leicester, Lincoln, Lancashire, Hertfordshire, and the south of England. Dr. Embleton contributed a description of *Loxomma Allmanii* from the Northumberland coal-field; Dr. Traquair, of Devonian fishes from Scannenae Bay and Campbellton, in Canada; and Mr. Smith Woodward, of *Onychodus* from Spitzbergen, and of six new species and two new genera of Liassic fishes. Dr. R. Laing read a paper on a Neolithic interment in Robin Hood Cave, and on the discovery of *Felis brevirostris* in a Pleistocene deposit in the same cavern.

The Section then joined with Section A to hear a joint paper by Profs. Thorpe and Rücker, on the relation between the geological constitution and magnetic state of the British Isles. In this the authors recorded that the magnetic elements had been determined at 200 stations in the United Kingdom, with the result that the declination was found to be subject to local or regional disturbing causes centred in a comparatively small number of spots or lines distributed in various parts of England. The regions mentioned are: (1) the fault-line of the Caledonian Canal; (2) the basalt of the Inner Hebrides; (3) the coal-field of South Scotland; (4) the region of South-East Yorkshire, where the Jurassic rocks are thin; (5) the basalt of Mid-Wales and Shropshire; (6) the line of the "London Palæozoic Ridge"; (7) the basalt of Antrim; (8) the igneous rocks of Connemara. All the principal masses of basalt, and those spots where geologists know or suspect the older rocks to be near the surface, form centres or lines of attraction. As the result of this and of the following reasons, the authors are strongly of opinion that the disturbance is due, not to earth-currents, but to local magnetic rocks, such as basalt, or others like the Malvern diorite, which, though not strongly magnetic in the laboratory, produces a deviation of 20′ of arc even at a distance of a mile from the axis. Only small earth-currents, or none, were detected at such places as Melton Mowbray; and near Reading and Windsor, where the disturbance was great, the earth-currents must circulate *round* the disturbed districts in a manner for which it would be difficult to find an adequate physical cause, while, if the currents are deep-seated, it is not easy to understand the extreme localization of their action. In connection with this paper we may note the exhibition, by Prof. Hull, of a piece of magnetically polar diorite, and a paper by Dr. Edward Naumann, in which he advocated a magnetic survey of the globe, and brought forward a set of results from Japan and elsewhere to show the dependence of magnetic lines on lines of fault, fissure, and elevation. He, however, attributed the magnetic disturbance to the deflection of earth-currents by the great lines of fissure and tectonic disturbance.

Tuesday was chiefly devoted to Pleistocene papers, opened by Dr. Crosskey, who exhibited a large map showing the distribution of Welsh, Lake Country, Scotch, and local erratics. His report described erratics reported by the Yorkshire Boulder Committee and by Mr. Bucknill in Lancashire, and drew attention to (1) the grouping of erratics from special localities; (2) the occasional mingling of groups; (3) the occurrence of high and low level erratics; and (4) the distribution of trails of the latter in accordance with existing physical features. Mr. Whitaker described a deep and steep-sided channel filled with drift in the Cam Valley; Mr. Lamplugh, a new locality for the Arctic shell bed in the boulder clay on Flamborough Head; and Mr. Howorth contributed two papers on which there was considerable discussion. In the first he combated the theory of an ice-cap, on the grounds that many northern lands had no drift, that the southern glaciation was contemporaneous and not alternate with the northern and that in New Zealand and Australia there is nothing corresponding to the drift phenomena of the northern hemisphere, that there is little or no evidence of other earlier glacial periods, that palæontological evidence is against such a theory, and that the advance of ice-sheets over hundreds of miles of plain without any *vis a tergo* is a physical impossibility; in the second, after showing that there is evidence of a connection in Pleistocene times between Siberia and America, not by way of Japan, but probably through the shallow Arctic seas to the north, he considers that the necessary elevation of 25 or 30 fathoms would make the great Siberian rivers flow southward, and terminate in an inland sea stretching east from the Caspian, just as the principal rivers of Russia (Siberia in Europe) now flow into the Black Sea and Caspian. In the discussion it was, however, pointed out that many of the rivers flowed far too rapidly to have their directions thus reversed.

Among the other papers were: one by Prof. Haddon, describing the volcanic and coral deposits of the islands in Torres Straits, where no proof of elevation or of subsidence was to be obtained; one by Mr. Dorsey, on the Witwatersrande Gold-fields; a Report by Mr. Bell, on the manure gravels of Wexford; and one by Dr. F. Clowes, describing rocks at Bramcote and Stapleford cemented by barium sulphate, and the occurrence of the same substance deposited in pipes and water-boxes connected with the pumps of Durham collieries.

On Saturday Mr. Starkie Gardner's report on the Osborne and Bembridge floras of the Isle of Wight and the correlation of the Bovey beds with beds of about Bracklesham age was read, followed by a short paper of Prof. Green's on the concretionary nodules formed by molecular rearrangement into radial crystalline groups of the tufaceous deposits of the magnesian limestone. Mr. Topley next gave an admirable *résumé* of the work of the Geological Survey in Northumberland and Durham, which have been mapped on the 6-inch scale, and published in two sets of "drift maps" and "solid maps" on the 1-inch. He noted the whole sedimentary series from the Silurian to the Trias, the glacial beds, and the numerous intrusive and interbedded igneous rocks. The last paper was an extremely interesting one by Mr. R. H. Tiddeman on concurrent faulting and deposit in Carboniferous times. The author describes three branches of the Craven group of faults, and then shows that there are vast differences between the quality of the Pendleside grits and Bowland shales on one side of the fault and the corresponding Yoredale series on the other, while the 5500 feet of Carboniferous limestone on the north side of the faults is in strong contrast to the 800 feet on the other side, suggesting great differences in the conditions of deposit. As the faults form the boundary between the two types of rocks, as there is no trace of transition there, and as the thickest beds are on the down-throw side, the author suggests that faulting must have gone on contemporaneously with the deposit. A note was appended describing knolls of crystalline limestone full of fossils and bordered by limestone breccias, which were regarded as reefs growing in the Carboniferous ocean.

Reviewing this list of papers, it is obvious that, though many of them were not of a class to interest the somewhat popular audience which listened to them, there are a large number of great scientific interest which mark a very considerable advance made in our knowledge during the past year.

THE BIOLOGICAL PAPERS AT THE BRITISH ASSOCIATION.

As has been the custom for the last few years, a good deal of time was devoted to the discussion of topics of general biological interest. The subjects selected for these discussions were, "The Transmission of Acquired Characters" and "The Utility of Specific Characters," which were respectively opened by Mr. E. B. Poulton, F.R.S., and Prof. Romanes, F.R.S. There were also an extremely large number of botanical and zoological papers, but no physiological papers, owing to the absence of most of the physiologists, who were attending the Physiological Congress at Basle. In the following account only a few of these papers are abstracted, as it would be impossible to do justice to all in a limited space.

Mr. Romanes opened a discussion on specific characters as useful and indifferent. The question to be debated was, whether *all* characters were adaptive, and had been brought about by natural selection, or whether there were not specific characters which had no utilitarian significance? The naturalists who hold the former view were apt to beg the question by assuming that, if a given character could not be explained as due to utilitarian principles, it was simply due to a failure to see the need for it; this way of dealing with the question is really unscientific dogmatism. The author had selected certain groups, and tabulated the various specific characters, placing on one side those which were conceivably of advantage, and on the other side those which were apparently useless; the latter were found to preponderate. This was especially clear in the coloration of birds: to take one-instance, the breast and abdomen of woodpeckers are variously coloured, and yet these parts of the body are habitually concealed; here it is most difficult to conceive how natural selection can have been the cause of the various modifications. It must, in fact, be admitted that other influences besides natural selection have led to the production of specific characters which are not in any way useful as such. Sexual selection, in the first place, although Mr. Wallace rejects it, must be considered as important. There is an enormous amount of evidence that climate—as we summarize a vast number of external conditions of life—has a uniform and permament influence upon specific characters. A striking evidence of this influence is seen in the faunas of caves; here we see a loss of coloration and other peculiarities in the most different groups of animals. It has been attempted to explain this change as due to natural selection acting directly upon their physiological constitutions, and so indirectly upon their colours. This explanation would be reasonable if only one class of animals were concerned; but to assume that representatives of the most diverse classes of animals are acted upon in an identical fashion by natural selection is to assume too much; the changes must be due to the direct influence of the environment. Weismann's use of "panmixia," or negative natural selection, to account for such changes, fails, inasmuch as it should also follow that the fauna of the deep sea, which is exposed to identical conditions as regards darkness, and even temperature, should show an absence of coloration; but it is notorious that the reverse is the case. Again, the rabbits of the island of Porto Santo, near Madeira, which are the progeny of a few pairs introduced in the fifteenth century, differ in certain peculiarities of coloration which cannot be regarded as adaptive: in so short a time as four years some of these rabbits, when brought to England, reverted to the original type; this seems to be the clearest case of the direct influence of climate. Food is known to have a direct influence on coloration, but as yet there is not very much definitely known about these influences; for instance, the bullfinch turns black when fed upon hempseed, and other birds change their colour when fed with cayenne pepper; there can be no doubt that various substances exist in nature which have a similar direct effect upon the plumage of birds which feed upon them. Isolation is another cause of non-beneficial change. So much, then, for specific characters. If the theory of natural selection is good as a theory of the origin of species, it must likewise be good as a theory of the origin of genera; and if specific characters must necessarily all be "useful," so must generic characters. If the doctrine of utility as universal be conceded to fail as regards genera and all the higher taxonomic divisions, it appears inconsistent to maintain that it must necessarily hold as regards species: it is not supposed to hold as regards varieties. This seems to be a most illogical position.

In a paper on the antherozoids of Cryptogams, by Mr. Alfred W. Bennett, the object of the author was to bring out the difference between the two modes in which the ciliated fertilizing organs of Cryptogams are formed, the first type being that which occurs in Vascular Cryptogams, Muscineæ, and Characeæ, the second in Algæ (excluding Characeæ). The essential character of the first type is that the antherozoid is formed from the nucleus only of its mother-cell, the whole of the rest of its protoplasm being consumed in the development of the antherozoid. The vibratile cilia which give to the mature antherozoid its power of rapid movement proceed from a peripheral layer of hyaline protoplasm belonging to the nucleus. In ferns and other vascular cryptogams these cilia are very numerous, forming a tuft attached to the anterior end of the antherozoid. The antherozoids of Muscineæ (Musci and Hepaticæ) and those of Characeæ have only two very long and slender cilia attached in the same position. The structure and mode of development of these organs is almost identical in these two classes. In the Fucaceæ, on the other hand, which may be taken as the highest type of Algæ with ciliated antherozoids, the structure of the antherozoid is altogether different. It is a naked cell, not inclosed in a cellulose-wall, with cytoplasm, nucleus, and pigment-spot; the two cilia both spring from a spot in close proximity to the eye-spot, although one of them is attached to the body of the antherozoid for a portion of its length. The importance of the above facts was pointed out in support of the view that the Characeæ are more nearly related to the Muscineæ than to the true Algæ.

Mr. Poulton read a paper "On the Supposed Transmission of Acquired Characters." The position taken up by Weismann is that acquired characters, *i.e.* characters produced by the incidence of external forces upon the individual body are not in any case inherited. The evidence for such transmission might be direct or indirect; to the former category would belong transmission of mutilations which would be undoubtedly impressed upon the individual body by external influences; the evidence might also be indirect; if it could be shown that evolution was impossible without accepting this principle we should have to accept it. The evidence of transmission of mutilations is not strong, and Prof. Windle has argued very forcibly that monstrosities were due to peculiarities of the ovum and not to external forces. The supposed hereditary effects of use and disuse were unsupported by any proof that the modifications of organs affected by use or disuse had been more complete or more rapid than that of organs not so affected. With regard to instinct, Dr. Romanes had suggested a difficulty—that was, the instinct of certain wasps to sting and paralyze the nerve centres of their prey. But it must be remembered that the benefits arising from this instinct were felt not by the wasps themselves, but by their progeny.

The subject was continued by Mr. Francis Galton, who read a paper entitled, "Feasible Experiments on the Possibility of transmitting Acquired Habits by means of Inheritance," in the course of which he said that feasible experiments have yet to be designed that shall be accepted as crucial tests of the possibility of a parent transmitting a *congenital* aptitude to his children, which he himself possessed, *not congenitally*, but merely through long and distasteful practice under some sort of compulsion. The requirements are to eliminate all possibility of parental or social teaching, to bring up all the descendants in the same way, to make simultaneous experiments on many broods during many generations, and, lastly, to economize time, money, and labour. This list of requirements points with emphasis to experimenting on creatures that are reared from eggs, as fowls, fishes, and moths. *Fowls.*—The largely extending practice of hatching eggs in incubators for commercial purposes, and the varied aptitudes of poultry, make them very suitable subjects. Birds are said to have an instinctive dread of various insects; hence mimetic insects, that are really good for food, are avoided by them. Do such insects exist, and could they be easily reared, which poultry would avoid at first, though experience would soon teach them to like and to eat greedily? Similarly as regards sounds and cries, which would frighten at first, but afterwards be welcomed as signals for food, &c. Would the stocks of two breeders, one of whom adopted such experiments as these and the other did not, differ in instinct after many generations? *Fish.*—The experiment (quoted by Darwin) of Möbius with the pike, using a trough of water divided by a glass plate into two compartments, in one of which was the pike and in the other were minnows, was mentioned as an example. The pike, after dashing at the minnows many times, and each time being checked and hurt by the glass plate, during some weeks, finally abandoned all attempts to seize them, so that when the plate was removed the pike never afterwards ventured to attack the minnows. The question, then, is, whether fish reared for some generations under conditions which compelled them to adopt habits not conformable to their natures would show any corresponding change of instinct. Of course each generation would be reared in a separate tank from its parents. *Moths.*—Experiments have been made for the author by Mr. Frederic Merrifield with *Selenia illustraria*, which has two broods yearly. They are being made for quite another purpose, but have already shown the ease of breeding hardy moths on a large scale when the art of doing so is well understood. All larvæ are fastidious in their diet, but it may well be that certain food which they would not touch at first would after a while be greedily eaten, and be found perfectly wholesome. Ezperiments on the lines here suggested ought to show the proportion of cases in which acquired aptitudes of several kinds are *certainty not* inherited. They might also, perhaps, show that in a small proportion of cases they *certainly are.* Thus limits would be fixed within which doubt remained permissible. The object of this paper is to invite experts to discuss the details of the most appropriate experiments.

Prof. F. O. Bower read a paper on the meristems of ferns as a study in phylogeny. The author has found as the result of examination of the growing points of root, stem, leaf, and of the sporangium in a considerable number of ferns, that as regards their complexity of structure these plants form a natural series, starting from the filmy ferns, which are the simplest, and proceeding through the Polypodiaceæ and Osmundaceæ to the Marattias: in the latter the whole structure of the meristems, as well as of the mature organs of the sporophyte, is bulky and massive, a character which is well suited to growth in subaërial and dry situations; while in the former the whole structure is relatively delicate, and less complex, and suited rather to a subaquatic habitat. A parallel progression from the simpler to the more complex is to be traced also in the prothallus or oophyte of these plants, and the general conclusion is drawn from these observations that the series of the Filicineæ illustrates—perhaps more clearly than any other phylum—the rise of a race of plants from the aquatic to the subaërial habit. Nevertheless they still retain in the mode of fertilization the trace of the aquatic habit, which is only lost in the higher Phanerogamic plants, where the pollen-tube renders unnecessary the presence of fluid water at the moment of fertilization.

The paper by Prof. Hartog, on the structure of *Saprolegnia*, contained an account of the structure of the nucleus and of its division, and also of some remarkable facts concerning fertilization; careful observation showed that nothing whatever passed from the antheridium into the oosphere or the oosporangium during fertilization.

In the paper entitled "Contributions to our Knowledge of the Fresh-water Oligochæta," by Mr. F. E. Beddard, the most important new point was the description of the sexual organs of *Dero*, which have not yet been described; they were stated to agree entirely with those of *Nais*, except that there were no genital setæ.

Mr. Robert Irvine and Dr. G. Sims Woodhead, in their paper on the secretion of carbonate of lime by animals, stated that hens supplied with any salt of lime produce normal egg-shells composed of carbonate of lime. They cannot make shells from magnesium or strontium carbonate. Crustacea, such as crabs, cannot assimilate sulphate of lime from the sea-water to form their exo-skeleton. They can form their shells from calcium chloride. In the egg-shell, the organic and inorganic material are both secreted by cells separated from the epithelial cells. In the crab-shell, the organic material (chitin) remains attached to the epithelial cells, and in this the lime salts are deposited, probably by a process of dialysis, while in the case of bone, the cells are not epithelial in character, the matrix, though separate, is closely associated with the cells, especially during its formation, and the lime is deposited in the matrix, apparently by a process of dialysis. Phosphoric acid, combined with alkalies and alkaline earths, acts as the carrier of the lime salt to the secreting cells. While in the blood, the lime salt is as a phosphate, it may be thrown out mostly as carbonate on meeting nascent carbonic acid at the secreting cells. Lime salts, of whatever form, are deposited only in vitally inactive tissue, such as bone matrix, chitin, or tissues that have undergone degeneration. Although the tissue be dead, deposition may go on. Carbonate of lime may be formed in sea-water as follows: the carbonate of ammonia produced by the decomposition of the effete products of animals, urea, &c., decomposes a portion of the sulphate of lime in the sea-water with the formation of carbonate of lime equivalent in amount to the carbonate of ammonia thus formed.

Sir John Lubbock read a paper on the shape of the oak-leaf and the leaves of the Guelder roses. The leaf of the evergreen oak is small in comparison with that of the English oak, and its margin is entire. During winter the leaf is protected by scales, which are not proportionately larger in the English oak; hence the leaf must be more folded in the bud, and the peculiar shape of the leaf may be shown by models to be due to the shortness of the bud in comparison with the length of the leaf; moreover, the two sides of the leaf are differently curved, hence the asymmetry. With regard to the Guelder roses, there are two species in this country which have very dissimilar leaves: in one form they are oval and very hairy when young; in the other they are trilobate, smooth, and furnished with stipules. In the former species the hairy covering protects the young leaves, but in the latter the outer leaves become tough and leathery, and encircle and protect the younger leaves; this brings about a close packing of the young leaves, which are folded so as to be stowed away in a small space; hence their trifid form. The presence of stipules is always associated with a lobed form of the leaf, and they apparently assume their thread-like form to fill up a space which would otherwise be left empty in the bud.

The object of the paper on the placentation of the dugong, by Sir W. Turner, was to put on record the fact that the placenta of the dugong is zonary and *non*-deciduate; it differs, therefore, in the latter character from the elephant, and in the former from its near ally the manatee.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Oxford.—The summary statement of lectures delivered during the past year shows that about ninety-five courses of lectures have been given in the subjects of the Faculty of Natural Science.

We may note the following among the lectures announced for this term:—

Prof. Sylvester will lecture on the resolution in integers of systems of linear equations with rational coefficients, and will reproduce an unpublished course of lectures given at King's College in 1869, on the relation of the theory of compound partitions of numbers to certain geometrical theories. Prof. Pritchard will lecture on planetary theory and on the Constellations.

Prof. Clifton, magnetism; Mr. Selby, the mathematical theory of electrostatics and magnetism.

Prof. Odling, diacidic olefine acids.

Prof. Green, stratigraphical geology and physical geology; Mr. Badger, palæontology.

Prof. Burdon Sanderson is unfortunately prevented from lecturing by serious illness, and Mr. Gotch and Dr. Haldane will lecture for him.

Dr. Tylor lectures on the development of religions, and Mr. Mackinder on the physical geography of the British Islands.

In the Medical Faculty, Mr. Thomson lectures on osteology, Dr. Collier on the methods of diagnosing disease of the heart, and Mr. Morgan on clinical surgery.

Scholarships and Exhibitions in Natural Science are offered for competition before Christmas by Balliol, Christ Church, and Trinity, and by Keble College.

Cambridge.—The Vice-Chancellor (Dr. Searle), in laying down his office, was able to relate that the executors of Mr. Newall had agreed to the conditions proposed to be made by the Senate as to the great telescope to be given to the University. The expense of transit, re-erection, and permanent work in promotion of stellar physics will be considerable.

The election of Mr. Jenkinson as Librarian gives the University an official who, in addition to his well-known classical and literary accomplishments, has no mean scientific qualifications. He was for some time Curator in Zoology, and is a member of the Botanic Gardens Syndicate and of the Council of the Cambridge Antiquarian Society. Men of science cannot regret Mr. Clark's retirement from the contest, for he literally could not be spared from the Museums, though otherwise highly qualified for the Librarianship.

There are very few new features in the science lectures this term. The list is, if anything, slightly longer, and would fill two of our pages; but there is nothing in it calling for special comment.

SCIENTIFIC SERIALS.

The *American Meteorological Journal* for September contains (1) an article by Prof. H. A. Hazen on cloud formation. The author considers that theories of storm generation and cloud formation are unsatisfactory. He has made a number of experiments, both with dry and damp air, on the formation of cloud by the cooling produced by exhaustion, the result being that he finds the amount of the latter to be only about one-fourth of what theory would indicate. The results obtained with dry and moist air were almost exactly the same. (2) State tornado charts for Alabama and Ohio, by Lieutenant Finley. (3) An article on the verification of weather forecasts, by H. Helm Clayton. He points out that all the methods adopted admit of considerable latitude in interpreting phenomena, so that the same forecasts, when verified by different persons, may differ widely as to the percentage of success, and he suggests an arrangement which may be applied to areas as well as to single stations, and which, at the same time, might be useful in studying the relative frequency of each phenomenon. (4) The distribution of wind velocities in the United States, by Dr. F. Waldo, deduced from the records of the self-recording anemometers at the stations of the Signal Service. In this article, which is unfinished, the author deals exclusively with the values of the constants derived from various anemometrical experiments in Germany and Russia.

The *Meteorologische Zeitschrift* for September 1889 contains a discussion, by Dr. J. Hann, of Parts iv. and v. of "Contributions to our Knowledge of the Meteorology of the Arctic

Regions," lately published by the Meteorological Council (see NATURE, vol. xxxviii. p. 625). He fully recognizes the value of this work, and the importance of a similar discussion of the observations collected during later expeditions. Dr. J. M. Pernter contributes an epitome of the Report of the Krakatão Committee of the Royal Society. Among the smaller "communications" may be mentioned (1) the description of a new registering apparatus for rainfall and wind, with electrical connections, in which the influence of the elements themselves is made to move the paper form, and the clock to record the indications, instead of the usual plan of the clock moving the paper (the principles of such an instrument were also referred to in the *Zeitschrift für Instrumentenkunde*, 1882, p. 206, and 1884, p. 300); (2) a note by Dr. Köppen, on the construction of isobars reduced to the level of 2500 metres, instead of to sea-level (the proposed plan is especially intended for use over large areas, where the differences of pressure and the altitudes of the stations are considerable, as, for instance, in Austria).

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, October 7.—M. Des Cloizeaux, President, in the chair.—Complement to the theory of thin weirs extending throughout the breadth of the bed of a water-course; approximate calculation, for depressed sheets, of the non-pressure at their lower face, according to the elevation of the surface down-stream, by M. J. Boussinesq.—New observations on the reciprocal displacements between oxygen and the halogens, by M. Berthelot. Fuming hydrochloric acid, in contact with air, does not yield chlorine, even after prolonged exposure to sunlight; but the addition of certain metallic chlorides (especially manganous chloride) causes it to react with oxygen, forming chlorine and water. This change is due to the formation and decomposition of a perchloride of manganese. Its bearing on thermo-chemical theory is pointed out.—On Raffinose, by the same. He describes a new hydrate, got by crystallization from aqueous alcohol, the formula being $C_{18}H_{32}O_{16} \cdot 6H_2O$ (the former one had $5H_2O$). Raffinose ferments wholly, with good beer-yeast. But with weak baker's yeast, the process stops, after forty-eight hours, when about a third has been affected. The raffinose seems to be broken up into a glucose, which ferments and disappears, leaving either a second sugar of the saccharose family, with a certain reducing power, or a mixture of two glucoses (one reducing).—Effects of an intermittent wind in soaring, by M. Marcy. A ball let off at the top of a board with sinuous profile, and descending series of heights, surmounts all those heights by gravity. Let off from the lowest height, it may be got back to the highest, if, each time it is rising, the board be jerked horizontally in the opposite direction. This experiment, suggested by M. Bazin, is applied to the case of the bird; an intermittent wind, acting as the bird rises, may enable it to gain height after each descent. (The movements of the ball M. Marey represents by photo-chronography.)—On transformism in micro-biology; limits, conditions, and consequences of the variability of *Bacillus anthracis*; researches on descendant or retrograde variability, by M. A. Chauveau. By continuous action of compressed oxygen on the *Bacillus*, one can obtain less and less resistant races or types, especially sensitive to the action of the attenuating agent, till at length they are found unable to vegetate in contact with it. Up to this limit, however, the *Bacillus* is pathogenic. It loses virulence, but keeps the vaccinal property throughout its existence. These new characters may be easily maintained by cultivation. And these special types of the *Bacillus* perhaps exist in nature.—On the invariants of certain differential equations and on their applications, by M. R. Liouville.—Determination of the difference of longitude between Paris and Madrid; an international research, carried out by MM. Esteban and Bassot. In 1863, MM. Le Verrier and Aguilar determined this difference indirectly, by measuring those between Paris and Biarritz, and Biarritz and Madrid. A direct determination was very desirable for geodetic purposes; and this, made with Brunner's portable meridian circles, and comparison of pendulums by chronographic inscription of telegraph signals (without relays) yields the value 24m. 6·00s. as against 24m. 6·08s. (Le Verrier).—On surfaces of which the ds^2 may be brought in various ways to the type of Liouville, by M. G. Kœnigs.—Synthesis of some oxygenated selenium compounds, in the aromatic series, by M. C. Chabrié.—Researches on fucusol, by M. Maquenne. This substance, obtained by Stenhouse from seaweed, proves to be a mixture of furfurol (10 parts) and methylfurfurol (1 part); the name should therefore be given up.—On the physiology of the trachea, by M. Nicaise. In normal, calm respiration, the trachea remains contracted, with unvarying diameter, the ends of the rings nearly in contact, also the borders. In strong respiration (shouting, singing, [&c.) the trachea dilates and elongates in respiration, the larynx rising; the reverse occurs in inspiration. He succeeded in registering these rhythmic movements. The dilatation is greatest at the upper part; it is permitted by the membranous portion, and is due to mechanical pressure of air. Compression of air by the dilated trachea plays an important part in singing, &c —On the pathology of nerve-terminations of muscles of animals and of man, by MM. Babes and Marinesco. By a new colouring method, they are able to follow the minute structure, and its alterations in atrophy, hypertrophy, segmentation, &c.—On a new *Proteromonas*, by M. J. Kunstler. This, found in the gray lizard of Gascony, is of S shape, and has a very long flagellum, two to five times as long as the body, starting usually from a globular enlargement. The name proposed is *P. dolichomastix*.—On the presence of pectic compounds in plants, by M. L. Mangin. These substances, he finds, play an important, if not preponderating *rôle* in the formation and growth of membrane; and he indicates methods of detecting their presence.

THURSDAY, OCTOBER 24, 1889.

JAMES PRESCOTT JOULE.

THROUGHOUT the world of science there has spread a feeling of profound regret at the death of Mr. Joule, which was announced a week ago in the columns of NATURE. On the evening of the 11th of this month he passed away at his residence in Wardle Street, Sale, near Manchester. For many years past he was in very feeble health. Indeed, as long ago as 1872 it was known publicly that he was far from strong. In that year he was President-elect of the British Association, but before the time of the autumn meeting he was obliged to relinquish the honour on account of physical weakness; and Prof. Williamson was called upon to occupy the position. In recent years Mr. Joule was living in complete retirement, carrying on, so far as his health would permit, such observations and experiments as could be conducted without bodily fatigue; and during this period he was able to edit with occasional brief notes, the two volumes of his collected papers which have been published by the Physical Society of London. The first of these important volumes appeared in 1884, and was noticed in NATURE (vol. xxx. p. 27). The second was published in 1887 (see NATURE, vol. xxxv. p. 461), and contained the papers which Joule wrote jointly with Dr. Scoresby, Sir Lyon Playfair, and Sir William Thomson. At the end of the latter volume there is a list of no less than 115 contributions to the various scientific societies and journals which were enriched by communications from his pen. The papers of Joule are remarkable in form as they are in substance. Of mathematics there is scarcely a line; but they are models of clearness, of depth, and of penetration into the hidden things of Nature; and the mathematician finds the experimental results stated and arranged in such a manner as to lend themselves readily to representation in mathematical symbols. Of experimenting he was a perfect master—full of elegant device, and clear in mind as to points of difficulty and places where error might creep in. That which, in the hands of almost anyone else, would have proved too difficult to lead to a trustworthy conclusion, in his hands was often made to yield an important law or generalization, or to afford an accurate numerical result.

In NATURE (vol. xxvi. p. 617) there appeared a biographical sketch of Mr. Joule; a few words may, however, be permitted here, in order to fulfil our duty to one of the greatest scientific leaders of the present century.

His work, taken as a whole, and without considering the relative importance to physical discoveries—that is to say, judged by the originality of the objects, and the means employed, the philosophic direction, the patient and persevering labour, and the results obtained—would be such as to place him in the front rank of philosophers. If account be taken of the importance and generality of his discoveries, as shown by their influence on the philosophical thought and material progress of the world, then, as the discoverer of the law that energy is in the same degree as indestructible and uncreatable as matter, it is with Newton and Dalton that he finds his place in the history of physical science.

The law of the conservation of energy, which in all schools of science, even the most elementary, is now taught as the foundation of each and all the branches of physical science—mechanics, physics, and chemistry—was, in 1841, as far from recognition as at any time since the discoveries of Newton had shown that, in their observed motions, the heavenly bodies strictly obeyed the laws of motion. The properties of friction, internal and external, with which it was found necessary to endow terrestrial material, and which properties were apparently nothing less than those of destroying energy, were still as far from explanation as the property of gravitation itself; while the continued production in the steam-engine of energy from the same material by the agency of heat, without any consumption of heat, as was then not only supposed, but counted as proved by the equality of the heat received from the boiler and discharged into the condenser, showed apparently nothing less than the creation of energy.

The study of heat which had taken place in the meantime had done nothing to remove these difficulties, for the observed fact that heat was susceptible of quantitative measurement, independent of temperature, had led to the hypothesis that heat was an imponderable substance —"caloric"—capable of penetrating matter and altering its temperature and state, but neither creatable nor destructible. The discoveries of electric phenomena tended to strengthen the caloric hypothesis by affording another imponderable substance. Nor was it only such difficulties in the way of the acceptance of the conservation of energy which kept back its discovery.

Energy, as a measure of mechanical potency, had never assumed a prominent place in mechanical philosophy, while the action by which it is converted into motion against resistance, had scarcely been recognized as a general measure of mechanical action, so that when, as continually happened, the idea of heat being a mechanical action thrust itself forward, there was no distinct measure of mechanical action at hand in which to gauge the equivalent.

Outside the schools of mechanical philosophy engineers engaged in constructing and using the steam-engine had long been led to recognize motion against resistance as the mechanical and commercial measure of potency. Under the names "work" and "accumulated work," these men had become familiar with what are now known as work and energy (actual and potential). It may be noticed that Rumford first recognized the true nature of the relation between heat and mechanical action by observing that two horses working steadily produced heat at a steady rate, but he did not reduce his results further; while Joule was so familiar with the action work, that he never hesitated as to the nature of the relation.

It is true that at the time when Joule commenced his work, not only had mechanical philosophy, as applied to astronomy and such abstractions as frictionless and perfectly elastic matter, reached to nearly its highest level, but the other branches of physical science, studied independently, were fast approaching their present stages. Dalton's discoveries of chemical equivalents had been made thirty years before, and chemistry had been advancing by leaps and bounds. The phenomena of electricity had been subject to the masterly handling of

Faraday. The law of the motion of heat had not only been experimentally determined, but had been theoretically discussed by Fourier. The specific heats of the elementary bodies, as well as the heat developed in combination, had to some extent been determined by Dulong. And the law connecting the quantity of electricity produced in voltaic batteries with the number of chemical elements separated, had been discovered by Faraday. So far, however, these various branches of physics and chemistry had been subjects of separate and distinct study. No suggestion of equivalence had been made between the heat of combination of the elements and the electric current that would be produced by the same combination effected in the battery. That heat was developed in conductors by electric currents was known, but again there had been no suggestion of an equivalence between the heat and the resistancc overcome. What are now known as the dynamo and motor had been invented by Sturgeon, showing that work could be done by the agency of electricity and electric separation effected by the agency of work, but again no equivalence between the amount of work and the energy of combination of the element in the battery had been surmised.

It was for Joule not only to suggest all these equivalences, but to experimentally determine all their numerical values[1] before he came to the equivalence of the work[2] spent in overcoming fluid, or solid, friction and the heat produced; and, again, between the work spent in compressing air and the heat produced.

The discovery of the mechanical equivalent of heat, important as it is, is but a poor expression for the outcome of this work, in which Joule converted what had till then seemed unquestionable cases of the destruction of energy into the most striking cases of its indestructibility. And although he propounded no theory, but simply declared himself to have believed in the indestructibility of *vis-viva*, or living force, he had, in the truest sense of the word, discovered the universal law that energy is indestructible and uncreatable. As Joule's work came to be apprehended, this law became accepted as its natural consequence in greater and greater significance, until now it stands the most general recognized law in the universe; relating not only to all matter but also the medium of space, which is thus found to possess the mechanical properties of matter and to be subject to the laws of motion.

The discovery of this law, bringing as it does the several branches of physical science into the domain of mechanical philosophy, fitly crowned all the work in physical science of the previous 150 years, of which it was the result. It also opened out a fresh platform for further discoveries—a platform which was immediately occupied in the erection of the compound sciences of thermodynamics, electrodynamics, and the dynamical theory of gases.

Joule was never prominently before the public. Ready to give himself with absolute devotion to the cause of science and the advancement of human knowledge, he yet preferred retirement and the calm labour of his laboratory to the excitement of public lectures and demonstrations. While he was keenly alive to the sympathy of friends, yet he worked for the most part alone, or in conjunction with one or other of the friends mentioned in the earlier part of this notice. He sought not at all for fame, but only for truth.

And yet honours in plenty came to him. He received honorary degrees from the most important Universities; he was honorary Fellow of many learned Societies at home and abroad. He was a Fellow of the Royal Society, and received from it the Gold Royal Medal in 1852, and the Copley Gold Medal in 1870. The Albert Medal of the Society of Arts was delivered to him from the hands of the Prince of Wales in 1880. In 1878 he received a letter from Lord Beaconsfield, announcing that the Queen had been pleased to grant him a pension of £200 per annum. This recognition by his country of his life of scientific labour was a subject of much gratification to Mr. Joule.

Special reference may be made to his connection with the Literary and Philosophical Society of Manchester. This commencing, as it practically did, at the age of fifteen, when he studied chemistry under Dalton in the rooms of the Society, continuing, by the most regular attendance at all the meetings, so long as his health permitted, and practically terminating with his death, must have been one of the most important circumstances of his life. Elected a member in the year of his greatest discoveries, 1842, he was Secretary in 1846, Vice-President in 1850, which office he held till his death, except during the ten years when he was President. He took the greatest interest in the welfare of the Society, and secured not only the veneration but love of all the members.

A man of science who left so deep a mark on his age ought to have been buried in Westminster Abbey, but unfortunately the necessary application could not be made, in consequence of the delay in the public announcement of his death. Prof. Osborne Reynolds, President of the Manchester Literary and Philosophical Society, has written to the *Times* urging that a monument should be erected in the Abbey, and that steps should immediately be taken to obtain, if possible, the consent of the Dean. This suggestion ought to meet with cordial and unanimous approval. Joule's name is one of which Englishmen may justly be proud, and the erection of a monument in Westminster Abbey would be the most fitting way in which they could express their appreciation of the splendour of his contributions to science.

THE LIFE OF SIR WILLIAM ROWAN HAMILTON.

Life of Sir William Rowan Hamilton. By Robert Percival Graves, M.A. Vol. III. "Dublin University Press Series." (Dublin: Hodges, Figgis, and Co. 1889.)

AT last the third and final volume of Graves's life of Sir William Rowan Hamilton has seen the light. It was our pleasure in former numbers of NATURE (vols. xxviii. p. 1, and xxxii. p. 619) to have reviewed the two earlier volumes, and we have now to congratulate the University of Dublin on the completion of an adequate biography of the most illustrious student that has ever issued from its halls. This present volume, of which we are now to speak, is as portly as its predecessors. It contains not less than 673 pages, and a very important feature of the work is the correspondence between Hamilton and De Morgan, which occupies more than half of the entire bulk.

The two earlier volumes described the career of Hamilton up to the year 1854. The great mathematician was then forty-eight years old, and the first of his two stupendous books on quaternions had been just published for the admiration and astonishment of the scientific world.

The abundant recognitions of the epoch-marking nature of this work were naturally extremely gratifying to its author. From numerous scientific Societies at home and abroad honourable distinctions poured in upon him. But we can readily comprehend the biographer when he tells us that Hamilton specially prized the tributes from such friendly and competent judges as Sir John Herschel and a few others of similar calibre.

It must, however, be recorded that those who expressed, and no doubt felt such admiration for the book had not always, as they themselves admitted, any very complete acquaintance with the subject. Herschel, for instance, says:—

"I got through the first three chapters of it with a much clearer perception of meaning than when I attacked it some three or four years back, but I was again obliged to give it up in despair."

Even though Hamilton and his intimate friend De Morgan corresponded for twenty-five years—even though De Morgan was himself a capable mathematician, whose labours led him in some degree towards the same line of investigation from which quaternions originated—yet he never succeeded in obtaining a competent acquaintance with Hamilton's theory. Most scientific men were apt to feel contented if they knew enough to make them reverence the awful volume which every mathematician likes to see on his shelves, but which we generally find that he likes to leave there.

It must be admitted that the hopes which Hamilton entertained as to the utility of quaternions as a mathematical calculus have not yet been fully realized. It seems to be the essence of modern mathematics that it should partake of the nature of exploration. For the furtherance of many departments of mathematics which are now ardently cultivated, a general and all-embracing calculus is not found so useful as are especial methods particularly contrived to the subject in hand. We may cite as an example of what we mean Klein's lectures on the Ikosahedron, which were so admirably reviewed in a recent number of NATURE (May 9, p. 35). The theory here involved may be regarded as typical of all that is best in modern mathematics; yet the methods which have been adopted are not those of any comprehensive calculus like quaternions; they are processes and lines of reasoning which naturally arise from the special character of the subject, and the same may be said with regard to other branches of mathematical research. Of course everyone admits the magnificence of quaternions viewed as a mathematical theory. It is indeed "a tract of beautiful country"; but, for the reason, apparently, that we have mentioned, it would seem that up to the present, at all events, the hopes which Hamilton entertained that quaternions should be largely used by mathematicians as a calculus have not been realized.

As to the value of quaternions we quote the following words of Prof. Tait, which occur in the preface of his well-known treatise on the subject, for probably there is no other living mathematician who could speak with equal authority:—

"The numerous examples I have given, though not specially chosen so as to display the full merits of quaternions, will yet sufficiently show their admirable simplicity and naturalness to induce the reader to attack the lectures and the elements; where he will find, in profusion, stores of valuable results, and of elegant yet powerful analytical investigations, such as are contained in the writings of but a very few of the greatest mathematicians."

The extraordinarily laborious habits of Hamilton are constantly referred to in this volume. He frequently speaks of working for twelve consecutive hours at mathematical research, and when immersed in these trances of discovery his regular meal hours were forgotten, and, unfortunately, he used to resort unduly to alcoholic stimulant. His relaxations, such as they were, may be conjectured from the following paragraph (p. 186) from a letter addressed to Dr. (now Sir Andrew) Hart by Hamilton the year before he died:—

"The fact is, that one of my early tastes was for metaphysics, and something has lately occurred to revive it. Another was for Eastern languages, and I chanced yesterday to light on the first sheet of a 'Persian grammar' written by myself forty years ago. These things, with others, may occasionally relax the bow—'*Non semper tendit*' but 'many tastes one power,' and my only *power* is mathematics."

As we have already stated, both the study of poetry and the writing of poetry were favourite recreations with Hamilton; and as this subject is so frequently mentioned in these volumes it may be well to mention what the biographer—himself an excellent judge—records on the matter (p. 128):—

"I will not here refrain from stating my own opinion, strengthened by that of friends specially competent to judge, that Hamilton's poems have, both in their diction and in their matter, qualities of enduring value; that, speaking generally, they are and will always be felt to be fresh, graceful, fervid expressions of states of feeling and thought, interesting in themselves and possessing a heightened interest from their being the heart's utterances of a man of gigantic mathematical powers and of strong and deep affections; and a few of them, it may be added, are so happy in thought and expression as to claim their place in the poetry of his country."

The closing years of Hamilton's life were spent in the preparation and the passing through the press of his second great volume, "The Elements of Quaternions." In the summer of 1865, his stupendous labours had at last reached their termination. His health, which had for long been failing, now gave way, and at last, from a complication of ailments, which included gout and bronchitis, he died on the 2nd of September, 1865.

An interesting chapter on the "characterizations" of Hamilton and his work closes the biographical part of the volume. A letter from Prof. De Morgan to Lady Hamilton (p. 215) contains the following passage:—

"I have called him one of my dearest friends: for I know not how much longer than twenty-five years we have been in intimate correspondence of most friendly agreement or disagreement, of most cordial interest in each other, and yet we did not know each other's faces. I met him about 1830 at Babbage's breakfast-table, and there for the only time in our lives we conversed. I saw him a long way off at the dinner given to Herschel about 1838, on his return from the Cape, and there we were not near enough, nor on that crowded day could we get near enough to exchange a word; and this is all I ever saw, and, so it has pleased God, all I shall see in this world, of a man whose friendly communications were among my greatest social enjoyments and greatest intellectual treats."

Hamilton was scrupulously sensitive about the feelings of others, and in his scientific work he took the most elaborate precautions that every particle of credit should be duly assigned to every mathematician whose labours had in the minutest extent anticipated his own. He had high personal courage and a keen sense of honour. It is recorded that he sent a hostile message to one who had challenged his veracity, and a due apology was exacted. The only approach that Hamilton ever had to a controversy about priority arose in the case of the discovery of conical refraction. MacCullagh put forward a claim to have virtually anticipated Hamilton. The sound judgment and lofty sense of right which were so characteristic of Humphrey Lloyd here averted what would have been an unpleasant dispute, and MacCullagh withdrew his pretension.

De Morgan says that in Hamilton's youth he used to be styled among his playmates the "defender of the absent," and from the same source we learn:—

"He relished the extremes both of simplicity and splendour; though in his own habits and manners as plain as possible, he thought much of the comforts of others and lightly of his own. When some housebreakers were caught on the premises and detained until they could be carried before a magistrate, he amused his family by directing that the fellows should be asked whether they preferred tea or milk for breakfast. A full memoir of his private and public life would present a genial combination of intellectual greatness, moral goodness, and piquant peculiarity of thought and manner, all brightened by never-ceasing benevolence of feeling, and toned by rare gentleness of manner."

Hamilton has left behind him an enormous bulk of manuscripts, of which not less than sixty great volumes have been deposited in the College Library. There are also many other papers unpublished, as, for instance, a stupendous letter to Dr. Hart, which contained about 240 large folio pages and a postscript of 60 additional.

The distinctive feature of this third volume of his life is the De Morgan correspondence, which, like the correspondence between Bessel and Olbers, will retain a permanent value. The opening letter of the series is from De Morgan, on May 8, 1841, in which he says: "I hardly know whether you remember that we made a little personal acquaintance some twelve years ago, when you were in London." The last is also from De Morgan, and the date February 3, 1865, relative to an application for a pension for the widow of the late Prof. Boole.

The correspondence, though largely on matters mathematical, ranges over a multitude of topics, classical and literary, logical and metaphysical, humorous and domestic. It sometimes glances at theology, occasionally condescends to refer to a practical question like the decimal system, but is almost wholly free from any reference to what are now generally known as the experimental or natural sciences, though we do indeed read of an electro-magnetic quaternion. From such an astounding mass of 400 pages it is difficult to cull passages which shall be regarded as samples. The collection is too heterogeneous to admit of such a process. It is, however, impossible not to feel how admirably the biographer has accomplished this part of his task. He has extracted from a mighty bulk of correspondence a collection so interesting that, after reading them through, we do not see any which we could wish to have been omitted.

It was three years after the interchange of letters had begun, and when Hamilton was thirty-nine years old, that De Morgan writes (p. 258):—

"I hope you are well, and taking care of yourself. Nobody gives you a good character in the second particular.

"The Astronomer-Royal in this country always lays down his work the moment he feels wrong, and plays till he feels right again. You have too much of our stock of science invested in your head to be allowed to commit waste. You are only tenant for life, and posterity has the reversion; and I don't see why you should not be compelled to keep yourself in repair."

Traditions of the state of Hamilton's study are still current. The awful masses of books and papers accumulated on the floor to such an extent that a lane had to be preserved for the perambulations of the Professor, who did much of his work standing at a blackboard, or walking up and down. Thus we can understand him writing to De Morgan on October 3, 1849 (p. 279):—

"If I lay a letter out of my hands for a few hours, without answering it, I am sure to find that it has been swept away and covered up, for the time, by the Charybdis of my other papers. No doubt, every such missing treasure may be expected, at some future time, to emerge to view, and may then be suddenly seized, by a bold and ready hand. Thus, from month to month, or at least from year to year, I find a note or two of yours eddying upward to the light; but, for the instant, your last long (and welcome) letter is invisible. However, I remember much of its contents, and shall send something now in answer to one, at least, of its 'loose thoughts.'"

As already mentioned, De Morgan could never be induced to devote himself sufficiently to quaternions to understand them. He often alludes to this, thus writing on October 11, 1849 (p. 283):—

"Nothing about quaternions will bore me, if I can only make it bore through me. Ink must be cheap in Ireland if you can afford to waste it on such a supposition as that."

Many amusing references are made by De Morgan to the contrast between his friendship to the Sir William Hamilton of Dublin, and his notorious controversies with the Sir William Hamilton of Edinburgh. Thus, on April 14, 1850 (p. 286):—

"Be it known unto you that I have discovered that you and the other Sir William Hamilton are reciprocal polars with respect to me (intellectually and morally, for the Scotch baronet is a Polar bear, and you, I was going to say, are a Polar gentleman, only I thought perhaps you might go and say I called you an Esquimaux). The intellectual polarity is of the kind, $\phi\psi(x) = -x$. When I send a bit of investigation to Edinburgh, the William

Hamilton of that ilk says I took it from him. When I send you one, you take it from me, generalize it at a glance, bestow it thus generalized upon society at large, and make me the second discoverer of a known theorem. He cuts my legs off; you make a pair of legs grow out of my head, and turn me upside down to stand upon them. His process after yours gives $\phi\psi(x) = -x$. Reciprocal polarity the last and most agreeable; your process involves no writing of pamphlets."

The gradual production of the books on quaternions are indicated by frequent allusions in the letters. On November 26, 1851, Hamilton writes (p. 291):—

"My book on the quaternions is advancing rapidly. I have just been correcting the slip which will bring it somewhat beyond 440 octavo pages. I first aimed at 200, but shall now congratulate myself if I get off under 500 pages. [It was ultimately 888.] You should be most welcome to copies of all the sheets hitherto printed, if I fancied that you would accept them, in the present state of the publication. In fact, I should *like* to send them, but think it not quite fair to *force* what may be thought a confidence on anyone."

To which De Morgan replies, in words that other authors will heartily appreciate (p. 293):—

"I beg you will send me the part printed, without scruple. There is a pleasure in reading while anything that strikes one may do service; it is the reviewer's feeling Christianized."

So much has been said about Hamilton's poems, and of the opinion he entertained of them, that it is well to read an authentic version of his own view of the matter in his letter of January 21, 1852 (p. 320):—

"If among your many and deep researches you have made psychology, as a sort of branch of natural history, one of them, you may feel some little interest in the following problem, which has often puzzled myself.

"Among the persons who know anything about my existence and my writings, I suppose that the majority would admit me to be a mathematician; while all, or nearly all, would say that I could only be regarded as a poet by courtesy.

"Does it not seem, then, to contradict one of the very tritest sayings about human nature that I care little, or not at all, about criticisms on my poetry, such as it is, while I own myself to be actually sensitive on the score of my mathematics?

"Wordsworth did me the honour to cut up, in a more slashing style than yours, some of my early poems. I think that I was less flattered than indifferent, although I did most highly prize the advantage of an intimacy with him.

"Slash away at my sonnets; but spare me, if you honestly can, a little praise for the quaternions, or, what will be far better, allow me the honour of *assisting* you to *use* them as a calculus, for such they certainly are."

Hamilton complains that he is ridiculed about the quaternions by people who know nothing of the method. De Morgan advises him to preface the book with a systematized body of results, on the ground that "every book should be provided with some palisade against mere talkers. . . . You will find the table of contents a useful outwork."

It would seem there was another class of quasi-scientific men of whom Hamilton, not without reason, had some dread, for we read (p. 360):—

"A story goes, that a person who read more than he digested once told a friend of his that he had heard people talk of 'Euclid,' and that he was curious to read the work. The other lent him a copy, and was surprised to find the borrower return it the next day with many thanks. 'What, have you read it?' said the lender. 'Yes, thank you,' replied the borrower. 'Read it?—read Euclid *through* in that short time?' 'Oh, if you mean the A's and the B's and the C's, I skipped all those.' The 'Quaternions' as well as the 'Formal Logic' may meet with some readers of that stamp."

To which De Morgan replies (p. 362):—

"When you tell the story about Euclid, remember that the man left out the A's and the B's and the C's and the pictures of scratches and scrawls. I once met a man, no strong mathematician, who said he read Airy's 'Gravitation' through on a bench in the front of his house."

We have learned in the earlier volumes of the almost miraculous talents which Hamilton displayed as a child for the acquisition of languages. It is therefore interesting to find him saying on April 16, 1852:—

"As to Sanscrit and Persian, I do not pretend to read them *now;* but my childish acquaintance with various languages may, as I have often since thought, have assisted me in my maturer study of mathematical symbols, and even in my attempts to enlarge the limits of mathematical expression."

An interesting letter to De Morgan on March 14, 1854, gives Hamilton's views on Auguste Comte's "Cours de Philosophie Positive," from which the following extract may be cited (p. 475):—

"These specimens, which I could easily multiply, may suffice to justify a profound distrust of Auguste Comte, wherever he may venture to speak as a mathematician. But his vast general ability, and that personal intimacy with the great Fourier which I most willingly take his own word for having enjoyed, must always give an interest to his *views* on any subject of pure or applied mathematics."

There were often long intermissions in the correspondence, generally on Hamilton's side, until at last De Morgan, by some genial and humorous attack, would succeed in reopening it. Witness the following:—

"If you are dead and buried, why can't you say so like a man, instead of leaving me to infer it from your silence."

And again on April 29, 1855 (p. 495):—

"Rouse out from the quaternions and write me a line. Remember that I, who have studied biography, and especially looked at the psychology of inventive mathematicians, do positively make affidavit, that if a man do not fallow, and shift courses, as they say, or used to say, in farming, he will put his head *out of heart.* If I had the power—supposing it true, as I hear, that you will not let quaternions alone for a while—I would put you into the commissariat, and make you copy out Balaklava stores, for six months. How are you all?"

These last lines remind us of a prescription recommended for another eminent mathematician, whose thoughts were apt to soar too far above terrestrial things. It was that he should serve for a couple of years as conductor to a London omnibus.

An appendix contains in the words of Hamilton himself what is designed to be as popular an account of the doctrine of quaternions as the subject will admit. It consists of two portions: firstly, an unfinished letter to his uncle, the Rev. James Hamilton, dated September 11

1846; the other an "elementary sketch," written after the publication of his volume of "Lectures on Quaternions." He here again insists on the combination of the notions of time and space in the quaternion.

> "And how the One of Time, of Space the Three
> Might in the Chain of Symbol girdled be."

The appendix also contains Hamilton's account of Mädler's attempt to show that the Pleiades are the central group of our sidereal system. The doctrine was unworthy of Hamilton's attention, and these pages are the only ones in this volume which we would gladly have seen omitted. Of infinitely more value are the remaining pages, in which we find a carefully compiled catalogue of all Hamilton's writings. There is also an interesting list of the chief unpublished manuscripts of Hamilton which have been preserved; and finally, before the capital index is reached, we have an enumeration, to which Prof. Tait has contributed, of the chief works of other mathematicians in which the quaternions have been employed.

It is impossible to read these volumes without acquiring a feeling of admiration amounting almost to reverence for the majestic intellect that they so adequately portray. In his youth Hamilton set before himself with deliberate aim the attainment of excellence in scientific work. Throughout his life he spared no pains, he flinched from no labour, to attain his ideal. With wonderful singleness and concentration he devoted his life to work. His career affords another illustration of the very close alliance if not actual identity between genius and the capacity for taking pains. If the quality of his work could not be surpassed, most assuredly its quantity could hardly be rivalled, and yet when we take leave of this work and ponder on the lessons it teaches it is perhaps hardly on the intellectual side of Hamilton's life that we shall find ourselves meditating. It is impossible to follow that exquisite correspondence between Hamilton and De Morgan without thinking of the rare but well-deserved good fortune which gave to De Morgan such a correspondent as Hamilton, which gave to Hamilton such a correspondent as De Morgan. On both sides these letters breathe a lofty spirit of truthfulness and honour and of attachment to whatsoever things are just and noble. Each shows a charming conception of the respect due to his friend and of the respect due to himself. Friendship such as these two men enjoyed was indeed a choice privilege. Hamilton shows himself not only as the consummate mathematician and philosopher, not only as the scholar and the poet, but as the high-minded gentleman with whom exalted conceptions of duty were habitual.

Finally, we must express our obligations to Mr. Graves for the admirable way in which he has completed his monumental task. He was intrusted with the preparation of the biography by Hamilton himself, and for laborious years he has devoted himself to the charge which his deceased friend laid upon him. Materials he had in abundance the most prodigal. He has selected copiously and he has selected judiciously, and he has told his wonderful story with a literary gracefulness that we most gratefully acknowledge. The memorable volumes of the "Lectures on Quaternions" and the "Elements of Quaternions" have a place on the shelves of all scientific libraries which are worthy of the name. Beside them should be ranged the three portly volumes in which Graves has recounted the life of that astonishing genius by whom Quaternions were invented.

THE ENGLISH TRANSLATION OF WEISMANN'S "ESSAYS."

Essays on Heredity and Kindred Biological Problems. By Dr. August Weismann. Authorized Translation, Edited by E. B. Poulton, Selmar Schönland, and Arthur E. Shipley. (Oxford: Clarendon Press, 1889.)

THIS is the fourth volume of a very useful series of translations of foreign biological memoirs, and the Delegates of the Clarendon Press are again to be congratulated on their choice of subject and editors.

As the editors' preface tells us, since Mr. Shipley's article, entitled "Death," in the *Nineteenth Century* for May 1885, first called the attention of English biologists to Prof. Weismann's essays, the interest in that author's conclusions and arguments has become very general. This interest has been stimulated and widened by the articles of various authors in NATURE, by Prof. Lankester's addresses at the Royal Institution, and, above all, by the great discussion introduced by Prof. Lankester at the meeting of the British Association in Manchester. No doubt a translation is superfluous, in these days of international science, to most biologists. But this is much more than a technical treatise on a technical subject. It is of interest to that far wider circle of readers and thinkers devoid of the time or the opportunity to wrestle with the involved German of the original. For to most the pith and kernel of the whole book is the criticism, perhaps the refutation, of the theory of the inheritance of acquired characters. That theory is of immediate importance to biology, but it is of equal, if remoter, importance to education and morality. We are certain that biologists do not enjoy a monopoly of education: we are by no means certain that they enjoy a monopoly of morality.

The translation is very accurate and unusually elegant: the foreign idiom has, to a large extent, been avoided, and there is little trace of the intricacies of Teutonic inversion. The footnotes are exceedingly useful, and many of them introduce important collateral matter. For instance, on p. 172, a concise and clear account is given of Mr. Francis Galton's earlier and somewhat parallel explanation of heredity.

The typography is excellent, but the absence of spaced type—a device of great utility in the original—is to be regretted.

The essays are translated in chronological order from the revised German editions. And so, by a consecutive perusal of the book, an historical conception of the wonderful series of inductions and inferences may be gained. Among the many converging lines of thought and work that led to the conception of the germ-plasma as the basis of heredity, two seem most clearly marked. In a prolonged study of the Hydromedusæ, Dr. Weismann discovered that the generative cells were formed only in certain localized areas. These special areas vary in position in different species, and the differences in position correspond to the different stages in a process of displacement occurring in the phylogeny of the Hydroids. In the actual development these stages are repeated, and the primitive germ-cells migrate from the ancestral to the present position. From this it followed that the germ-cells contained something *sui generis:* something that could not be derived from the tissue-cells.

The first and third essays, on the other hand, show how a more or less theoretical consideration of death as a factor in biology led to the establishing of an actual continuity of life from individual to individual in genealogical series. In all animals above those consisting essentially of a single cell, this continuity of life is confined to the generative cells, and it is the other, or somatic, cells alone that are necessarily mortal.

Such converging lines led to the provisional hypothesis of a continuity of germ-plasma as the basis of heredity—the hypothesis in fact, to take a simple instance, that it is the eggs that have been forming the hens, and not the hens the eggs, and so with their ancestors from the remotest of times. With this new view came the discussion of the inheritance of acquired characters and the brilliant interpretations and investigations of parthenogenesis and polar bodies. Essay VII., on the supposed botanical proofs of the transmission of acquired characters—which has not before appeared in any form in English—and Essay VIII., on the supposed transmission of mutilations, are valuable contributions to the questions raised by the general theory.

There can be no doubt but that Dr. Weismann's essays will be for long a source of inspiration and stimulus to supporter and adversary, and this valuable translation must prove of great service in making better known what, if it never advances beyond the stage of a provisional hypothesis, has already been of the utmost service to biology.

P. C. M.

OUR BOOK SHELF.

Chambers's Encyclopædia. New Edition. Vol. IV. (London and Edinburgh: W. and R. Chambers, 1889.)

In this volume of the new edition of "Chambers's Encyclopædia," subjects from "Dionysius" to "Friction" are dealt with. So far as we have been able to test it, we have found that the volume is in no respect inferior to its predecessors. The subjects include some that are of great scientific interest and importance, and these have been intrusted to writers whose names are a sufficient guarantee for the character of their work. Prof. Tait writes the article on force, Dr. W. Peddie those on energy and ether, and Prof. Cargill G. Knott that on electricity. Dynamos, the electric light, and the electric railway are described by Prof. J. A. Ewing. The theory of evolution is presented by Prof. Patrick Geddes, who, while expounding his own doctrine, tries to give a perfectly fair account of the opinions of thinkers with whom he only in part agrees. Dr. H. R. Mill has a good article on the earth, and Prof. James Geikie discourses with his usual clearness on Europe and on earthquakes. To the article on France, Prince Kropotkin contributes the geographical section. Prof. A. H. Keane is the author of the article on ethnology; and Dr. Henry Rink has a short but interesting paper on the Eskimo. These and other articles on scientific subjects in the present volume cannot fail to maintain the high reputation of "Chambers's Encyclopædia" for accuracy and thoroughness.

Farm Live Stock of Great Britain. By Robert Wallace, Professor of Agriculture at the University of Edinburgh. Second Edition. (Edinburgh: Oliver and Boyd. London: Simpkin, Marshall, and Co. 1889.)

This is a second edition of a work already reviewed in Nature. The most important point of difference between it and the first edition is the introduction of 100 excellent plates, executed by Angerer and Göschl, of Vienna, from photographs taken from life. Pictures are, no doubt, of great assistance to a description, but, as the author justly observes, photographs, although accurate, fail in some respects to do justice to animals. This he attributes to the awkward positions they assume while standing, and the constancy of their motion while they remain on their limbs. It is also, no doubt, partly due to the higher elevation of the eye of the observer than the camera as usually employed. The levelness of the back and of the belly lines is destroyed by the camera when placed horizontally so as to strike the broadside of the animal. Prominences are shown against the light, which in ordinary observation do not disturb the levelness of the carcass. The work has a strictly pastoral and agricultural interest.

Days with Industrials; or, Adventures and Experiences among Curious Industries. By Alexander H. Japp, LL.D. (London: Trübner and Co., 1889.)

This book is a reprint, with additions, of a number of articles which have appeared from time to time in various periodicals of a popular character. The articles deal with such subjects as quinine, rice, pearls, amber, common salt, Burton ale and Dublin stout, petroleum, canaries, bedsteads, railway-whistles, knives, forks, and postage-stamps—as heterogeneous a mixture, in fact, as the contents of Mrs. Jellaby's famous cupboard. Dr. Japp writes in a chatty and agreeable style, and his book may be safely given to young people, with the certainty that they will imbibe no false notions of science.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

Lamarck *versus* Weismann.

I had not intended to reply to Mr. Cunningham's criticism of a passage in my book which he thinks is pure Lamarckism (see Nature, July 25, p. 297); but now that Prof. Ray Lankester adopts the same view, I will make a few remarks upon the case. Mr. Cunningham italicizes the words, "the constant repetition of this effort causes the eye gradually to move round the head till it comes to the upper side," and claims this as a Lamarckian explanation. But if we italicize the following words, which occur three lines further on, "*those usually surviving whose eyes retained more and more of the position into which the young fish tried to twist them,*" we shall see that the survival of favourable variations is, even here, the real cause at work. For the transference of the eye to the upper side was a useful change—perhaps, under the peculiar conditions of existence and development—an absolutely essential one. The amount to which the eye could be twisted and retained in its new position was variable, as all other such characters are variable. Those individuals who had this faculty in the greatest degree were among those that survived, and it is not at all necessary to assume that any portion of the change *due solely to the effort* was inherited, but only that those individuals which were the most favourably constituted in this respect transmitted their peculiar constitution to their offspring, and thus the twisting would take place earlier and earlier in the development of the individual Even Darwin himself, who believed in the heredity of acquired variations, says that "the *tendency to distortion* would no doubt be increased through the principle of inheritance"; and this is really all that is necessary. In most of the higher animals symmetrical development of the two sides of the body is of vital importance, and is strictly preserved by natural selection; but more or less defect of symmetry often occurs as a variation or monstrosity, and in cases where such asymmetry was useful these variations would be preserved and increased by selection and heredity. An altogether erroneous view is taken of the fact of effort being used in this case, as if it were something unusual. But in all cases selection produces changes which are useful and whose use is often indicated by effort. The giraffe uses effort in stretching its neck to obtain food during a drought; the antelope exerts itself to the utmost to escape from the leopard; but it is now recognized that it is not the individual change produced by this *effort* that is inherited, but the favourable constitution which renders extreme effort unnecessary, and causes its possessors to survive while those less favourably constituted, and who therefore have to use greater effort, succumb. In the case of the developing flat-fish also, the effort indicated the direction of the useful modification, and any variations tending either to the right kind of asymmetry or to a mobility of the eye, admitting its being twisted and retained in its new position, during the growth of the individual, would be certainly preserved.

I wish to take this opportunity of thanking Prof. Ray Lankester for his careful and appreciative review of my book. I am too well aware of my own deficiency in training as a naturalist not to admit all the shortcomings which he so tenderly refers to. It is quite refreshing to me to read at last a real criticism from a thoroughly competent writer, after the more or less ignorant praise which the book has hitherto received. I admit also that the term "laboratory naturalist," to which he demurs, was not well chosen. I meant it as the opposite, not so much to "field naturalist" as to "systematic naturalist"; and it still seems to me that the gentlemen he refers to as not being "laboratory naturalists" are still less "systematic naturalists," in the sense of having specially devoted themselves to the observation, description, and classification of more or less extensive groups of species of living organisms. ALFRED R. WALLACE.

A Mechanical Illustration of the Propagation of a Sound-Wave.

HAVING to prepare some lectures on sound, I wished, if possible, to illustrate, without any very complicated apparatus, the way in which a sound-wave is propagated.

The following method suggested itself to me. As I have not met with the method while examining a large number of works on sound and wave motion, I venture to send a description of it to NATURE, as it may perhaps be of use to some students of acoustics.

A row of pendulums of equal length, *a*, *b*, *c* . . . *l* (Fig. 1) are suspended from a rod AB; in order to start the pendulums,

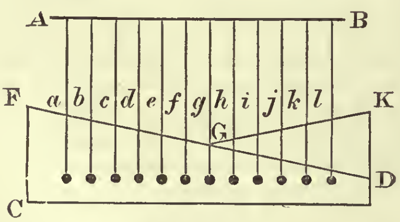

FIG. 1.

the bobs are held against an angular-shaped board, FCD, the rod being held in a plane slightly behind the plane of the board; if now the rod and pendulums be raised together vertically, *l* will first swing, then *k*, and so on, till all are free: when the pendulums are raised with a uniform velocity, then each pendulum starts at an equal period of time after the one which is next to it; the result is that a wave-motion is seen to run along the line of bobs as they vibrate to and fro. Such an arrangement has been used to illustrate wave-motion, as each bob moves with harmonic motion. But such an arrangement does not illustrate directly those compressions and rarefactions whereby sound is propagated. A slight movement, however, of the rod at once makes it do so. If, while the pendulums are vibrating, the rod from which they are suspended be turned in the horizontal plane through a right angle, the direction of the swing of each pendulum is not changed, and all the pendulums swing in the same plane. This will become clear from (Fig. 2), where the pendulum bobs viewed along OX appear to trace out wave-motion; the relative position of the bobs after the rod which supports them is turned through a right angle is shown along OY; the motion then illustrates mechanically those movements of air-particles which, when in compression and rarefaction, propagate a sound-wave. If the rod be turned back through a right angle, the wave-motion is again restored. The illustration must be taken with the obvious defect, viz. that the bobs move in arcs, and not in straight lines.

Care should be taken that the amplitude of vibration be not greater than the distance between the points of suspension minus

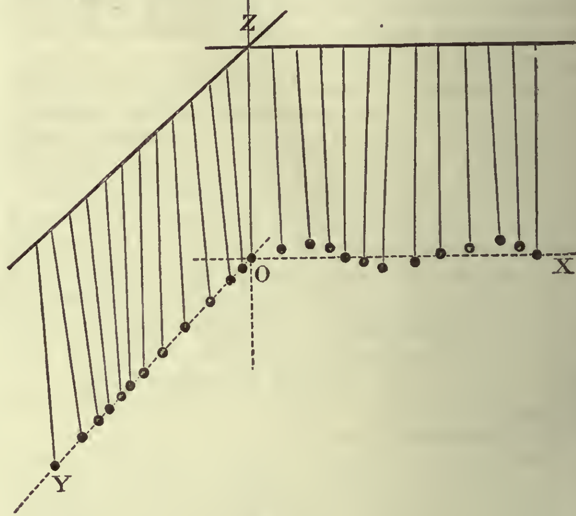

FIG. 2.

the diameter of a bob, otherwise the bobs will hit each other when vibrating in the plane YZ.

Twelve pendulums made of lead bullets 1·5 centimetre in diameter, suspended from threads 30 centimetres long, with a distance between each of 5 centimetres, were found to answer well by the author.

If the board used for starting the pendulums be made of the angular shape, FGK, then the movement of the bobs in their second position illustrates the propagation of sound on each side of its origin. FREDERICK J. SMITH.

Trinity College, Oxford, October 1.

On some Effects of Lightning.

THE twisting of one of the two trees near St. Albans, which were struck in such a remarkable manner by lightning, may well have been caused by the fall of the top of the tree, as Mr. Griffith suggests, and not directly by the lightning.

I have been unsuccessful in ascertaining whether the core of the tree is situated nearer that side where the explosion seems to have been most violent; but a more detailed examination only enforces the conclusion which Mr. Griffith and I arrived at, that the explosion must have occurred inside the stem, if not actually at the core of the tree.

The effects in this case can meet with no explanation from the supposition that the lightning passed between the bark and the tree, generating thereby sufficient steam to blow off the bark and shatter the stem—an explanation which Mr. Maclear suggests in his letter of September 25. I doubt if any source of heat would ever convert water so quickly into steam as to endow it with the power which dynamite has of shattering a hard object lying in contact with it, while the gases formed are restrained by the comparatively feeble resistance of the bark and outer air; nor can we suppose that sufficient heat could pass into the stem to generate steam there adequate for such an explosion, even if the uncharred condition of the wood did not prove incontestably that the temperature had not been raised very high. It seems more probable to me that such explosions must be caused by the lightning electrolysing the liquids in the stem, and thereby causing the sudden production of large volumes of gases at the ordinary temperature.

In answer to Mr. Griffith's query, I may state that the two trees are 34 yards apart; that there is no other tree in a direct line between them, though there are two about 4 yards from this line, and about midway between them; that the trees are certainly not isolated in any way, since there are fifteen trees within less than 34 yards of one of them, and about the same number within the same distance of the other.

48 Bryanston Square. SPENCER PICKERING.

Yew Trees in Berks.

A COMMUNICATION from Mr. Walter Money respecting two yew trees which were planted in the churchyard of Basildon, Berks, by Charles, Lord Fane, in 1726, has appeared lately in some of the papers (*North Wilts Herald*, October 4, 1889, and *Standard*), in which he refers to the dimensions recorded in the parish register, taken in 1780 and 1796, and again by my father in 1834. He adds his own observations on the growth taken this year. As I happen to have the original notes made by the late Prof. J. S. Henslow, dated "1834, August," it may be not uninteresting to record them. He writes as follows:—

"Measurements of yew trees at Basildon Churchyard, planted in 1726; taken near the ground:

		Ft.	In.	
Tree to south, 1780	... ...	6	3	According to Register.
1796	... ...	8	6	
1834	... ...	8	9	[J. S. H.]
,,	(at 4 feet)	6	$10\frac{1}{2}$	
[1889	... ...	9	10	Mr. Money]

Tree to north [1780 and 1796 not recorded in register]:

			Ft.	In.	
Roots lately injured by digging graves.	1834	... ...	9	$2\frac{1}{2}$	[J. S. H.]
	,,	(at 4 feet)	6	$9\frac{3}{4}$	
	[1889	... ...	9	6	Mr. Money]

"From the three observations of 1780, 1796, and 1834, it would appear that the period of rapid growth stopped about 1796; but it seems probable that the measurement here is somewhat too great compared with that of 1780, as well as with that of 1834; for

Growth to		Ft.	In.		Lines.		Lines.		Years.	Lines per ann.
1780	...	6	3	=	900	gives	300	diam. of gr. in	54,	*i.e.* $5\frac{1}{2}$
1796	...	2	3	=	324	,,	108	,, ,,	16,	,, $6\frac{3}{4}$

"Allowing this measurement to be wrong by 6 inches, it will reduce it to a greater probability also with that of 1834; and we shall have—

Growth to		Ft.	In.		Lines.		Lines.		Years.	Lines per ann.
1796	...	1	9	=	252	gives	84	diam. of gr. in	16,	*i.e.* $5\frac{1}{4}$
1834	...		9	=	108	,,	36	,, ,,	38,	,, 1
[1889	...	1	1	=	156	,,	52	,, ,,	55,	,, 1]

"N.B.—The increase between 1780 and 1796 is too great, supposing the same parts to have been measured; and between 1796 and 1834 it is too little; therefore 1796 either took in too much of the circumference of the roots, or perhaps 1780 a little above them. Possibly the soil had become somewhat raised since 1796.

[Since 1834 the growth for the last fifty-five years will be seen to be exactly the same per annum, or 1 line.]

[With regard to the rate of increase at a height of 4 feet from the ground, he adds the following additional note.]

"Now the rate of increase of 4 feet from the ground is slower than that near the root, upon the whole, in the proportion of one-fourth, nearly. Taking, therefore, this fact with the indications given above, we may average the growth of the stem at 4 feet in the following way:—

"Diameter at 4 feet = $\frac{990}{3}$ lines = 330 (in 1834). Dividing this by the age, or 108 years, it gives 3 lines per annum nearly.

"Also 1780 to 1796 gives 84 lines for 16 years, *i.e.* 5 lines per annum.

"As it seems not to have grown much in the last twenty-eight years (*i.e.* up to 1834), if we allow 1 line for this period, and distribute for the eighty years of rapid growth, we get the following result; thus:—

First 20 years at	$3\frac{1}{2}$ lines	=	70	Young growth.
,, 40 ,,	4 ,,	=	160	
,, 20 ,,	3 ,,	=	60	
,, 28 ,,	$1\frac{1}{2}$,,	=	42	Settled period."

GEORGE HENSLOW.

Maxwell's "Electricity and Magnetism."

THERE is apparently a trifling slip in § 360 of Maxwell's "Electricity and Magnetism." The ratio of the resistance of pure iron at 100° C. to the resistance at 0° C. is there stated to be 1·645. This ratio is evidently calculated from the results given in Matthiesen's paper on the influence of temperature on the electric conducting power of thallium and iron (Proc. Roy. Soc., 1862–63). The true ratio for pure iron annealed in hydrogen is 1·6255. The other ratios mentioned in the paragraph are correctly deduced.

HERBERT TOMLINSON.

King's College, Strand, October 12.

AN EXAMINATION OF SOME POINTS IN PROF. WEISMANN'S THEORY OF HEREDITY.[1]

PROF. WEISMANN'S views on heredity and allied phenomena have met with such general acceptance that I feel it to be presumptuous on my part to attempt any criticism of them. I cannot but think, however, that a statement of the difficulties which they present to me, and of the inconsistencies which appear to exist in the argument, may be of value, not indeed as a refutation, but as drawing attention to those points which seem to require further elucidation.

It will be necessary for me to state Prof. Weismann's argument, and I shall endeavour, in so doing, to represent it as fully and as fairly as my apprehension of it will admit, and as far as possible in his own words. But this is a matter of no small difficulty, inasmuch as the argument has to be traced through a number of separate essays, even though these essays have been collected into one volume and translated into English. All the references which I make relate to the English edition.[2]

The fundamental fact upon which the whole argument is based, and which Prof. Weismann appears to have fully established, is that the body of unicellular organisms (monoplastides), as also that of undifferentiated multicellular organisms (homoplastides), is immortal, at any rate potentially. This position is clearly stated in the following passage (p. 25):—

"The process of fission in the Amœba has been recently much discussed, and I am well aware that the life of the individual is generally believed to come to an end with the division which gives rise to two new individuals, as if death and reproduction were the same thing. But the process cannot truly be called death. Where is the dead body? What is it that dies? Nothing dies; the body of the animal only divides into two similar parts, possessing the same constitution."

Death is, on the contrary, a characteristic feature of differentiated multicellular organisms (heteroplastides); but even in these forms there is still an immortal part, for the reproductive cells which develop into new individuals are evidently as potentially immortal as the Amœba. In these higher organisms, therefore, the mortal cells are to be distinguished from the immortal. This distinction is drawn by Prof. Weismann as follows (p. 122):—

"It is necessary to distinguish between the mortal and the immortal part of the individual—the body in its narrow sense (*soma*) and the germ-cells. Death only affects the former; the

[1] This paper is an expansion of some remarks contributed to the discussion on "The Transmission of Acquired Characters," which took place in Section D during the recent meeting of the British Association at Newcastle.

[2] Weismann, "On Heredity" (Oxford: Clarendon Press, 1889).

germ-cells are potentially immortal, in so far as they are able, under favourable circumstances, to develop into a new individual, or, in other words, to surround themselves with a new body (*soma*)." (See also p. 158.)

This statement is further explained on p. 205:—

"Strictly speaking, I have therefore fallen into an inaccuracy in maintaining (in former works) that the germ-cells are themselves immortal; they only contain the undying part of the organism—the germ-plasm; and although this substance is, as far as we know, invariably surrounded by a cell-body, it does not always control the latter, and thus confer upon it the character of a germ-cell."

Similarly, the substance of the body is termed somatoplasm (p. 104). Moreover, the germ-plasm is stated to be localized in the nucleus of the germ-cell (p. 179).

The first difficulty which presents itself is to understand how the mortal heteroplastides can have been evolved from the immortal monoplastides or homoplastides. The explanation which Prof. Weismann offers is as follows (p. 27):—

"Let us now consider how it happened that multicellular animals and plants, which arose from unicellular forms of life, came to lose this power of living for ever.

"The answer to this question is closely bound up with the principle of division of labour which appeared among multicellular organisms at a very early stage, and which has gradually led to the production of greater and greater complexity in their structure.

"The first multicellular organism was probably a cluster of similar cells, but these units soon lost their original homogeneity. As the result of mere relative position, some of the cells were especially fitted to provide for the nutrition of the colony, while others undertook the work of reproduction. Hence the single group would come to be divided into two groups of cells, which may be called somatic and reproductive—the cells of the body as opposed to those which are concerned with reproduction. This differentiation was not at first absolute, and indeed it is not always so to-day. Among the lower Metazoa, such as the Polypes, the capacity for reproduction still exists to such a degree in the somatic cells, that a small number of them are able to give rise to a new organism—in fact, new individuals are normally produced by means of so-called buds. Furthermore, it is well known that many of the higher animals have retained considerable powers of regeneration; the salamander can replace its lost tail or foot, and the snail can reproduce its horns, eyes, &c.

"As the complexity of the Metazoan body increased, the two groups of cells became more sharply separated from each other. Very soon the somatic cells surpassed the reproductive in number, and during this increase they became more and more broken up by the principle of division of labour into sharply separated systems of tissues. As these changes took place, the power of reproducing large parts of the organism was lost, while the power of reproducing the whole individual became concentrated in the reproductive cells alone."

It is clear that this explanation, plausible as it seems to be, leaves untouched the real question at issue; the question as to how mortal cells could have been evolved from immortal. Prof. Weismann himself seems to have been conscious of this, for on p. 139 he reverts to the subject as follows:—

"It may be objected that cells of which the ancestors possessed the power of living for ever, could not have become potentially mortal (that is, subject to death from internal causes) either suddenly or gradually, for such a change would contradict the supposition which attributes immortality to their ancestors, and to the products of their division. This argument is valid, but it only applies so long as the descendants retain their original constitution. But as soon as the products of the fission of a potentially immortal cell acquire different constitutions by unequal fission, another possibility arises. Now it is conceivable that one of the products of fission might preserve the physical constitution necessary for immortality, but not the other, just as it is conceivable that such a cell—adapted for unending life—might bud off a small part, which would live a long time without the full capabilities of life possessed by the parent cell; again, it is possible that such a cell might extrude a certain portion of organic matter (a true excretion) which is already dead at the moment it leaves the body. Thus it is possible that true unequal cell-divisions, in which only one half possesses the condition necessary for increasing, may take place; and in the same way it is conceivable that the constitution of a cell determines the fixed duration of its life, examples of which are before us in the great number of cells in the higher Metazoa, which are destroyed by their functions. . . . But the reproductive cells cannot be limited in this way, and they alone are free from it. They could not lose their immortality, if indeed the Metazoa are derived from the immortal Protozoa, for from the very nature of that immortality it cannot be lost. From this point of view the body, or *soma*, appears in a certain sense as a secondary appendage of the real bearer of life—the reproductive cells."

Prof. Weismann here comes to closer quarters with the real question at issue, but still he does not fully face it. He invokes the principle of "unequal fission" to account for the acquisition of "different constitutions" by the products of fission, but he offers no explanation whatever of the *modus operandi* of unequal fission. He makes no suggestion as to the constitution of the body of the Protozoa; whether it consists, in his opinion, entirely of germ-plasm, and if not, whether or not the germ-plasm is localized in the nucleus. The only criticism which can be made is that the bare mention of "unequal fission" is not a sufficient answer to the objection "that cells, of which the ancestors possessed the power of living for ever, could not have become potentially mortal." It appears to me that any satisfactory answer to this objection must include the assumption that the immortal ancestors already contained a substance which was potentially mortal. It is impossible to conceive that unequal fission can take place in a cell consisting throughout of essentially the same kind of substance.

Very much the same difficulty presents itself in connection with the development of the embryo from the ovum or germ-cell; in the one case it is phylogenetic, in the other ontogenetic. Prof. Weismann goes into far greater detail in this latter case, and the statements which he makes concerning it may perhaps be intended to throw some light on the former.

The germ-cell, as pointed out above, is characterized by containing germ-plasm; and this germ-plasm is localized in the nucleus. There is one point which Prof. Weismann does not mention, and that is as to the nature of that portion of the germ-cell (including the cytoplasm and part of the nucleoplasm) which does not consist of germ-plasm. Of what, then, does it consist? It must consist of somatoplasm: there is no alternative. The germ-cell, then, consists mainly of mortal somatoplasm, and contains in its nucleus a certain amount of immortal germ-plasm. But, as shown in preceding quotations, Prof. Weismann holds that the whole germ-cell is immortal. In view of the constitution of the germ-cell, this view seems to be paradoxical, but it appears to be explained on the assumption that the substance of the nucleus determines the nature and character of the cell, though Prof. Weismann does not altogether commit himself to this assumption (see pp. 185, 205, 210).

From this point of view Prof. Weismann's suggestion that the development of mortal from immortal cells is due to unequal fission, seems to be quite intelligible, not only ontogenetically, but also phylogenetically, if we venture to assume that the constitution of a Protozoon is essentially the same as that of a germ-cell. It is easy to imagine that the nucleus of a Protozoon may be divided into two parts, one of which contains the whole or the greater part of the parental germ-plasm, the other containing none or only a small portion of it; the two resulting cells would be respectively immortal and mortal, and, supposing they remained coherent, would represent the reproductive and somatic portions of a heteroplastid body. Similarly, if such a division of the nucleus of the germ-cell took place, the two resulting cells would represent the reproductive and somatic portions of the body of the embryo.

But this does not appear to be Prof. Weismann's view of embryogeny. On the contrary, he holds strongly that the germ-plasm of the ovum gives rise, in part at least, to the somatoplasm of the embryo. Thus, on p. 168 he says:—

"I have called this substance 'germ-plasm,' and have assumed that it possesses a highly complex structure, conferring upon it the power of developing into a complex organism. I have attempted to explain heredity by supposing that in each ontogeny a part of the specific germ-plasm contained in the parent egg-cell is not used up in the construction of the body of the offspring, but is preserved unchanged for the formation of the germ-cells of the following generation."

It is not a little remarkable that Prof. Weismann should not have offered any suggestion as to the conception which he has formed of the mode in which the conversion of germ-plasm into somatoplasm can take place, considering that this assumption is the key to his whole position. He has been at considerable pains to controvert the view that somatoplasm may be converted into germ-plasm; but in making this attack he has overlooked the necessity for defence. There is really no other criticism to be made on an unsupported assumption such as this, than to say that it involves a contradiction in terms. The idea of the conversion of germ-plasm into somatoplasm is quite as impossible as that of the conversion of somatoplasm into germ-plasm. It is absurd to say that an immortal substance can be converted into a mortal substance. If such an apparent change takes place, the only possible conclusion is that the so-called immortal substance was never truly immortal, inasmuch as it must have always possessed the potentiality of mortality.

It may perhaps be represented that the foregoing criticisms are altogether of too minute and detailed a character to affect the general validity of Prof. Weismann's argument. My answer is that I understand Prof. Weismann to imply that his theory of heredity is not—like, for instance, Darwin's theory of pangenesis—"a provisional or purely formal solution" (Weismann, p. 166) of the question, but one which is applicable to every detail of embryogeny, as well as to the more general phenomena of heredity and variation.

We may now proceed to the consideration of Prof. Weismann's theory of heredity. The essential features of it are given in the following paragraphs (p. 73):—

"Among these unicellular organisms, heredity depends upon the continuity of the individual during the continual increase of its body by means of assimilation.

"But how is it with the multicellular organisms which do not reproduce by means of simple division, and in which the whole body of the parent does not pass over into the offspring?

"In such animals the power of reproduction is connected with certain cells, which, as germ-cells, may be contrasted with those which form the rest of the body; for the former have a totally different *rôle* to play; they are without significance for the life of the individual (that is, for the preservation of its life), and yet they alone possess the power of preserving the species. Each of these can, under certain conditions, develop into a complete organism of the same species as the parent, with every individual peculiarity of the latter reproduced more or less completely. How can such hereditary transmission of the characters of the parent take place? How can a single reproductive cell reproduce the whole body in all its details?"

Prof. Weismann's answer to these questions is as follows:—

"We have an obvious means by which the inheritance of all transmitted peculiarities takes place, *in the continuity of the substance of the germ-cells, or germ-plasm*. If, as I believe, the substance of the germ-cells, the germ-plasm, has remained in perpetual continuity from the first origin of life, and if the germ-plasm and the substance of the body, the somatoplasm, have always occupied different spheres, and if changes in the latter only arise when they have been preceded by corresponding changes in the former, then we can, up to a certain point, understand the principle of heredity; or, at any rate, we can conceive that the human mind may at some time be capable of understanding it" (p. 104).

"Now if it is impossible for the germ-cell to be, as it were, an extract of the whole body, and for all the cells of the organism to despatch small particles to the germ-cells, from which the latter derive the power of heredity; then there remain, as it seems to me, only two other possible, physiologically conceivable, theories as to the origin of germ-cells, manifesting such powers as we know they possess. Either the substance of the parent germ-cell is capable of undergoing a series of changes which, after the building-up of a new individual, leads back again to identical germ-cells; or the germ-cells are not derived at all, as far as their essential and characteristic substance i concerned, from the body of the individual, but they are derived directly from the parent germ-cell.

"I believe that the latter view is the true one. . . . . propose to call it the theory of the 'continuity of the germ plasm,' for it is founded upon the idea that heredity is brough about by the transference, from one generation to another, of a substance with a definite chemical, and, above all, molecula constitution. I have called this substance 'germ-plasm,' and have assumed that it possesses a highly complex structure, conferring upon it the power of developing into a complex organism. I have attempted to explain heredity by supposing that in each ontogeny a part of the specific germ-plasm contained in the parent egg is not used up in the construction of the body of the offspring, but is reserved unchanged for the formation of the germ-cells of the following generation" (p. 167).

"I believe that heredity depends upon the fact that a small portion of the effective substance of the germ, the germ-plasm, remains unchanged during the development of the ovum into an organism, and that this part of the germ-plasm serves as a foundation from which the germ-cells of the new organism are produced. There is, therefore, continuity of the germ-plasm from one generation to another. One might represent the germ-plasm by the metaphor of a long creeping root-stock from which plants arise at intervals, these latter representing the individuals of successive generations" (p. 266).

This theory appears to fully account for the transmission and maintenance of ancestral characters; but of course it depends on the assumption that the germ-plasm is a substance of great stability. This is, in fact, Prof. Weismann's view (p. 271):—

"The germ-plasm, or idioplasm of the germ-cell (if this latter term be preferred), certainly possesses an exceedingly complex minute structure, but it is nevertheless a substance of extreme stability, for it absorbs nourishment, and grows enormously without the least change in its complex molecular structure."

In spite of the simple, and apparently satisfactory, explanation of the phenomena of heredity which this theory affords, there are, nevertheless, serious difficulties in the way of its acceptance. It is open to criticism even from Prof. Weismann's own standpoint. The fate of the germ-plasm of the fertilized ovum is, according to Prof. Weismann, to be converted in part into the somatoplasm of the embryo, and in part to be stored up in the germ-cells of the embryo. This being so, how are we to conceive that the germ-plasm of the ovum can impress upon the somatoplasm of the developing embryo the hereditary character of which it (the germ-plasm) is the bearer? This function cannot be discharged by that portion of the germ-plasm of the ovum which has become converted into the somatoplasm of the embryo, for the simple reason that it has ceased to be germ-plasm, and must therefore have lost the properties characteristic of that substance. Neither can it be discharged by that portion of the germ-plasm of the ovum which is aggregated in the germ-cells of the embryo, for under these cumstances it is withdrawn from all direct relation with the developing somatic cells. The question remains without an answer.

Still more is the theory open to criticism from the standpoint which I have established above. It is clear that the theory of the continuity of the germ-plasm, as explaining heredity, is only valid on the assumption that the germ-plasm of the ovum gives rise to the somatoplasm of the embryo. But I have shown above that the conversion of germ-plasm into somatoplasm is inconceivable; and, even if it be admitted, it cannot be seriously maintained that the whole body of the embryo is, in any case, developed solely from the germ-plasm of the ovum. On the contrary, since the embryo is developed from the *whole* of the nucleus and more or less of the cytoplasm of the ovum, it must be admitted that the non-germ-plasm, or somatoplasm, of the ovum provides a large part of the material in embryogeny. It is an obvious inference that, under these circumstances, hereditary characters may be transmitted from the parent to the offspring, not only by the germ-plasm, but also by the somatoplasm, of the ovum.

It might be replied to these criticisms that, even if it be admitted that germ-plasm cannot be converted into somatoplasm, and also that the somatic cells of the embryo are derived from the somatoplasm of the ovum, it is still conceivable that the nuclei of the somatic cells of the embryo may contain a certain amount of the germ-plasm of the ovum, not enough to confer upon the somatic cells the properties of germ-cells, but sufficient to determine their growth and differentiation in accordance with the hereditary tendencies of which the germ-plasm is the bearer. But this view does not appear to be held by Prof. Weismann, whose opinion with reference to the presence of germ-plasm in somatic cells is as follows (p. 211):—

"I believe I have shown that theoretically hardly any objections can be raised against the view that the nuclear substance of somatic cells may contain unchanged germ-plasm, or that this germ-plasm may be transmitted along certain lines. It is true that we might imagine *a priori* that all somatic nuclei contain a small amount of unchanged germ-plasm. In Hydroids such an assumption cannot be made, because only certain cells in a certain succession possess the power of developing into germ-cells; but it might well be imagined that in some organisms it would be a great advantage if every part possessed the power of growing up into the whole organism, and of producing sexual cells under appropriate circumstances. Such cases might exist if it were possible for all somatic nuclei to contain a minute fraction of unchanged germ-plasm."

After alluding to the fact that new plants can be developed from leaves of Begonia which have been cut off and laid in moist sand, Prof. Weismann continues:—

"But I think that this fact only proves that, in Begonia and similar plants, all the cells of the leaves, or perhaps only certain cells, contain a small amount of germ-plasm, and that, consequently, these plants are specially adapted for propagation by leaves. How is it, then, that all plants cannot be reproduced in this way? No one has ever grown a tree from a leaf of the lime or oak, or a flowering plant from the leaf of the tulip or convolvulus. It is insufficient to reply that, in the last-mentioned cases, the leaves are more strongly specialized, and have thus become unable to produce the germ-substance; for the leaf-cells in these different plants have hardly undergone histological differentiation in different degrees. If, notwithstanding, the one can produce a flowering plant, while the others have not the power, it is of course clear that reasons other than the degree of histological differentiation must exist; and, according to my opinion, such a reason is to be found in the admixture of a minute quantity of unchanged germ-plasm with some of their nuclei."

It appears, therefore, to be Prof. Weismann's opinion that it is only in special cases that germ-plasm is present in somatic cells, and that, when present, it confers on the somatic cells the properties of germ-cells, though it is difficult to reconcile this opinion with the following statement on p. 205:—

"Strictly speaking, I have therefore fallen into an inaccuracy in maintaining (in former works) that the germ-cells are themselves immortal; they only contain the undying part of the organism—the germ-plasm; and although this substance is, as far as we know, invariably surrounded by a cell-body, it does not always control the latter, and thus confer upon it the character of a germ-cell."

I would submit, therefore, that, inasmuch as Prof. Weismann offers no evidence to prove the continuity of the germ-plasm of the ovum with the somatoplasm of the embryo, his principle of the continuity of the germ-plasm cannot be regarded as a satisfactory theory of heredity; and I would point out that the facts of embryogeny seem to confer upon the idea of a continuity of the somatoplasm at least as high a degree of probability as upon that of a continuity of the germ-plasm.

We come, finally, to Prof. Weismann's explanation of variation, a connected statement of which is to be found on pp. 277 *et seq.*, from which I may make the following quotations:—

"The origin of hereditary individual variability cannot indeed be found in the higher organisms—the Metazoa and Metaphyta; but it is to be sought in the lowest—the unicellular organisms. In these latter the distinction between body-cell and germ-cell does not exist. Such organisms are reproduced by division, and if, therefore, any one of them becomes changed in the course of its life by some external influence, and thus receives an individual character, the method of reproduction insures that the acquired peculiarity will be transmitted to its descendants. If, for instance, a Protozoon, by constantly struggling against the influence of mechanical currents in water, were to gain a somewhat denser and more resistant protoplasm, or were to acquire the power of adhering more strongly than other individuals of its species, the peculiarity in question would be directly continued on into its two descendants, for the latter are at first nothing more than the two halves of the former. It therefore follows that every modification which appears in the course of its life, every individual character, however it may have arisen, must necessarily be directly transmitted to the two offspring of a unicellular organism" (p. 277).

"We are thus driven to the conclusion that the ultimate origin of hereditary individual differences lies in the direct action of external influences upon the organism. Hereditary variability cannot, however, arise in this way at every stage of organic development, as biologists have hitherto been inclined to believe. It can only arise in the lowest unicellular organisms; and when once individual difference had been attained by these, it necessarily passed over into the higher organisms when they first appeared. Sexual reproduction coming into existence at the same time, the hereditary differences were increased and multiplied, and arranged in ever-changing combinations" (p. 279).

"It is, however, obvious that sexual reproduction will readily afford such combinations of acquired characters, for by its means the most diverse features are continually united in the same individual, and this seems to me to be one of its most important results.

"I do not know what meaning can be attributed to sexual reproduction other than the creation of hereditary individual characters to form the material upon which natural selection may work" (p. 281).

In the essay entitled "On the Number of Polar Bodies and their Significance in Heredity," Prof. Weismann explains his conception of the mode in which sexual reproduction promotes variability, showing, with the assistance of diagrams, how the nuclear germ-plasm of a fertilized ovum contains germ-plasms derived from the ancestors of both parents.

The conception of the process of variation which the preceding passages (as well as others) produce in the mind of the reader is that unicellular organisms acquired, during the period of their entirely asexual reproduction, a number of individual differences; and that, since the appearance of sexual reproduction, these ancestral characters have been combined in an infinite number of ways, leading to the evolution of all existing varieties of plants and animals, to say nothing of all the varieties which have perished in the struggle for existence. It would, in fact, appear that Prof. Weismann denies the acquisition of any new individual characters due to the influence of external conditions by any except unicellular organisms.

This being his view, we find, as might be expected, that Prof. Weismann opposes the assumption of the transmission, by means of sexual or amphigonic reproduction, of characters which he terms "somatogenic" (p. 413); that is, of characters which have manifested themselves in the *soma* of an individual, not spontaneously, but as the result of the operation of external forces or conditions; and he critically sifts the evidence for such transmission with results which, it must be admitted, tell in favour of his views.

For all that, Prof. Weismann does not take up an altogether uncompromising position with reference to this point; in fact, his statements of opinion are so fluctuating that it is difficult to determine what his position exactly is: witness the following quotations:—

". . . and it is impossible to imagine any way in which the transmission of changes, produced by the direct action of external forces upon the somatic cells, can be brought about" (p. 80).

"Hence it follows that the transmission of acquired characters is an impossibility . . ." (p. 266).

"For the germ-cells are contained in the organism, and the external influences which affect them are intimately connected with the state of the organism in which they lie hid. If it be well nourished, the germ-cells will have abundant nutriment; and, conversely, if it be weak and sickly, the germ-cells will be arrested in their growth. It is even possible that the effects of these influences may be more specialized; that is to say, they may act only upon certain parts of the germ-cells. But this is indeed very different from believing that the changes of the organism which result from external stimuli can be transmitted to the germ-cells, and will re-develop in the next generation at the same time as that at which they arose in the parent, and in the same part of the organism" (p. 103).

"Still we cannot exclude the possibility of such a transmission occasionally occurring; for, even if the greater part of the effects must be attributed to natural selection, there might be a small part in certain cases which depends on this exceptional factor.

"A complete and satisfactory refutation of such an opinion cannot be brought forward at present; we can only point out that such an assumption introduces new and entirely obscure forces, and that innumerable cases exist in which we can certainly exclude all assistance from the transmission of acquired characters" (p. 100).

"If, on the other hand, acquired differences are transmitted, this would prove that there must be something wrong in the theory of the continuity of the germ-plasm, as above described, and in the non-transmission of acquired characters which results from this theory" (p. 268).

"It seems to me that the problem of the transmission or non-transmission of acquired characters remains, whether the theory of the continuity of the germ-plasm be accepted or rejected" (p. 403).

I would remark, with reference to the statement that it is impossible to imagine any way in which somatogenic changes can be transmitted, that such a transmission is quite conceivable, and is even probable, when the continuity of the somatoplasm is borne in mind. If the ovum contains somatoplasm, as we are driven to assume, and if, as cannot be denied, the somatoplasm takes part in the formation of the body of the embryo, then it is not impossible that changes induced in the body of the parent, by the action of external conditions, may be transmitted to the offspring through the somatoplasm of the ovum. The discontinuity of the somatoplasm must be proved before the impossibility of the transmission of somatogenic characters can be considered to have been established.

But if Prof. Weismann is not prepared to admit that there is more than a remote possibility that variation may, in some degree, be due to the transmission of somatogenic characters, he makes a large concession in admitting that new characters may be acquired in another way, and, being transmissible, lead to variation. The first hint of this view is to be found on pp. 98, 99:—

"These changes—such, for example, as are produced by a strange climate—have always been looked at under the supposition that they are transmitted and intensified from generation to generation, and for this reason the observations are not always sufficiently precise. It is difficult to say whether the changed climate may not first have changed the germ, and if this is the case the accumulation of effects through the action of heredity would present no difficulty" (p. 98).

"It must be admitted that there are cases, such as the climatic varieties of certain butterflies, which raise some difficulties against this explanation. I myself, some years ago, experimentally investigated one such case, and even now I cannot explain the facts otherwise than by supposing the passive acquisition of characters produced by the direct influence of climate" (p. 99; see also above quotation from p. 103).

It is again mentioned on p. 271, but it is not prominently asserted until p. 410, where Prof. Weismann says:—

"I have never doubted about the transmission of changes which depend upon an alteration in the germ-plasm of the reproductive cells, for I have always asserted that these changes, and these alone, must be transmitted. If anyone makes the contrary assertion, he merely proves that he does not understand what I have said upon the subject. In what other way could the transformation of species be produced, if changes in the germ-plasm cannot be transmitted? And how could the germ-plasm be changed except by the operation of external influences, using the words in their widest sense? . . ."

On pp. 402–403 Prof. Weismann defines his view more clearly:—

"It is certainly necessary to have two terms which distinguish between two chief groups of characters—the primary characters which first appear in the body itself, and the secondary ones which owe their appearance to variations in the germ, however such variations may have arisen. We have hitherto been accustomed to call the former 'acquired characters,' but we might also call them *somatogenic*, because they follow from the reaction of the *soma* under external influences; while all other characters might be contrasted as *blastogenic*, because they include all those characters in the body which have arisen from changes in the germ. In this way we might perhaps prevent the possibility of misunderstanding. . . . Among the blastogenic characters, we include not only all the changes produced by natural selection operating upon variations in the germ, but all other characters which result from this latter cause."

The point is again mentioned on p. 433:—

"It is therefore possible to imagine that the modifying effects of external influences upon the germ-plasm may be gradual and may increase in the course of generations, so that visible changes in the body (*soma*) are not produced until the effects have reached a certain intensity."

It is not a little remarkable that, after insisting so strongly, as in the passage previously quoted, on the extreme stability of the germ-plasm, Prof. Weismann should be prepared to admit that it is in so high a degree susceptible to the action of external influences. He is, however, inclined to complain, in the passage on p. 410, that this view of the production of blastogenic changes by external influences has been ignored; but the readers of the earlier essays may well be pardoned for inattention to this point, as it is only casually mentioned there, and is not put forward as an integral part of his theory of variation. No one reading the statement of his theory of variation on p. 277 would infer that Prof. Weismann attached any importance to the effect of external influences on the germ in producing new characters. In fact, Prof. Weismann himself seems hardly to realize how inevitable such a conclusion is. If it be admitted that unicellular organisms acquire new characters under the operation of external influences, it cannot consistently be doubted that this also takes place in germ-cells.

It seems to be necessary, therefore, to modify the conception of variation founded upon the above-quoted paragraph from p. 277, by introducing into it the operation of external influences upon the germ. We now see that though sexual reproduction greatly promotes variation in consequence of the ever-new combination of ancestral characters in each fertilization, yet another efficient cause of variation is the direct action of external influences on the germ, giving rise to blastogenic characters.

But this modified conception of the causes of variation comes into collision with Prof. Weismann's statement (p. 277) that "the origin of hereditary individual variability cannot indeed be found in the higher organisms—the Metazoa and Metaphyta; but it is to be sought for in the lowest—the unicellular organisms," a collision which is much to the detriment of the latter; for, if it cannot be denied that external influences give rise to blastogenic characters, then it cannot be maintained that "the origin of hereditary individual variability cannot be found in the higher organisms." On the contrary, it must be admitted that the modifying influence of external conditions continually affects not only unicellular organisms, but also the germ-cells of the Metazoa, producing new characters, thus inducing variation, in both.

This conclusion leads to the consideration of a point of great interest. In accordance with his view of the pre-eminent importance of amphigonic reproduction in causing variation, Prof. Weismann asserts the lack of variability in parthenogenetic forms, in the following words (p. 290):—

"If my theory as to the causes of hereditary individual variability be correct, it follows that all species with purely parthenogenetic reproduction are sure to die out; not, indeed, because of any failure in meeting the existing conditions of life, but because they are incapable of transforming themselves into new species, or, in fact, of adapting themselves to any new conditions. Such species can no longer be subject to the process of natural selection, because, with the disappearance of sexual reproduction, they have also lost the power of combining and increasing those hereditary individual characters which they possess."

The views contained in this paragraph appear to me to be completely at variance with the facts known concerning the Fungi, among plants. Thus, in the Saprolegnieæ, all the known forms, including several genera and many species, are parthenogenetic; the sexuality of the Ascomycetes is still the subject of discussion, but it is admitted that many genera and species of these Fungi are certainly asexual; and the sexuality of the Æcidiomycetes is extremely doubtful. These plants show no apparent tendency to die out, in spite of the absence of sexuality. But it may be replied that these families may be in the stage in which sexuality is just disappearing, and in which they are still adequately adapted to their conditions of life. Such an objection cannot apply, however, to the Basidiomycetes. These Fungi are not only entirely asexual, but it would appear that they have been evolved in a purely asexual manner from asexual ascomycetous or Æcidiomycetous ancestors. The Basidiomycetes, in fact, afford an example of a vast family of plants, of the most varied form and habit, including hundreds of genera and species, in which, so far as minute and long-continued investigation has shown, there is not, and probably never has been, any trace of a sexual process. How are we, then, to account for all the variation which has taken place in this group, quite independently of amphigonic reproduction? On this point Prof. Weismann says (p. 275):—

"If it could be shown that a purely parthenogenetic species had become transformed into a new one, such an observation would prove the existence of some force of transformation other than selective processes, for the new species could not have been produced by these latter."

It appears to me beyond doubt that, in the Fungi, new species have been developed from parthenogenetic forms, but I leave it to Prof. Weismann to suggest what "force of transformation other than selective processes" may have been operative.

It is not, however, argued that the variation of the higher Fungi is as great as it might have been had they possessed sexuality; for there can be no doubt that sexual reproduction does very materially promote variation. It seems probable, in fact, that the absence of sexuality in these plants may be just the reason why no higher forms have been evolved from them; for in this respect they present a striking contrast to the higher Algæ in which sexuality is well marked.

Since it is clear that new hereditary characters can be produced by the action of external influences on the germ, the outcome of Prof. Weismann's investigation of the phenomena of variation is that he has given prominence to the fact that new hereditary characters need not be apparent in the body of the parent, but that, on the contrary, the somatogenic characters are just those which are least likely to be transmitted. This is essentially the same position, though stated in more precise terms, as that taken up by Darwin, who held that it is not the sudden variations, due to altered external conditions, which become permanent, but those slowly produced by what he termed the accumulative action of changed conditions of life.

With this I close my criticisms, not because there are no other points which might be discussed, but because I have already touched upon many of them in my "Lectures on the Physiology of Plants" (Cambridge, 1886), and because I desire at present to deal solely with the more fundamental parts of the theory. I have, I think, said enough to show that, interesting and suggestive as is Prof. Weismann's theory of the continuity of the germ-plasm, it by no means affords, at least in its present form, so complete and ready an explanation of the facts of embryogeny, heredity, and variation, as the enthusiasm of some of his more ardent disciples would have us believe.

SYDNEY H. VINES.

Oxford, September.

NOTES.

WE regret to announce the death of Mr. John Ball, F.R.S., which took place somewhat suddenly at midnight on Monday last. We understand that the funeral will take place to-morrow (Friday), at 11 a.m., at St. Thomas's, Walham Green.

THE Reports of the Eclipse Expedition of 1886 are at length ready for publication, and will be issued immediately as separate numbers of the Philosophical Transactions. The first, "On the Total Solar Eclipse of August 29, 1886," is by Captain Darwin, Dr. Schuster, and Mr. Maunder; the second, "On the Observations made at the Island of Carriacou," is by the Rev. S. J. Perry; the third, "On the Determination of the Photometric Intensity of the Coronal Light," by Captain Abney and Prof. Thorpe; and the fourth, "On the Observations made at Grenville, in the Island of Grenada," by Mr. H. H. Turner.

THE collection of objects brought back by Prof. Haddon from various islands in Torres Straits is now to be seen in a part of the Eastern Assyrian room at the British Museum, on the upper floor of the north-east angle of the building. Special interest attaches to the anthropological specimens included in this valuable collection.

THE list of names to be recommended for the new Council of the London Mathematical Society at its annual meeting, on November 14, differs from that of last year in the following respect: the names of Prof. Cayley, F.R.S., and of Prof. W. Burnside will be submitted to fill up the vacancies caused by the retirement of Dr. E. J. Routh, F.R.S., and Prof. Hart, of Woolwich.

The Library of the Royal College of Surgeons will, as an experiment, be, for the remaining portion of the present year, open in the evening. On each week-day except Saturday the hours will be from 11 a.m. to 9 p.m.; on Saturdays the Library will be closed at 1 p.m.

A Physical Society is to be formed in Liverpool. It will hold its meetings at University College, and Prof. Oliver Lodge has consented to be nominated as first President. The preliminary meeting will be held in the Physics Theatre of University College, at 8 o'clock on Wednesday evening, November 6, Prof. Oliver Lodge in the chair. The Secretary (*pro tem.*) is Mr. Thomas Tarleton, 1 Hyde Road, Waterloo, Liverpool.

Mr. John W. McCoy, who died in Baltimore lately, bequeathed his library, with 100,000 dollars, to the Johns Hopkins University.

On Monday a statue of J. B. Dumas, the chemist, was unveiled at Alais, his native town, by M. Faye, French Minister of Agriculture.

Like many other schools, Fettes College, Edinburgh, has long been provided with chemical laboratories, but has had no room specially adapted for the teaching of physical science. This want has been met by the construction during the summer of a well-appointed physical laboratory fitted up both for lectures and for practical work by boys themselves. There is a well-arranged supply of gas and water, several stone slabs for delicate instruments affected by oscillations, screens for projection experiments, a heliostat window and system of blinds for darkening the room for experiments on light. A smaller room leading off from the main room is reserved for special work, and is also fitted up as a dark room for photography. The laboratory is close to the boys' workshop, and to the workshop of the resident carpenter and mechanic.

An interesting Report by Sir Brandford Griffith, Governor of the Gold Coast, has lately been issued by the Colonial Office. It describes at considerable length a tour through the interior of the colony, undertaken for the purpose of investigating the gold deposits and examining the gold-mines at work. The Governor comes to the conclusion that the country is rich in gold, and that it is merely a matter of the necessary time and scientific application for the metal to pay well for extraction. He finds, also, that "earnest and well-considered attempts" are now being made to secure success. An appendix containing a special Report on the Winnebah district and its mineral wealth is added.

At the first meeting of the new session of the Geological Society of Glasgow, Mr. John Young exhibited a fine series of specimens of Polyzoa and Monticuligrora, comprising over twenty species, which he had this summer discovered at Kirktonhelm, East Kilbride. He remarked that the shale which holds these organisms lies between the first and second Calderside limestones. Most of the specimens were taken from blocks of shale which had been partially burnt in the lime-kilns, the rock in its natural condition being of a gray colour, but changed by contact with heat into yellowish gray. From this change of colour the fronds of the Polyzoa, with their lace-like structure, stand out much more prominently than when the shale is in its original state. They have also the advantage of being very much hardened, whereas the shale is naturally very friable, decomposing almost whenever it is exposed to the action of the weather. Mr. James Bennie, of the Geological Survey of Scotland, read a paper, "Things New and Old from the Ancient Lake of Cowdenglen." Up to 1867 the picturesque little valley of Cowden, beyond Crofthead, on the road to Ayrshire, was not known to possess any features of special geological interest, but in that year, having been chosen as the route of the direct railway to Kilmarnock, it was invaded by the navvy with pick and shovel, to the utter destruction of all its natural beauties. The gradients being steep, the excavations were extensive, and at one point the bed of an ancient lake was cut through, containing deposits of mud and peat lying between two distinct layers of boulder clay. These stratified deposits were found to contain numerous remains of animal and vegetable life, both of higher and lower forms, and, as their presence afforded strong evidence of the great ice age, a controversy arose between the upholders of a single glacial period and those who believed in two or more. Of late years there has been a revival of interest in old lake deposits, which led the author to re-examine the subject and the specimens of the deposits in his possession. Always a supporter of the "interglacial" or successive theory of ice periods, he re-stated his case in the present paper, bringing forward a fresh accumulation of proof.

Messrs. King, Mendham, and Co., of the Western Electrical Works, Bristol, have sent us a sample of a very convenient pocket galvanometer which they are now making. It is about the size of an ordinary watch, the ring suspender acting also as a binding screw. It is not only a detector galvanometer, but can be used for the absolute measure of currents up to one ampere. The dial is accordingly graduated one half in degrees, and the other in milliamperes, and is so made that either half can be brought to the top whilst the needle remains in a vertical position. The front portion carries the dial and magnetic needle, and the back part of the case contains the bobbins wound with copper wire, the resistances of which have been measured and particulars furnished with the instrument. Small stands are also supplied for laboratory use if required. The instrument is beautifully finished, and we strongly recommend it to all who use batteries in any shape or form. To those who use electricity for medicinal purposes, where the current is of prescribed strength, such an instrument must be indispensable, and its importance to electric-bell fixers and telephone and telegraph worker is obvious. To economical users of batteries it will recommend itself, as many a good cell may be saved by the detection of the one which is really at fault. Full instructions are supplied with each instrument.

A good word has at last been said for the sparrow in America. In England this impudent bird is decidedly popular, but our kinsfolk in the United States consider him an unmitigated nuisance. Captain W. F. Segrave, British Consul at Baltimore, writing on the subject in a recent Report, warns the Americans that their policy in waging war against the sparrow may prove to be a mistake. "The great 'blizzard' of March 1888," he says, "destroyed multitudes of sparrows, and as a consequence, the past and present summers have seen a vast increase in grubs and caterpillars. Already in many large cities the inhabitants through the public press are complaining of the destruction of their ornamental trees, the diminished number of sparrows being unable to keep in check the vast increase which has taken place in noxious grubs, worms, and caterpillars."

The third and concluding portion of Prof. Kikuchi's (of Tokio) work on geometry has just reached us. It is entitled "Rittaikikagaku," or "Solid Geometry." He has not been able to derive assistance in its compilation from the work of the Association for the Improvement of Geometrical Teaching, as the syllabus of this subject is yet in an embryo state. If we may judge from the figures, he has adapted portions of Euclid xi., 1–21, and of Wilson's "Solid Geometry," with a brief treatment of the regular solids and the elements of spherical geometry. There is an appendix of the equivalents of English terms written in Japanese and Roman letters.

MESSRS. GURNEY AND JACKSON have in the press "A Handbook of European Birds," by James Backhouse, Jun. The author explains that, having frequently experienced the need of a handy reference volume on European birds, he has been at great pains to meet this want, by endeavouring to produce a complete series of short general descriptions, in a convenient form either for the portmanteau or the pocket. The work will be published by subscription during the autumn or early spring.

THE last published number (31) of *Excursions et Reconnaissances*, the official scientific and learned journal of the French possessions in Indo-China, contains the first of a series of articles, by M. Aymonier, the well-known scholar, on the writing, dialects, history, manners, and customs of the Chams, the ancient masters of Annam proper. The present instalment deals with the grammar, and is illustrated by some lithographs of their writing and their curious cursive alphabets. These are followed by a portion of a Romanized version, with a translation, in French prose, of an Annamite rhymed tragedy.

IN our abstract of the chemical papers at the British Association (p. 587) we gave an account of the paper on alloys read by Messrs. Heycock and Neville. These gentlemen send us the following expansion of our statement:—"(1) Our experiments lead us to the conclusion that the *molecule of aluminium when in solution in tin is* $Al_2 = 54$, and not, as stated, that its atomic weight is different from the accepted value. (2) We stated that the mere application of Raoult's method to alloys does not decide the molecular weight of metals in solution, because we have no standard molecule, of which the molecular complexity in solution is certainly known, to take as unity. By applying Van 't Hoff's theory of solution to alloys of tin, we calculate a number for the fall in the freezing-point produced by one *molecule* of metal in 100 molecules of tin which is almost identical with the constant fall found in our experiments for *one atom* of metal in 100 of tin. Hence we conclude that, with the exception of aluminium, and possibly indium, all the seventeen metals we have examined have single atom molecules when in solution in tin. Our experiments, therefore, in the main, confirm Prof. Ramsay's results obtained by another method, and E. Tamman's results with amalgam."

METHYL HYDRAZINE, $CH_3—NH—NH_2$, the simplest derivative of hydrazine or amidogen, $\begin{matrix} NH_2 \\ | \\ NH_2 \end{matrix}$, has been isolated by Dr. Gustav von Brüning in the Chemical Laboratory of the University of Wurzburg (*Liebig's Annalen*). It is a clear and very mobile liquid, boiling at 87° C., and possessing a most violent affinity for water, resembling in this respect the recently-isolated hydrazine itself. Its odour is very similar to that of methylamine, and the vapour produces a white cloud in the air due to absorption of moisture to form minute drops of the liquid hydrate. Brought in contact with water, it instantly dissolves with evolution of great heat. It reduces Fehling's solution in the cold, and decomposes nitrous acid with copious evolution of free nitrogen. Its hygroscopic character is so pronounced that it attacks the skin in a most painful manner, and rapidly destroys corks or caoutchouc stoppers. The mode of preparation finally adopted by Dr. von Brüning is in reality very simple, the only difficult operations being those involving its separation from water. It consists in first converting the mono-methyl derivative of urea, $CH_3—NH—CO—NH_2$, into the nitroso-compound, $CH_3—N(NO)—CO—NH_2$; this, upon reduction with zinc dust and glacial acetic acid, yields the corresponding hydrazine urea, which in turn is broken up by boiling with hydrochloric acid into carbonic anhydride, ammonia, and methyl hydrazine. In practice, 50 grams of nitrate of methyl urea are dissolved in warm water, and the solution cooled until crystals begin to form. Crushed ice is then added to keep the temperature as low as possible during the addition of the calculated quantity of solid sodium nitrite; the moment the nitrite is added, the nitroso-compound commences to separate in small yellow lamellæ, and may be obtained recrystallized from ether in much larger slightly yellow tables. The reduction of this nitroso body is then effected by suspending it in water and adding glacial acetic acid and zinc dust, the latter in small portions at a time, with constant agitation. The cold solution, filtered from excess of zinc dust, is then saturated with hydrochloric acid, and afterwards evaporated to a syrupy consistency. The syrup is next boiled for some hours with a concentrated solution of hydrochloric acid in a flask connected with an inverted condenser, after which the liquid is neutralized with a strong soda solution at a low temperature, and sufficient excess of soda added to redissolve the precipitated zinc hydrate. The alkaline solution is then distilled in steam, when the base rapidly and completely passes over, ammonia and methylamine escaping as gases. After removal of most of the dissolved ammonia and methylamine by boiling in the flask supplied with inverted condenser, the base is converted to its acid sulphate, $CH_3—NH—NH_2 . H_2SO_4$, and the crystals of this salt are distilled with a concentrated solution of soda containing pieces of solid sodium hydrate. The last trace of ammonia escapes, while the methyl hydrazine condenses in the cooled receiver. After allowing the distillate to remain in contact with solid soda for twenty-four hours, and then re-subjecting it to distillation, it is still found to contain water. It was, however, finally freed from water by heating to 100° C. in a sealed tube with anhydrous barium oxide.

THE additions to the Zoological Society's Gardens during the past week include a Pigtailed Monkey (*Macacus nemestrinus* ♂) from Java, presented by Mrs. Cosh; three Common Hedgehogs (*Erinaceus europæus*), British, presented by Mr. H. Pelham Curtis; two Cayenne Aracaris (*Pteroglossus aracari*) from Macey, Brazil, presented by Mr. Thomas Watson Permain; a Red and Blue Macaw (*Ara macao*) from Central America, presented by Mr. Robert Romer, Q.C.; a —— Hawk (*Asturina* sp. inc.) from Brazil, presented by Mr. J. E. Wolfe; a Well-marked Tortoise (*Homopus signatus*), a Rufescent Snake (*Leptodira rufescens*), three Smooth-bellied Snakes (*Homalosoma lutrix*), a Many-spotted Snake (*Coronella multimaculata*), a Cape Adder (*Vipera atropos*) from South Africa, presented by the Rev. G. H. R. Fisk, C.M.Z.S.; two Macaque Monkeys (*Macacus cynomolgus* ♂ ♀) from India, deposited; six Indian Pythons (*Python molurus*), an Indian Cobra (*Naia tripudians*) from India, purchased.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1889 *OCTOBER* 27—*NOVEMBER* 2.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on October 27

Sun rises, 6h. 48m.; souths, 11h. 43m. 55·9s.; daily decrease of southing, 4·9s.; sets, 16h. 40m.: right asc. on meridian, 14h. 8·0m.; decl. 12° 57′ S. Sidereal Time at Sunset, 19h. 5m.

Moon (at First Quarter October 31, 9h.) rises, 10h. 12m.; souths, 14h. 29m.; sets, 18h. 39m.: right asc. on meridian, 16h. 54·0m.; decl. 20° 49′ S.

THE GEOGRAPHICAL PAPERS AT THE BRITISH ASSOCIATION.

SCIENTIFIC geography did not form a prominent feature in the Geographical Section at Newcastle. As was right and proper in so important an industrial centre, it was evidently intended to devote special attention to commercial geography. The success was only partial. It will have been seen that the President, Sir Francis De Winton, devoted a considerable part of his address to pointing out some of the important practical applications which may be made of geographical knowledge. Again, one of the ablest and most instructive papers read in the Section was by Dr. Hugh Robert Mill, on the Physical Basis of Commercial Geography. A *necessary preliminary*, Dr. Mill pointed out, to the study of commercial geography is a full acquaintance with topography, especially with the names and positions of all commercial towns. A *necessary accompaniment* to the study of commercial geography is a knowledge of the ever-varying relations between regions of supply and demand, the incidence of tariffs, and the political and social conditions of countries. The *physical basis* of commercial geography, which underlies and gives unity to the whole subject, is a knowledge of the resources of the earth as regards the various existing forms of matter and modes of energy, the best means of separating, combining, and modifying these so as to produce commodities, and the way in which commodities can be best transported. Commerce being the artificial redistribution of the matter and energy of the world, a knowledge of the general properties and the unchangeable laws of matter and energy should take a chief place in the training of commercial men. A general acquaintance with this practical science, which may be termed *applied physiography*, or *practical earth knowledge*, ought to be possessed by all merchants, and a special branch should be familiar to each. Amongst the advantages which would thus be gained are:—(1) The merchant would understand the principles of the production and manufacture of his goods. (2) He would know in many cases, without aimless and extravagant experiments, where it is possible to produce any special commodity in great abundance. (3) He could, to a great extent, anticipate the frequent changes in staple commodities by knowing what other commodities it is possible to produce in the regions now yielding the staple only. (4) He would understand the best and shortest routes between trade centres. Illustrations and arguments showing the importance of these statements were given in Dr. Mill's paper, and a large map of the commercial development of the world was shown. Dr. Mill has thus done something to give definite shape to a conception of commercial geography. The fact is, applied geography in general, like applied chemistry or applied physics, implies a sound knowledge of the subject as a science. If the facts and principles of the subject are thoroughly known, their application need not be difficult. This application cannot be said to have been very successful in Section E. The evident object in view was to exemplify by special examples the principles laid down in the President's address and in Dr. Mill's paper. Thus we had a series of papers on what purported to be the commercial geography of a number of countries or regions. The geography, however, in most cases was conspicuous by its absence. The papers were certainly most useful in their way, and doubtless would be of some commercial value. Thus Colonel Mark Bell's paper on the great Central Asian trade route from Peking to Kulja and Semrechensk, and to Yarkand and India, abounded with original information collected by an acute observer, and it is hoped will be published in full by the Royal Geographical Society. But the minute details dwelt upon by the author were quite unsuited to an audience. Mr. R. S. Gundry's review of industrial and commercial progress in China was admirable in its way, and the views enunciated by the author original and suggestive. The conclusion come to was that a more widespread desire for progress and radical financial reform will be required before China is likely to rival Japan in the completeness of its transformation.

There was as usual a considerable number of African papers, some of them really good even from the geographical standpoint. Governor Moloney gave much useful information on the Yoruba country and its various tribes, his paper, however, being mainly occupied with suggestions as to its industrial development. The same may be said of Captain Lugard's paper on Nyassaland, and Mr. Rankin's on the Zambesi. The Rev. R. P. Ashe's paper on Buganda contained little not already published in his recent work; it dealt mainly with the natives, their political organizations, their religion, manners, and customs. Captain E. C. Hore's paper on Lake Tanganyika was one of the best in the Section. The author, who has lived ten years on the lake, described its geographical position, as occupying the central depression of the heights of Africa, from the surrounding barrier of which descend the furthest sources of the great rivers; referred to its outlet, the Lukuga, and remarked upon certain earthquake phenomena, and the aspect of the depression and of the bed of the lake. He gave a general description of the lake, with the results of meteorological observations and notices of scenery, and aspects of the lake under various changes of weather. He described the natives living on the shores of the lake and within the central depression, as representing all the great African families, and gave some account of their arts and industries, and of the produce of the lake region. He sketched the African routes and lines of communication as converging towards or crossing the lake, and the present available approaches to the lake from the east coast. He then referred to the position of the lake amongst and in relation to present claims and operations in Central Africa, pointing out what European enterprise has already achieved on the lake.

An excellent paper in physical geography was that of Mr. Flinders Petrie on Wind-Action in Egypt, the results of his own recent observations in the Nile Delta. He stated that the underlying motions of the Delta are depression on the coast and upheaval at Ismailiyeh. Above these movements great changes have been made by wind-action; in some sites at least 8 feet of ground has been removed and deposited in the water. This has partly caused the great retreat of the Red Sea head, and tends to form the characteristic swamps of this district. Formerly the Delta was a desert tract, with valleys inundated by the Nile. Before historic times the Nile valley was deep in water, partly estuarine, partly fluvial, and great rainfall then took place. That this was in the human age is shown by the position of worked flints.

Mr. Batalha Reis, in his paper on recent Portuguese explorations in Africa, put in a claim for exploring activity on behalf of Portugal which it would be difficult to substantiate. Mr. E. G. Ravenstein made some important corrections in the course of the Upper Nile as laid down in recent German maps.

Mr. Basil Thomson's paper, on his recent expedition to the D'Entrecasteaux and Louisiade Islands, was the same as that given some time ago to the Royal Geographical Society, and reported in NATURE. Dr. Carl Lumholtz's paper, on the present and future of Queensland, was highly interesting and useful from a colonial point of view. He, moreover, gave some of the results of his own observations during the time he lived with the natives as one of themselves. He found them to be undoubted cannibals, and predicts their early extinction.

One of the most original and scientific papers in the Section was that of Dr. Guppy on the south coast of West Java. The author dealt with a part of Java which has not been much described. It is one of the least familiar portions of this large island, a circumstance due partly to its paucity of anchorages and to the difficulty in landing; partly to its having been allowed to become in some places a kind of menagerie; and partly, also, to the fact that it lies remote from the chief seats of government. Now that the Netherlands Indian Government are rapidly carrying out their systematic survey of the Preanger Residency, it will not be long before the south coast of West Java will be much better known than it is at present; and the recent extension of the central railway to Garoet and Tjirajap will do much to effect this end. The author's tracks over West Java would make a chequered pattern on a map; but he has thought it best not to refer to localities already well known—localities which are now yearly visited by hundreds of visitors. Taking the central railway as his base, he performed nearly all the distance on foot, walking about 560 miles in all. In the paper he endeavoured to give a general idea of this south coast alone. The huge volcanic cones were landmarks to him, and nothing more; they had been well described by Junker and others, so he resisted the temptation of climbing them, and reserved his main efforts for the examination of the little-described and remote south coasts of the Preanger and Bantam Residencies. The object he had in view was to ascertain what physical evidence there was for the belief that the west end of Java was originally united with Sumatra. In this paper the author showed that all the evidence on the Java side of the Sunda Strait points to the opposite conclusion. Zoological evidence cannot be held sufficient to establish the previous connection between two islands without the physical evidence of such a change. The problem, as usually stated, seems to begin at the wrong end of the matter. Given the present distribution of plants and animals, it is then attempted to explain the previous arrangement of the land, and this is done too often without appealing to the physical evidence at all. In tracing geographical changes in the past, it would seem more reasonable to adopt an opposite method; but in the great majority of cases affecting the distribution of animals, it would be wiser in the first place to assume the *status quo*, and fall back when that fails on the physical evidence of the presumed changes.

As was rightly pointed out by Mr. H. J. Mackinder, Dr. Guppy's apparent contempt of the argument from zoological distribution is to be deplored. Hitherto it has been regarded, and rightly so, by the ablest biologists and geographers, as one of the surest and most valuable keys to past geographical conditions; and it will require much more powerful arguments than Dr. Guppy was able to adduce in his paper to cast it aside.

In a paper on recent explorations in Peru and Bolivia, Mr. H. Guillaume described the efforts which have been made by Peruvian and Bolivian explorers and traders to open up the rivers and the dense forest country lying between them. Colonel Labre since 1872 has been endeavouring to open communication from the Purus to the Beni. He explored the River Itury and its affluents several times, as to the character and navigability of which he has contributed much new information. Padre Nicolas Armentia explored the Madre de Dios in 1885, and resided for some time in the country of the Araonas Indians. From its mouth for 280 miles the river receives no important tributary; the Padre believes it has a navigable course of 400 miles for steamers. Mr. Guillaume described in detail the gold-bearing region at the source of the Madre de Dios. He then referred to the explorations of Senor Carlos Fry on the Ucayli and its tributary, the Urubamba.

Mr. Theodore Bent's paper, on his recent visit to the Bahrein Islands in the Persian Gulf, was a contribution of some originality on the present condition, the antiquity, the inhabitants, and past history of this interesting group. Dr. Nansen's paper on Greenland was identical with that given to the Geographical Society, and already reported in NATURE.

The Report presented to this Section by Mr. Joseph Thomson, on the geography and geology of the Atlas Mountains, can hardly be said to contain anything that has not already appeared in his narrative, except the lists of plants and of Coleoptera.

On the whole, it will be seen that the Geographical Section has not a very brilliant account to render.

THE MECHANICAL PAPERS AT THE BRITISH ASSOCIATION.

AMONG the papers read in Section G, after the President had delivered his address, was one by Mr. Alex. C. Humphreys, on water-gas in the United States. Water-gas is produced by the decomposition of steam by incandescent carbon. The two ways of effecting the decomposition, the intermittent and continuous, were described. In the first a cupola furnace is used: a blast of air raises the fuel to the necessary temperature; when this is effected the air is cut off and steam turned on, the blowing in of air and steam occurring intermittently. In the continuous process, steam is passed uninterruptedly through retorts containing carbon, which are heated externally, or steam and air are forced in continuously through a cupola furnace; but the latter process has the disadvantage of the resultant gases containing nitrogen. Water-gas has no light-giving properties so that it has to be carburized for illuminating purposes, or employed to raise some solid substance to a white heat. The different processes in vogue were described, and their theory explained. In conclusion the author gave expression to the belief that the day of gas, fuel-gas, was rapidly approaching; that even the great rival of gas, the electric light, may yet be dependent on it for the cheapest means of producing the electric current. Then will the gas engineer and the electrical engineer, shoulder to shoulder, be striving to correct the present wasteful strains on Nature's storehouses.

Precautions to be adopted when the electric light is supplied by means of transformers, by Mr. Killingworth Hedges. In a paper the author read at the Southport meeting of the British Association, he urged the necessity of regulations, and the adoption of proper safety appliances, in connection with electric lighting. In this paper he refers to the danger incurred when currents of high tension are converted into pressures suitable for incandescent lamps by means of transformers. The precaution necessary in such cases is either to earth the secondary circuit—which, however, has certain disadvantages—or to connect one or both of the leads to a safety appliance, which would automatically divert any excess current to earth, and at the same time shut off the supply in that portion of the faulty circuit by the fusion of the lead wire or mica-foils in the main cut-outs. Numerous experiments have been made with a vacuum protector, designed by the author, to ascertain the distance which an alternating current of high E.M.F. will leap across the two electrodes, which were fixed in the opposite ends of a glass tube from which the air had been partially excluded. The results differ from those observed by De la Rue with continuous currents; the following phenomenon was noticed—that the arc, after starting between the two points, almost invariably extended itself to a bow-shape and ran back to the base of one or both of the platinum electrodes, one of which nearly always fused, leaving the other intact.

Electric launches on the Thames, by Prof. G. Forbes, F.R.S. Launches are chiefly wanted in the summer; to prevent injuries to banks the speeds should not be high, so that a comparatively small supply of accumulators is required. The author experimented with the *Delta*, 33 feet long, 6 feet beam, fitted with forty-four cells, weighing 2520 pounds. She is steered by a wheel in front within reach of three handles required to work her. The first is to put the current on or off; the second for half or full speed, and the third for going ahead or astern. The first is mechanically locked with the others, so that they cannot be moved without first cutting off the current. Fusible cut-outs are inserted to prevent injury to the motor if the propeller becomes jammed. The batteries are under the seats on each side of the boat, thus leaving clear space for passengers, of which she could carry twenty. The pull at full speed gives 1·44 horse-power, or 1074 watts, including electrical losses, slip, and all friction. The average pressure at the motor terminals during the run was 78 volts, and the average current 23 amperes, which gives 1794 watts expended. This gives a total efficiency of 60 per cent. The author suggested that negotiations should be opened with the Thames Conservancy to establish charging stations, as there was likely to be a great demand in the future for electric launches.

Series electrical traction (Northfleet Tramways), by Mr. Edward Manville, M.Inst.C.E. The economical distribution of electrical power over long distances involves the use of a current of high potential, and by running the motors in series the advantages of high potential are secured. The main features of a series electrical tramway are a dynamo producing a current of constant quantity, a closed metallic circuit of which travelling motors at all times form a part without ever being short-circuited, or having the current supply cut off from them, and the regulation of the power developed by the motor and absorbed by it without interrupting the continuity of the circuit. An insulated cable connected to one terminal of the generator traverses the whole length of the line, and is interrupted at distances of 20 feet, the divided ends being connected with the opposite faces of a "spring jack," which is at the same time the automatic switch and contact point. The current collector, which is the same length as and carried by the car, is constructed so as to pass between the faces of the "spring jack," and conduct the current to the motor without at any time short-circuiting it or interrupting the main circuit. In series running, there is little danger of damage to the motor by careless driving, or reversing while running; in descending a gradient there is positive advantage in checking the speed of the car by altering the field connections, so that the armature tends to revolve in the opposite direction to that in which the car is travelling; the power that would otherwise be lost in braking is thus added to that produced by the generator.

Telephonic communication between London and Paris, by Mr. W. H. Preece, F.R.S. The difficulty of such a communication was not the distance, 275 miles, between the two towns, as in the United States speech is maintained between New York and Boston, 350 miles apart; but the insertion of underground wires at each end, and of a cable in the middle, places difficulties in the way that have to be surmounted. The author has experimented on the cables between Dover and Calais and others, and finds the conditions to be fulfilled simple. The circuit must be metallic, the material copper, and the product of the resistance of the line and its capacity must not exceed 7500 for very good, 5000 for excellent, and 2500 for perfect speech. A circuit approaching as nearly as possible one between London and Paris was made on an artificial cable, and found to comply with the requirements.

On the purification of sewage and water contaminated with organic matter by electrolysis, by Mr. W. Webster. The paper was divided into four sections, of which the fourth referred to the use of the electric current. The fact that water and the salts contained therein are easily decomposed if the current is of sufficient intensity is the explanation of the whole system. The changes taking place in sewage when electrolyzed depend chiefly on the splitting up into their constituent parts of sodium, magnesium, and other chlorides, nascent chlorine and oxygen being set free at the positive and the bases at the negative pole.

The strength of alloys at different temperatures by Prof. W. C. Unwin, F.R.S. In 1877, the Admiralty made some experiments as to the effect of variation of temperature on the tenacity of copper, Muntz metal, and phosphor bronze, and found that up to 500° F. the tenacity diminished proportionately with increase of temperature; in the case of gun metal, on the other hand, the tenacity diminished regularly up to 300° to 350°, but beyond this temperature there was a sudden reduction in the strength, which was found to be as low as half that at ordinary atmospheric temperature, whilst at 500° it became *nil:* the gun metal tested consisted of alloys of copper, tin, and zinc combined in different proportions. The author determined to make a series of experiments, the results of which he brought before the Association. The various alloys used, which are tabulated below, were heated in an oil bath, the temperatures employed, being all below that of the boiling of mercury, were read by means of a mercury thermometer. The results were plotted on a diagram, and given in tables, and show that the decrease of tenacity follows a regular law in each case; the temperature was given in degrees Fahrenheit, and the tenacity in tons on the square inch.

Temperature.	Yellow brass.	Cast brass.	Delta metal.	Muntz metal.	Gun metal.	Phosphor bronze.
Ordinary Fahr.	24·09	12·45	31·16	24·68	11·66	16·06
400°	21·23	11·11	26·58	20·84	11·06	12·30
500°	18·33	7·69	23·83	18·81	7·84	11·11
650° about ...	14·40	3·23	16·04	17·15 (615°)	4·82 (600°)	8·17

The influence of variation of temperature on the ductility of the same alloys was also experimented on, and was found to vary with the different alloys; with brass and gun metal there was little elongation before fracture; with Muntz metal it was considerable. In these cases the ultimate elongation diminished with increase of temperature, but in the case of Delta metal it increased. These experiments are of a very important character, and were carried out by the author on account of the very high pressures, and therefore temperatures, at which modern steam-engines are worked.

Central station heating and power supply, by Mr. W. W. Phipson. The system consists in the constant circulation of water at high temperature and pressure (viz. 400° F. and 250 pounds per square inch) from boilers at the supply station, through supply mains covered with non-conducting material, and back to the boilers by means of return mains, the circulation being maintained by pumps. Service boxes to supply the houses are fixed under the footpaths, which are connected to the mains by an inch pipe. From these boxes the house supply is taken by means of copper pipes. A vessel, called a converter, is fixed inside the house, whose use is to permit the water to resolve itself into steam, the pressure of which is controlled by means of a reducing-valve fixed on the copper pipe, before it enters the converter. From this converter the house services are taken. If a supply of both heat and power is required, double or compound converters are used with two reducing-valves, the power being taken from one and the heat from the other.

A curve ranger, by Mr. Alex. P. Trotter. The instrument is an application of the twenty-first proposition of the third book of Euclid, viz. the angles in the same segment of a circle are equal. A half-silvered mirror, such as is used in sextants, is mounted on an axis at one end of a bar, the other being provided with a sight. The motion of the mirror on its axis allows its inclination to the sight to be adjusted. To set out a curve, a pole is set up at each extremity, and the mirror is suitably adjusted. When the poles are seen, the one direct through the unsilvered part and the other by reflection in the silvered part of the mirror in apparent coincidence, and in the middle of the field as shown by the vertical line engraved on the mirror, the instrument is then at the point on the curve required. The mirror being clamped in position, the observer walks in the direction of the curve, and at suitable intervals places himself so that the poles at the extremities of the curve are seen in apparent coincidence.

On the application of the transporting power of water to the deepening and improvement of rivers, by Mr. W. H. Wheeler, M.Inst.C.E. The object of the paper is to show that the transporting power of water may be applied to the proposed purpose, and that under favourable conditions this can be accomplished by breaking up shoals, or the natural bed of a river, by mechanical agency and by mixing the material with the water, and allowing it to be carried away to the sea or estuary in suspension. The author has designed an improved apparatus, which, whilst disintegrating the shoal, mixes its material with the water, allowing it to be effectively transported by the ebb current clear of the channel to be improved.

THE ANTHROPOLOGICAL PAPERS AT THE BRITISH ASSOCIATION.

THE work of the Section commenced on Thursday, September 12, by Mr. Francis Galton, F.R.S., reading a paper on the advisability of assigning marks for bodily efficiency in the examinations of candidates for the public services. In the recent report of H.M. Civil Service Commissioners, they state that, a scheme of competition for physical qualifications having been brought before the notice of the War Office, it was not accepted, on the ground that the authorities were "completely satisfied with the physique of the young men who came to them through our examinations." The marks, as at present, of the candidates whose places lie near the dividing line between success and failure, run pretty evenly; therefore it is contended that the State would obtain better servants if such moderate marks were allowed for physical qualifications as to insure the selection of the most efficient in body from among those who are nearly on a par intellectually.

Mr. Galton also read a paper on the principle and methods of assigning marks for bodily efficiency. Two separate considerations are involved in the just determination of a scale of marks, which are usually mixed up in unknown proportions. (1) Absolute performance—on the principle that if the daily output of one man is greater than that of another, he should be more highly paid, or marked, in that proportion. (2) Relative rank—on the principle that superiority, however small, insures success in competitions, and therefore the order of merit deserves recognition independently of the absolute amount of performance. The general conclusion is, that before proceeding to decide on scales of marks numerous measures should be discussed, made of persons of the same age and social class as the candidates, so that the quality of the men hereafter to be dealt with shall be statistically determined. The next step is to decide upon the relative weights to be allowed for absolute performance and for relative rank. Then, after a few other obvious preliminaries have been settled arbitrarily, consistent scales of marks could be at once drawn up.

A paper on left-leggedness, by Mr. W. K. Sibley, was read, in which the author contended that man is either naturally or artificially right-handed and left-legged, and, in walking, tends unconsciously to bear to the right; while the lower animals, on the other hand, appear nearly always to circle to the left. The left foot is more frequently the larger in the male than in the female sex, and the percentage of feet of the same size is greater in the female. The percentage of the right larger than the left is very constant, whereas the numbers of the left larger and those in which both feet are the same size are much more variable.

Prof. D. J. Cunningham read a paper on the occasional eighth true rib in man, and its possible relationship to right-handedness. In seventy subjects examined the anomaly occurred fourteen times, *i.e.* in 20 per cent. It was found twice in the male for every once in the female. Five cases were bilateral, nine cases were unilateral, and of these no less than eight exhibited the anomaly on the right side. From this Prof. Cunningham considered that it was just possible that the anomaly might have some connection with right-handedness.

The following papers were also read :—Dr. W. Wilberforce Smith, on the early failure of pairs of grinding teeth ; Dr. Ridolfo Livi, on the development of the wisdom teeth ; Prof. D. J. Cunningham, on the proportion of bone and cartilage in the lumbar section of the vertebral column in the apes and in different races of men. Prof. Cunningham also exhibited the model of the head of a man stated to be 106 years old, with the brain exposed, *in situ;* and the model of the head and shoulders of a young orang-utan, with the brain exposed, *in situ.*

On Friday, September 13, His Excellency Governor Moloney, C.M.G., read a paper on African airs and musical instruments. He distributed the airs geographically as follows :—A, Gambia ; B, Ewe or Dahomey ; C, Yoruba ; and D, Houssa. In the first division specimens were given of *Bambara, Mandingo,* and *Volof* melodies, while *Popo* and *Dahomey* airs illustrated section B. The *Yoruba* division included *Lagos, Ibadan,* and other airs, and reference was made to several *Houssa* melodies. These countries were topographically described, and brief reference was made to their musical instruments and to the native minstrels. The paper concluded with an explanation of what is known as the "*drum language.*"

Mr. Paul B. Du Chaillu read the next paper—the Vikings the direct ancestors of the English-speaking nations. The author described the early civilization and antiquities of the North-men, and dwelt upon the beauty of their ornaments and weapons, and also upon the similarity of Scandinavian and English ornaments belonging to the Early Iron Age, and the love of the Northern people for the sea. He spoke of the three maritime tribes of the North, according to the Romans, and of the fleets of the Sueones in the time of Tacitus ; of the expeditions of the so-called Saxons and Franks, and of the home of these tribes ; of the proofs from antiquities found in the North of the commerce of the North-men with the Roman Empire and with Greece ; and also pointed out that the tribes of Germania were not a seafaring people, and were uncivilized, according to Roman writers. He gave an account of the probable origin of the names "Saxon" and "Frank," and spoke of the early settlements in Britain by the North-men during the Roman occupation, and of how the name of England might have been given to part of Britain. He alluded to the different countries of the Jutes, and how the language of the North and that of England was similar in early times, and that England was always called by the North-men one of the Northern lands. He mentioned the English and Frankish chronicles, in which the Sueones, Danes, and North-men are described, and that neither Saxons or Franks were a sea-faring people either at the time of Charlemagne or at any earlier period, and he dwelt on the mythical settlement of Britain by Hengist and Horsa, given by the English chronicles, which is quite contrary to the Roman records, Sagas, and archæology, and concluded by expressing his belief that the North-men, or Vikings, were the direct ancestors of the English people.

Canon Isaac Taylor contributed further researches as to the origin of the Aryans. Since the Manchester meeting of the Association in 1887, when the author read a paper on the same subject, he had re-examined the whole question from the anthropological rather than from the philological point of view. Assuming that there had been no migration of any new race into Europe since the Neolithic period, he contended that anthropologists have established the existence in Europe of four distinct prehistoric races, which might be reasonably connected with four existing types, which occupied nearly the same regions as the four prehistoric races. We have (1) the tall northern dolichocephalic race, the Canstadt race of De Quatrefages, which is the Scandinavian race of Penka, and the Eguisheim race of other writers. The stature of this race amounted to 5 feet 10 inches. It was platycnemic, prognathous, and dolichocephalic, with a mean cephalic index of from 72 to 73. The only pure descendants of this race are the North Germans and the Swedes. This Scandinavian or North-German type is maintained by Penka and other German writers to represent the primitive Aryans, who conquered the other European races and imposed on them their own Aryan speech. (2) We have a second type, also dolichocephalic, called the Silurian type by Prof. Rolleston, which is found in the long barrows of England. The normal stature was short, averaging 5 feet 4 inches ; 6 inches less than that of the other dolichocephalic race. The cephalic index is between 73 and 74. This race was orthognathous, and swarthy, with dark curly hair, oval face, and feeble muscular development. It is now represented by the Welsh of Denbighshire, by the Irish of Kerry and Galway, by some of the Scotch clans, by the Spanish Basques, the Corsicans, the Sicilians, the Berbers, and the Guanches of the Canary Islands. (3) We have a tall northern brachycephalic race, represented in the round barrows of the Bronze Age in England, in the tumuli of Denmark and some caves of Belgium. The average stature was 5 feet 8½ inches, the mean cephalic index was 81. It was macrognathous—with projecting teeth and powerful jaws, a square powerful chin, and a face quadrangular rather than oval. It is almost certain that the hair was light, either red or reddish-yellow. It was, in all probability, the race which introduced Celtic speech into England, and is now represented by the tall, yellow, freckled Irish, by some Highlanders, by the Danes, and most of the Slaves, by the Esthonians, and by many Finno-Ugric tribes. (4) The fourth prehistoric race was also brachycephalic, but short in stature. It never penetrated to England, but is represented in the sepulchral caves of the Lesse in Belgium. The stature was from 5 feet to 5 feet 3 inches ; the mean cephali index was 84 ; it was orthognathous and acrocephalic. It is now represented by the short dark population of Central France, more especially by the Auvergnats, the Savoyards, and the French Basques. It is found in the Rhætian Alps and among the Lapps. The hair is black and straight, and the eyes are dark. These four types and no others appear to have occupied Europe in the Neolithic period. It is difficult to find for them unexceptionable names, but we may for convenience call the first the Scandinavian type, the second the Silurian type, the third the Slavic type, the fourth the Auvergnat type. We have to determine which of these four races was probably the original Aryan race. The primitive Aryans must have either been by race Scandinavians or Slavo-Celts, and one must have imposed Aryan speech on the other. The Celts seem to have been in a higher stage of culture than the Germans, and therefore it is more probable that the Celtic race Aryanized the Teutonic race than that the Teutonic race Aryanized the Celtic race. Two hypotheses are possible—either the human race originated in Europe, bifurcating into the African and Asiatic races ; or we may suppose the white or European race to have originated from the union of the yellow race of Asia and the black race of Africa.

Canon Taylor also read a paper on the ethnological significance of the beech. While the Latin *fagus* and the Gothic *boka* denote the beech, the word has come to mean the oak in Greek. The author endeavoured to show that the word *fagus* originally denoted the beech and not the oak, also that the Greeks entered Hellas from the north-west. The range of the beech is limited. It is a lover of chalk soils, and does not grow east of a line drawn from Königsberg to the Crimea. West of this line we must therefore put the cradle of

Latin, Greek, Celtic, and Teutonic peoples, as they had the same name for the tree prior to their linguistic separation. The Lithuanian and Slavonic tongues must have originated east of this line, as their name of the beech is a loan-word from the German. The early home of the beech seems to have been limited to France, Central and Southern Germany, Northern Greece, and Northern Italy. If, as has been contended, the cradle of the European Aryans was in Central Asia, where the beech is unknown, it is difficult to explain how the ancestors of Celts, Latins, Greeks, and Teutons migrating, at different times and by separate routes, to lands where the beech abounds, should have called it by the same name, modified in each case by the fundamental phonetic laws of the various languages. It is easier to believe that the cradle of the Aryans was, so to speak, astride of the beech line, the ancestors of Celts, Latins, Greeks, and Germans living to the west of it, and those of the Lithuanians and Slaves further to the east.

In a paper by Mr. Hyde Clarke, on the right of property in trees on another's land, as an origin of rights of property, the author stated that his attention was first called to the subject, as a Land-judge or Commissioner in Asia Minor, in 1862, in granting compensation for olive-trees belonging to one or more individuals on the fields of others, and for honey-trees or hoards of wild honey in State or Communal forests. The author had found evidence as to the existence of the custom in Borneo, with regard to Tapang or honey-trees, and in Chota Nagpore as to the Mhowa, a tree furnishing food, spirit, oil, &c. In China a lessee has the right to bamboo, &c., grown by him. The practice in the Turkish Empire he found extended into the European provinces, as applied to plum-trees in Bosnia. In Ireland it was recognized in the Brehon Laws as an individual property separate from tribal property. It is probable that the personal right of the first discoverer of honey and similar trees is to be regarded as the origin of an individual right of property rather than any right in land, which is of no value in a primitive community. Even cultivable land belonged to the community, and was distributed by lot yearly.

A paper by the Rev. J. Wilson, on an hypothesis of a European origin of early Egyptian art, was also read.

On Monday, September 16, Dr. Garson exhibited an anthropometric instrument specially designed for the use of travellers. This instrument occupies very little space, and its weight is scarcely more than that of a detective camera. It can be used for taking all measurements of length and diameter with ease and accuracy.

Mr. Francis Galton, F.R.S., exhibited an instrument for measuring the reaction time to sight and sound signals, and explained that they heard much about the quickness of hand and eye. When anyone saw or heard a thing he made a movement, and between the sight and the movement many physiological processes took place so quickly that the flash of lightning was nothing to it. The instrument he exhibited was intended to make an accurate measurement of the time which elapsed between the seeing or hearing of anything and the time occupied in making a certain movement afterwards.

Dr. Thomas Wilson gave an account of the Smithsonian Institution in the United States of America, and its work relating to anthropology.

In a paper by Dr. MacLaurin, on the British race in Australia, the author said that he did not think there was any distinct type of configuration in the Australian-born inhabitant which was sufficient to distinguish him from the ordinary Englishman, Scotchman, or Irishman. The muscular vigour of the British Australian race could be estimated by the readiness with which it entered into athletic exercises, and the result of this had been evident in the number of sculling champions and cricket teams that had recently visited this country. The population was increasing through the excess of births over deaths, which showed that the vitality of the race had not been diminished by transplantation to Australia.

Mr. H. H. Risley next read a paper on the study of ethnology in India. It was shown that the population of Northern India comprised three distinct types, viz. :—(1) A leptorhine dolichocephalic type of tall stature, fair complexion, and high facial angle, apparently corresponding in all points, except hair and complexion, with the Aryan type as defined by Herr Karl Penka, of Vienna. (2) A platyrhine dolichocephalic type of low stature, black or very dark complexion, and low facial angle. The wider racial affinities of this type are uncertain, and it is tentatively and conjecturally described as Australioid. (3) A mesorhine, platyopic, brachycephalic type of low stature, yellowish complexion, and low facial angle, described, in virtue of its low naso-malar index, as Mongoloid. The types thus worked out by anthropometric methods were shown to correspond with certain ethnographic groupings independently ascertained. In the Aryan and Australioid types the social status of each caste or tribe is found to vary inversely as its nasal index; tribes with the highest index having the lowest social rank, and *vice versâ*. In the brachycephalic group social status appears to vary with the cephalic index. An attempt was made to deduce a theory of the probable origin of caste, and also to account for the custom of exogamy by the operation of the law of natural selection.

Prof. A. C. Haddon read a paper on some former customs and beliefs of the Torres Straits islanders. The natives of Torres Straits are divided into two distinct tribes—the eastern tribe, which inhabits Uga, Erub, and the Murray Islands; and the western tribe, which occupies all the remaining islands. The islanders were divided into clans, each clan having some animal for its totem, such as the dugong, turtle, dog, cassowary, snake, shark, &c. The women used to have a representation of their totem cut on the small of the back. In the western tribe the lads on entering into manhood underwent a month's isolation in the bush. In the eastern tribe two elaborate ceremonies attended the initiation of the lads, but the discipline does not appear to have been so severe as in the other tribe. It was the custom in the western tribe for the women to ask the men in marriage. On the other hand, in the eastern tribe the men proposed to the women, and the women had to undergo a period of partial seclusion previous to marriage. The eating of food together was a feature in marriage. Belief in sorcery was universal, and all sickness and death were attributed to the charms of the medicine-man. There were also rain and wind makers.

Some observations on the natural colour of the skin in certain Oriental races, by Dr. J. Beddoe, F.R.S., was read. The author made numerous observations of this kind in the course of a voyage round the world. In most cases he found the colour of the clothed and protected body much lighter than is generally supposed. The capacity to tan, or become darker by exposure, varies much: thus the Melanesians are naturally lighter than the Australians, but they burn much blacker.

The following papers were contributed by Dr. R. W. Felkin: the normal temperature of the Soudanese, Negroes, and Europeans in Tropical Africa; and the differences of sensibility between Europeans and Negroes, and the effect of education in increasing the sensibility of Negroes. Some anthropological notes collected by Mr. Edward Beardmore at Mowat, Daudai, New Guinea, were also read.

On Tuesday, September 17, Dr. Fridtjof Nansen read a paper on the Esquimaux. He said they were a race by themselves, and he did not think anthropologists agreed yet as to their real origin. He thought that tradition showed the Esquimaux really came from America. The Esquimaux of Greenland were now divided into two classes—those on the west coast who had been civilized by the Danes, and those on the east coast who were uncivilized. Esquimaux were seen in the north in 1823. The eastern Esquimaux had warmer clothes than the western ones. The young girls wore their hair loose, but afterwards they put it up in a knot at the top of the head, as a sign that they were ready for marriage. The Esquimaux, as a rule, lived in small tribes, and as many as ten families often lived in one hut. The Esquimaux had no written laws, but they had unwritten laws, which were kept strictly. The head of the house and the chief of the tribe was the best catcher of seals. As to property, they did not really know that word. No man had anything for himself, and any seals caught were divided between the families. They did not steal from each other, but they liked to steal from Europeans. Murder was not uncommon amongst the Esquimaux, and the punishment was really nothing at all. The men married as soon as they could catch sufficient seals to provide for a wife. Near relations, such as cousins, never married. On the east coast some men had two wives, the reason being that one wife could not prepare all the seals they caught. The children were not punished. Weak and deformed children, and those who lost their mothers, were as a rule thrown outside the house or into the sea. Old people, who were ill, were often thrown into the sea. He thought the time would come when the Esquimaux would be extinct.

The Rev. G. Rome Hall read a paper on Northumberland in prehistoric times. On the east coast of England no trace of the Cave-men had as yet been found further north than Norfolk.

We came, after an immense and unknown lapse of time, to the Neolithic period, when the earliest inhabitants of Northumberland, who were, so far as can be ascertained, cognate with the Basques and Lapps, crossed the Tyne in small family or tribal bands. Though probably never numerous, their polished weapons and implements had been frequently found. Considerable hoards of bronze had been found near Alnwick, Rothbury, and Wallington. Beads of gold were discovered in a barrow at Four Laws, or Chesterhope. Near Bellingham, in North Tynedale, a gold armlet was found. Burial by inhumation was customary in the later Stone Age, and cremation followed. Interments were sometimes in split oak coffins, found at Featherstone, but usually in stone-lined graves, the body being doubled up as in the posture of sleep, sometimes with an iron food-vessel placed near the head. The author explained the migrations of the people in early times. To the Iron period we owed the introduction of the greater part of the names of local mountains, hills, rivers, and streams, as the Tyne from "don" or "tan," the water. The bronze-using invaders may have landed in England about B.C. 1000, and the Iron Age in Northumberland might have begun about B.C. 500 or 400. Modern Northumbrians, he concluded by remarking, might perchance owe more than they thought to the combination of racial characteristics resulting from the continuity of life proceeding from even prehistoric times down to the present day.

Sir William Turner read a paper on implements of stags' horn associated with whales' skeletons found in the Carse lands of Stirling. He showed that skeletons of whales had been found, together with implements of stags' horn. The discovery of these horn implements showed that when the fertile land now forming the Carse of Stirling was submerged below the sea-level, the surrounding high lands were inhabited by a hardy Caledonian race, who manufactured useful tools and weapons from the antlers of the red deer. It was probable that the whales had been stranded during the ebb of the tide, and that the people had descended from the adjacent heights, and, with the aid of their chisels of horn, had spoiled the carcass of its load of flesh and blubber. There was nothing in the shape of those implements to lead anyone to suppose that they could be used in the chase of the whale. The period of this people was probably covered by that termed the Neolithic, the termination of which was stated to be from 5000 to 7000 years ago.

Mr. Bernard Hollander read a communication on the relations between brain-functions and human character, with the view of showing the possibility of a scientific phrenology.

The following papers were also read:—Prof. G. J. Romanes, F.R.S., on the origin of human faculty; Prof. Frazer, on a new method of illustrating the topographical anatomy of the brain; Mr. George Weddell, notes on classification in sociology; Mr. S. B. J. Skertchly, on fire-making in North Borneo, and on some Borneo traps; Mr. James Macdonald, on manners, customs, and superstitions of South African tribes.

THE MAORIS.

An unusually lengthy Report from the Registrar-General of New Zealand on the condition of that colony, which has lately been laid before Parliament, contains some interesting information respecting the present condition of the Maoris. Mr. Brown says that, according to the traditions of the Maoris, their ancestors first arrived in New Zealand from an island in the Pacific Ocean, to which the name of Hawaiki is given. Since that event it appears, from genealogical sticks kept by the *tohungas*, or priests, that about 20 generations of the race have lived. The number of the Maori race at the time of the first foundation of the colony, in 1840, was estimated at about 80,000. Twenty years previously the number had been estimated at 100,000. In 1857 an enumeration of the race was made, from which it appeared that the number of males was then about 31,667, and that of the females about 24,303; and of those whose sex was not stated, 79; a total of 56,049. Subsequent attempts at enumeration have been made; but, owing to the objections felt by natives to stating their numbers, and to the difficulties experienced in obtaining information in those parts to which the European was not allowed free access, with not wholly satisfactory results. The latest, and probably most accurate, of these enumerations, was made in 1886. This gave the number of males as 22,840, and the females as 19,129; a total of 41,969.

That there has been a serious decrease in the numbers of the race of late years is the general opinion of all competent to judge, and a consideration of the numbers of each sex, and the proportion living at each age-period, leads to the conclusion that in all probability the decrease is still progressive. In 1886 the proportion of females was 83·75 to every 100 males. In the European portion of the population the proportion was 85·28 females to 100 males. The proportions are not relatively comparable, as the excess of European males over females is caused by immigration; but there is no external cause to account for the Maori males being more numerous than the females. In the European portion of the population, under 20 years of age, the proportion was 100 males to 99 females; in the Maori population under 20, the proportion was 100 males to 87 females. The males under 15 years of age were in the proportion of 31·82 to every 100 of the male population, and the similar proportion among the females was 33·59; these being less than the proportions in 1881—an evidence of a low birth-rate, or high juvenile mortality, leading to a racial decrease.

On comparing the proportions living at each quinquennium under 20, and each decennium above that period, with the corresponding proportions in the population of England, and that of the New Zealand European, it is found that at all ages under 20 the proportions among the Maoris are far less than among the other two populations, and at each age-period above 40 the Maori proportions are far higher. It is, of course, a fair inference that the causes of these larger proportions at the higher age-periods are two-fold—namely, a low birth-rate, and a high death-rate among the younger members of the community. This is borne out by the much smaller proportions of young children to those in either the English or New Zealand European communities. The smaller proportion of females (83·75) to males (100) also shows a greater mortality among the adult females than among the males, as 42·29 per cent. of the females living were under 20 years of age, but only 39·70 per cent. of the males were under 20. The manifest decrease in the numbers of the race is much to be regretted, for the Maoris show great aptitude for civilization, and they possess fine characteristics, both mental and physical, and rapidly adopt the manners and customs of their civilized neighbours. In mental qualifications they can hardly be deemed as naturally an inferior race, and the native members of both the Legislative Council and the House of Representatives take a dignified, active, and intelligent part in the debates, especially in those having any reference to Maori interests. The Maoris contribute largely to the taxation of the country through the Customs duties; and, having regard to the relations now subsisting between the races, they may be regarded as constituting an important element of strength in the population of the colony.

On the subject of the education of the natives, Mr. Brown says the number of native village schools at the end of 1887, either supported or subsidized by the Government, was seventy-nine, an increase of eight on the number in 1886. In addition, there were two more subsidized private schools for the education of Maori children only, and seven boarding-schools for native children, the cost of whose maintenance was paid either by Government or out of endowments. The number of Maori children attending school at the end of 1887 was 2812, viz. 1612 males and 1200 females. These included children of mixed European and Maori blood, who live as members of native tribes. The following is a statement of the number of Maori children who were attending schools in 1886 and 1887:—

	1886.	1887.
At public European schools	475	343
At native village schools	1910	2215
At subsidized or endowed boarding-schools	162	156
At private European or native schools	100	98

There was thus an increase of 165 on the number of native children who were being educated in 1887. There was a decrease of 132 in the number attending European public schools, but an increase of 305 on the number attending the native village schools.

The information supplied respecting the age of the Maoris at the census of 1881 was very incomplete, and therefore only a merely approximate estimate can be given as to the numbers living at the usual school ages, 5 to 15. Out of a Maori population of 22,840 males and 19,129 females, the ages of 21,724 males and 17,936 females were given as either under or over 15 years. The proportion of those under 15, if applied to the whole of the population, would give 7226 males, and 6420 females under 15 years of age. If it be assumed that the numbers living under 5 years of age bear the same proportion to the whole number under 15 years of age as in the European portion of the population, the above numbers would give 4596 Maori males and 4082 Maori females between 5 and 15 years of age. As all the children attending the private and public schools may be fairly taken at over 5 and under 15 years of age, and the ages of those attending native schools are ascertainable, it may be roughly stated that nearly 32 per cent. of the Maori boys and nearly 27 per cent. of the Maori girls between 5 and 15 years of age attend schools.

SCIENTIFIC SERIALS.

Reale Istituto Lombardo di Scienze e Lettere, Rendiconti, vol. xxii. fasc. xv.-xvi.—It appears from experiments here described by Signor Sormani that the Bacillus and spores of tetanus may be drawn into the respiratory passages by inhalation, or even injected into the bronchial tubes, without producing tetanus. The Bacillus is probably anaërobic, unable to develop in presence of oxygen. The tetanus called *rheumatic* is thought to be of traumatic origin really, the wound being slight, and but little of the virus introduced. Tetanus is most common in Northern Italy; its maximum being in Lombardy and Emilia, where people frequently work, in the hot season, with bare feet. They are attacked in the proportion of 100 males to 30 females. The mortality in hospitals is about 44 per cent of those attacked.—We note two medical papers: on recent innovations in treatment of free inguinal hernia (Signor Scorenzio), and on fibroma of the breast (Signor Sangalli).—An inquiry into the nature and uses of the *stufe* and warm baths of the middle and later ages is summarized by the author, Signor Corradi.—Signor Maggi writes on the principles of the theory of potential functions, and there are continuations of mathematical papers by Signors Oschieri and Giulio.

Bulletin de l'Académie Royale des Sciences de Belgique, No. 8, 1889.—M. Massart here seeks to account for the penetration of spermatozoïds into the egg of the frog by the resultant attraction of the gelatinous mass round the egg, which, absorbing water, presents a gradually increasing density inwards. If a piece of the episperm of linseed or quince be put in water containing spermatozoïds, the mucilaginous matter round it swells similarly, and, during the twenty minutes this continues, the spermatozoïds are attracted, and make their way to the centre. When the absorption ceases, they stop too. The gelatinous covering of the frog's egg, separated from the latter, in water, affects them similarly. M. Massart holds that sensibility to contact is the explanation of the phenomena (not mechanical attraction, nor a sense of the direction of the current).—M. de Heen describes a simple new apparatus for measuring the heat conductivity of some homologous organic liquids, and shows that, in a given series, the conductivity diminishes with increasing molecular weight; but the square of $\frac{1}{c}$ varies generally less rapidly than the weight. He also discusses the dilatability of liquids in relation to molecular movements.—M. Henry studies the volatility of normal cyanic ethers, and of poly-oxygenated carbon compounds; finding the simultaneous presence of oxygen and nitrogen, or the accumulation of oxygen, at one point in the molecules, a powerful cause of it. He has also a short paper on monohaloid ethers of ethylenic glycol.—M. Dewalque supplies some phenological figures for Liége, Spa, &c. A valuable paper on the svastika appears in the section *des lettres*.

SOCIETIES AND ACADEMIES.

LONDON.

Entomological Society, October 2.—The Right Hon. Lord Walsingham, F.R.S., President, in the chair.—Mr. F. P. Pascoe exhibited a number of species of Coleoptera, Lepidoptera, Hymenoptera, Neuroptera, Hemiptera, Orthoptera, and Diptera, collected by himself during the past summer at Brindisi, and in Greece and the Ionian Islands.—Mr. J. W. Douglas sent for exhibition specimens of *Lygus viscicola*, Puton, a species new to Britain, taken at Hereford, in September last, by Dr. T. A. Chapman.—Mr. R. McLachlan, F.R.S., exhibited nearly 100 specimens of Trichoptera recently collected in Iceland by Dr. P. B. Mason. Only six species were represented, and of these five had been previously recorded from the island. Mr. McLachlan remarked on the great amount of variation existing in some of the specimens.—Mr. E. B. Poulton, F.R.S., exhibited a mounted specimen of the yellow powder from the cocoon of *Clisiocampa neustria* under a power magnifying 188 diameters. The powder was thus seen to consist of crystals so minute that the form could only just be made out under this power; it was present in a crystalline form in the Malpighian tubules, and discharged from the anus of the larva. A discussion ensued as to the functions of the Malpighian tubes, in which Mr. Stainton, F.R.S., Lord Walsingham, Dr. P. B. Mason, Mr. McLachlan, and Dr. Sharp took part.—Mr. Poulton also exhibited some photographs of the living larvæ of *Hemerophila abruptaria*, showing different depths of colour which had been induced by experiment; the larvæ had been rendered very light in colour by being surrounded by green leaves and stems only, whereas they had become extremely dark when numbers of dark twigs were intermingled with the leaves of the food-plant. Mr. F. Merrifield said that Dr. Chapman had recently obtained similar results from experiments made with the larvæ of *Ennomos alniaria*.—The Rev. Dr. Walker exhibited, and read notes on, a number of Coleoptera, Neuroptera, Hymenoptera, and Diptera, which formed the second instalment of the collection which he had recently made in Iceland.—Mr. R. South exhibited a specimen of *Luperina nickerlii*, Freyer, caught in Lancashire last August. He also exhibited, and read notes on, a long series of *Boarmia repandata*, bred from larvæ collected in North Devon. Mr. Poulton, Mr. Merrifield, and Lord Walsingham took part in the discussion which ensued.—Mr. J. J. Walker, R.N., exhibited a collection of Coleoptera made during the past summer in Cobham Park, Kent. Thirty-three species were represented, amongst which were the following, viz. *Eros minutus*, *Philonthus fuscus*, *Homalota hepatica*, *Abræus granulum*, *Anisotoma grandis*, *Agaricophagus cephalotes*, *Thalycra sericea*, *Cryptophagus ruficornis*, *Platytarsus setulosus*, &c.—Herr Jacoby exhibited a curious Phytophagous beetle found by Mr. J. H. Leech in the Corea. He stated that he was unable to determine the species, as was also Mr. J. S. Baly, to whom he had submitted the specimen.—Mr. R. Adkin exhibited specimens of *Retina resinella*, received by him from Forres. Lord Walsingham remarked that he had never seen the species in Scotland, but that it was not uncommon in Germany.—Mr. W. Dannatt exhibited a male specimen of *Papilio antimachus*, Drury, received from Lukolela, a station about 500 miles from the mouth of the Congo. He stated that the species, although very rare, had a wide range, as three other specimens of it had been received from the Stanley Falls, which were more than 800 miles further up the Congo.—Lord Walsingham exhibited specimens of the larva and imago of *Cidaria reticulata*, collected in the Lake District, and sent to him by Mr. Hodgkinson.—Mr. J. Jenner-Weir exhibited fore-wings of the males of *Argynnis paphia*, *A. adippe*, and *A. atlantis*, denuded of the scales, in order to show that there was no dilatation or thickening of the median nervules and submedian nervure in that sex of these species; but that the apparent dilatation was produced by a dense mass of scales crowded together on each side of the nervules. He also read a short paper on the subject entitled "Notes on the Nervules of the Fore-Wings in the Males of *Argynnis paphia* and other Species of the Genus." Mr. Jenner-Weir said he was supported in his views by the opinions of Mr. S. H. Scudder, Dr. Staudinger, and Dr. Schatz.

SYDNEY.

Linnean Society of New South Wales, July 31.—The following papers were read:—Description of a new species of Iodis, with remarks on *Pielus imperialis*, Olliff, by Thomas P. Lucas. For the new species of Iodis—of which three specimens were recently captured in Brisbane by Mr. Illidge—the name of *P. illidgei* is proposed. The second part of the paper consists of critical remarks on *P. imperialis*, Olliff, which the author states is identical with *P. hyalinatus*, Schäffer.—The examination of kinos as an aid in the diagnosis of Eucalypts; Part 1, the Ruby Group, by J. H. Maiden. The author refers to a previous paper, in which he shows that Eucalyptus kinos may readily be grouped into three great classes, according to their behaviour with water and with spirit. Briefly, he divides them into (1) the Ruby Group, which consists of ruby-coloured kinos, the members of which are soluble either in cold water or in cold spirit. (2) The Gummy Group, whose members are soluble in cold water, but very imperfectly in spirit, owing to the gum they contain. (3) The Turbid Group, whose members are soluble in hot water or in hot alcohol, but the solutions become turbid on cooling, owing to the presence of catechin. He then deals with the first group, and shows that, with one anthereally doubtful species, the members are identical with the group Renantheræ of Bentham and Müller's anthereal classification. He shows how the examination of kinos is a valuable aid or supplement in the diagnosis of Eucalypts, and concludes this part with an account of all the ruby kinos at present known to science.—On Rhopalocera from Mount Kosciusko, New South Wales, by A. Sidney Olliff. In this short paper some sixteen species are recorded from specimens obtained by Mr. R. Helms, a most painstaking and energetic collector, who recently made an excursion, chiefly in the interests of entomology, on behalf of the Australian Museum. The collection contains both the species described from the mountain by Mr. Meyrick, as well as a new Xenica, proposed to be called *X. correæ*.—Note on the fructification of *Phlebopteris alethopteroides*, Etheridge, fil., from the Lower Mesozoic Beds of Queensland, by R. Etheridge, Jun. From the examination of additional material the author has been able to determine an arrangement of the sori similar to that in *P. polypodioides*, Brongn., and other known species of the genus.—Note on the bibliography of Lord Howe Island, by R. Etheridge, Jun. This paper is supplementary to a recently-published work ("Lord Howe Island: its Zoology, Geology, &c.," *Mem. Austr. Mus.*, 1889, No. 2), and gives a digest of certain valuable reports by Dr. Foulis, Mr. White, Captain Denham, R.N., and Dr. J. Dennis MacDonald, contained in the "Votes and Proceedings of the Legislative Council of New South Wales for 1853," and with which, when contributing to the above-mentioned work, the author had been unable to meet

PARIS.

Academy of Sciences, October 14.—M. Des Cloizeaux, President, in the chair. — Presentation of vol. iv. of the "Collection of Memoirs relating to Physics," published by the French Physical Society, by M. C. Wolf. This volume is devoted to the pendulum; and contains memoirs by La Condamine, Borda, Cassini, Prony, Kater, and Bessel. M. Wolf supplies a bibliography and chronology of works on the pendulum from Galileo's time to 1885; also an historical introduction. The fifth volume will deal with the same subject.—Reciprocal displacements between the halogen elements and oxygen; hydrobromic and hydriodic acids, by M. Berthelot. A *dilute* solution of iodide of potassium remains an indefinite time colourless in presence of oxygen; but it is otherwise with a *saturated* solution, owing to the formation of a small amount of tri-iodide. Dilution of the yellow liquor with fifty times its volume of water (or more) removes the colour almost entirely; dissociation of the tri-iodide allowing the potash to react fully with the iodine.—On transformism in pathogenic microbiology; limits, conditions, and consequences, of the variability of the *Bacillus anthracis*; researches on ascendant or reconstituant variability, by M. A. Chauveau. The natural Bacillus, with its virulence quite removed by compressed oxygen, may be revivified by degrees, thus: it is cultivated in *bouillon*, to which fresh blood of, *e.g.*, a guinea-pig is added, and in very rarefied air; it then becomes fatal to mice, guinea-pigs, rabbits, &c., and is vaccinal to small ruminants, but does not kill them. Cultivation of this Bacillus in *bouillon* to which sheep's blood is added renders it fatal to small ruminants, and probably vaccinal to the ox.—New relation between sugars and furfuric compounds; constitution of methylfurfurol and of isodulcite, by M. Maquenne. Distilling isodulcite ($C_6H_{12}O_5$) with dilute sulphuric acid, he got some pure methylfurfurol ($C_6H_6O_2$) identical with that obtained from Fucus; and he infers the presence of isodulcite in tissues of marine plants. Its relations to arabinose suggest that it may be much more widely diffused than has been supposed.—On the physical properties of the free superficial layer of a liquid, and of the layer of contact of a liquid and a solid, by M. Van der Mensbrugghe.—On doubly harmonic linear elements, by M. L. Raffy.—On the area of certain ellipsoidal zones, by M. G. Humbert.—On the fermentation of raffinose, in presence of different species of beer-yeast, by M. D. Loiseau. A claim of priority.—Observations on the communication made by M. Ch. E. Guignet, at the meeting of September 30 last, by MM. C. Vincent and Delachanal. The addition of ammoniacal sulphate of copper to the juice of sorbs precipitates sorbite itself, so the production of this precipitate does not prove the presence of mannite nor its separation from sorbite.—On the optical analysis of oils and of butter, by MM. E. H. Amagat and Ferdinand Jean. They describe a method based on variation of the index of refraction of various oils, and of the melted fatty matter of butter, due to the presence of adulterating substances.—On air contained in the soil, by M. Th. Schlœsing, *fils*. He has improved on the method adopted by MM. Boussingault and Léwy thirty years ago; he forces into the ground a steel tube with conical point, the opening of which is temporarily closed by wire. The upper end is connected by means of a capillary tube with a bulb, from which mercury is withdrawn on lowering a small connected reservoir; thus the air of the soil is drawn in. He finds abundant gaseous oxygen in the soil, and much variability at different times; details are promised.—On a musculo-cutaneous strip, in form of a flap, applied to the restoration of eyelids, by M. Léon Tripier. The strip is dissected out from one eyelid and transferred to the other side.—On the exploration and the formation of *avens*, by MM. E. A. Martel and G. Gaupillat. These *avens* are natural, open, deep pits, found in numbers on calcareous plateaus. The authors hold that four factors participate in their formation: (1) previous dislocations of the ground; (2) surface waters (erosion); (3) interior waters (erosion, hydrostatic pressure, falling in); (4) chemical phenomena. Frequently only three or two of these factors have been in operation. It is only accidentally that the *avens* communicate with subterranean rivers.

THURSDAY, OCTOBER 31, 1889.

"OXFORD AND ITS PROFESSORS."

A TRENCHANT article in the last number of the *Edinburgh Review* arraigns and passes judgment on the University of "Oxford and its Professors." The evidence clearly establishes the facts that the lectures of the great majority of the Professors are but poorly attended, and that, in spite of the efforts of two Commissions, the relations between the University and the Colleges, regarded as allied educational institutions, are not satisfactory. On the causes of this unhappy state of things we do not desire to dwell, but, although agreeing on many points with the author of the article, we must protest strongly against one of the remedies which he suggests.

"Why," he asks, "should not the Universities recognize the principle of division of labour? . . . Why, for instance, should not Cambridge provide thoroughly for the teaching of natural science; and Oxford as thoroughly for that of theology? . . Let the Universities abandon individualism and accept individuality. Let one group of allied subjects be studied in Oxford; another at Cambridge."

It is true that the Reviewer thinks that "a University ought to provide a liberal education, competent to form the basis of that technical training which is special to every trade and profession," but he contends that "beyond this general course, the minutely differentiated special studies into which human knowledge is now necessarily distributed must be recognized and ordered."

We are convinced that an attempt of this sort to confine the special studies of each University to particular lines would do infinite harm. It is not only the students, but the teachers, who are benefited by mingling with others who are their intellectual equals, but whose intellectual activities are put forth in other directions.

It is easy to say that London is within an hour and a half of Oxford or Cambridge, and that London society will widen views which might otherwise contract, and prune down eccentricities which might become serious defects. It is not, however, true, and it is not likely to become true, that the average teacher in a University has society of this sort open to him in early life. More and more frequently—to their honour be it said—lads who begin in the elementary school fight their way to University distinction. Others who start from a position of greater social advantage move "at home" in circles in which literary or scientific ability is rare, and in which they are much more likely to be spoiled by indiscriminate admiration than restrained by judicious criticism.

For a large number of young Fellows of Colleges, the High Table and the Common Room furnish, during the most impressionable years of life, the highest intellectual and social society to which they can attain; and many of those who travel beyond these limits extend the bounds of their acquaintance chiefly among those who are interested in the same special studies as themselves.

It would therefore work terrible mischief if the gulf between specialists were widened by driving them into different Universities. Oxford, we may be sure, would fight to the death against being converted into a mere school of theology. It is said that one of its Colleges some years ago refused an endowment of many thousands which was fettered with the condition that it should benefit only members of a particular Church; and in this temper the suggestions of the Reviewer would be met.

Surely no man who wished well either to the Universities, or to religion, or to science, would desire to see future curates relegated in a body to the Isis, and would-be demonstrators to the Cam; or would mould a Common Room on the pattern of a Clergy House, while a Combination Room was fashioned into a likeness of the Secretarium of the British Association.

Nor do we adopt this view merely on the ground that it is well that students of other branches of knowledge should be leavened by mingling with those who cultivate science. No critic is so unsparing, so useful, and so inoffensive as an intimate friend, and scientific men need criticism as much as others. A hint that, however valuable the scientific results of a treatise may be, they are announced in execrable English, can be conveyed by a college chum better than by anybody else. The Huxley or Tyndall of the future will sometimes be none the worse for the reminder that his predecessors, if they popularized science, did not vulgarize it, and that scientific papers which possibly contain useful additions to knowledge are certainly literature, and, as such, must be tried by the ordinary canons. In short, it is on behalf of the younger scientific men that we claim that those among them who study in our Universities shall not be deprived of the advantage of intimate relations with fellow-students of their own standing, whose aims in life, and modes of thought, are other than theirs.

The argument from economy is sufficiently met by the above considerations, but it is absurd to contend that there is not room for two great schools of science in the Universities, if proper means are taken to fill them.

In every provincial town, Colleges are springing up which are far better equipped than were the Universities themselves some twenty years ago, and the number of their students steadily increases. In Cambridge, the scientific lecture-rooms and laboratories are full to overflowing; and we cannot but believe that, if Oxford is less successful, the comparative failure is due either to temporary causes, or to some defect of organization which could be discovered and remedied.

According to the Reviewer, the relations between the Professoriate and the Colleges are not harmonious, and, if this be so, natural science is probably more injuriously affected than any other branch of study. Centralization, harmful in many cases, is essential in the teaching of a subject which at present attracts a small number of very advanced students, while the machinery for the instruction of elementary students must necessarily be expensive. That it can be attained without trenching on the legitimate privileges of the Colleges is proved by the fact that, in spite of the existence of the Collegiate system, Cambridge has become a great school of science.

SUBJECTS OF SOCIAL WELFARE.

Subjects of Social Welfare. By the Right Hon. Sir Lyon Playfair, K.C.B., M.P., LL.D., Ph.D., F.R.S. (London: Cassell, 1889.)

IN this volume Sir Lyon Playfair has collected a series of his essays, speeches, and lectures, composed or delivered during the last half-century. The volume is divided into three parts, the first dealing with questions relating to public health, the second with various economic problems, and the third (of course) with educational topics. Though most of the essays are more or less scientific in character and mode of treatment, only one is purely scientific, viz. that on "Sleep and some of its Concomitant Phenomena," which contains, with a few alterations, the substance of a lecture delivered before the Royal Institution in 1846.

The whole forms a volume which, if it will add nothing to the great reputation of the author, is eminently readable, and exhibits his usual power of apt illustration and dexterous handling of masses of facts. It is not, indeed, a book which many will read from cover to cover, for, as is natural when we consider the conditions under which its contents were originally produced, there is a considerable amount of repetition both in the subjects and in the mode of treatment. But readers in search of trenchant arguments and pointed illustrations on such debated questions as vivisection and vaccination will find both in the lucid and pithy discourses devoted to these subjects by Sir Lyon Playfair; and there is a great variety of interesting economic facts drawn both from Europe and America in the second part of the volume, which deals with industrial wealth. We cannot, however, candidly say that we regard the second section of the book as satisfactory. Much of it was originally intented to serve a definite and temporary purpose—to confute an adversary or to reassure wavering adherents of Free Trade—and for such a purpose it was well adapted. It came under the head of what an eminent politician has called the literature which to-day is and to-morrow is (or at least should be) cast into the oven, and its preservation will, we fear, serve no useful end. When, for example, Sir Lyon Playfair declares that, "so far as regards politics, ethics, sculpture, painting, and architecture, the world has advanced little beyond, if it has reached, the position attained by Greece and Rome. These, though they grace, do not now form the foundation of a nation's prosperity. That is formed from the applications of science to industry," he is expressing an opinion which may have been the passing sentiment of a moment, but which he will hardly care to have permanently associated with his name.

One of the weakest of the papers is that on bimetallism. Sir Lyon Playfair does not appear to realize the point of view of the bimetallist economists, who, however unpractical they may be, are not wanting in theoretic knowledge and power of analysis, and who are certainly not in such a state of fog as to the cause and regulator of the values of the precious metals as their critic seems to suppose. Such men as President Walker, whose exposition of the question is not lacking in clearness, certainly never subscribed to the opinion gratuitously thrust upon bimetallists by Sir Lyon Playfair, that the value of gold and silver can be fixed by statute *independently* of the state of demand and supply. But a very brief examination of the subject will make it clear that the establishment by a considerable number of nations of a legal ratio between the values of gold and silver would be a most powerful factor in altering the conditions of demand, by making the two metals alternative for the purpose for which they are most largely used. This automatic action of the "bimetallic bond" would be comparatively insignificant in the case of a single nation surrounded by monometallic countries, because the neighbouring countries would offer such a wide area for the overflow of the dearer metal, which might thus all drain away before matters could readjust themselves; but it would become theoretically very powerful if four or five of the great nations could unite for the establishment of the double currency. The real objection to such a policy arises from the practical difficulty of forming a strong international monetary union, and the physical fact that silver is much heavier and more inconvenient to carry than the equivalent value in gold. These difficulties are very real in practice, but it is useless to suppose that the bimetallic position is turned by an appeal to the action of the Chinese Emperor Wang-Mang, who is said to have proclaimed a legal ratio of value between (*sic*) five shells—in which attempt he very naturally failed.

It is time also that economic writers gave up the vague references to supply and demand as the cause of all things; as though supply and demand were ultimate facts incapable of being further analyzed and explained. "These *laws*," says Sir Lyon Playfair, "are all-powerful, and no statute *law* of one nation or of ten combined nations can prevail against them." (The italics are ours.) Now what is this but a revival of the old confusion between the two meanings of the word "law," which once led a writer in a leading Review to question the use of economic laws unless enforced by the police? In other essays Sir Lyon Playfair declares (with truth) that Protection raises prices and lowers wages. Is not this a case of a statute law "prevailing against," or (as we should put it) modifying, the conditions of supply and demand?

In the same lecture on bimetallism Sir Lyon Playfair told the National Liberal Club that "gold might be stationary in quantity *and value*, while the prices of commodities might fall from causes having no relation to it, and then its appreciation or power of increased purchase would be a contemporaneous fact but not a cause of the depreciation." How can "value" be stationary while "purchasing power" rises? The meaning of the passage is not obscure; but the looseness of phraseology is deplorable in a science in which strictness in the use of terms is so essential. Would Sir Lyon Playfair say that a schoolboy had not gone up in class because it was the fault of his companions that they had gone down?

A far more thoughtful essay is that on the displacement of labour by modern inventions, in spite of the use of such loose phrases as "labour has suffered much less than capital," and the old confusion between changes in the *rate* of profit on capital and the (totally distinct) *amount* of profit reaped by the capitalist. Sir Lyon Playfair was personally acquainted with the three great discoverers, Oersted, Faraday, and Wheatstone, who have revolutionized commerce by their electrical researches; and he views the changes which are taking place in modern industrial conditions from a large and philosophic point of view, seeing in them the inevitable dislocations and friction resulting from a slow and difficult readjustment of industry consequent on new discoveries. To take one case. The discovery of the mode of making madder from coal tar has reduced the importation of natural madder into this country from 22,000,000 pounds in 1872 to 2,000,000 in 1887. What has become of the former madder-growers? To what industry have they betaken themselves? What class of producers have they in turn displaced by so doing? Sir Lyon Playfair does not attempt to follow out such questions as these, bnt his essay suggests them, and it would be well if they received more attention than has hitherto been usual among economists.

There are several articles dealing with various phases of industrial competition. They all expose the fallacies of fair trade, and all lead up to a demand for technical education. Sir Lyon Playfair has here used to advantage the facts collected in his recent visit to America; but when so many sound arguments lay ready to his hand, where was the necessity of resorting to the essentially unsound reasoning that Protection is conclusively shown to have lowered wages because the wages in *some* unprotected trades (carpenters, bakers, and printers) are higher than wages in *some* protected trades (cotton-spinners, weavers, tailors, and machine-makers)?

The third part of the volume deals with questions of education. Here Sir Lyon Playfair is more at home. Long before technical education became a fashionable cry, he had urged its importance upon the public, and he has lived to see in some measure the fruition of his endeavours, of which the speeches and lectures collected in the volume before us form no unimportant share. The subjects treated range from primary education (on which there is a reprint of a very interesting address delivered at a very interesting time, viz. immediately after the passage of Mr. Forster's Act of 1870) to the relations of the Universities to professional education, on which, as might be expected, Sir Lyon Playfair takes a strong and decided line. "Each profession," he says, "has its own foundation of liberal culture. At present the Universities try to build all professions on one uniform foundation, though this is as foolish as it would be to build a palace, a gaol, or an infirmary on a single ground plan common to all. The professions have indicated by their special literary examinations what their several foundations should be; and if the Universities know how to extend their obligations to modern society, they should have little difficulty in again assuring their original purpose of affording a liberal culture to the professions. The Universities would gain in strength and the professions in dignity and in efficiency." This was spoken in 1873, and the last sixteen years have seen a very marked advance on the part of the old Universities in the direction indicated by Sir Lyon Playfair, though many authorities will still disagree with his general conclusion.

An interesting address is inserted on technical education, which, though delivered in 1870, contains matter for thought at the present day, and reminds us how long the British public have taken before awaking (if indeed they can yet be said to be awake) to the importance of doing something as a nation to raise the standard of instruction in the principles of science and art applicable to industries. We could wish, indeed, that Sir Lyon Playfair, who so powerfully calls attention to the need, had given us a little more in the way of positive suggestion; there are parts, too, of the essay which may be taken to encourage the heresy that the province of the technical school is to replace the custom of apprenticeship and take the place of the workshop. We are strongly in favour of the movement for technical education, and we hailed even the Government measure lately passed, halting and inadequate as it is, as being at least a step forward in the right direction. But if it is to be used to encourage the teaching of a smattering of a large number of trades, instead of giving a thorough training in scientific and artistic principles of more widespread application, it may be that it will do more harm than good; and it is time, now that the measure has become law, for the advocates of technical education to make themselves heard with no uncertain voice upon this all important point. Meanwhile, it is no small praise to say, and we say it with truth, that there is no man living to whom the advance of public opinion on the subject of technical education in recent years is so much due as to the author of "Subjects of Social Welfare."

SERVICE CHEMISTRY.

Service Chemistry. By Vivian B. Lewes, Professor of Chemistry, Royal Naval College, Greenwich. (London: Whittingham and Co., 1889.)

IN this book Prof. Lewes treats of chemistry in its relations to the subjects which are of immediate interest and importance to our naval and military services. Although primarily intended for the officers passing through the Royal Naval College, much of the matter of the book has a direct bearing on the work of the soldier. The necessity for such a book is obvious. Of course, as Mr. Lewes is careful to point out, there is but one chemistry, and its principles and theories are the same, no matter how the science is made subservient to the wants and different callings of men. But it is manifestly absurd to suppose that our soldiers and sailors need to be taken over the whole field of chemical science in order to obtain such a knowledge of those principles as will be of use to them in their professions. No doubt, in the interests of knowledge itself no course of instruction can be too extended, but in the case of the officers of both branches of the service there is the practical difficulty of time. The scheme of instruction at our naval and military colleges is so elaborate, and the amount of time allowed for study is, comparatively speaking, so limited, that it is absolutely necessary that the teachers of chemistry in such colleges shall restrict themselves to the treatment of the relations of chemistry to the practical work of the services. Nor will the teachers have cause to complain of any lack of subject-matter for their lectures. Even if the young officer came to his work with a fuller knowledge of the elementary principles and facts of chemical science than is usually furnished to him at school, so that his teacher at college could at once proceed to treat of its technical bearings so far as these have reference to the work of the soldier and sailor, there would still be ample matter for even the most extended course of instruction that would be practically possible. Of this fact Prof. Lewes's book gives ample evidence. The general character of our public-school education, in spite of recommendations of Royal Commissions and British Association Committees, and repeated warnings of men like Huxley and Spencer that the conditions of modern civilization imperatively require a readjustment of the curriculum of our schools, is still such that the teacher has to assume an entire ignorance of even the most elementary facts of physical science. The students at the Royal Naval College are no doubt largely recruited from the public schools. Any well-devised scheme of school instruction ought, one would think, to give them such a knowledge of the rudiments of chemistry as to obviate the necessity for the teacher to spend a considerable fraction of the limited time at his disposal in discussing such matters as nomenclature and notation, formulæ and equations, the simple laws of chemical combination, effects of temperature and pressure on gases, and so on. But Prof. Lewes no doubt, as indeed his book demonstrates, finds it absolutely necessary to deal with these preliminary matters in the outset of his course. Hence the book naturally divides itself into two portions—one, and of course the most important portion, treating of the technical relations of chemistry to the work of the services; and the other treating of such of the general principles of the science as are necessary to an intelligent appreciation of these relations. The latter portion, of course, precedes the former in the actual plan of the book.

It is, however, characteristic of the eminently practical character of the book that Prof. Lewes loses no opportunity of pointing the moral by some reference to a "service" fact. Thus he has occasion to treat of the chemistry of the galvanic battery, and what he has to say about the electro-chemical behaviour of metals leads up to the question of the fouling of ships' bottoms; the possibility of strong galvanic action set up in iron ships causing the destruction of the screw shafting and rudder-posts, &c.; the effect of mooring a copper-bottomed vessel to an iron pier, &c. No officer intelligently following a course of instruction such as this can be blind to the influence which science is capable of exerting on the work of his profession. The sailor whose respect for a fluid which is so useful in navigation is so profound as to forbid him to drink of it, would doubtless have that respect intensified by the account which Prof. Lewes gives of the physical and chemical characters of water, although, possibly, the section on filters and filtering media may have only an abstract interest for him. This chapter, of course, contains nothing but what is the common property of text-books; but it is put together in such a manner as to show the bearing of the facts on the every-day life and work of the sailor. The chapters on Boiler Incrustation and on Ventilation are also capital illustrations of the way in which the service aspects of the matter are dealt with throughout the book. A short account of carbon, its oxides, and simplest hydrides, naturally leads up to a description of the manufacture of coal-gas, the nature of luminous flames, the causes of fire-damp explosions both in the mine and in the holds of vessels; whilst the chapter on fuel is of especial interest, from the manner in which the results obtained by the Commission on the Navy coal, and the reports as to the value of liquid fuels, are summarized and discussed. The methods of calculating the evaporative value of fuel from percentage composition, and the mode in which such calculations are checked by calorimetric determinations, are also described, and their precise value indicated. The subject of Explosives naturally takes up a considerable space. The mode of manufacture of service powders, cocoa powders, amide powder, &c., is fully described and illustrated, and the nature of the chemical changes on firing gunpowder, as determined by Noble and Abel, Lenck, Karolyi, Bunsen, and Schischkoff, is explained in detail. The chapters have indeed been put together with special care, and contain much that has not yet been incorporated with any other text-book, not only as to details of manufacture, composition, and mode of decomposition, but also as regards proving and keeping. This question of the effects of storing in overheated and badly ventilated magazines is extremely important, especially in regard to powders for large ordnance, and the little that is at present known on the subject is stated in the book.

Only such compounds of the metals and non-metals are dealt with as have immediate relation to service questions. In treating of the action of light upon silver salts the author gives a concise account of the more important methods of photography with special reference to dry-plate work; and the book concludes with a chapter on the chemical nature of the more generally used inorganic pigments, and on the causes of corrosion and fouling of ships' bottoms and marine boilers. This constitutes one of the most valuable sections of the work, and embodies the results of much reading and original investigation.

We congratulate Prof. Lewes on having compiled a most useful and eminently practical work. It of course makes no pretensions to be a complete manual of inorganic chemistry, but it seeks to deal in the most direct manner with those matters which are of special interest to the class of readers for which it is specially intended. It is capitally printed, and for an English text-book, unusually well illustrated; indeed, the entire "get up" of the work reflects great credit on the publishers. The book is, on the whole, well up to date, and every care has apparently been taken to verify statements of numbers and constants. The mode of decomposition of potassium chlorate given on p. 66 should, however, be amended in view of the work of Teed, and of Frankland and Dingwall; and the statement as to the action of peroxide of manganese in facilitating the breaking up of the chlorate requires alteration. It may also be pointed out, in view of the passage on p. 70, that oxygen compounds of fluorine *are* known, *e.g.* the oxyfluoride of phosphorus. Chlorine also *has* been solidified, and the statements as to the boiling and melting points of bromine and iodine given on pp. 315, 317, and 320 are conflicting. The figure on p. 379 is hardly a sufficiently accurate representation of a puddling furnace. However, these are but minor blemishes that can readily be rectified in the second edition which we trust may be speedily called for.

WATTS' DICTIONARY OF CHEMISTRY.

Watts' Dictionary of Chemistry. Revised and entirely rewritten, by M. M. Pattison Muir, Fellow of Caius College, Cambridge, and H. Foster Morley, Professor of Chemistry at Queen's College, London. Vol. II. (London: Longmans, Green, and Co., 1889.)

THE appearance of the second volume of the new edition of "Watts' Dictionary" will be welcomed, not only by chemists of every persuasion, but by all who love and work at science. This volume, reaching from

"Chloral" to "Indigo," not only gives descriptions of all important chemical elements and compounds contained between these two heads, but contains short articles on matters of general chemical interest, both of theory and of practice. The editors desire to give their work a truly international character, and we find valuable contributions, not only from eminent English specialists, but from equally competent authorities in Washington, Baltimore, and Sydney; whilst the presence of articles from the pen of a lady—Miss Ida Freund, of Newnham—indicates that scientific research and exposition are no longer to be confined to the hands and heads of the so-called stronger sex.

In turning over the eight hundred pages of this closely but clearly printed volume, one is first struck by the enormous mass of detail with which the editors have had to deal. Not what to print, but what to leave out, is the problem which all writers whose hard fate it is to have to record the present condition of chemical science have to try to solve. So enormous is the number of chemical substances which each day brings forth, so complicated are the questions of theory which their existence raises—questions which therefore vary from day to day and from month to month—that to give a clear and yet complete account of them may indeed be said to "pass the wit of man." Still, this, like other difficult problems, has to be attempted, and upon the way in which the attempt is made depends the success or failure of a work of this kind. Unless the student can gain a clear and correct idea of the present condition of the science as regards the special subject of the article upon which he seeks information, the book is worse than useless. Unless the specialist can find at least some sort of light and leading, and is supplied with references for detail to the work done by his forerunners, the "Dictionary" will be of but poor service to him. I venture, however, to think that, tried by both these standards, the verdict of the public will be that the editors have acquitted themselves well, and that this second quarter of the new chemical "Dictionary" will rank as high as the first already does, and will bear favourable comparison with the older parent volume—now, alas, with its author, numbered with those whose names have for us only an historic interest.

A dictionary merely confined to an enumeration of the names, composition, properties, and constitution of the many thousands of chemical compounds now known, like the classical work of Beilstein—however valuable, nay essential, to the student in the higher terms of the series—is not what the beginner or the general scientific reader or worker needs. He must have access to a book in which both the general and the special problems of the science are discussed with full knowledge of the position of the day. That this necessity has been understood, and carefully provided for, is seen by the list of articles furnished by special contributors, as well as by glancing at those written by the editors themselves. In that on "Chemical Classification," by Mr. Muir, we find an able statement of the case, with the modest introduction that "in the following article nothing more is attempted than to sketch the outlines of the methods by the employment of which a fairly satisfactory scheme of chemical classification may be attained," followed by the well-known definition of scientific classification given by Jevons in his "Principles of Science." The article on "Crystallization," by Mr. Harry Baker, is a model of perspicuity, and, whilst much shorter than the article on the same subject in the former edition, is sufficiently comprehensive for those who wish to gain a knowledge of the principles of this important branch.

Of all the special articles, perhaps that by Prof. J. J. Thomson, of Cambridge, on "Chemical Equilibrium," and that on "Dissociation," by Prof. Threlfall, of Sydney, are the most interesting and important. Both of these articles seem to give a new tone to ordinary chemical life; they introduce the chemist to fresh fields and pastures new. They point to the fact that the stream dividing chemistry from physics has been bridged over, not only at one point but at many, and that certain chemical phenomena which beforetime have been considered as apart and distinct can now be shown to be capable of mathematical treatment, as belonging to the domain of molecular physics.

Whilst, however, in certain directions chemistry is rapidly becoming a branch of physics, there are other chemical phenomena which ally themselves with those classed as biological, and of the most important of these the "Dictionary" gives us an example in an excellent though too short article on "Fermentation and Putrefaction," by Dr. Rideal. Prof. Ira Remsen, of Baltimore, contributes two articles, one on "Equivalency" and one on "Formulæ." In this latter he reminds us of a fact known to but few that the symbolic notation introduced by Dalton in 1808 had been preceded by an attempt, though a less satisfactory one, in the same direction by Hassengratz and Adel in 1787, though we may be sure that of this attempt the Manchester philosopher was in blissful ignorance.

Other special articles, such as those on "Combustion and Flame," by Prof. Thorpe, on "Dextrin," by Mr. O'Sullivan, on "Cinchona Bark," by Mr. David Howard, amongst many others, have only to be mentioned to show the value and interest of the volume, which (in spite of necessary shortcomings, and of occasional unavoidable errors, which some may care to seek for, though I do not) appears to me to be well worthy of the name it bears, of the house which publishes it, and of the science which it expounds, and this is saying a great deal.

H. E. ROSCOE.

OUR BOOK SHELF.

Index of Spectra. By (W. Marshall Watts, D.Sc., &c. Revised Edition. Manchester: Abel Heywood and Son, 1889.)

DR. WATTS is to be congratulated upon the completion of his great undertaking—namely, to collect all the existing measurements of laboratory spectra, and arrange them in a manner convenient for reference. Since the last edition of the book was published, seventeen years ago, spectroscopic research has made enormous progress, as a comparison with the new edition will show. This is no doubt partly due to the increased number of workers, and instrumental advances, and to a large extent to the extension of the spectroscopic field into the ultra-violet and infra-red. In the old tables the limits of the spectra were practically 394 and 670, whereas in the new ones the lines range from 204 to 770. Spectroscopy has also advanced in another direction. It was formerly believed that each substance had its own characteristic spectrum, from which there was no departure; but subsequent researches have shown that the spectrum does not entirely depend upon the substance under examination, but also upon the conditions of temperature and pressure. In the old tables, for example, only one spectrum of oxygen was recorded, but now no less than three are given. Hydrogen, again, has now two spectra recorded, and nitrogen three, including Hasselberg's important observations.

The wave-lengths given in Ångström's "Spectre Normal du Soleil," with a few small corrections, are still taken as the standards for reduction. The tables printed in the Reports of the British Association Committee form the basis of the new edition, but there are also many important additions. One new feature is the addition of a column giving oscillation frequencies, in number of waves per centimetre *in vacuo*, which will no doubt be appreciated most by investigators of the molecular origin of spectra. Tables of the spectra of various compounds, such as ammonia, alumina, and other oxides, chlorides, iodides, &c., and water, are also given. The different substances are arranged alphabetically as in the old edition, and at the head of each there are full references to books and memoirs. The introductory matter has also been considerably expanded, and now forms an excellent guide to spectroscopic scales and methods of mapping. The use of a lens to throw an image of the light source on to the slit, a method which has yielded many valuable results, is, however, unfortunately omitted. The book will be heartily welcomed by all who are engaged in spectroscopic work, and no recommendation of ours is necessary.

A Text-book on Steam and Steam-Engines. By Prof. Andrew Jamieson, M.Inst.C.E. (London: Chas. Griffin and Co., 1889.)

WE welcome with pleasure the fifth edition of this work. Few engineering text-books are intelligible to the average student. Many writers, in dealing with even the simplest engine or mechanical contrivance, completely fog the reader's understanding by the undue use of mathematics and abstruse formulæ. The volume before us is the best yet published for use in the engineering classes at our schools and colleges. Prof. Jamieson has treated the subject in a sensible and useful manner; his examples are worked out as simply as possible; and the descriptions throughout the work are those of a practical man who knows his business.

The new edition contains many extensive and important additions both to the text and illustrations. The chapter on locomotives has been considerably enlarged and improved. An express-engine built by Messrs. Dubs and Co., the eminent Glasgow locomotive builders, is taken as an example, and many well-executed scale-drawings are given as illustrations. Even with these additions the chapter does not do justice to this important branch of engineering, and Prof. Jamieson must not overlook the fact that he has many locomotive engineer apprentices attending his Glasgow classes. The few paragraphs on the compound locomotive are decidedly weak. Mr. Webb's compound locomotive "The Experiment" is excellent ancient history, no doubt; but why not describe the more recent Webb compounds, or, better still, the Worsdell and Von Borries two-cylinder compounds, now doing such good work on the North-Eastern and many foreign railways?

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

An Unusual Geological Sequence.

IN a late expedition to the north-west coast I have come upon evidence of a fact which was quite new to me—namely, that the well-known Cambrian red sandstones of Ross and Sutherland do not always rest upon the Archæan gneiss, but occasionally on dark blue stratified rocks with which the sandstones are perfectly conformable. For many years I have been familiar with the ordinary sequence, according to which the Cambrian or "Torridon" sandstones rest unconformably on the Archæan gneiss with nothing interposed between them. Nowhere in Sutherland, or in Loch Torridon, so far as I have observed, is there any variation in this order, and I have stood on some hills in Sutherland where the Cambrian sandstones are represented by only a few remaining cakes of conglomerate which lie bedded almost horizontally upon highly unconformable gneissic strata. I was therefore mnch surprised to see in a little creek on the eastern shore of the Island of Rāāsay, a low precipice of the red sandstone terminating in conformable beds of a rock of very dark colour, and with a texture but little crystalline. The sudden and violent change of colour at once attracted my attention, and on landing and obtaining specimens I found there could be no mistake that the Cambrian sandstones here rest upon some older rock totally different in mineral character from the Archæan gneiss, and equally different from themselves.

Pursuing this (to me) discovery, I examined the eastern face of the same island, where its precipices include fine escarpments both of the Secondary and of the older rocks. There, at one point, I found the same unusual sequence beautifully distinct. The sandstones are represented by a bed of strong conglomerate, and this bed rests conformably upon well stratified rocks of a blue, or dark blackish-blue colour, with a fracture far less crystalline than most of our Silurian slates on the mainland of Argyllshire.

Following up the same clue, I found that on the western shores of the Island of Scalpa, these blue rocks underlie in great thickness the red sandstones which form the bulk of the island, and which are exclusively seen by all who approach it from the eastern and northern sides.

I now understand that this fact has been for some time known to Dr. Geikie, and that the officers of the Survey under him have come across it with equal surprise, in certain parts of Ross-shire. But, so far as I know, it has not been published, and is not generally known.

In one specimen which I obtained on Scalpa there are obscure indications of Annelid borings, together with calcareous cavities, which are very suggestive of an organic origin.

If these rocks really belong to the Cambrian series, as this complete conformability would imply, and if they have been wholly removed in all but a few spots, before the Torridon sandstones were laid down, the fact gives one a good deal to think of both as regards the intervals of time which they represent, and as regards the agencies of change which must have been at work.

To what horizon do these blue rocks belong? The Sutherland fossils from Durness are thought to be among the very oldest Silurian forms. Below these come the great white quartzites of the same county. Below them, again, unconformably, come the Torridon sandstones, and lowest of all come these subsequent blue beds—not at all metamorphosed—less crystalline than many of the secondary rocks. Yet they must be amongst the very oldest sedimentary rocks known to us.

I may add that I found by actual experiment that in a deposit now forming here, of the same blue colour, Annelid burrows develop precisely the same ferruginous stains which I find in the Scalpa specimen before referred to. ARGYLL.

Inveraray, Argyllshire.

Mr. Galton on Natural Inheritance.

MR. GALTON'S recent ingenious book on natural inheritance suggests some remarks on the value of his method and results. In the first place, it is plain that the method of probable error, which he uses, is only applicable with any certainty to cases where a multiplicity of unknown or unanalyzed causes ("accidents," pp. 19, 55) determines some mathematically measurable quality. Eye colour, artistic faculty, and temper, to which Mr. Galton applies his method, are not mathematically measurable qualities, and his results, self-consistent though they are, are scientifically untrustworthy because of variation in the standard of popular judgment in such matters. Stature, however, comes properly within the range of his method, and Mr. Galton has made the most of this point.

The method employed by Mr. Galton may be styled a mathematical interpretation of the law of uniformity of nature as apparent in the tendency of progression and regression to an average for all new examples of measurable qualities. (By the way, it is curious that Mr. Galton does not employ the term progression, instead of making regression cover all movements both upward and downward to an average. Rise to an average is certainly progress.) The comparatively easy method of average in dealing with such problems as heredity in the lump is hardly, what Mr. Galton claims it to be, the pioneer method in the "science of man" (p. 62). Indeed, the method of chance is infertile in both biology and sociology so far as it mistakes statements of average tendency as in any wise comparable in value to the particular predictions given by inductive inquiry. The continued use of such terms as accident and chance to cover a multitude of undetermined particular causes may be directly hurtful so far as this tends to slur over the patient investigation of special cases. The greatest so-called accidental variations, or "sports," have, of course, their reason in a peculiar conjuncture of influences, and the exact determination of these, specially with reference to stable stocks, would be of the greatest scientific and practical value. The method of chance can never be an aid to progress, for it always fails in particular predictions, and reduces our outlook to the level plain of averages.

In a book on natural inheritance we should expect some thorough treatment of the relation of heredity to other factors, and a clear exposition of how it can be isolated from them in its effect, especially upon stature. But the statistics employed are avowedly statistics of stature and not of heredity: how, then, are the results made to stand not merely for stature but also for heredity? Mr. Galton concludes that his results for stature are really laws of heredity because of the peculiar relations of the ratios obtained (p. 132), and also because the results are confirmed by general deductions from the laws of chance (p. 102). But as to this first point we must regard it as assumed rather than proved that kinship is to be measured by the comparison of ratios of deviations amongst kin. If we knew from other investigations or *a priori* that the influence of heredity on regression is in the numerical order given, then Mr. Galton's results would be merely confirmatory evidence. The laws of heredity must be based on the facts of heredity, or it must be clearly shown by the method of elimination that given results can only be ascribed to heredity. Does Mr. Galton accomplish this? He slurs over other influences than heredity (*e.g.* education, p. 156), or he hastily concludes them to be in harmony with heredity (*e.g.* natural selection, p. 119). He also does not satisfy us on the equal influences of parents in heredity (p. 98), which is a fundamental assumption for his process. That the average regression of the son to the general average of stature is by one-third parental deviation (p. 104) does not, on the face of it, prove anything with regard to transmission of stature. I cannot see that Mr. Galton has clearly shown this ratio to be more than a law of stature as determined by all influences and not by heredity alone. To make the ratios obtained a "measure of family likeness" (p. 132) is certainly unproved till it is shown that heredity alone enters into the data upon which the ratios are founded. It is plain that in any case, whether the cause be heredity alone or heredity plus many other influences, certain definite ratios will be obtained for father, son, brother, &c.

As to the way in which an abstract calculation of the laws of chance confirms Mr. Galton's statistics, it is enough to observe that no evidence is adduced why the results attained should not stand for the multiple "accidents" of environment, nourishment, occupation, heredity, &c., rather than to "accidents" of heredity alone. Mr. Galton fails to prove that his ratios are not the mathematical expression for the operation of the law of frequency of error as applied to the chance operation of heredity plus other agencies, rather than the formula for heredity simple and unadulterated.

But stature is undoubtedly modified by many prenatal conditions which do not come under the head of heredity, and it is certainly modified by climate, nourishment, and occupation. It is quite likely that human dwarfs might be raised upon the same principles as the Japanese dwarf trees. Mr. Galton makes no deduction from his statistics for other influences than heredity, and his results stand as the expression of the law of frequency of error applied to qualities which are the effect of many complex causes beside heredity. HIRAM M. STANLEY.

Lake Forest University, October 5.

Head Measures at Cambridge.

I AM pleased to be able to say, with reference to criticisms by your correspondents on the trustworthiness of the head measures at Cambridge, and on the deductions made by myself from the results obtained by Dr. Venn after he had discussed the first batch of them, that he is now about to discuss a second batch. The observations that have since accumulated are about equal in number to those already dealt with, and the new results will afford an efficient check upon the value of those already published. I hope also that Dr. Venn may find adequate material to determine the "probable error" of a single head measure, by means of the differences (discussed under obvious restrictions) between the recorded measures of the same persons at different times. We shall then be better able than we are now to estimate the degree of reliance to be placed on the mean value of any given number of head measures. FRANCIS GALTON.

Trimorphism in *Scabiosa succisa*.

THIS species is usually described as gynodiœcious. Hooker ("Student's Flora") thus refers to it. Darwin ("Forms of Flowers") says, "I have observed the existence of two forms in our endemic *S. succisa*"; further, "From what Lecoq says ('Géographie Botanique') *S. succisa* appears to occur under two forms in France"; and again, "According to Lecoq, the female flower-heads of *S. succisa* are smaller than those of what he calls the male plants, but which are probably hermaphrodites." Hermann Müller ("Fertilization of Flowers") also speaks of *S. succisa* as existing under two forms in Germany.

I have recently discovered that the species really exists, in this country at least, under three very distinct forms, viz. (1) the original hermaphrodite; (2) the small female form described by Lecoq; and (3) a second female form, larger even than the hermaphrodite, and differing from the first in a very remarkable manner. I will describe the three forms in detail.

No. 1 (hermaphrodite). Average measurements of 100 capitula: diameter at the base $\frac{13}{16}$ inch, height $\frac{17}{32}$ inch. Average number of florets per capitulum 86 (highest 111, lowest 53). Corolla lavender. Filaments incurved in bud, afterwards erect, and twice as long as the corolla-tube. Anthers pink. Style about $\frac{7}{16}$ inch long, thin, remarkably erect, purple, glabrous. Plane of stigma at right angles to the style. Development of style does not take place till anthers have fallen, when stigma becomes viscid.

No. 2 (straight-styled female). Average measurements of 50 capitula: diameter $\frac{5}{8}$ inch, height $\frac{3}{8}$ inch. Average number of florets 61 (highest 79, lowest 52). Florets very small. Corolla with a deep lilac tinge. Stamens abortive, filaments very short, within the tube. Rudimentary anthers yellow. Style about $\frac{3}{8}$ inch long, otherwise precisely as in No. 1, but development begins as soon as the floret opens.

No. 3 (bent-style female). Average measurements of 150 capitula: diameter $\frac{7}{8}$ inch, height $\frac{9}{16}$ inch. Average number of florets 58 (highest 79, lowest 22). Florets very large, and more loosely packed on the receptacle. Corolla blue, with a lavender tinge. Stamens as in No. 2. Style about $\frac{9}{16}$ inch long, very stout, much swollen at the base (? honey-gland), usually white, stigma green. Plane of the stigma much inclined. Styles much bent and twisted. The whole surface of the corolla clothed with long stellate hairs. These are thickest on the face of the limb, which in the other forms is quite glabrous. The style is also thickly covered with similar hairs, which are much crowded immediately below the stigma. To these hairs an immense number of pollen-grains may be found adhering. The hairs are not fully developed until the stigma is mature.

Forms in some respects intermediate between Nos. 1 and 2, and between Nos. 1 and 3, are occasionally found, and this might be expected, as Nos. 2 and 3 are obviously descended from the hermaphrodite No. 1. I have never, however, found a single individual in any sense intermediate between Nos. 2 and 3, which appear to be two distinct female forms developed from No. 1 along different lines.

These two forms, it will be observed, differ remarkably from each other in the following points, viz. size of capitulum, size of florets and arrangement on the receptacle, colour of corolla, stoutness, colour and general form of style, and in the absence or presence of stellate hairs.

The stellate hairs are utilized to catch stray pollen-grains detached from the bodies of insect-visitors coming from neighbouring hermaphrodites, most of which would otherwise be wasted. As it is, they are retained by the hairs until the arrival of other insects, which in depressing the already bent and twisted styles bring their viscid stigmas into contact with the pollen-grains collected by the hairs of adjacent florets—a result facilitated by the manner in which the stigma is set on the style. By this arrangement the chances of fertilization are much increased, as each stigma generally receives a full share of pollen.

With regard to the relative size of the three forms it is remarkable that while one of the female forms is so much smaller than the hermaphrodite (as is the case, according to Darwin, in all gynodiœcious species known to him), the other even exceeds it in size. It is also noteworthy that the capitulum of the second female form, although larger than that of the hermaphrodite, contains a much smaller number of florets, and these are very large.

I can discover no rule as to the distribution of the different forms. In one station near here (a large common) all the plants are hermaphrodites. In a certain wood where the species abounds, the "bent-styled" females appear to be nearly as common as the hermaphrodites, while no "straight-styled" females can be found. In another wood, not half a mile distant from the first, the "bent-styled" form is almost entirely supplanted by the "straight-styled," which is plentiful. Lastly, in a fourth station (a barren strip of ground by the roadside), all three forms are found growing together. ARTHUR TURNER.

Box Hill, September.

On the Aquatic Habits of Certain Land Tortoises.

IT has always proved of more or less interest to me to observe the method of aquatic locomotion adopted on the part of any of our strictly terrestrial vertebrates, and never is this more keen than when the opportunity has been afforded to study the swimming propensities of certain of our Reptilia. Most snakes swim well, but who of us has not been surprised upon first observing the violent wriggling, froward-propelling motions of some of the smaller lizards when they are thrown out into the water some little distance from the shore? The American chameleon (*Anolis principalis*) well illustrates this last; and this lizard, in common with others, seems to possess an actual dread of getting into deep water. For a long time it has been known that most species of the so-considered stricter types of land tortoises soon drown when placed in water of any considerable depth, and it would be but natural to suppose that such species would avoid that element as far as possible, but I have found this by no means always to be the case. Take the ordinary land turtle of the United States (*Cistudo carolina*) for example: it will voluntarily enter the water under certain circumstances. Not long ago the writer noticed one of these hunting for food in three or four inches of water along the edge of a pond that had rising banks; and the first time I discovered the nest of this variety the eggs were deposited in the water in a depression at the miry margin of a marsh. But this is not all, for if we place one of these reptiles upon a little island of land, well removed from the shore, and surrounded by water several feet in depth, and withdraw to watch its movements, we note that as soon as it satisfies itself as to its position, it will, without further ado, take at once to the water and swim to the nearest shore. It does not, however, sink beneath the surface, but, holding its head high out of that element, and filling its lungs with air, strikes out vigorously, with alternate pairs of feet, until it accomplishes its purpose, and regains the mainland. How far one could swim in this manner I am unable to state, but that it would not exceed a few yards I am quite certain. Nevertheless, even the power to accomplish the feat to the extent indicated might, under a variety of circumstances, have its influence upon the distribution of the species, or of any species of typical land tortoise, and it would be interesting to know how far this power may be enjoyed by this class of reptiles generally.

Delambre's Analogies.

FOUR of the most important formulæ in spherical trigonometry were given by Gauss, without proof, in his "Theoria Motus Corporum Cœlestium" (1809), and were therefore called Gauss's theorems or analogies.

They were, however, given by Mollweide in Zach's *Monatliche Correspondenz* for November 1808, and before that by Delambre in the *Connaissance des Temps*, issued in April 1807, so that they are now justly ascribed to the latter.

They may be deduced in the most simple manner from Napier's analogies, and thus easily remembered.

Napier's analogies are—

$$\tan \tfrac{1}{2}(A + B) = \frac{\cos \frac{1}{2}(a - b)}{\cos \frac{1}{2}(a + b)} \cdot \cot \tfrac{1}{2}C \qquad (\alpha)$$

$$\tan \tfrac{1}{2}(A - B) = \frac{\sin \frac{1}{2}(a - b)}{\sin \frac{1}{2}(a + b)} \cdot \cot \tfrac{1}{2}C \qquad (\beta)$$

$$\tan \tfrac{1}{2}(a + b) = \frac{\cos \frac{1}{2}(A - B)}{\cos \frac{1}{2}(A + B)} \cdot \tan \tfrac{1}{2}c \qquad (\gamma)$$

$$\tan \tfrac{1}{2}(a - b) = \frac{\sin \frac{1}{2}(A - B)}{\sin \frac{1}{2}(A + B)} \cdot \tan \tfrac{1}{2}c \qquad (\delta)$$

$$\text{Let } m \cdot \sin \tfrac{1}{2}(A + B) = \cos \tfrac{1}{2}(a - b) \cos \tfrac{1}{2}C \,. \qquad (1)$$

$$\therefore\ m \cdot \cos \tfrac{1}{2}(A + B) = \cos \tfrac{1}{2}(a + b) \sin \tfrac{1}{2}C \,. \qquad (2)$$

These are numerator and denominator of (α).

$$\text{Let } n \cdot \sin \tfrac{1}{2}(A - B) = \sin \tfrac{1}{2}(a - b) \cos \tfrac{1}{2}C \,. \qquad (3)$$

$$\therefore\ n \cdot \cos \tfrac{1}{2}(A - B) = \sin \tfrac{1}{2}(a + b) \sin \tfrac{1}{2}C \,. \qquad (4)$$

Numerator and denominator of (β).

Square, and add—

$$\therefore\ m^2 + n^2 = 1.$$

Divide (4) by (2), and it follows by (γ) that—

$$\frac{n}{m} = \tan \tfrac{1}{2}c;$$

$$\therefore\ m = \cos \tfrac{1}{2}c,\ n = \sin \tfrac{1}{2}c.$$

Substitute these values, and (1), (2), (3), (4), are Delambre's analogies. R. CHARTRES.

Classified Cataloguing.

THE principle suggested by Mr. Petrie, on "Classified Cataloguing" (NATURE, August 22, p. 392), is already successfully used in many of the chief libraries of the United States, having been originated by Mr. Melville Dewey, while Librarian at Amherst College. It is equally applicable to collections of all kinds, and the classification has already been extended to a considerable extent in certain departments, particularly in botany, and is capable of unlimited extension. It possesses all the advantages mentioned by Mr. Petrie, but is broader, inasmuch as it includes all subjects.

In the "Decimal Classification" of Mr. Dewey (Boston, 1885, second edition), we find, for illustration, under 500, General Science; 580, Botany; 583, Dicotyledonæ; 583·9, Apetalæ; 583·95, Unisexuales, 583·951, Euphorbiaceæ; 590, Zoology; 598, Reptiles; 598·13, Chelonia, &c.

If an extension of this system, which would, I have the means of knowing, be most acceptable to Mr. Dewey, were to be adopted for general museum use, the advantages would be incalculable. JAS. LEWIS HOWE.

Polytechnic Society, Louisville, Kentucky.

Valuable Specimens of Vertebrates for Biological Laboratories.

WHAT specimens of Vertebrates are the best to be used by the student in the biological laboratory? This is certainly a very important question. In Europe, the following animals are generally dissected: some fish, the common frog, the pigeon, the rabbit, or the guinea-pig. The frog is a very aberrant member of the Batrachia, and it would be very instructive for the student to examine a more typical representative of the class. Such a one is the American Proteus (*Necturus maculatus*, Ref.), used at Cornell University, Ithaca, N.Y. During the last few years I have received many specimens of Vertebrates from two fishermen—Mr. Russell Dee and Mr. F. C. Audibert, from Marietta, Ohio. Lately, Mr. Audibert has written to me that he could procure any quantity of material, if wanted, and he would charge only 25 cents. (a little over one shilling) for each specimen. From the list of specimens sent to me by Mr. Audibert I select the following, which appear the most important for laboratory use :—

Accipenser maculosus, Les.
Polyodon folium, Lat.
Lepidosteus osseus, L.
Necturus maculosus, Ref.
Menopoma alleghaniensis, Daud.
Trionyx muticus, Les.

The instructive value of these specimens is certainly very great, and the low price could enable any biological laboratory to secure this material. G. BAUR.

New Haven, Conn., September 30.

"Darwinism."

IT has now become to me a matter of amusement to note how those naturalists who of late years have drifted most widely from the doctrines of evolution as these were held by Darwin, habitually accuse me of Darwinian heresy because I have not seen any adequate reason to depart from those doctrines in their entirety. Perceiving that there has been some change of relative position, while failing to perceive that the movement has been altogether on their own side, these naturalists represent that I have been falling away from Darwinism, when the fact is that they have been advancing beyond anything that was ever countenanced by the judgment of Darwin—and even expressly accepting the view which he so vehemently rejected, viz. that of regarding natural selection as the sole cause of organic evolution. Thus, for example, when in NATURE of October 10 (p. 569) Prof. Ray Lankester gravely designates my paper on physiological selection a "laborious attack upon Darwin's theory of the origin of species," it becomes evident how fast and far he has travelled from his Darwinism of two or three years ago. For, to put it briefly, unless it can be shown that Darwin considered natural selection the only possible cause of organic evolution, and did not consider sterility between allied species as probably due to some other principle of change, it is obvious that there *can* be nothing in my "additional suggestion on the origin of species" which may in any sense be designated an attack upon the distinctively Darwinian theory. Yet it is with regard to these very points that the opinion of Darwin was steadily opposed to that of Wallace; *i.e.* to the present opinion of Lankester. Therefore, quite apart from any question touching the truth of this "additional suggestion" or "supplementary hypothesis" (which, however, I may here parenthetically remark, will soon be shown to be in no way seriously affected by Mr. Wallace's sole remaining criticism), it is sufficiently evident that, when the object of publishing the hypothesis was expressly and repeatedly stated to have been that of meeting the main difficulties which had been advanced against the theory of natural selection, the present designation of this hypothesis as an elaborate attack upon that theory is simply absurd.

But my object in now writing is to state, *apropos* of Prof. Lankester's remarks on the inadequacy of Mr. Wallace's criticism of Mr. Gulick's paper, that I have just received a communication from the latter gentleman (who writes from Japan), requesting me to exercise my discretion as to publishing in these columns a reply to that criticism. Unfortunately this reply is too long for insertion, and as I do not see how it can be curtailed without serious detriment, I have refused to incur the responsibility of publishing it in an abbreviated form. At the same time it seems but just to let the readers of NATURE know that a full reply to Mr. Wallace's criticisms (in these columns and elsewhere) has been prepared; since otherwise the silence of its author might be misinterpreted.

To me it appears that Mr. Gulick's work is much the most profound that has ever been published on the important matters of which it treats (viz. isolation in all its forms, with its consequences in "segregate breeding" and "divergent evolution"); and therefore I am glad to take this opportunity of recognizing his priority, by some fifteen years, in thinking out, and largely verifying by his researches on land shells, the theory of physiological selection. GEORGE J. ROMANES.

Geanies, Ross-shire, October 12.

Sunset Glows.

IT is a curious fact that a revival of sunset-glows, similar to those described by Sereno E. Bishop in a letter published in NATURE for August 29 (p. 415), was observed in Western New York at almost precisely the same time that he saw them at Honolulu. I inclose a clipping from the *Rochester* (N.Y.), *Democrat and Chronicle*, which was published on July 21 :—

"The skies at evening show signs of the gradual return of the red light. It will be of interest to ascertain if the phenomenon reappears as the solar disturbances continue to increase in energy to the maximum. It is quite apparent now that the minimum has been passed, and the tendency is toward an increase in the number and in the violence of solar disturbances. There are certainly three and probably four well-defined disturbances at present." M. A. VEEDER.

Lyons, New York, September 13.

"The Teaching of Science."

I BEG that the following alterations may be made in the "Suggestions for a Course of Elementary Instruction in Physical Science," printed in NATURE of October 17.

HENRY E. ARMSTRONG.

P. 602, Problem II., line 11 from above, read "by means of iron" instead of "by means of phosphorus."

P. 603, Problem VII., line 20 from below, instead of "when metals are heated with acids," read "when metals are dissolved in acids."

P. 604, Problem IX., line 31 from above in right-hand column, read "dried hydrogen," instead of "dried oxygen."

P. 605, Problem XII., line 17 from above in right-hand column, read "zinc oxide," instead of "lime oxide."

TELESCOPES FOR STELLAR PHOTOGRAPHY.[1]

II.

IN considering the essentials of a good system of control for equatorial clocks, it is necessary to keep in view the exact conditions required. It is not sufficient that the controlling apparatus (of whatever form it may be) should simply bring the *rate* of the clock, which has been interfered with by some adventitious disturbance, correct once more ; it must do more, it must correct this error. For, suppose a star be set on the slit of a spectroscope, and the clock started, and say, as in Dr. Huggins's case, a photographic plate inserted for a two hours' exposure. Now suppose that five minutes after the commencement of the exposure, an error of one-tenth or two-tenths of a second occurs from some disturbing cause (a fragment of dirt on the tooth of a wheel, or other cause) ; if the controlling apparatus be of such a nature as simply to bring the clock-rate correct again, the position of the telescope will be the above quantity, one-tenth or two-tenths of a second, in error for the remainder of the exposure, although the rate may be absolutely correct for the whole times. In other words, the star will have moved off the slit, by a quantity equivalent to what the instrument would move in one-tenth or two-tenths of a second, and will continue off the slit for the remainder of the two hours. So it will be seen that no controlling apparatus is of any use whatever, unless, as well as keeping the rate uniform, it corrects the errors that have crept in. In consequence of not keeping this point in view, many most ingenious but useless arrangements have been from time to time proposed. A little consideration will show that this arrangement meets all requirements.

The above arrangement is somewhat similar to Dr. Gill's.

[1] A Paper read by Sir Howard Grubb, F.R.S., before the Society of Arts, on April 18, 1888. Continued from p. 444.

It is simpler to attach to any existing clock, but not so delicate as his, and is open to the same objections. It is, however, capable of very good work, as may be judged from the chronograph sheet of the Dunsink Observatory chronograph.

The third is the form of control which I devised for Mr. Isaac Roberts, and which has been so successful with him, and with Prof. Pritchard (who has had it recently attached to the Oxford equatorial), that photographs have been exposed with the telescope to which it has been attached for fifteen minutes, and yielded perfect images of stars without any hand and eye guiding.

The arrangement consists, firstly, of a *remontoire* train, driving a good mercurial or other compensated pendulum—the driving of this train being of course entirely independent of the equatorial clock giving motion to the telescope; secondly, of a detector apparatus, which detects any difference between the rate of this standard pendulum and the equatorial clock; and thirdly, of a correcting apparatus, which corrects automatically any error discovered by the detector. This corrector itself consists of two parts—an "accelerator" and a "retarder"—and these we will first proceed to describe.

In S S′ S″ is one of the shafts, between the driving train of the equatorial clock and the worm which drives the right ascension sector, this shaft being cut into three parts, denoted by the letters just named. At one end the portion S of the shaft carries a wheel, 1, immediately adjoining which is the wheel 2, mounted on the portion S′ of the shaft. At the other end of this last-named section of the shaft is fixed a third wheel, 3, which is almost in contact with the wheel 4, fixed on the end of the shaft S″. The shafts S and S′ also have mounted freely on them the brass disks, *d d′*, which adjoin the two pair of wheels referred to above. Each of these brass disks is furnished with a stud on which a small pinion is mounted, the pinion *p*, belonging to the disk *d*, gearing across the pair of wheels, 1–2; while the pinion *p*, belonging to the disk *d′*, gears across the pair of wheels, 3–4.

Under normal conditions, if no error exists in the equatorial clock rate, the arrangement of wheels and pinions just described revolves as one piece, the three sections, S S′ S″, of the shaft rotating at the same speed; but it is possible by an arrangement which we shall explain presently, to stop the rotation of either of the disks, *d d′*, and as soon as this occurs the pinion of the stopped disk has to act as a transmitter of motion from one of the wheels into which it gears to the other. If the two wheels of each pair had the same number of teeth, the speed of both wheels would still remain the same, but in reality the number of teeth in the two wheels of each pair is different, and hence the stopping of one of the disks, *d* or *d′*, causes a variation in the rate of rotation of the two adjoining wheels relatively to each other. For instance, in the case of the first pair of wheels, let wheel 1 have 30 and wheel 2 have 29 teeth, and suppose that the shaft S is rotating once every 60 seconds. Thus, if the disk *d* be stopped, the wheel 2 will be made to revolve in $\frac{29}{30}$ of the time occupied by the wheel 1, or in other words the rate of the section S′ of the shaft will be accelerated to one revolution in 58 seconds. In the same way by reversing the positions of the wheels in the other pair 3–4, the stoppage of the disk *d′* can be made to effect a retardation of the portion S″ of the shaft relatively to S′. The edges of the disks *d* and *d′* are cut into very fine teeth, and the stoppage of the disks when desired is effected by causing a comb attached to the armature of an electro-magnet to engage with these teeth.

The whole apparatus just described constitutes a very convenient arrangement for accelerating or retarding the driving motion imparted to the telescope by the equatorial clock, and that it is capable of very good work is shown by the photographs which have been taken by Prof. Pritchard and Mr. Roberts, in which the star disks are perfectly round, though exposed for 15 to 60 minutes, and no hand guiding used.

I have now to describe how this apparatus is, when necessary, automatically brought into action by the "detector."

In Figs. 5, 6, and 7,[1] W is a scape-wheel mounted on the sixty-second spindle of the controlling clock, and driven from that spindle through a spiral spring, X X, so that no error in the equatorial clock can affect its rate or that of the standard pendulum. On the same spindle there is also mounted behind the scape-wheel an ebonite disk, E E, Fig. 5; this disk, which is driven by the equatorial clock, carrying two insulated rings, *b b′*, which are respectively connected metallically with two platinum plates, B B′, inserted in the face of the disk. Between the scape-wheel and the ebonite disk there is also mounted loose on the spindle a lever, A A, which carries at one of its ends a platinum bridge, B, which is of such a length as to fit between the platinum plates, B B, and which in its mid-position bears against a piece of rock crystal let into the ebonite disk between the two plates just named. At the other end the lever, A A, is formed into a fork, between the arms of which projects a pin carried by the scape-wheel; the arms of the fork are provided with set screws,

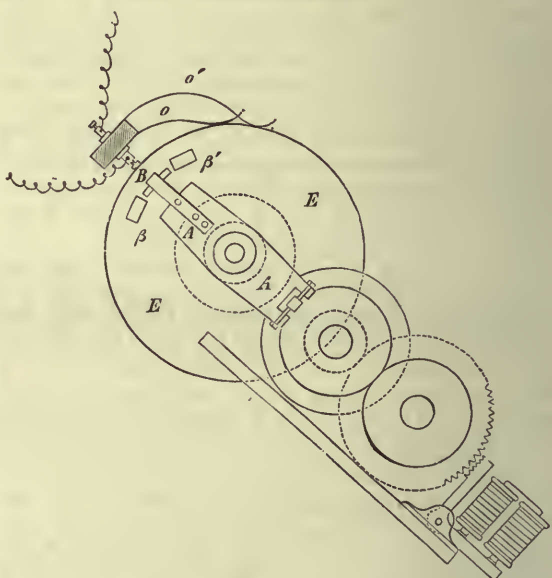

FIG. 5.

by means of which the amount of play allowed to this pin in the fork can be adjusted.

The insulating rings, *b b′*, are electrically connected with the accelerator and retarder already described by means of fine platinum wires, O O′, wiping against them, and the action of the whole arrangement is as follows. The scape-wheel, W, being driven by the control clock, has an intermittent movement corresponding to the beats of the pendulum, while the ebonite disk, E E, being driven by the equatorial clock, has a constant movement, so that even if the scape-wheel and disk make a whole revolution in the same time, the pin carried by the scape-wheel will be constantly oscillating between the pins of the fork at one end of the lever, A, this lever being driven by friction from the ebonite disk. The pins just named are adjusted so as to allow of this oscillation taking place without interference, so long as the rates of the equatorial and control clocks remain uniform, but if the equatorial clock either loses or gains with respect to the standard, the pin on the scape-wheel comes into contact with one of the fork pins of the lever, A, and shifts that lever on the spindle, bringing the bridge, B, into contact with one of the platinum plates,

[1] These blocks have been kindly lent by the editor of *Engineering*.

B or B′, and transmitting a current which brings into action the accelerator or retarder as may be required. The period during which the accelerator or retarder remains in action will depend upon the amount of the error to be corrected, and the proportions of the pairs of wheels, 1, 2, and 3, 4. With the proportions described above, the correction introduced is one-thirtieth of the rate, so that, to correct an error of one-fifth of a second, the accelerator or retarder, as the case may be, would have to remain in operation $\frac{30}{5} = 6$ seconds. As soon as the correction has been made, the lever, A, will resume its normal position, and the bridge, B, coming then between the two platinum plates, B B′, a current will cease to be transmitted, and the accelerator or retarder thrown out of action.

It is to be noted that the apparatus above described not only corrects any temporary disturbance of the equatorial clock rate, but cancels errors which have already occurred.

It will be seen that the third form of control is free from the objections of the first and second. The detector part of the apparatus is close to the screw spindle, only removed from it by one pair of wheels, and the correction is not applied in the same manner by checking the speed of the clock, but by introducing a differential gear, which acts until the error be cured, and then drops out of gear automatically.

The fourth and last form of control, however, is that to which I would invite your special attention, for I believe it to be capable of results beyond all the others.

I have endeavoured in it to select all the good points of the other forms, and to combat the weak points. I may not have as yet produced it in as perfect a form as is possible, but I am satisfied it is capable of development into a very perfect control, and even at present it is the most perfect I have constructed.

As long as the control applied its correction by altering the speed of the governor, it was necessary to keep down the *vis inertia* of the governors, but now, as the correction is not applied in this way, I have made the governor very heavy, and running at a very high speed.

The *vis inertia* of the governor is represented by some 10,000 foot-pounds per minute; consequently it is little affected by any small or short differences in friction or driving powers.

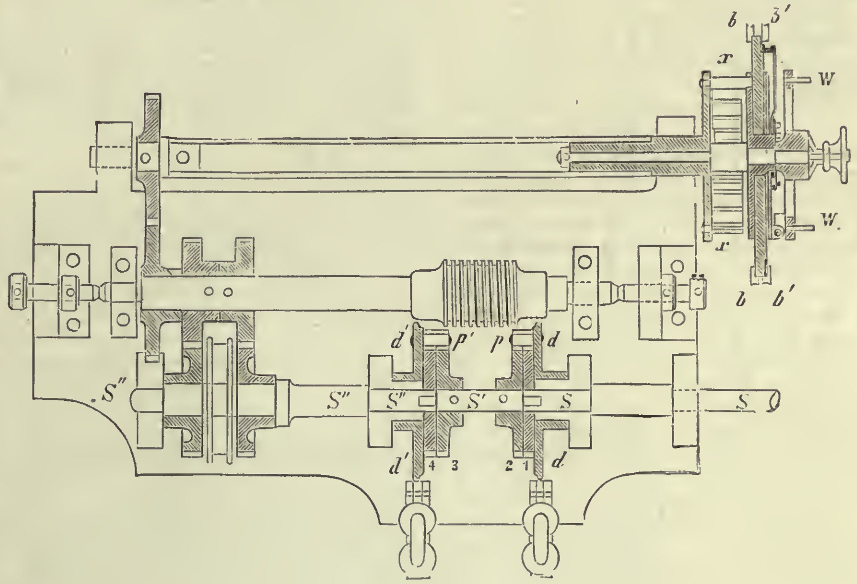

Fig. 6.

Again, at the suggestion of Dr. Gill, I make the governor spindle gear directly into the counter spindle of the screw, in order to have as few wheels and pinions to deal with as possible. Errors of wheels behind the governors have nothing whatever to do with the accuracy of its rate.

As to the nature of the control, I use Dr. Gill's form of detector and my own form of corrector, viz. accelerator and retarder. I use Dr. Gill's detector because it seems to be capable of being made on a larger scale than mine, and consequently ought to be more delicate.

I now propose to say a very few words on the optical part of the instrument.

The first question that naturally occurs is whether a refractor or reflector should be used. I own that when I first considered the subject I inclined to the belief that reflectors would be found to be the most suitable; and in a paper of mine, which was read before the Royal Astronomical Society last spring, I urged that comparative trials should be made before a final decision was arrived at. I have found reason, however, to modify my views on this point.

My reason for thinking that the reflector might possibly prove the best was founded on the consideration that in reflecting instruments rays of all refrangibilities are brought to a focus at one and the same point, whereas in the refractor rays of various refrangibility have different foci, and the best we can do is to so arrange the curves that those rays most active in impressing the photographic plate may be brought as nearly as possible to the one focus.

If we draw a curve which represents the position of the focal point for various rays of the spectrum in an object-glass corrected for photo work, it will be something like this figure (Fig. 8). The same for a reflector will be represented by a straight line. Looking at these curves it is certainly a natural conclusion that the reflector ought to be best, and therefore it was that I urged that a fair comparative trial should be made between the reflector and refractor as to their suitability for this work.

The Congress, however, decided upon the use of refractors, from the simple fact (as Dr. Gill says) that the best work done (to that time) had been done by refractors, not taking into consideration the very much more favourable conditions under which the refractor photographs were taken. Since that time further experiments have been made with both forms of instruments, which tend to show that, as against the refractor of the ordinary construction, the reflector can well hold its own, but that while it is obviously impossible for the optician to improve the field of the reflector, it is by no means impossible to do so with the refractor, and time and patient experimenting have shown that, by a modification of the curves of an objective, equally good definition of the central pencil can be obtained, combined with a very much better and flatter field, so that, however well reflectors could compete with the ordinary form of refractor, they cannot do so with forms constructed with special reference to field.

It should be borne in mind that the question of field is one which the optician was never before asked to consider

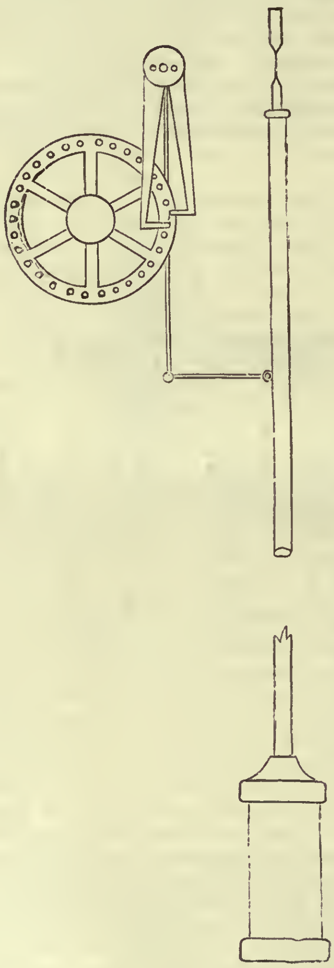

Fig. 7.

in telescope objectives. The field of such a sized telescope used for visual work would not be more than $\frac{1}{2}°$, even with the lowest power. It has been found possible to obtain good definition over a field of 2° with either reflector or the ordinary form of refractor, and with the modified form considerably more. This question of field is, as I said, a very important one, for on it depends the amount of time required to complete the survey. If one instrument gives equally good definitions over 3° square, *i.e.* nine square degrees, as another does over 2° square, *i.e.* four square degrees, it is evident that the first instrument, equally energetically worked, is capable of completing the survey in less than half the number of years it is possible to do with the second instrument.

There is one point connected with this question of field which is of great importance.

Various forms of objectives give various characters of images of star disks at the edge of the field. Some give a bright nucleus with a tail like a comet, some assume a form approaching to a cross, and some give elliptical disks.

Of course perfection would mean absolutely circular disks all over the plate, but when this cannot be obtained, the last or elliptical disks are very much preferable to either of the others. It is quite possible to fairly estimate the most central point in an ellipse if the illumination over it be tolerably equal, but in the case of the comet or irregular form this is not possible.

The newer forms of objectives are peculiar in that the distortion of the lateral star images are of their least objectionable character.

It has been suggested that good results might be obtained by using the new "Jena" glass with rational spectra, but I have made inquiries respecting this, and it is not considered by the makers themselves that this glass in its present state would be suitable for the purpose of these photographic objectives. Until the permanency of that glass be thoroughly tested by exposure to various climates for some years, it does not appear safe to use it for such important work as this. There can be little doubt, however, that for ordinary visual work this glass, if capable of being made into large disks, will allow of the production of objectives superior to anything hitherto made.

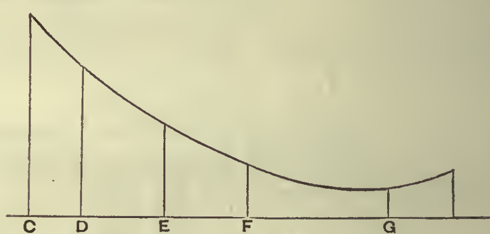

Fig. 8.

I ought perhaps to mention that it is possible to make an objective which can be adjusted to work either as a photographic or visual objective.

By separating the lenses of an ordinary objective, the chromatic correction can be so much reduced as to render it suitable for photographic work, but unfortunately the spherical aberration is reduced at the same time and definition destroyed.

Prof. Stokes, however, suggested to me that by constructing an objective in such a manner that the crown lens would be unequally convex by a certain amount, and that the spherical aberration would be correct when the flatter side was outermost, that then the chromatic aberration could be reduced as before by separating the lenses, and the reduced correction for spherical aberration raised by turning the crown lens with its more convex side outerwards.

This I tried, and found act perfectly.

I described this last spring at the Royal Astronomical Society, but it has since been re-invented in America.

It remains for me now only to describe how these new photographic objectives are tested.

The testing of objectives for visual work is a matter almost altogether of eye experience.

In these photographic objectives a different course must be adopted, as the image appears to be badly corrected to the eye when it is rightly corrected for photographic rays.

The Paris Congress decided that the rays G of the spectrum should have in their objectives a minimum focus; how is the correction to be verified? It is usual in the testing of the chromatic aberration of objectives, by those whose eye experiences cannot be a sufficiently accurate guide, to allow the image of a star, as found by the objective, to fall on the slit of a spectroscope, and to judge of the focus of each particular ray by the breadth of the spectrum at that ray. Wherever the light is brought to a focus the spectrum is of insensible breadth. When it is out of focus, a more or less sensible breadth, by moving the spectroscope in and out of the position of maximum and minimum foci, can be obtained.

I tried this plan, but found it very unsatisfactory, as it was very difficult to determine the exact place where the spectrum was narrowest, the curves being so very shallow.

After much thought I arrived at the following very simple and efficient plan, which I described in full, as it may be useful to some for other purposes. It should be remembered that the object is to get the focus of the objective for various parts of the spectrum.

If, therefore, we could obtain various objects when light was derived for such portions, and such portions only, of the spectrum as we required, our object would be accomplished.

I take a spectroscope with a fairly large dispersion equal to about 2 prisms of 60° and with a pencil of light of about 2° diameter. I remove the observing telescope, and substitute one of very long focus, so that the linear dimensions of the spectrum shall be as large as possible. I observe with this the solar spectrum, and note the position of such lines as I intend to work on. I then remove the eye-piece and insert in its place a tube carrying a small convex mirror. The apparatus is left till dark, and a small electric glass lamp attached outside the slit. The observing telescope is then placed at such a reading as I know will bring any certain line into the centre of the field, and on looking at the small mirror through a long slit which is purposely made on the top of the tube to allow it to be viewed from the front, you see a small bright star whose light is due to that particular line in the spectrum, and to no other part. The apparatus is placed at a sufficient distance in front of the photographic telescope, and these stars are the objects examined. In this way I can produce a small bright star of a colour corresponding to any of the lines in the spectrum, and the foci of these, as observed in the photographic telescope, can be measured with great exactitude.

There are, of course, small matters of detail which I have been unable to touch upon in the present communication, many of which are very important for the effective working of these instruments, and which require special treatment. I have, however, confined myself to the principal and more important parts, but I trust that I have been able to show that we have at least made a substantial advance; and it remains for us to hope that when these instruments are placed in the hands of astronomers they may yield a rich harvest of work, and leave their mark on the history of astronomical science.

HOWARD GRUBB.

ON THE PRINCIPLE AND METHODS OF ASSIGNING MARKS FOR BODILY EFFICIENCY.[1]

THE question to be solved is of this kind. Suppose that one man can just distinguish a minute test object at the distance of 25 inches, another at that of 35, and again another at 45 inches, how should we mark them? We should be very rash if we marked them in the proportion of 25, 35, and 45, or even if, for some good reason, we had selected 25 as the lowest limit from which marks should begin to count, we should mark them as 0, 10, and 20.

[1] Read at the British Association, by Francis Galton, F.R.S.; but slightly revised, in order to introduce the diagrams herewith printed. Followed by remarks on experiments made at Eton College, by A. A. Somerville.

Two separate considerations are concerned in the just determination of a scale of marks—namely, absolute performance and relative rank, which are apt to be confused in unknown and varying proportions.

Absolute performance is such as is expressed by the 25, 35, and 45 inches just spoken of. It is perfectly correct in some cases to mark, or let us say to pay, for this, and this alone, upon the principle of piece-work—namely, that the pay ought to be proportionate to the work accomplished, or to the expected output in after life.

Relative rank is, however, on the whole, a more important consideration than the absolute amount of performance by which that rank is obtained. It has an importance of its own, because the conditions of life are those of continual competition, in which the man who is relatively strong will always achieve success, while the relatively weak will fail. The absolute difference between their powers matters little. The strongest even by a trifle will win the prize as completely as if he had been strongest by a large excess. Undertakings where many have failed, are accomplished at last by one who usually is very little superior to his predecessors, but it is to just that small increment of absolute superiority that his success is due. Therefore it is clear that relative rank has at least as strong a claim for recognition as absolute performance, if not a much stronger one. They have each to be taken into separate consideration, and each to be separately marked. The precise meaning intended to be conveyed by the phrase "relative rank" will be better understood further on.

Recurring to the example of keenness of eyesight, let the test object be words printed in diamond type, and the persons tested be Englishmen of the middle classes, between the ages of 23 and 26, then the performance of readtng diamond type at 25 inches happens to be strictly mediocre. Fifty per cent. of the many persons who were tested performed better than this, and 50 per cent. performed worse. The 35-inch performance was exceeded by only 2½ per cent. of the persons tested; and as to the 45-inch performance, it has not in my experience been reached at all. I have had altogether 12,000 persons tested in this way, of both sexes and of various ages, but not one of them has succeeded in reading diamond type at the distance of 45 inches. It is very rare to find one who can do so at 40 inches. Wherever superiority in eyesight is eminently desirable, it would be absurd to make the marks for the three supposed cases to run proportionately either to 25, 35, and 45, or to 0, 10, and 20. The achievement of 45 inches would deserve much higher recognition. Relative rank and absolute performance should not be confused together.

I use the term relative rank in a large sense, with reference to all persons who have been, or are likely to become, candidates, and not to the small number of them who may happen to be present at a particular examination. Statistical tables concerning the class of persons in question have to be compiled from past examinations, and the rank of the individual has to be determined amidst these. I have often described how this is to be done ("Natural Inheritance," p. 38, Macmillan and Co., 1889), but the diagram (Fig. 1) is, I think, the simplest of all forms for the use of an examiner. It tells at a glance the rank held by a man among his fellows in respect to any single and separate faculty. The class from which it is constructed might consist of any large number of persons subject only to the condition that the distance between the limits *within which* it extends shall be always divided into centesimal grades; that is to say, running from 0° to 100°. The grades are printed along both the top and the bottom of the diagram, and refer alike to every line. As a specimen of the way to read it, let us take the line of keenness of eyesight among the males. Here we see that the performance of reading diamond type at the distance of 25 inches is appropriate to grade 50°; or, as already stated, 50 per cent. of all the persons tried did worse, and 50 per cent. did better. Therefore the performance in question is exactly mediocre. Again, 30 inches corresponds to grade 80°; in other words, 80 per cent. did worse and the remaining 20 per cent. did better. The method on which this diagram is constructed is of universal application. Calling the particular class of persons to which it refers, for brevity, by the letters I.H.E. (International Health Exhibition), then the rank of any individual among the I.H.E. males, aged 23-26, in respect to any of the qualities therein named, can be most easily ascertained; also among the I.H.E. females of the same ages.

This method admits of being extended in more than

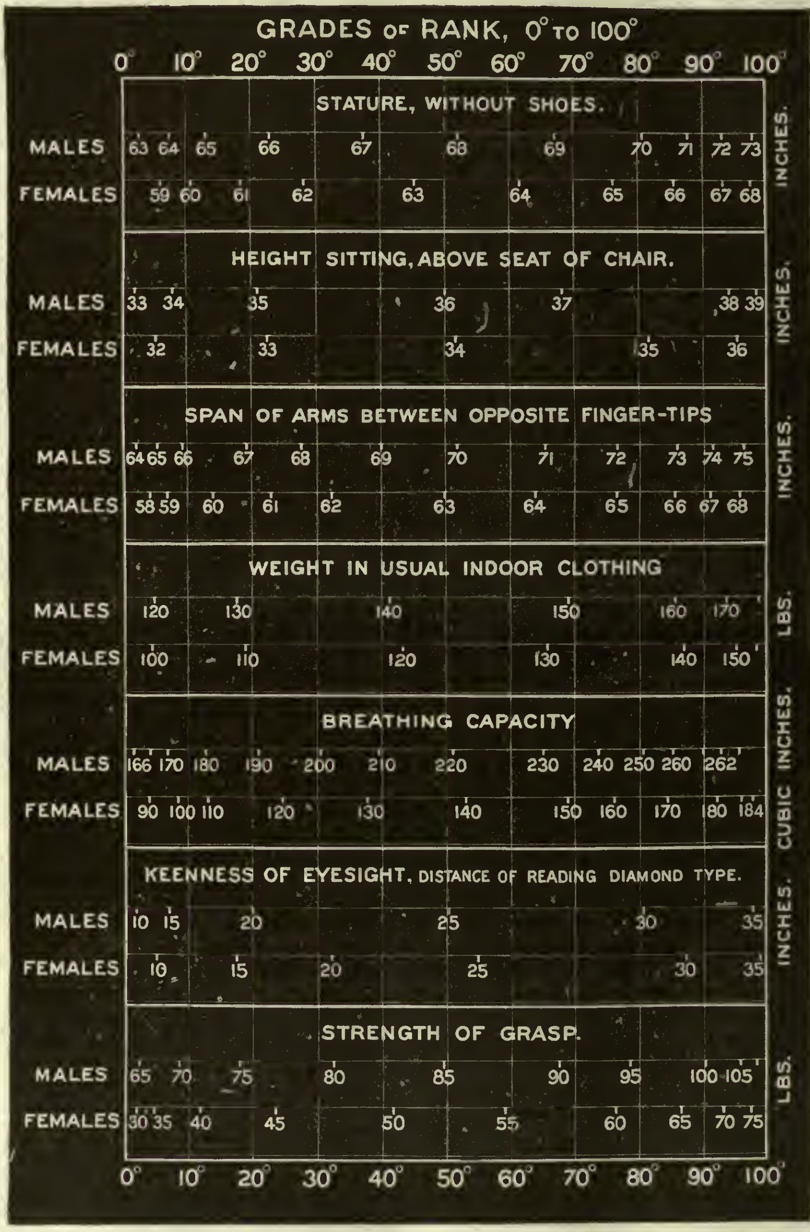

Fig. 1.

one way. That for which there is most call is where the rank of the quality immediately in question, has to be considered in reference to some other quality. Thus it is of little use to know the breathing capacity of the man unless we also know his stature or his weight. Lungs capacious enough to enable a small man to labour violently without panting would be wholly insufficient for the ordinary purposes of a giant, just as an excellent little boiler for a small steam-engine would be ineffective with a large one. The diagram (see Fig. 2) appropriate to the case we are considering, could not be compressed into a single line, but requires many. Successive lines in that figure refer to the successive statures of 60 inches, 61 inches, and so on up to 72 inches. A diagram of breathing capacities for each of these statures was constructed in pencil, on the principle of one of the lines in Fig. 1; then bold lines were drawn from above downward to connect all the pencilled entries of the same value, just as isobars, isotherms, and other contour lines are drawn (to which the general name of *isograms* might well be given). This completed the figure, which hardly needs further description, either how to make or to use it. The importance of taking stature into account now becomes very evident. A breathing capacity of 220 cubic inches in a man of 72 inches stature has the rank of only 6°, but in a man of 60 inches it has the rank of 94°. Fig. 3 shows in a similar way the grade of any given strength of grasp, when the weight of the person is taken into account.

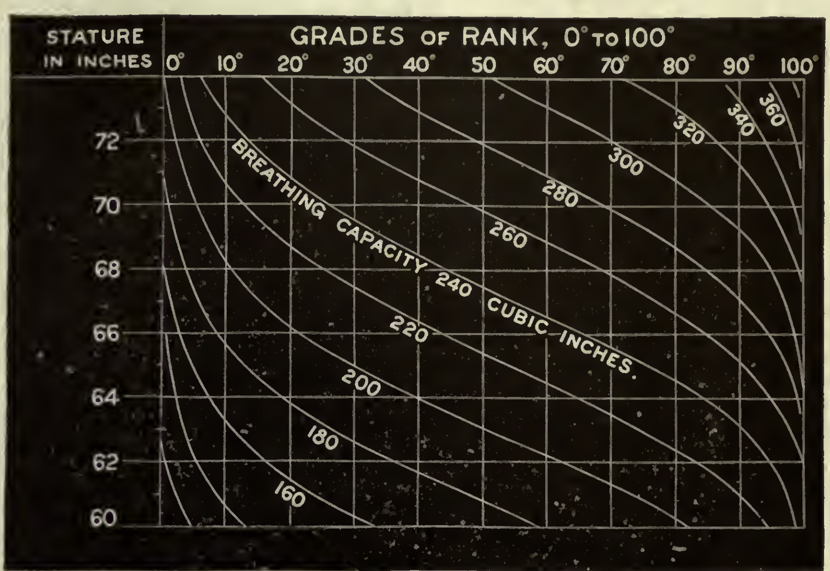

FIG. 2.

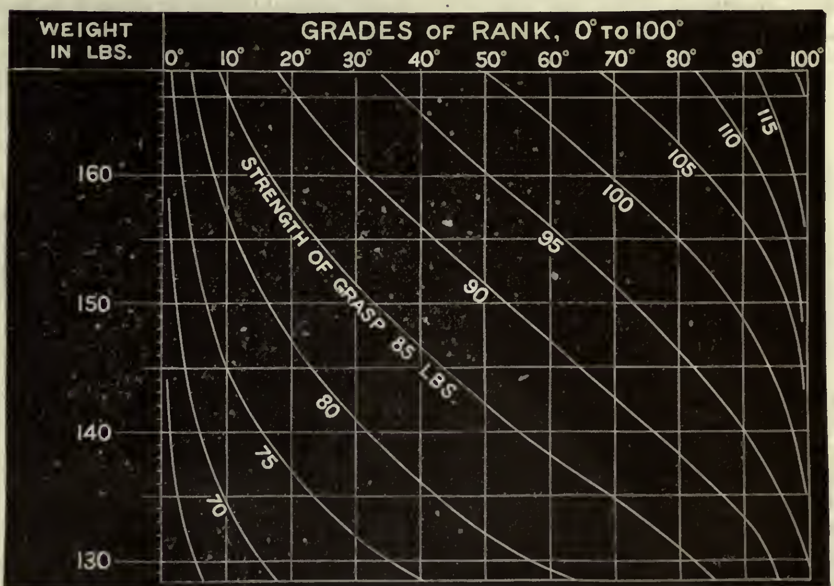

FIG. 3.

When the quality that has to be marked depends upon more than one other quality—as it may be desired to mark breathing capacity with reference *both* to weight and to stature—the simplest plan is to make a separate diagram for each inch or second inch of stature, which is quite near enough. I have, however, contrived to make a single page serve for the whole process by using a sliding strip of paper. I have submitted it for inspection, but do not care to describe it.

A strong reason for giving prominence to relative rank is that it affords the only feasible way of measuring many qualities; differences in absolute performance being inferred from rank, according to a principle now familiar to most anthropologists, by using the well-known table of the probability integral. A small table based on the latter, but of a totally different form, that I have lately more than once published (*op. cit.*, p. 205, and NATURE, vol. xxxix. p. 297). is very convenient for this sort of work. The following is a brief extract from it :—

Grades of Rank from 0° *to* 100°, *together with the Deviations*[1] *from the Mean Values at those Grades.*

Grades.....	0°	10°	20°	30°	40°	50°	60°	70°	80°	90°
Deviations	– infinity	– 1·9	– 1·3	– 0·8	– 0·4	0·0	+ 0·4	+ 0·8	+ 1·3	+ 1·9
Grades.....	91°	92°	93°	94°	95°	96°	97°	98°	99°	100°
Deviations	+ 2·0	+ 2 1	+ 2·2	+ 2·3	+ 2·4	+ 2·6	+ 2·8	+ 3·1	+ 3·5	+ infinity

Some of the consequences of marking separately the relative rank and the absolute performance are seen by the next table. Here the relative rank is in each case supposed to count between the grades of 50° and 100°. Then, if it alone is considered, a man who stands at the grade of 99° in a class that ranges within the limits of 0° and 100°, will be seen to get very nearly the full amount of ten marks, whereas if absolute performance is alone considered, he would get no more than seven marks. The full number of ten could be never actually reached, but only closely approached at some such high grade as 99·99 . . .°. The figures in this table would have run very differently if the marks for relative rank had begun after 90° and not after 50°. Still more so, if the lower limit had been 99°, and more still if it had been 99°·9. It seems to me most reasonable, on the whole, that they should usually begin after 50°, as in the table :—

Proportion of marks assigned to		Rank, 0° to 100°.				
Relative.	Absolute.	55°	75°	95°	99°	99·99 . . .°
All.	None.	1·0	5·0	9·0	9·8	10·0
½	½	0·7	3·5	6·9	8·4	10·0
⅓	⅔	0·6	3·0	6·2	8·0	10·0
¼	¾	0·5	2·7	5·8	7·7	10·0
None.	All.	0·4	2·0	4·8	7·2	10·0

The general conclusion to which these remarks lead is, that before arranging scales of marks, the first step is to measure a large number of persons who are of the same class as the expected candidates; this has already been done to a considerable extent at Cambridge, at Marlborough College, and elsewhere. Thence to make tables, and to deduce diagrams from them like Fig. 1 in some cases, and like Figs. 2 and 3 in others. These will exactly determine the qualities of the men to be dealt with, in a statistical sense. It is now the part of those who have to fix the scales of marks to determine the grade at which rank shall begin to count, and to arrange the weight to be given respectively to relative rank and to absolute performance in each sort of examination. This and a few other obvious preliminaries having been settled, the construction of consistent scales of marks would follow almost as a matter of course.

Experiments at Eton College on the Degree of Concordance between different Examiners in assigning Marks for Physical Qualifications. By A. A. Somerville.

An experiment was made at Eton in July last, with the object of obtaining information upon the following points: (1) whether it is possible to frame a system of marking for physical excellence, based partly upon Mr. Galton's system, and partly upon medical examination; (2) whether marks assigned by medical examiners would be as safe a test of excellence as those assigned, *e.g.* by examiners in English essay. The experiment was conducted as follows:—A list of points was drawn up with the help of two able medical men. These points were: (1) breathing capacity, as tested by the spirometer; (2) hearing—(3) eyesight, tested by Snellen's type; (4) strength, tested by the grip dynanometer; (5) endurance, tested as follows—after the maximum reading of the dynamometer had been obtained and registered for strength it was again (as nearly as possible) obtained, and the number of seconds during which the candidate could hold the needle of the dynanometer between this reading and the reading 10 below it was taken by a stop-watch; (6) relation of height to weight; (7) girth and shape of chest; (8) general muscular development; (9) health record, particular inquiries being made as to rheumatism, asthma, and scarlatina: (10) general aspect and condition.

The first five points depend solely upon measurement, and consequently the marks of the two doctors are the same for those points. The next point was marked, partly by impression and partly by reference to a table of averages, but it might be made to depend altogether upon averages. The seventh and eighth points were marked partly by measurement of chest, arms, and legs, and partly by examination. The last two points depend altogether upon medical opinion, and involved a thorough medical examination. Ten marks were assigned for each point, and the examination was conducted independently by the two doctors in separate rooms. Thirty-two boys were examined: (1) twenty Army Class boys, including ten successful candidates at the recent Sandhurst and Woolwich Further Examinations, two members of the Cricket XI., and two members of the Rowing Eight; (2) six other members of the XI.; (3) the remaining six members of the Eight. The following table gives the final results, average differences per cent. being calculated with reference to a maximum 50, as the marks for the first five points are the same for the two examiners. (N.B.—Letters are substituted for the names of the boys.)

Army Boys.						Six Members of the XI.			Six Members of the Eight.		
A	58½	58	K	53	56½	A	60	59	A	78¼	79¾
B	74	75¼	L	71½	77	B	59	61	B	73	71½
C	81½	83	M	57	62	C	68¼	71¾	C	76¾	78¾
D	68	69½	N	59½	65	D	77¾	71¾	D	76½	73½
E	72½	70½	O	64	70½	E	58	65¼	E	67	70¼
F	44¾	46¼	P	51½	58	F	64¾	73½	F	71¼	76½
G	65¼	68¼	Q	57	65¼						
H	66½	63½	R	60½	70½						
I	69¼	72¾	S	53¼	62¼						
J	72	76½	T	57	70½						

Army Boys: Greatest difference . . . = 13½; Least difference . . . . = ½; Average difference . . . = 9·5 Per cent.

Six Members of the XI.: Greatest difference . = 8¾; Least difference . . . = 1; Average difference . = 9·5 Per cent.

Six Members of the Eight: Greatest difference. . = 5¼; Least difference . . . = 1½; Average difference. . = 5·5 Per cent.

Average difference for 32 boys . . . . = 4·375 for max. 50
= 8·75 per cent.

Nineteen of the twenty Army boys were subsequently examined in English essay, the essays being marked independently by two examiners, with the following results :—

A	55	50	H	15	10	N	50	25
B	45	50	I	40	60	O	70	35
C	40	35	J	65	40	P	30	65
D	20	25	K	25	15	Q	45	20
E	15	12	L	35	20	R	60	25
F	55	40	M	15	30	S	40	15
G	35	25						

Greatest difference . . . . = 35
Least difference . . . . = 3
Average difference . . . . = 16·7 Per cent.

[1] The unit by which the deviations are measured is half the difference between the performances of the persons who respectively occupy the grades 25° and 75°.

Comparing the average difference, 16·7 per cent., between the marks of the examiners in English essay, with the average difference, 9·5 per cent., for the same boys, between the marks of the medical examiners, it seems fair to conclude that the marks assigned by the latter are at least as trustworthy as those given for English essay, which may be taken as a sample subject in a literary examination.

It is hoped that similar experiments will be undertaken at other places, so that materials may be obtained for the comparison and discussion of different systems of marking, and for the construction, ultimately, of the best systems. Such experiments would be rendered all the more valuable by the introduction of fresh points of examination, and by variations in the method of assigning the marks for the different points.

NOTES.

AT a meeting of the Council of the Royal Society held on October 24, it was resolved that a Committee should be appointed to consider the desirability of raising some national memorial of the late Dr. Joule, and to take such action thereupon as they might think advisable. Sir Henry Roscoe was appointed the provisional Organizing Secretary.

THE Walker Engineering Laboratories in connection with University College, Liverpool, will be opened on November 2. The Lord President and Council of the College will entertain Sir Andrew Barclay Walker, Sir John Coode, the members of the Engineering Committee, and other distinguished guests at luncheon, served in the Walker Laboratories; and in the afternoon a public meeting will be held in St. George's Hall, at which Sir John Coode, President of the Institution of Civil Engineers, will deliver an address, and the annual distribution of medals and prizes will take place. In the evening there will be a reception at the Walker Laboratories, when the formal declaration of opening will be undertaken by the Hon. Lady Walker.

THE annual exhibition prepared by the South London Entomological and Natural History Society was opened at the Bridge House Hotel, London Bridge, S.E., yesterday, and will be open again this evening. These exhibitions have become so popular that on the last several occasions upwards of 2000 visitors have attended each evening.

DR. S. WEIR MITCHELL, of Philadelphia, has been elected President of the Congress of American Physicians and Surgeons, which will meet in Washington in September 1891.

As it is expected that the Forth Bridge will be opened for passenger traffic in the spring of 1890, it is intended that the event shall be celebrated by the holding of an International Exhibition in Edinburgh, specially devoted to electrical and general inventions and industries. The Exhibition is under the patronage of the Queen; and the Marquis of Lothian, Secretary of State for Scotland, is the President. The Vice-Presidents include the Lord Provost of Edinburgh, the Lord Provost of Glasgow, the Lord Mayor (elect) of London, Mr. Edison, and Sir John Fowler. The executive have secured a site of about ninety acres in extent, within easy walking distance of the centre of the town. On Monday, at a special meeting of the Electrical Trades Section of the London Chamber of Commerce, a resolution was agreed to, appointing a Committee to consider the conditions on which it might be advisable to take part in this Exhibition.

A CONVERSAZIONE will be given by the Geologists' Association on December 6.

A STATUE of the French chemist, Nicolas Leblanc, is about to be unveiled at Saint-Denis. Leblanc was born at Issoudun in 1753, and died in 1806. He had a manufactory at Saint-Denis.

THE following Science Lectures will be given at the Royal Victoria Hall during November:—November 5, Mr. A. P. Laurie, on "Dust"; November 12, Mr. W. Furneaux, on "The Heart, and how it beats"; November 19, Prof. Judd, "The Forge of the Blacksmith God"; November 26, Mr. J. E. Marr, "Greenland's Icy Mountains."

THE Morley Memorial College for Working Men and Women, adjoining the Victoria Hall, has begun a very vigorous life. Over 450 students have joined within three weeks of the opening day. In fact they come in with somewhat embarrassing rapidity, and volunteers (both ladies and gentlemen) are urgently wanted, both to teach classes and act as librarians. Six librarians are wanted to take one evening a week each, from 8 to 10. The library has received a valuable present from Mr. Passmore Edwards, who has given 1000 books. Others have given smaller parcels, so that the book-cases which have been provided are quite inadequate, and more are needed.

MR. WILLIAM BURGESS, the founder and proprietor of the Midland Counties Fish Culture Establishment, died on Sunday, at Malvern Wells.

LLOYD'S Agent at the Dardanelles telegraphed as follows on October 28, 9.45 a.m.:—"An earthquake was felt here on Saturday. Very little damage has been done. Sigri Lighthouse, Mytilene, destroyed, also loss of life in island."

PROF. H. G. SEELEY finds that the pubic bone, which is of large size, does not enter into the acetabulum in the Plesiosaurian genus Colymbosaurus from the Oxford Clay. In that genus, the clavicle and inter-clavicle are developed as small separate ossifications, on the visceral aspect of the large scapular arch, and hence are not usually seen.

AT the recent meeting of the Congress of German Men of Science and Physicians at Heidelberg, Herr O. Ammon submitted to the Anthropological Section some interesting results of observations he had made in Baden. These observations related to 5000 soldiers. The tall men had generally long skulls, or skulls of medium length, whereas the short men had round skulls. Most of the round-skulled men came from the Black Forest; the long-skulled usually belonged to the valley of the Rhine, and were especially numerous in towns and in the neighbourhood of the castles of ancient families. From this fact Herr Ammon concluded that the round-skulled men had been the original inhabitants of the Rhine valley, that they had been driven from it by long-skulled invaders, and that the latter had established themselves near the settlements of their victorious leaders. Having shown that there is a certain relation between the height of the figure and the shape of the skull, Herr Ammon went on to indicate the relation between fair hair and blue eyes. No fewer than 80 per cent. of the men with blue eyes had fair hair. He found also that physical growth is generally quicker in the case of the brown-eyed than in that of the blue-eyed type.

AT the last meeting of the Andersonian Naturalists' Society of Glasgow, amongst the papers read was one by Mr. R. Turner Vice-President, on the Uredineæ and Ustilagineæ. He explained the relations of these microscopic Fungi to other plants, and their position in the vegetable kingdom. They are all parasitic upon some living plant, and consist of two essential elements—spores and mycelium. The spores are very diverse, the mycelium very similar. The same mycelium gives rise to several different kinds of spores, each of these being formerly regarded as a different genus. The production of cluster-cups and of the spermagonia, with their so-called spermatia, was described. It was shown that these spermatia have been by no means established as equivalent to pollen in function. As an example of heterœcism, the life-history of *Puccinea graminis* was traced: first, the æcidiospore stage on the barberry, then the rust on wheat, succeeded by mildew, and finally, the germination of the telentospores and the production again of æcidium on barberry. Many other instances of heterœcism were adduced, and some problems suggested for the consideration of members of the Society. The Ustilagineæ were then shortly referred to, and *Ustilago segetum*, the corn-smut, given as a familar example. The paper was illustrated by diagrams, specimens, and the sections shown under the microscope.

In a paper read before the Royal Danish Academy in February, M. Adam Paulsen gave some interesting particulars of observations made with the object of determining the height of the aurora. Two theodolites were used, the observing telescopes of which were replaced by short tubes having small holes at the eye ends and metallic cross wires at the other ends. Two of the stations were situated in the same magnetic meridian, on opposite banks of the fjord of Godthaab, at a distance apart of 5800·4 metres. The vertical circles of the two theodolites were placed in a common plane by means of observations of "blue fire" signals given at each station. Signals were also exchanged on the appearance of an aurora which it was thought possible to measure, so that simultaneous observations were secured, and it was previously agreed to direct the instruments to the base of the auroral arc. The observations at Godthaab gave heights for different auroræ ranging from 0·6 to 67·8 kilometres. A second series of observations with the same apparatus and methods was made in 1885 by MM. Garde and Eberlin at Nanortalik, near Cape Farewell, the base-line in this case being 1247·8 metres, and the values determined here were 1·6 to 15·5 kilometres. The results obtained by the staff of the Swedish International Expedition at Spitzbergen, with a base of 572·6 metres, range from 0·6 to 29·2 kilometres. These observations therefore lead to the conclusion that auroræ are by no means confined to the highest parts of our atmosphere, but that they occur almost indifferently at all altitudes. In support of this view, M. Paulsen gives accounts of several appearances of auroræ beneath the clouds and the summits of mountains. It is interesting to compare the new values with those given by previous observers. M. Flögel calculated the heights of several auroræ which appeared in the autumn of 1870, and concluded that only the very lowest parts of the aurora came at all within the limits of our atmosphere; he gave the actual limits as 150 to 500 kilometres. For an aurora on October 25, 1870, M. Reimann found a height of from 800 to 900 kilometres, and Nordenskiöld came to the conclusion that the mean height of auroræ was about 200 kilometres. On the other hand, Lemström has observed auroræ as low as 300 metres, and M. Hildebrandsson has seen auroræ in a completely clouded sky. Considering all the facts of the case, M. Paulsen inclines to believe that in the temperate zone, auroræ only appear in the higher layers of the atmosphere, whereas in the auroral zone, properly speaking, the phenomenon is generally produced in the lower layers.

In the new Quarterly Statement issued on behalf of the Palestine Exploration Fund, it is stated that Dr. Torrance, of the Scottish Mission, has undertaken to conduct a series of meteorological observations at Tiberias for the Fund. Should Dr. Torrance be able to carry out this undertaking, the observations will, with those made at Sarona, now being published by Mr. Glaisher, and those made by Dr. Chaplin at Jerusalem, and reported in the Quarterly Statement for 1883, place the Society after a few years in the possession of materials for a fairly complete account of the meteorology of Palestine. Tiberias is 682 feet below the level of the Mediterranean, and the Society hopes that, as no regular series of meteorological observations has ever been made in such a depressed situation, the results may be exceptionally interesting. As the neighbourhood of Jericho is becoming, to some extent, a place of residence for Europeans, the Society trusts that opportunity may before long present itself for meteorological observations there also.

Symons's Monthly Meteorological Magazine for October contains a climatological table for the British Empire for the year 1888, from which we extract the following interesting details. Adelaide had the highest shade temperature, 107°·5, on December 25, and was the driest station. Winnipeg had the lowest shade temperature, −46°·4, in February, the greatest mean daily range, 22°·5, and the lowest mean temperature, 32°·3. Colombo (Ceylon) had the highest mean temperature, 80°·9, and the greatest rainfall, 101·06 inches. Malta had the least rainfall, 13·75 inches, and was the least cloudy station. The highest temperature in the sun was registered at Calcutta, 165°·4; while London holds the unenviable position of the dampest and most cloudy station.

The *Annuaire de l'Observatoire Municipal de Moutsouris* for 1889 contains a considerable amount of meteorological information. Observations appear to have been made in connection with every branch of this science, and the tables, showing the results obtained in this and former years, are well constructed; the whole being discussed by M. Léon Descroix, from an agricultural and hygienic, as well as the meteorological, point of view. In addition to this, M. Albert Lévy contributes an elaborate series of analyses of air and water, samples of which had been gathered from various sources; and Dr. Miquel his eleventh memoir on the micro-organisms that are found in them.

Mr. James R. Gregory has issued a catalogue of his valuable collection of meteorites. The formation of this collection was begun nearly thirty years ago, and now Mr. Gregory finds that he can number upwards of 300 distinct "falls," "which," he says, "really places my collection among some of the largest in Europe as regards the number of falls, and in the average weight and excellence of the examples." As to arrangement, he has adopted, with a few variations, the principle of the new Catalogue of the British Museum collection in chief.

It has been generally supposed that the mango weevil infests the pulp of the fruit, but in a letter read at a recent meeting of the committee of the Agri-Horticultural Society of Madras, from Mr. C. I. Denton, forwarding specimens of mangoes, called by the Canarese the bee mango, he states that the peculiarity of the fruit is that the stone contains a bee existing on the kernel. Specimens of the insect were forwarded by the Madras Agri-Horticultural Society to Mr. Coates, of the Indian Museum, who identified them as *Cryptorhynchus mangifera*, the mango weevil, whose normal habitation is in the pulp of the fruit, and not within the stone. The fruit sent to the Society was carefully examined, and the pulp was, in every case, free from the insect, which was only discovered when the stones from which the pulp had been removed were broken open.

A third edition of Mr. Thomas Greenwood's "Free Public Libraries" is being prepared. Three years ago, when the first edition of this work was published, the total number of adoptions of the Acts during thirty-six years was only 133. At present there are 190.

A book on "The Birds of Essex," by Mr. Miller Christy, is to be published by subscription. It will form the second volume of the "Special Memoirs" of the Essex Field Club. The author has been collecting materials for this work for more than fifteen years, and he says that 271 species of birds are described as having been met with in Essex—a number which has been exceeded hitherto by very few other counties.

We have received the official report of the proceedings of the thirty-seventh meeting of the American Association for the

Advancement of Science, held at Cleveland in August 1888. The volume, we need scarcely say, contains addresses, reports, and papers of great interest. The Presidential address, delivered by Prof. S. P. Langley, is on the history of our present views about radiant energy.

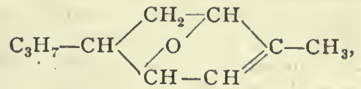
THE latest issue of the Proceedings of the Royal Society of Edinburgh (Session 1888–89) includes pp. 257–320 of vol. xvi. The following are the contents:—On the relation among the line, surface, and volume integrals, by Prof. Tait; the development of diarthrodial joints in birds and mammals, by David Hepburn; electrification of air by flame, by Sir Wm. Thomson; on the placentation of the halicore dugong, by Prof. Sir William Turner; on the geographical distribution of some tropical diseases, and their relation to physical phenomena, by R. W. Felkin (with 16 plates); quaternion note on a geometrical problem, by Prof. Tait; the solubility of carbonate of lime in fresh and sea water, by W. S. Anderson.

THE thirteenth part of Cassell's excellent "New Popular Educator" has been issued. It includes a good coloured plate representing the Rosegg glacier.

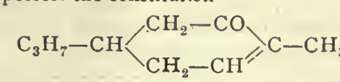
THE Glasgow and West of Scotland Technical College has issued its Calendar for the year 1889–90. We have received also the new Calendar of the University College of Wales, Aberystwith.

AN interesting paper on Japanese lacquer, read lately by Mr. R. Hitchcock before the Chemical Society of Washington, has been printed in the Proceedings of the United States National Museum. Japanese lacquer is the product of a tree, the *Rhus vernicifera*, D.C., which grows throughout the main island of Japan. It attains a large size, the trunks sometimes measuring a metre in diameter. It is said the tree will live for forty years, but only comparatively young trees are valued for the production of lacquer. Having yielded for several years they are cut down, the lacquer extracted from the branches, and young trees take their places. Having given an account of the chemical composition of lacquer, and described the uses to which it is applied, Mr. Hitchcock urges that it should receive more attention than has hitherto been devoted to it by manufacturers in America. "It gives a surface to wood," he says, "much harder than our best copal varnish, without brittleness. It takes a polish not to be excelled, which lasts for centuries, as we may see in the old treasures of Japan. It is proof against boiling water, alcohol, and, indeed, it seems to be insoluble in every agent known. It is the best possible application for laboratory tables. I have a set of photographer's developing trays that have been in use for more than a year, and I find them excellent and cheap. In Japan it is used for many household articles." Unfortunately, lacquer poisoning from the fresh material is a serious danger. According to Rein, the poison is a volatile acid, and Mr. Hitchcock suggests that it might be removed by a heat that would leave the lacquer uninjured.

AN isomer of camphor, $C_{10}H_{16}O$, has been prepared by Drs Wallach and Otto in the chemical laboratory of the University of Bonn (*Liebig's Annalen*). This new substance is a liquid, to which the name pinol is provisionally given, possessing a very strong camphor-like odour. It is obtained by the action of hydrochloric acid upon a well-cooled mixture of turpentine oil, glacial acetic acid, and ethyl nitrite. The hydrochloric acid is gradually added in the form of a concentrated solution, and its addition is followed by the separation of crystals of the nitroso-chloride of pinene, one of the terpenes, and the formation in the solution of pinol, the new camphor. The whole is allowed to stand for about twelve hours at a low temperature to complete the precipitation of the first-named body, after which the crystals are filtered off, and the filtrate is subsequently distilled in steam. A rapid evolution of gas occurs at the commencement of the distillation, after which the pinol is quietly conveyed over in the steam. The distillate separates into two distinct layers, and the aqueous layer is readily separated by means of a funnel. The dried distillate is then freed from acetic ether by fractional distillation, and the higher boiling portion again distilled in steam. This redistilled product is similarly separated from water, dried, and finally itself subjected to fractional distillation: when the principal fraction, consisting of pinol with a small quantity of impurity, passes over between 182° and 188° C. The liquid thus obtained is found to possess in a very marked degree the odour of camphor, and it can be freed from the last traces of impurity by taking advantage of the action of bromine upon it. Bromine yields with pinol a beautifully crystalline dibromide, $C_{10}H_{16}OBr_2$. On diluting the distillate, therefore, with twice its volume of glacial acetic acid, and running in a thin stream or drops of liquid bromine, the colour of the latter rapidly disappears, and, on evaporating, splendid rhombic crystals of this dibromide are obtained. In order to recover the pinol in a pure state from the recrystallized dibromide, about a hundred grams of the latter are boiled with excess of alcoholic potash for a whole day, and the product distilled in steam, separated from water, dried with solid potash, and repeatedly fractionally distilled. Finally, pure pinol is obtained, boiling constantly at 183–84°. Analyses of this product conclusively point to the formula $C_{10}H_{16}O$, the same as that of ordinary camphor. Its constitution is proved to differ, however, from the latter body by the nature of its oxidation products. Both potassium permanganate and dilute nitric acid oxidize it to carbonic anhydride, oxalic acid, and terebic acid, $C_7H_{10}O_4$. The only possible constitution compatible with these facts is



while ordinary camphor is generally assumed on Kekulé's authority to possess the constitution



An extremely interesting fact about pinol is that its nitroso-chloride readily reacts with β-naphthylamine to form a base of the formula $C_{20}H_{24}N_2O_2$, isomeric with quinine. This is the first base of this empirical formula which has yet been artificially prepared. Solutions of both the base and its salts present similar fluorescent phenomena to those of quinine and its salts.

THE additions to the Zoological Society's Gardens during the past week include a Gaur (*Bos gaurus* ♂) from Pehang, Malay Peninsula, presented by Sir Cecil C. Smith, K.C.M.G.; three Blue-crowned Hanging Parrakeets (*Loriculus galgalus*) from Malacca, presented by Mr. A. Baker; a Short-tailed Capromys (*Capromys brachyurus*) from Cuba; two Reed Buntings (*Emberiza schœniclus*), British, purchased; three Dingo Dogs (*Canis dingo* ♂ ♂ ♀), a White Goshawk (*Astur novæ-hollandiæ*), a Berigora Hawk (*Hieracidea berigora*), a Brush Turkey (*Talegalla lathami* ♀), an Australian Thicknee (*Œdicnemus grallarius*) from Australia, received in exchange.

OUR ASTRONOMICAL COLUMN.

THE NATAL OBSERVATORY.—The Report of this Observatory for 1888, which has recently come to hand, is a somewhat meagre one, and is chiefly occupied with the routine daily meteorological observations. The small record of astronomical work achieved may perhaps be explained by the circumstance that the Superintendent, Mr. Nevill, has recently been appointed Government Chemist and Official Assayer for Natal, that a laboratory was erected for him in the early part of the year, and that he has already commenced his official duties in his new capacity.

Of direct astronomical work the Report only records the routine work in connection with the maintenance of the system of colonial time signals; a number of observations of the zenith distances of northern stars and circumpolars both above and below the Pole, for the comparison of declinations as observed at Observatories on either side of the equator; and some progress as having been made in the observation of pairs of equi-zenith distance stars for the determination of the latitude of the Observatory. The various computations undertaken at the Observatory have been pushed forward much more zealously. These embrace the comparison of the Greenwich lunar observations for the decade 1878–87 with Hansen's lunar tables; the reduction of Mr. Campbell's observations of the lunar crater Murchison A, made at the Arkley Observatory in the years 1882–84; and the reduction of the third year's tidal observations at Durban.

THE SPECTRUM OF R ANDROMEDÆ.—Mr. Espin, who has recently discovered bright lines in the spectra of several long-period variables of Secchi's third type, has added another to the list; R Andromedæ, at the maximum just passed, showing a number of bright lines, F being very bright, so bright as to appear to project beyond the spectrum. The spectrum of the star had manifestly undergone a great change from the time when Dunér made the very thorough study of it which he has recorded in his work on "Les Étoiles à Spectres de la Troisième Classe." Five of the seven variables included in Mr. Lockyer's Species 10 of this type have now shown bright lines at maximum, whilst Gore's Nova Orionis, which should certainly be included in the same species, would make a sixth. The two stars in which bright lines have not yet been observed are R Leonis Minoris and α Herculis.

COMET 1889 *d* (BROOKS, JULY 6).—The following ephemeris is in continuation of that given in NATURE for October 3 (p. 550):—

Ephemeris for Berlin Midnight.

1889.	R.A. h. m. s.	Decl. ° ′	Log *r*.	Log Δ.	Brightness.
Nov. 1	23 41 40	2 32·2 S.	0·2977	0·0625	1·8

SEISMOLOGICAL WORK IN JAPAN.[1]

THE seismological work which has been accomplished in Japan is to a great extent described in fourteen small volumes published by a Society which was organized in 1880 to study phenomena connected with earthquakes and volcanoes. This Society is called the Seismological Society of Japan. An epitome of a portion of this work is to be found in nine Reports on the volcanic phenomena of Japan issued by this Association. A glance at the first few volumes published by the Seismological Society shows that the attention of its members was directed towards seismometry. For several years attempts were made to record earthquakes by using the old types of earthquake instruments, such as columns balanced on end, bowls or tubes filled with liquid, pendulums with pencils or pointers writing on paper or smoked glass. The records obtained from instruments of this order were, however, gradually recognized as being too indefinite; the instruments indicated that shakings had taken place, but they failed to measure them. All investigators recognized that to measure the movement of the earth it was necessary, while the movement was going on, to obtain a steady point or platform relatively to which the motion might be measured. By the patient labours of investigators in Japan, which have extended over many years, this has been accomplished, and we now have pendulums and other forms of instruments which for small displacements are in neutral equilibrium, so that when the frames carrying these instruments are shaken back and forth or up and down there are certain portions of them which remain at rest. From these steady points pointers project which write the movements or magnified representations of these movements upon suitably prepared surfaces.

From the simple pendulum and style, tracing its movements in sand, and costing but a few pence, elaborate instruments, embracing many new mechanical contrivances, and writing their movements with delicate siphons on continuously running bands of paper, have gradually been evolved. With the assistance of these instruments many thousands of diagrams, each of which represents in absolute measures the back and forth motions of the ground during an earthquake, have been obtained, and we now know the true nature of earthquake movement. We have learnt that, in many earthquakes which are quite perceptible and sometimes even alarming, the amplitude of motion may not exceed a millimetre, while if it reached 25 millimetres, or an inch, we might expect cities to be ruined.

The results which have flowed from a study of these diagrams are numerous and interesting. We now know that the direction of movement in any given earthquake is continually varying. At one moment a point on the surface of the earth may be moving north and south, and the next moment it may be moving east and west, while at other times it may be following a path too intricate to be easily described.

More interesting observations relate to the period and amplitude of the earth's motion, from which may be calculated the destructive power, which depends partly on the maximum velocity and partly on the suddenness of movement. Some earthquakes commence with preliminary tremors, which have been recorded with a frequency of eight or ten waves per second.

The back and forth movements of considerable amplitude which constitute the shock or shocks in an earthquake usually have a period of one or two seconds, while the ordinary back

[1] A Paper, by Prof. John Milne, of the Imperial University of Japan, Tokio, read at the British Association.

and forth movements, constituting a greater part of the shaking that is sensible, have usually a period of from three to five per second. At the end of a disturbance the wave-period is almost always very much greater than it is at the commencement or middle of a disturbance. Quite recently an earthquake was recorded in Japan, having a period of from six to eight seconds.

Observations like this are undoubtedly valuable from a scientific standpoint, but many observations are of practical importance. For example, we now know that a seismic survey can be made of any given piece of property, and as the result of such a survey it may be found that buildings erected on one side of the given area may suffer very much more than those upon the other side. Again, we know that, because in severe earthquakes the motion at the bottom of a comparatively shallow pit is very much less than it is upon the surface, buildings may be partially cut off from earthquake motion by giving them proper foundations.

In addition to the theoretical and practical results which have flowed from the study of earthquake diagrams, mechanical science has gained something from the new types of machines that have been evolved. Now we know how to make pendulums astatic. New combinations in clockwork have been invented, new governors for machinery designed, some of which have already proved themselves useful for other purposes than earthquake machinery. One machine, which has been the outcome of seismological work in Japan, and which promises to be of practical value outside the domain of seismology, is an instrument which records the vibrations in a railway train. With diagrams of these vibrations before us, we are enabled to time a train between stations, to see when it went quickly and when it went slowly, to note the duration of stoppages, to detect irregularities on a line, as, for instance, those which may occur at crossings and points, those due to a want of ballast, variations in gauge, imperfections in bridges, &c.

Seismometrical observations have not alone been confined to the observation of earthquakes proper, but observations have been made upon disturbances produced by explosions of substances like dynamite and gunpowder, the falling of heavy weights, and the moving of trains, &c. The records obtained from these experiments have perhaps taught us more about the nature of earth vibrations than we have obtained from the observation of actual earthquakes. So far as surface disturbances in superficial soil are concerned, we now know that the phenomena they present are anything but what we might anticipate as likely to occur in a theoretically elastic material.

An extremely practical subject which has received attention in Japan has been observations and experiments upon the effects produced by earthquakes upon buildings; an account of them —many of which have been successfully put into practice by builders—is now being published as the fourteenth volume of the Seismological Society's Transactions. As this particular subject is of such vital importance to the Government of Japan, who are continually erecting European structures, it is at the present time being discussed by a Committee of engineers, architects, and others, summoned for the purpose by the late Viscount Mori, Minister of Education.

The Imperial Government of Japan, by establishing in the Meteorological Department an Earthquake Bureau, and in the Imperial University a Chair of Seismology, have given an impetus to seismological investigation in general. In several parts of the country seismographs have been established, and, at between 600 and 700 stations, records are kept of all disturbances which are felt. From these records we are now able to study the distribution of seismic activity, both with regard to space and time. For instance, we now know that the greater number of shocks originate on or near the eastern coast; we know that there are many "centrums," from some of which weak, and from others strong, shocks originate; that, on the average, we feel in Japan at least two shocks per day.

Inasmuch as earthquake disturbances are relatively superficial, we may consider the area of disturbance as a very fair estimate of seismic effort. In 1885 the land area shaken was about 660,000 square miles, and in 1886 it was about 562,000 square miles.

Here we have the commencement of a series of interesting figures which may, perhaps, be related to a heat-gradient—to the fluctuations in the flow of the Black Stream, or to something not yet thought about.

Hitherto, when studying earthquakes in relation to meteorological changes, the position of the moon, the seasons, &c., we have been compelled to take very imperfect catalogues of shocks which have originated from "centrums" as independent of each other as most volcanoes are of each other. Now we are getting material which will enable us to study a group of earthquakes which have come from a given origin. Disturbances in the ocean have not been overlooked, and the waves which Japan has sent to America, and those which America has returned, have been carefully investigated, and average depths of the ocean along several lines have been determined. In all instances it appears that the depths calculated from the transmission of a sea-wave are a little less than the depths obtained by averaging the soundings. Does this mean that there is an incompleteness in the formulæ which have been used? or does it mean that sailors have allowed their line to run a little after striking bottom?

Other investigations which have been made relate to the effects produced by earthquakes upon the lower animals; and one investigator, Prof. Sekiya, at one time kept pheasants purposely to observe their behaviour at the time of an earthquake. A conclusion arrived at is that pheasants, geese, horses, and other animals often show decided symptoms of alarm a few seconds before the occurrence of a severe shaking. The reason of this probably is that they are more sensitive to preliminary tremors than human beings.

The relationship between volcanic phenomena, earth currents and magnetism, and earth disturbances, has not been unnoticed, while mathematicians and physicists have had new problems suggested to them respecting the determination of earthquake origins, the depth of "centrums," the force required to cause destruction like the shattering and overturning of structures, the propagation of surface waves, &c.

The observations of late years respecting the destruction of submarine cables have led Mr. Forster, of Zante, to the opinion that certain earthquakes are the immediate result of submarine landslips, and suggested to Japanese observers that something might be learnt by periodical soundings made along the Japanese shores. Volcanoes have not been overlooked, and many new facts have been obtained for vulcanologists. For instance, we now know that many volcanoes have a definite curvature dependent upon the density and strength of the materials of which they are built, and given any two of these three quantities—curvature, density, and strength—we may determine the third; thus, as pointed out by Mr. Becker, of the United States Geological Survey, may not the shape of lunar volcanoes, with an assumption as to the density of the material of which they are composed, lead to an opinion as to the materials out of which they are made?

About the extremely minute movements called earth tremors, which are probably in all places and at all times to be observed, much has been done. For three or four years, by a specially-contrived instrument, these have been recorded automatically. The investigation of these records has led to the conclusion that earth tremors are closely connected with wind. When a heavy wind is blowing, tremors are usually strongly marked, but the more curious result is that they are often very marked in calm weather. An inspection of the tri-daily weather maps published in Japan shows that on these occasions a heavy wind is blowing against high mountains 60 to 200 miles distant. From this it appears that earth tremors outrace storms inland, much in the same way that small waves outrace storms upon the ocean. Insomuch as earth tremors accompany heavy barometrical gradients, and these are related to the outpouring of fire-damp in our mines, it would appear a legitimate investigation to study the behaviour of a tromometer, say in the Newcastle area, in relation to the escape of underground gas. Hitherto I believe that investigators in Great Britain have been observing seismometers rather than tromometers.

With these few remarks respecting the general nature of investigations which have been made and are yet going on in Japan, I will enumerate a few phenomena which require explanation, and suggest a few investigations which have yet to be undertaken.

Large earthquakes are usually preceded by a series of short-period vibrations. These vibrations have an amplitude of about one-tenth of a millimetre, and six to ten of them occur per second. With a seismograph giving great multiplication, it is probable that still smaller and more rapidly recurring waves may be recorded. These hitherto unseen portions of an earthquake may be the cause of the sound-phenomena of earthquakes, and the movements which, although not felt by human beings, alarm the lower animals. Why are the larger movements of an earthquake preceded by tremors of this description?

The rate at which earthquake motion is propagated is sometimes very high. From Toronto to Ontario in the Charleston earthquake of 1886 the velocity was over 15,000 feet per second, whilst at the destruction of Flood Rock, in 1885, velocities of 20,000 feet per second were observed.

As was suggested by Sir William Thomson, observations like these may mean that the rigidity of the Earth is greater than that of surface rocks. If it is so, then, as Sir William suggested, extended observations may lead to the determination of these rigidities. In connection with this, it must be remarked, that, both for artificial as well as for natural disturbances, the velocity of transmission varies with the intensity of the initial disturbance, the nature of the medium, and it becomes less as a disturbance radiates. General Abbot, however, in one instance noted an increase in velocity as a disturbance radiated.

What is perhaps closely connected with the above, or what at least is analogous, is the fact that at a given station the wave-period becomes longer as a disturbance dies out, and it also becomes longer as a disturbance radiates. One inference to be drawn from this may be that long-period earthquakes originate at a distance, a wave flattening out as it radiates, pretty much as it does in the ocean; but Sir William Thomson has suggested that a long-period disturbance may be related to the dimensions of the focal cavity. Recently, in Tokio, an earthquake having a period of about eight seconds was observed. For seismographs to record this, they must have been tipped from side to side.

Another point of interest is that for *small* displacements period increases with amplitude, but after a certain amplitude is reached the period is either constant or only increases very slowly. This observation apparently harmonizes earth motions with those of ideally elastic bodies.

Another set of interesting observations is the relationship between normal and transverse movements. At a short distance from an origin the normal movement distinctly outraces the transverse motion, but when the amplitude of the normal motion has been decreased until it practically equals that of the transverse motion the separation between the movements is *nil*. A curious feature, especially in normal movements, is the fact that near an origin the movement inwards or towards the source of the disturbance is greater than it is outwards; further, as a normal wave radiates it may be observed to gradually break up into two waves, in consequence of which a diagram taken at one station may be very different from one taken at another.

In conclusion, I will point out a few observations which, on account of the expense they involve, the difficulty of obtaining observers, &c., have not, or at least only partially, yet been undertaken:—

1. *Velocity of Earthquake Propagation.*

The importance of determining the velocity of earthquake propagation has already been noted, and it has been shown that on account of the difference in the aspect of diagrams at neighbouring stations it cannot be done on a small area. The Imperial Telegraph Department of Japan is at the present moment giving its assistance in this matter, but as so much depends upon telegraph operators who have duties to attend to, a number of specially constructed timepieces are required.

2. *A Gravity Observatory.*

Many years ago Sir William Thomson suggested the importance of an observatory to determine whether there are changes in the value of G. In Japan we have a country where superficial and probably subterranean and suboceanic changes are taking place very rapidly. Last year the greater portion of a mountain was blown away, and an area measuring 12 miles by 10 miles was, in ten minutes, or less, buried from 30 to 100 feet beneath a stream of earth and rock. What is going on beneath our volcanoes we do not know, but every now and then they pour out volumes of solid matter. Along the coast we have a sharp and deep depression, perhaps the deepest on the face of the globe. Do submarine landslips take place along this coast, as they most certainly have done in other parts of the world?

Lastly, may there not be an apparent change in the value of G, dependent upon the time at which the observations have been made? At certain seasons tremor storms are very marked, and may not their minute movements have a cumulative effect upon the small swings of pendulums used in gravity determinations. Pendulum observations of the ordinary kind have been made in many parts of Japan, from the summit of Fujiyama to the Bonin Islands, but neither in Japan nor in any other portion of the world—so far as the writer is aware—has a pendulum been swung at a given point for a considerable period of time.

3. *Observations on Submarine Changes.*

Many of the Japanese earthquakes originate near the deep submarine depression which has been spoken about. If any of these are due to suboceanic land slides or sinkings, as have been observed in the Mediterranean and in the Atlantic, such changes might be noted by periodical soundings, and perhaps even by the records of tide-gauges.

4. *Magnetic Observations.*

Dr. Edmund Naumann called attention to the fact that near certain Japanese volcanoes there have been abnormal changes in declination. The volcanic rocks of Japan are exceedingly magnetic, and they are of enormous extent. Many of the rocks in Fujiyama will deflect an ordinary compass needle through 180°. Now, as these rocks are sometimes hot and sometimes cold, whilst at the time of an eruption, and possibly at other times, there are subterranean shiftings in the positions of these magnetic masses, could not these changes be noted by establishing a magnetic observatory on the side, say, of a recent volcano like Fujiyama?

5. *Bending of the Earth Crust due to Tidal Load.*

Some years ago, in conjunction with Mr. John Stoddart, Manager of the Takashima Colliery, the workings of which extend a considerable distance beneath the Pacific Ocean, the writer, by means of a simple apparatus, endeavoured to measure any movement of the roof of the mine which might be occasioned by the rise and fall in the tide. Unfortunately, the apparatus together with other instruments were lost by a complete subsidence in one portion of the workings, and these observations, if they are of any value, have to be recommenced.

6. *Tromometric Observations.*

A continuous automatic observation of earth tremors has hitherto only been made in Tokio. Might not these observations be continued in a coal-mining region to determine whether these minute earth movements, which are certainly connected with barometrical changes, hold any relation to the outflow of fire-damp.

7. *Earth Currents.*

Have earth currents any relationship to earth tremors and to earthquakes? Earth currents are produced when the ground is shaken by an explosion of dynamite, but this might be due to the increase or diminution of pressure in the earth plates causing changes in chemical activity. Have earth currents been observed in the vicinity of an active volcano, or in relation to some large earth fracture?

8. *Earth Oscillations.*

In Japan the borings of marine shells, 10 or 12 feet above high-water mark, in very soft rock which easily disintegrates, shows that there has been a rapid movement in the earth's crust relatively to sea-level. Is it likely that this could be measured, and the axis of the movement be determined, by repeating, at intervals of twelve months, the levelling of two lines running as nearly as possible at right angles to each other? It has been suggested that, if the movement is rapid, say 1 inch per year in a large bay like that of Tokio when the rise and fall of the tide is small, the isochronous observation of records obtained under approximately similar conditions from a series of tide-gauges, the level at each gauge relative to some fixed point on the neighbouring rocks being known, might furnish data which would be of value in the measuring of earth oscillations.

These, then, are a few suggestions respecting work which might perhaps be better carried out in Japan than in most other countries. They are laid before this meeting for the purpose of obtaining an opinion as to how far they may be regarded as legitimate subjects for investigation; and if the members of the meeting will freely criticize them, or suggest other lines of research, a benefit will be conferred upon workers in Japan, and on all who are interested in earth physics.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The Smith's Prizes have been adjudged as follows:—To H. F. Baker, B.A., of St. John's College, for his essay entitled "The Complete System of 148 Concomitants of Three Ternary Quadrics, in terms of which all others are expressible as Rational Integral Algebraic Functions, with an Account of the Present Theory of Three such Forms." To J. H. Michell, B.A., of Trinity College, for his essay entitled "The Vibrations of Curved Rods and Shells." The adjudicators place the two names in alphabetical order, not desiring to assign precedence to one essay over the other. Mr. Baker and Mr. Michell were bracketed Senior Wranglers in 1887.

SCIENTIFIC SERIALS.

Revue d'Anthropologie, troisième série, tome iv., cinquième fasc. (Paris, 1889).—A chart of the colour of the eyes and hair in France, by M. Topinard. The author explains at length the methods he has adopted in elaborating the great mass of materials supplied him by the 2000 collaborators, at home and abroad, who responded to his appeal when, in 1886, at the suggestion of Dr. Beddoe, he undertook to examine the relations between the colour of the hair and the eyes among different peoples. In this chart of the general distribution of the blonde and the brunette types in the several departments of France, the variations between the extremes of these elements are clearly indicated by various shades from white to black. We are thus able at a glance to observe that while France generally admits of being divided into two great zones, the one occupying the north-east and the other the south-west of the French territories, each includes one or more departments in which an opposite type crops up. In most instances this anomaly may be accounted for by the early history of the invasions and foreign settlements to which France was subjected before its various parts were welded together. Thus it appears that the blonde races entered both by land from the Low Countries on the east, and by sea from Belgium, the Franks and Burgundians having invaded the country on one side, while Franks, Saxons, Normans, and Britons advanced on the opposite side. Similarly, men of the brunette type entered France on one hand from the Ligurian coasts of the Mediterranean, and on the other from Iberia. A curious fact is mentioned by M. Topinard—that, while the blonde races followed the left bank of the Rhone valley, the dark races advanced along the Bay of Biscay as far as the Vendée, where the two came into contact, the latter being soon repulsed, and forced to follow the course of the Loire as far as Blois. By a comparison f the various tables it appears that some departments show a predominance of one colour in relation to the eyes, and an opposite one in regard to the hair. There is, however, only one department which can be classed as being blonde in relation to the hair and brunette in regard to the eyes. This, and various other anomalies, presenting great interest from an ethnological point of view, have been considered by M. Topinard with his usual ability, and although he treats only of the relative distribution of colour in the eyes and hair among the French people, his paper is a model for similar investigations, and worthy the gratitude of all ethnological inquirers.—Kashgaria, and the passes of Tian-Shan, by Dr. N. Seeland. In this concluding number of his contributions to our scanty knowledge of this part of Turkestan, the writer describes his visit to the city of Aksou, lying on a plain 3500 feet above the level of the sea, and not far from the River Aksou-Daria.—The Stone Age in Italy, by M. P. Castelfranco. This is a concise, yet comprehensive, description of the human and other osseous remains, and of the various objects found in the Palæolithic stations of Italy in recent years, giving all necessary details concerning the times of discovery, and the character of the several caves and stations where they occurred. As yet there is no evidence of the existence of man in Italy in the Tertiary age; his appearance there being apparently not earlier than the close of the Quaternary, and contemporaneous with *Ursus spelæus*. The period of the Cave-dwellers must, however, have coexisted with certain phases of civilization, since, in Liguria more especially, jade arms are found blended with bone and stone weapons and other implements in the graves of these Italian Troglodytes, whose remains closely resemble those of the Cro Magnon men. Thus far, the finds in Italy, which the author describes at great length, do not admit of being referred with any exactitude to the successive periods of the Palæolithic Age recognized elsewhere. The value of M. Castelfranco's treatise is increased by an appendix of bibliographic notices, which will be found of great use to the English reader.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, October 21.—M. Des Cloizeaux, President, in the chair.—Researches on the relations existing between the physical characters of plants and the proportion of elements of fertility in the soil, by M. G. Ville. The composition of the soil influences colour, size, weight, general aspect, the amount of carotine, and that of chlorophyll. In plants with nitrogen predominating (hemp, wheat, &c.), least carotine is found when a manure without nitrogen has been used; in those with potash predominating (potato, vine), when potash has been suppressed. The variations in chlorophyll correspond to those of carotine. For each plant there is a time when the contrasts of colour reach their maximum. M. Ville shows, in a diagram, how a hemp plant varied with different manures.—Observations of Barnard's comet (September 2, 1888) 1889, I., made with the 0·38 m. equatorial of Bordeaux Observatory, by MM. G. Rayet and Courty, by M. G. Rayet.—On a method of measuring the flexure of a mural circle, independently of the telescope, by M. Périgaud. A rigid rod, the length of the diameter, is attached to the axis, so as to be able to turn round it and be fixed in any position. Divisions traced on it, near the ends, are examined through two microscopes 180°, apart. After one reading, the circle is turned 180°, and a second reading taken.—On the invariants of a linear and homogeneous differential equation, by M. Mittag-Leffler.—On surfaces of which the ds^2 is reducible in several ways to Liouville's form, by M. G. Kœnigs.—On the simultaneous synthesis of water and hydrochloric acid, by MM. P. Hautefeuille and J. Margottet. Mixtures formed by adding chlorine to the gaseous elements of water, or oxygen to the elements of hydrochloric acid, were exposed to the electric spark. If the volume of chlorine is more than half the hydrogen, the ratio of the numbers of equivalents of water and hydrochloric acid formed is always less than unity, and it diminishes rapidly with increase of the chlorine; when it is double the hydrogen, the water ceases to be appreciable. When oxygen is added to the elements of hydrochloric acid, the above ratio is always less than unity, but varies only between narrow limits, in increasing the ratio of volumes of O and H from $\frac{1}{4}$ to 3.—On the existence of sulphate of phosphonium, by M. A. Besson. Dry gaseous phosphoretted hydrogen passed into sulphuric acid kept at 20° to 25° below zero, is largely absorbed, the liquid becoming syrupy. The product is then pretty stable, and may be kept at a few degrees below zero. On decanting, a white very deliquescent crystalline mass is found, which seems to be sulphate of phosphonium. Thrown into water at ordinary temperature, it is decomposed with a crackling noise, liberating phosphoretted hydrogen without reduction of sulphuric acid. The white mass, as it rises to the ordinary temperature, decomposes with reduction of sulphuric acid and oxidation of phosphorus.—On the action of ammoniacal sulphate of copper on sorbite and on mannite (a reply), by M. Guignet.—On the *rôle* of ammonia in the nutrition of the higher plants, by M. A. Müntz. He finds, by experiment with bean, maize, hemp, &c., that such plants can directly absorb ammoniacal nitrogen by their roots; the nitrification of ammonical manures not being indispensable to their utilization.—On the mucous canals of Cyclopterides, by M. F. Guitel. There are three systems of these, two maxillo-opercular (one on each side), and one median, with symmetrical halves. Each half of the latter system (in *Liparis*) has eleven orifices, and each maxillo-opercular system seven, making thirty-six. Full details are given.—New contributions to the geological study of the Lower Alps, by M. W. Kilian. In the Upper Jurassic epoch there seem to have been a series of coralligenous reefs in the position of the mountains of Ubaye; and a shallow part of the Oolitic sea is here indicated. The eastern limit hitherto assigned to the Lower Cretaceous sea should be put back considerably.—On a new way of preparing oxamide and oxamic acid, by M. E. Mathieu-Plessy. Oxalate of ammonium is introduced into fused nitrate of ammonia, and the whole kept four hours between 170° and 175°.—Attempt to produce an iodide of nitrogen photometer, by M. G. Lion. This is based on comparison of the volumes of nitrogen produced in equal times, by the light examined, and by a light standard.—Volumes on the life and works of D'Alembert (Bertrand), and on the flight of birds (Marey), &c., were presented.

BERLIN.

Meteorological Society, October 8.—Dr. Vettin, President, in the chair.—Prof. Assmann spoke of his meteorological experiences on the Sentis (Canton Appenzell). In order to be able to reply to the objections which have been raised in many quarters against his aspiration-thermometer, he submitted this instrument, in the form which it has now assumed, to a testing under the most unfavourable conditions. The instrument ought to record the temperature of the surrounding air alone even when exposed to the most intense solar radiation, and not be in any way affected by the latter. In order to determine whether it conforms to the above requirement or not, he lived for four weeks on the Sentis, and found, as the outcome of several thousand experiments, that the instrument thoroughly acts up to what is required of it, when its form, as originally exhibited to the Society, is modified so that a constant current of air is drawn through the metallic tube which surrounds the thermometer by means of an arrangement of clock-work. This clock-work is attached to the upper end of the tube, and drives a fan with considerable velocity, thus forcing the air out of the tube at the top and drawing it up from the lower portion of the tube; by this means a rapid constant current of air is kept streaming over the bulb of the thermometer. He had previously satisfied himself by direct experiments with hot water that the indications of the thermometer are not in any way affected, even when the temperature of the metal tube which surrounds it is raised to 20° C. above that of the surrounding air. On the Sentis, however, the direct solar radiation never raised the temperature of the metal tube by more than 3° C. The solar radiation, measured by means of a blackened thermometer *in vacuo*, was 33° C., while at the same time the temperature of the air was 3° C. Simultaneously with the speaker's own measurements of temperature on the Sentis, Dr. Siegfeld, in Munich, made similar measurements with a similar instrument in a balloon floating at a height equal to that of the Sentis peak; and further, at the same time, a corresponding set of experiments were carried on in a balloon at Berlin. It is his intention to publish an account of these interesting experiments in some scientific treatise which will appear shortly. Dr. Assmann further described the arrangement of the meteorological station on the Sentis, his testing of the instruments which it contains, and a prolonged series of very interesting observations on thunderstorms, which were of daily occurrence: these storms were remarkable for the suddenness of their development, and the very striking cloud-formations by which they were accompanied, the latter being recorded photographically. One of his most striking experiences was of a fall of hail which lasted for an hour and a half, the hail falling from a cloud which was not more than 350 metres above him. He concluded his address by a very full description of a series of observations on cases of St. Elmo's fire which were characterized by acoustical rather than optical phenomena.—Lieutenant Gross gave a short account of the balloon journey which he made in order to determine, simultaneously with the observations on the Sentis, the temperature of the air in the higher regions above Berlin. The balloon reached an elevation of 3600 metres, at which height the temperature recorded was − 7° C., the temperature at the earth's surface being at the same time + 25° C.—Dr. von Dankelmann exhibited a series of curves of temperature and air-pressure which had been registered in Cameroon by means of self-recording instruments.

Diary of Societies.

LONDON.

FRIDAY, NOVEMBER 1.

PHYSICAL SOCIETY, at 5.—On Electrifications due to the Contact of Gases with Liquids: J. Enright.—On a New Electric Radiation Meter: W. G. Gregory.—On a Physical Basis for the Theory of Errors: Dr. C. V. Burton.

GEOLOGISTS' ASSOCIATION, at 8.—On Metal Mining: Upfield Green.

SATURDAY, NOVEMBER 2.

ESSEX FIELD CLUB, at 7.—Exhibition and Remarks thereon.—Delegate's Report of the British Association Conference of Local Societies at Newcastle-on-Tyne: William White.—On Collecting Diptera; with Remarks on the Diptera of Epping Forest: E. Brunetti.—Notes on the Pleistocene Deposits at Felstead, Essex: J. French.

MONDAY, NOVEMBER 4.

ROYAL INSTITUTION, at 5.—General Monthly Meeting.

TUESDAY, NOVEMBER 5.

ZOOLOGICAL SOCIETY, at 8.30.—On New Indian Lepidoptera, chiefly Heterocera: Colonel C. Swinhoe.—On the Genus Urothoë and a New Genus Urothoides: Rev. Thomas R. R. Stebbing.—List of Birds collected by Mr. Ramage in St. Lucia, West Indies: P. L. Sclater.—On the Relations of the Fat-bodies of the Sauropsida: G. W. Butler.

UNIVERSITY COLLEGE BIOLOGICAL SOCIETY, at 5.—The Defence of Plants against Animals: F. Ernest Weiss.

WEDNESDAY, NOVEMBER 6.

GEOLOGICAL SOCIETY, at 8.—Contributions to our Knowledge of the Dinosaurs of the Wealden, and the Sauropterygians of the Purbeck and the Oxford Clay: R. Lydekker.—Notes on a "Dumb Fault" or "Wash-out" found in the Pleasley and Teversall Collieries, Derbyshire: J. C. B. Hendy. Communicated by the President.—On some Palæozoic Ostracoda from North America, Wales, and Ireland: Prof. T. Rupert Jones, F.R.S.

ENTOMOLOGICAL SOCIETY, at 7.—Notes on the Entomology of Iceland: Rev. Dr. Walker.—Additional Notes on the Genus Hilipus: Francis P. Pascoe.

UNIVERSITY COLLEGE CHEMICAL AND PHYSICAL SOCIETY, at 4.30.—The Nature of Electricity: Dr. A. H. Fison.

THURSDAY, NOVEMBER 7.

LINNEAN SOCIETY, at 8.—On a Collection of Dried Plants chiefly from the Southern Shan States, Upper Burma: Colonel H. Collett and W. Botting Hemsley, F.R.S.

CHEMICAL SOCIETY, at 8.—The Isolation of a New Hydrate of Sulphuric Acid existing in Solution: S. U. Pickering.—Further Observations on the Magnetic Rotation of Nitric Acid, of Hydrogen Chloride, Bromide and Iodide in Solution: Dr. W. H. Perkin, F.R.S.—On Phosphoryl Trifluoride: T. E. Thorpe, F.R.S., and F. T. Hambly.—On the Acetylation of Cellulose: C. F. Cross and E. Bevan.—On the Action of Light on Moist Oxygen: A. Richardson.—Anhydracetophenonebenzil and the Constitution of Linius lepideus: Drs. Japp, F.R.S., and Klingsman.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

The Viking Age, 2 Vols.: P. B. du Chaillu (Murray).—Alternative Elementary Chemistry, 2nd edition: J. Mills (Low).—Charts of the Constellations: A. Cottam (Stanford).—The Birds of Oxfordshire: O. V. Aplin (Oxford, Clarendon Press).—Topics in Geography: W. F. Nichols (Boston, Heath).—An Introduction to Chemical Science: R. P. Williams and B. P. Lascelles (Ginn).—Five Months' Fine Weather in Canada, &c.: Mrs. Carbutt (Low).—Survey of India Department Report, 1887–88 (Calcutta).—Science of Every-day Life: J. A. Bower (Cassell).—The Teacher's Manual of Geography: J. W. Redway (Boston, Heath).—Elementary Physics: M. R. Wright (Longmans).—Experimental Science: G. M. Hopkins (Spon).—Special and Atomic Energy, 2 parts: F. Major (Eyre and Spottiswoode).—Introductory Lessons on Quantitative Analysis: J. Mills and B. North (Chapman and Hall).—Elements of Physiology: J. H. E. Brock (Chapman and Hall).—Solutions to the Questions set at the May Examinations of the Science and Art Department, 1881–86, Machine Construction: H. Adams (Chapman and Hall).
