breaches of continuity,¹ or may remain continuous. According to Mönckeberg and Bethe, the changes occur first near the lesion, and gradually extend towards the periphery, the rate of progress varying in different fibres, *e.g.*, proceeding more rapidly in sensory than in motor fibres.² Eventually, almost all the myelin, as well as the broken-down axis cylinder, disappears, and the nerve is only represented by its connective tissue sheaths and the tubes of neurolemma, which are occupied by a granular multinucleated protoplasm. Within these tubes fine fibres may become developed,³ but whether these are of a nervous nature cannot be stated; they cannot function as nerves, for they are not in continuity with any other nerves or nerve cells. Regeneration only occurs by an outgrowth from the central end of the cut nerve fibres. Each of these appears ultimately to throw out several root-like sprouts, which, unless they become entangled in cicatricial tissue, tend to grow down along the sheaths of the degenerated peripheral nerve fibres, and thus eventually to find their way to the periphery. Probably only one of the sprouts ultimately carries on the functions of the fibre, and the others disappear. The new fibres become surrounded early by a thin medullary sheath, which gradually becomes thicker, and a neurolemma also ultimately becomes developed around them. Under the most favourable circumstances, the new nerve fibres take from one to two months to become sufficiently regenerated to perform their function, and cases in which a rapid recovery of function has been reported to succeed nerve section, must be explicable either by a duplicate source of innervation (this may especially be the case with sensory nerves) or by the section having been incomplete. If the observation of v. Gehuchten and Nélis upon the disappearance of the sensory nerve cells of the vagal ganglion, after section of their peripheral fibres, is correct, and is a phenomenon of general occurrence, it is difficult to see how the sensory fibres in a cut nerve ever become regenerated. Restoration of function in such cases may perhaps often be explained by an ingrowth of sensory nerve fibres from adjacent areas of distribution. Other observers have, however, not hitherto confirmed these statements so far as the spinal root ganglia are concerned; indeed, the cells of these ganglia are stated to show rather less change after section of their nerves than do the anterior horn cells of the spinal cord.

No clear evidence has been obtained in mammals of regeneration of nerve fibres within the nerve centres, after artificially produced lesions.⁴ *A priori*, one would expect such regeneration to occur, and certain observations seem to indicate a commencement of regeneration,⁵ but it is never completed. Probably the cicatricial tissue offers an insuperable obstacle to the growth of the sprouting fibres. Some regeneration of severed posterior root-fibres may occur,⁶ but it does not appear to extend into the posterior column of the spinal cord. Sherrington⁷ found in the central stump fine medullated fibres, resembling those

of regenerating nerve, even after the posterior root ganglion had been removed.

It is a remarkable but unexplained fact, that the regenerating fibres which are growing along the old nerve sheaths find their way eventually to the same structures (muscles, skin, blood vessels) that they were distributed to before section and degeneration had occurred. In this connection, Langley's observations upon the regeneration of the cut cervical sympathetic of the cat¹ may be noticed. These show that the nerve fibres in that nerve, which are of very different functional distribution, some carrying impulses to the dilator pupillæ, others to blood vessels, others to hair muscles, others to secretory cells, nevertheless, after section and regeneration, are found to effect connection with the same cells in the superior cervical ganglion as before; *e.g.*, the fibres in the first thoracic anterior root still give, on stimulation after regeneration, dilatation of the pupil and movement of the membrana nictitans; those in the third thoracic root still mainly produce contraction of ear vessels, and so on. Even more striking are the experiments of the same observer upon the results of joining the central cut end of the vagus to the peripheral cut end of the cervical sympathetic. These show that the vagus fibres, when regenerating under these circumstances, make connections with the cells of the superior cervical ganglion of the sympathetic, so that all the effects of stimulating the cervical sympathetic can now be produced through the vagus.

It is not difficult to understand why the part of the nerve fibre which is cut off from the nucleated body of the parent cell, should undergo degeneration, for this is a phenomenon which is exhibited by all cells; the nucleus being essential for the maintenance of nutrition of all parts of the cell. But it is much more difficult to comprehend the occurrence, under these circumstances, of the changes which have been described under the name of chromatolysis, and the degeneration which follows those changes in the case of certain cells. Actual degeneration does not extend along the axis cylinder backwards for any great distance; the greater part of the central end of the nerve fibre remains to all appearance unaltered. Nor can the chromatolysis be alone due to arrest of function of the nerve cells, since, although this might be alleged for the sensory cells, which no longer receive the usual nervous impulses from the periphery, the same cannot be admitted for the motor cells, which must receive impulses by reflex and voluntary paths as before. Perhaps the explanation is to be found in the fact that, in the first instance, the section of the nerve and the chemical and electrical changes thereby set up, and, secondly, the inflammatory and cicatricial changes in the wound, maintain a constant excitation of the cut ends of the nerve fibres, and thus keep the cells in continual activity. The changes produced (chromatolysis and swelling of the cells) are, in fact, changes which accompany activity, and they can be also brought about by the production of local inflammation, and by the application of a chemical stimulus (salt) to nerve-endings, as well as by the section of the nerve. This would not suffice to explain the difference which has been described by v. Gehuchten between the ultimate behaviour of motor and sensory nerve cells, the former of which undergo, after about fifteen days, a gradual process of reparation; whereas the latter, at least those of the vagus ganglion, fail to become repaired, but, on the contrary, are eventually completely degenerated. This may, however, well be due to

¹ *Journ. Physiol.*, Cambridge and London, 1892, vol. xiii.; and 1895, vol. xviii. p. 280. See also this volume, article "Sympathetic," p. 691.

the *prolonged cessation of function* of the sensory cells, since, after the irritation produced by the severance of the nerve and cicatrisation of the wound had passed off, they would be receiving no nervous impulses, and would then tend to obey the general law, that atrophy results from loss of function. The motor cells, on the other hand, would still be receiving reflex and possibly also voluntary impulses, and their activity would thus be maintained until the cut nerve fibres were regenerated. In the event of these failing to become regenerated—as in the case of an amputated limb—the motor nerve cells also become atrophied.¹

Various other conditions besides those above noticed may determine chromatolysis in nerve cells, *e.g.*, certain drugs, such as acetate of lead,² arsenic,³ bromine, antipyrin, cocain,⁴ strychnin;³ intoxicants such as alcohol in large doses,⁵ and malonic nitrite⁶ (which can be antagonised by hypo-sulphite of soda); poisoning by disease-toxins, *e.g.*, the toxins of rabies and tetanus³ (which can be antagonised by the corresponding antitoxins);⁷ acute local anæmia (as by compressing the aorta),⁸ and a rise of body temperature experimentally induced.⁹

Whether the nucleated cell body plays any part in the starting of nerve impulses, or in their modification, or has any other function than that of regulating the nutrition of the nerve cell and its processes, is a matter not easy to decide. Bethe (cited on p. 597, note 3) found (in the crab) that the cell bodies are not essential to the performance of reflex actions. In the case of the fibres of the posterior roots of mammals and most vertebrates, there is no necessity for the nervous impulses to go through the nerve cell at all, nor is their passage appreciably delayed in traversing the ganglion.¹⁰ It would, however, be of interest to

¹ Warrington (*Journ. Physiol.*, Cambridge and London, 1898, vol. xxiii. p. 112) has found chromatolysis to occur a certain time after section of posterior roots in the motor cells of the anterior horn of the same side (chiefly of the postero-lateral group), and in a few cells on the other side of the cord. He ascribes this result to the loss of afferent impulses which normally impinge upon those cells. After section of an anterior root, nearly all the cells of the corresponding segment of the cord show some sort of change of the same kind.

¹⁰ This statement, due originally to Exner (*Arch. f. Physiol.*, Leipzig, 1897, S. 567) has been confirmed as the result of a series of experiments upon the posterior roots of the frog, which were performed at my request by B. Moore and H. W. Reynolds ("Internat. Cong. Physiol.," Aug. 1898, *Journ. Physiol.*, Cambridge and London, 1898, vol. xxiii. Suppl., p. 56). They were careful to insure that the nervous impulses took the same path through the cord to produce the excitation of the muscle, which was to serve as the signal, both when the root was stimulated between the cord and the ganglion, and when the nerve was stimulated beyond the ganglion, by cutting all the root bundles of the nerve employed except one. A contrary result, namely, a delay of some 0.02 second in traversing the ganglion, which was got by Wundt, was probably due to the fact that, on account of the method which he employed, the nervous impulses in the two cases did not take exactly

ascertain whether there is any delay in cases where the nerve impulse is *compelled* to pass through the body of the nerve cell, as it must do, for example, in bipolar cells; this is a point which has yet to be determined.

The only chemical change which has been noticed in the bodies of nerve cells, as the result of activity, is a change in the direction of acidity, due apparently to the formation of lactic acid, as in muscle. That the fatigue products of the nerve centres and of muscles are similar, is shown, first, by the fact that the muscles may give evident signs of fatigue, merely as the result of prolonged nervous (mental) activity;¹ and, secondly, by the evident fact that muscular fatigue is detrimental to nervous (intellectual) activity in general, and not only to the particular parts of the central nervous system which come into action during the muscular effort. In nerve fibres the only change which is apparent as the result of excitation is the change of electric potential which accompanies the passage of the nervous impulse. It might be expected that when the nerve centres are set in activity, the cells in which the impulses are started would also exhibit changes of potential. But, probable as this is, the demonstration of the fact is beset with serious difficulties; and, in spite of attempts which have from time to time been made to overcome these difficulties, our knowledge on this subject has remained in a very fragmentary and indecisive condition.²

The question whether the "sense of effort," which is closely associated with the "sense of fatigue," is due to changes originating in the nerve cells, or to sensory impressions passing to the nerve centres from the contracting muscles, has been much debated.³ The probability is, that its origin is from both sources, and that the effects are accentuated, with the supervention of fatigue, by the accumulation of waste products of both nervous and muscular metabolism in the circulatory fluid.

Conduction within and between nerve cells.—It was conjectured by Golgi that the dendrons of a nerve cell were not for the conduction of nerve impulses, but might merely serve the purpose of rootlets, and thus aid to obtain pabulum for the nutrition of the cell. This conjecture has, however, been abandoned, since it has been discovered that in many cases nervous impulses, in passing along a nerve cell, must of necessity traverse one or more dendrons as well as the axon. Granting, however, that both dendrons and axons serve as nerve conductors, the question suggests itself, Is there any specific difference in the manner or direction by which the two kinds of processes conduct impulses?

van Gehuchten⁴ and Ramón y Cajal⁵ have attempted to lay down, as a general law of conduction in the nerve cell, the proposition that all nervous impulses within the cell are axipetal, that is, that they all pass

the same path through the cord to produce the reflex movement which was used as a measure of the relative time occupied.

towards the attachment of the axis cylinder and leave the cell by that process. In other words, that the direction of conduction in the dendrons is centripetal, in the axon centrifugal; this has been termed the "law of axipetal conduction." This is included in the more general statement by W. James,¹ that nerve impulses take always a particular direction in the nervous system, and never naturally the reverse direction ("law of forward direction"): that there is, in short, a kind of valved action which permits passage of impulses in one direction only.

The law of axipetal conduction is no doubt true for many cells, but it will not hold good for the typical sensory cell. This, in its simplest

FIG. 306.—Diagram to illustrate the "law of axipetal conduction" in motor nerve cells. A, axis cylinder process; B, nucleus; a, fibrils of cell body; b, c, e, Nissel bodies; d, fibrils of dendron. The arrows indicate the direction of nerve impulses.—Cajal.

FIG. 307.—Diagram to illustrate supposed lines of conduction in a spinal ganglion cell.—a, body of cell; b, its axis cylinder process; c, fibre of posterior root; d, peripheral fibre; e, termination of axis cylinder of another cell (?sympathetic); m, ramifications of nerve fibres in spinal cord; p, ramifications at sensory surface.—Cajal.

and original form, is a bipolar cell with two axons and no dendrons, and the nervous impulses produced at the periphery pass towards the cell by one axon, and away from it by the other. The contention that the peripheral process, although possessing all the characters of an axon, must be considered a dendron, because it conducts centrifugally, merely begs the question.

Although nothing whatever has been ascertained regarding the nature of the change which is set up in the nerve element, and which travels along it as what is called the nervous impulse, it is clear, from an examination of the electrical change which accompanies its

passage along a nerve, that it passes in the form of a wave, rising at any point of its course to a certain intensity, and gradually falling from this crest to a point at or even slightly below the normal. It would further appear, from observations conducted by the same method upon the nerve centres, that if the body of the cell is stimulated by a prolonged or intense stimulus, the nervous impulses which are discharged tend, even if the stimulus be uninterrupted, to become discontinuous; in other words, to exhibit a rhythm of a more or less regular character. Such rhythm can be also investigated by the effect it produces upon the muscles which are connected with the nerve elements in activity. Tracings of muscular contraction, or of the changes in electrical potential which accompany the contraction, exhibit a curve with waves corre-

¹ "Principles of Psychology," 1890, vol. ii.

sponding to the rhythm at which the nervous impulses have passed along. By both these methods it appears that such nerve cells as those of the motor region of the cerebral cortex, and the motor cells of the anterior horn of the spinal cord, tend, whether stimulated either directly or indirectly (*e.g.*, reflexly), to respond by discharging nervous impulses at the rate of about ten or twelve per second, unless the stimulation be at a less rate than this, in which case the response is at the same rate as the stimulation. Under some circumstances, however, the rate of rhythmic discharge may be more rapid than ten or twelve per second, or it may be as slow as five per second, the muscular response in the latter case being of a clonic character. What it is which determines this difference in different cases and under different conditions, is not at present known; in discussing the manner in which the nervous impulses pass from one cell to another, we shall have occasion again to refer to it.

We have so far confined our attention almost entirely to the changes which occur within the limits of a single nerve cell; we have next to inquire how these changes may be propagated from one nerve cell to another.

The introduction of the method of Golgi, and especially its employment by Cajal, dealt a severe blow to the then prevalent hypothesis, that the propagation of nervous impulses from cell to cell took place through a continuity of their dendrons, which were thought to be united in a network which everywhere pervaded the grey matter (J. Gerlach). At the same time, it exhibited an explanation by which this hypothesis could be replaced, since it showed that although there may be no continuity of processes of nerve cells, there undoubtedly is close contiguity or even actual contact. This is sometimes effected by the embracing of the body of one cell by the ramifications of the axon of another,¹ sometimes by the interlocking of the dendrons of one cell with the dendrons or with the ramified axon of another, or even of more than one other cell. It is convenient to have a short term by which to speak of the union of one nerve cell with another by this close contiguity of processes with cell body or of processes with processes, presumably without actual continuity of substance. Foster² has employed the term "synapse"³ to denote such conjunction, an expression which may provisionally be adopted.

It has been conjectured that the extent of contact of the adjacent nerve cells at the synapses may vary from time to time, such variations being brought about by a contraction or expansion of the ramified processes by which the contact is effected, analogous to the amoeboid movements of protoplasm in general; and, further, that the effects of drugs in diminishing or increasing the resistance of the nerve centres to the passage of nervous impulses might be produced in

¹ W. A. Turner and W. Hunter (*Brain*, London, 1899, vol. xxii. p. 123) have described a *network* covering the cell body of nerve cells in the grey matter of the central nervous system, which they regard as the terminal apparatus of the axis cylinder processes of other nerve cells. A basket-like ending, extending over both cell body and dendrons, was described by Semi Meyer (*Ber. d. k. sächs. Gesellsch. d. Wissensch., math.-phys. Cl.*, Leipzig, 1897, S. 475), who came to the same conclusion; Martinotti, *Ann. di freniat.*, Torino, 1897, p. 253; and Golgi, *Boll. d. Soc. med.-chir. di Pavia*, Milano, April 19, 1898. Cf. also Held, who describes a concrescence of the axon of one nerve cell with the body or dendron of another cell, *Arch. f. Anat. u. Entwicklungsgesch.*, Leipzig, 1891, 1893, and 1897.

² "Text-book of Physiology," 1897, vol. iii. p. 929.

³ From *σύν* and *ἄνω* clasp.

a similar way.¹ This conjecture opens up a wide field of speculation, since it is possible to extend it so as to embrace the explanation of many physiological and psychical conditions.² Such speculations, however, unless they have been tested experimentally, do not lie within the scope of this work. No one has been able to see any amœboid movement in the nerve cells of vertebrates, and the only direct evidence of such movement in nerve cells, that we have any knowledge of, has been furnished by Wiedersheim,³ who observed slow changes of form to occur in ganglion cells of the central nervous system of a minute crustacean. It is true that various observers have described in Golgi preparations, appearances in the processes of nerve cells after excitation, or after the action of anæsthetics and other drugs, which they interpret as indicating a withdrawal or retraction of the finer processes. But it cannot yet be accepted as proved that the changes which are described are invariable concomitants of alterations in the functional condition of the cells, still less that they are the cause of the functional conditions.⁴

Every nervous path is formed of a chain of nerve cells. The chain of the simplest reflex process may be conceived as composed of only two cells, the sensory and the motor, or afferent and efferent, root-cells, and in such a chain there would be only one place of adjunction, where the central process of the sensory cell comes in contact with the dendrons or the cell body of the motor cell. On the other hand, a path which includes any of the higher nerve centres or any complex nerve processes, must have a chain of several cells, with a synapse at the place of contact between each two links in the chain. There is reason to believe that the additional delay ("lost time"), which is characteristic of the passage of nervous impulses through the nerve centres, is due to a block at each synapse; that, in fact, the nervous impulses are momentarily arrested at these places of contact of the nerve-cells with one another. And it is not improbable that the relative number of these blocks will furnish a key to the differences which are found to obtain in the reaction time for different reflexes and psychical processes.⁵ The differences of reaction time are too great to be accounted for simply by the fact that the nervous impulses are sent along paths of different

¹ It appears certain that nicotin, in blocking the passage of nervous impulses along a nerve path, acts upon the synapses (Langley).

² The production of both natural and hypnotic sleep has been supposed to be due to retraction of processes of the nerve cell, leading to a partial separation of the synapses between some cells (Lépine, *Compt. rend. Soc. de biol.*, Paris, 1895; Duval, *ibid.*, 1895; and "L'amœboidisme du système nerveux," *Rev. scient.*, Paris, 1898); Rahl-Ruckhard, *Neurol. Centralbl.*, Leipzig, 1890, Bd. ix. S. 199). Lugaro (*Riv. di patol. nerv.*, Firenze, 1898), on the other hand, considers that the condition of sleep is concomitant with a general diffusion or protraction of nerve cell processes, and the state of attention with retraction of some of the processes and gemmules, so that the paths of conduction for nerve impulses are thereby narrowed, and the impulse waves become intensified.

⁵ The relative strength of the blocks in different individuals may also be the physical cause of the individual differences in reaction time for the same stimulus. As is well known, these differences gave rise amongst astronomers to the term "personal equation" being applied to the difference in noting the time of an observation which is found to obtain, with a considerable degree of constancy, between any two observers.

length in the various cases; it is more than probable that they pass through an increasing number of nerve units (*i.e.* nerve cells), according to the increased complexity of the psychical process involved. And this, according to the theory of isolated units (neurone theory), would mean the passage across as many synapses, which are probably the parts of the nerve chain where relative blocks occur.

If we assume (and the assumption is not a very improbable one) that in the same individual, under the same conditions, the lost time of block at each synapse is about the same, we can arrive at a general idea of the relative number of synapses which are passed; in other words, the number of nerve cells in a chain called into action in various psychical processes.

A careful study of the differences in reaction time, and of other examples of "lost time," in the passage through nerve centres, may help us to form a conception of the amount of delay which each synapse is responsible for. We may therefore advantageously consider some of the facts which have been accumulated upon this point.

The reduced reflex time which occurs in the lower part of the frog's spinal cord, when a reflex contraction of the homonymous gastrocnemius is produced by stimulation of a posterior root, has been determined by Wundt,¹ who found the minimal amount to be only 0·008 second.² For a crossed reflex the delay over and above this was only about 0·004 second, and the same for a reflex movement of the other limb on the side stimulated. If we assume that for the crossed reflex only one additional nerve cell is interpolated, we obtain 0·004 second as the lost time of the synapse; whereas, if two additional cells are assumed to be interpolated, the lost time at each synapse would be only 0·002 second. Since the reflex has a lost time of 0·008 second, at least two, and perhaps four, synapses are involved in the path of the most simple reflex through the nerve centre.

The reduced reflex time³ of the closure of the eyelid on excitation of the skin of the lid, was found by Exner to be as much as 0·047 second.⁴

It would appear probable, therefore, that the time occupied by any simple reflex act is far too long to be produced merely by the passage of the nervous impulses across a single set of synapses (*e.g.* between the sensory and the motor cells), but we must assume a far greater complexity of arrangement, and the intermediation of several intercalated cells.

The great difference between the time taken in the eyelid reflex and that produced by stimulation of a posterior root, may be due to the fact that there is a choice of paths for afferent impulses; that under ordinary circumstances of natural excitation of the nerve-endings in the skin, the nervous impulses take a course tending to produce co-ordinate movements and involving a chain of several nerve cells, but that in the abnormal conditions of direct and more severe excitation of the nerve fibres, the impulses take the shortest possible course, and call into play a less complex nervous mechanism.

It was found by Exner⁵ that the total lost time between the excitation of

¹ "Untersuch. z. Mechanik d. Nerven u. Nervencentren," Stuttgart, 1876, Abth. 2.

² Gotch found the reduced reflex for the electrical discharge in *Malapterurus* to be also 0·008 second (see this volume, p. 589).

³ *I.e.* the time obtained after deducting from the total time of the response—(1) That occupied in the passage of the sensory and motor nervous impulses from and to the eyelid; and (2) that occupied by the period of latent stimulation of the orbicularis palpebrarum.

⁴ *Arch. f. d. ges. Physiol.*, Bonn, 1874, Bd. viii. S. 526.

⁵ "Exper. Untersuch., etc.," *Arch. f. d. ges. Physiol.*, Bonn, Bd. viii. S. 532.

the frog's cerebral hemisphere and the response of the leg muscles is 0.05 second.¹ Langendorff and Krawsoff² further found a difference of about 0.02 second between the lost time obtained on stimulating the cerebrum and that obtained on stimulating the cut surface of the medulla oblongata. This, therefore, represents in the frog the lost time of the cerebral cortex itself. Almost the same figure (0.015 second to 0.02 second) was obtained for the cortex of the dog by François-Franck and Pitres,³ Bubnoff and Heidenhain,⁴ and by Novi and Grandis.⁵ Wilson⁶ gives a closely corresponding result for the latency of the optic lobes of the frog.

The time of response (reaction time) by a voluntary movement (usually of the hand) to a stimulus applied to one of the sense organs, varies, as has been said, with different individuals and in the same individual according to his physiological condition at the time. There

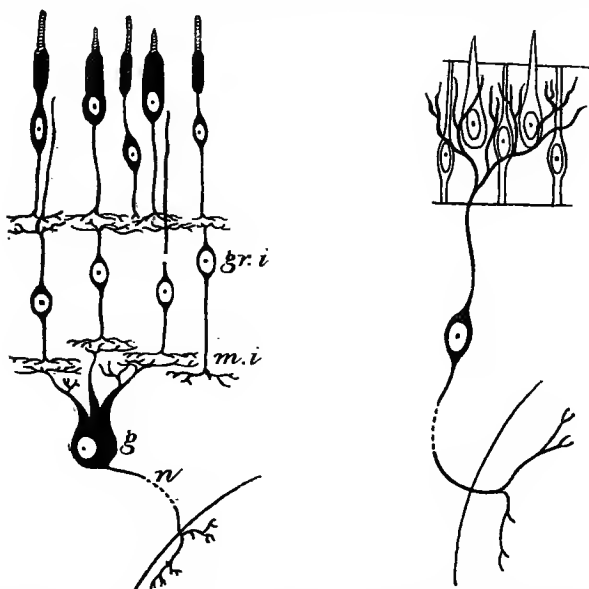

FIG. 308.—Diagram to show the relative number of the synapses in the visual and auditory organs.—G. Retzius.

is, further, a notable difference between the reaction times for different sense organs stimulated in the natural way. This is shown by the following figures from Richet,⁷ which represent the mean results arrived at by various authors:—

Source of Excitation.	Reaction Times.
Sudden sound	0.150 second.
Electric flash	0.195 "
Touch on skin	0.145 "

¹ Similar results have been got in the dog by Franck and Pitres (François-Franck, "Leçons," 1887) and others, and in the monkey by myself (*Internat. Monatschr. f. Anat. u. Physiol.*, Leipzig, 1888, Bd. v.).

⁷ "Dictionnaire de physiologie," Paris, tome iii. p. 19.

Even with the same sense differences are observed, for it has been noted that the response to an electrical stimulus of the skin of the forehead may demand a longer time than an electrical stimulus of the hand;¹ hence, probably, the difference of acuteness of perception of the different terminal organs influences the result.

In the case of the eye and ear, the length of path being approximately the same, the reaction times might have been expected to be equal, whereas this is far from being the case. It is a significant fact that there are a larger number of synapses in the nerve chain along which nervous impulses, started by the falling of light upon the retina, pass to reach the sensorium, than is the case with the auditory path, for in the retina alone there are at least two synapses, namely, between the cone-fibres and the inner granules, and between the inner granules and the ganglion cells, whereas in the cochlea there are no synapses, these being first met with in the part of the auditory path which lies in the medulla oblongata (Fig. 308).

Another explanation which has been put forward regarding the length of the optical reaction time, depends upon the hypothesis that the peripheral excitation of the nerve fibres is of the nature of a chemical change, as contrasted with the mechanical excitation of auditory and tactile nerve fibres. This, if true, may account for a part of the delay, but can hardly be responsible for the whole, since it is not likely to be longer (nor even so long) in the case of the retinal elements as in muscle, where it is certainly not more than 0.0025 second (see article on "Muscle" in this volume, p. 169).

The reaction time is dependent upon many conditions, and is therefore extremely variable. The following are the most important sources of variation:—

1. *The temperament of the individual.*—Contrary to what might perhaps have been expected, individuals of a phlegmatic temperament have, as a rule, a shorter reaction time than those of a mercurial temperament—probably because they are less liable to have their attention distracted from the act which they are performing.

2. *Age.*—In old age the reaction time becomes slow.

3. *Practice and attention.*—These tend up to a certain point to diminish the time.

4. *Fatigue,* on the other hand, tends to increase it.

5. *Intensity of stimulus.*—The reaction time is shortened by increasing the intensity up to a certain point; this shortening may be very marked.

6. *Season.*—The reaction time is shorter in winter than in summer.

7. *Drugs.*—Alcohol and morphia increase, coffee diminishes it. It is further affected by various other drugs. It also varies in disease.

The total reaction time is of course compounded of several factors. There is—(1) The time of propagation of the stimulus to the terminal nerve apparatus (which may be practically disregarded as far as most sensations are concerned); (2) the latency (inertia) of the terminal or recipient apparatus; (3) the time occupied by the passage of the nerve impulses to and within the lower centres; (4) the transmission from these to the higher centres (sensory and association centres) and that occupied by changes taking place in the nerve cells here; (5) the transmission to and within the motor cerebral centres; (6) the passage of the volitional impulses herein generated to the nerve cells of the spinal cord; (7) the generation of fresh nerve impulses in these cells; (8) their passage

¹ Kries and Auerbach, *Arch. f. Physiol.*, Leipzig, 1877; Hall and Kries, *ibid.*, 1879, Suppl., S. 1; Vintschgau, *Arch. f. d. ges. Physiol.*, Bonn, 1880, Bd. xxii. S. 87.

down the motor nerves to the voluntary muscle employed for giving the signal; and, lastly, (9) there is the period of latency of this muscle.

Attempts have been made to estimate the reaction time in the higher centres, or, in other words, the time taken by the processes (perception, apperception, and volition) going on in the nerve cells of the cerebral cortex, by making allowance for each and all the other processes, and subtracting the sum from the gross reaction time. The resultant would be the time occupied by a psychical act of the simplest kind, and has been termed "reduced reaction time"; but, considering that many of the above factors are not ascertainable with any degree of accuracy, it is obvious that the mode of its estimation renders the number obtained (0.08 second is given by Exner for a special case) of very little value. A better result might be got by ascertaining the time occupied in performing a movement as a simple reflex, and subtracting this from the gross reaction time performed as a voluntary act in response to a stimulus; it would still be necessary, however, to make an allowance for the time of transmission between the lower and higher level centres. Nevertheless, for want of anything more accurate, we may provisionally accept 0.08 second as the time taken up by a voluntary reaction, *i.e.* for the block occurring in transmission between the nerve cells of the brain.

If the psychical process be rendered somewhat more complex than is needed for the performance of a simple voluntary reaction, by the presentation of a dilemma,—*e.g.*, as when the person experimented upon is required to react only when the skin is stimulated at one of two places, or when one of two sounds is heard or pictures seen,—the reaction time is found to be lengthened by from 0.03 to 0.14 second.¹ Or if there is not only the simple dilemma, but also a choice between two modes of response to the signal, it may become lengthened by as much as 0.184 second, according to Wundt (but other observers have not obtained so marked an increase).² Or there may be a choice not between two but between several modes of stimulation; and this, according to the complexity of the psychical process involved, still further lengthens the reaction time.³ But the differences observed with different individuals become much more marked as the complexity of the psychical process is increased.

A modification of the ordinary reaction time experiment was employed by Donders, to determine the extra time involved in deciding the path which a voluntary impulse shall take, the person experimented on being stimulated upon one foot, and being called upon to react with the hand of the same side, or to react to a vowel sound by repeating the same sound. The extra time involved over and above the ordinary reaction time for the simple psychical process involved was found in such a case to be about 0.036 second; this has sometimes been termed the "volitional" time.⁴ The introduction of the simplest possible arithmetical process, such as the response to a number

¹ Donders, *Arch. f. Anat., Physiol. u. wissenschaft. Med.*, 1868; Wundt, "Elements of Physiological Psychology," vol. ii. Sometimes termed "discrimination time."

² *E.g.* Cattell, *Mind*, London, 1886, vol. xi.

³ The literature of this subject is given at some length by Richet, "Dictionnaire de physiologie," tome ii. pp. 34 to 36.

⁴ Cattell found that, although the reaction time is shortened by an increase in the intensity of the stimulus, the volitional time is not affected (*Brain*, London, 1885, vol. viii. p. 512).

not by the same number but by a certain small multiple of it, has been found to produce a further delay of about 0.075 second, and so on.

Another question which may be here briefly considered, is, whether the nervous impulses are actually passed on from one cell to the other at the synapses, or whether new impulses are set up in the second cell, as a result of a stimulation received from the first one. The only facts which we have to guide us here are furnished by observations of the following character:—One of the limb muscles of an animal (dog, monkey) is connected with a myograph, and the part of the cerebral cortex being first found, excitation of which produces contraction of the muscle, the grey matter of that part of the cortex is removed, and the electrodes are placed on the subjacent corona radiata. If now the fibres of this, containing of course the fibres of the pyramidal tract derived from the cells which have been removed, are stimulated by a rapidly interrupted faradic current (50 per second), the muscle curve shows an incomplete tetanus, with waves of about 10 or 12 per second.¹ Now, since nervous impulses are being generated in the fibres of the pyramidal tract at the rate of 50 per second, if they passed unaltered to the cells from which the nerves to the muscle employed take origin, the muscle should respond by a complete tetanus, as it would do if the motor nerve itself were stimulated at this rate; it is therefore clear that a new rate of rhythm has been started in the motor cells of the anterior horn, and it is probable that fresh nervous impulses are set up within them.² In such a case as this, we may conceive the stimulus which provokes the nerve impulses in the second nerve cell to be the change of electrical potential (action-current) which accompanies the nervous impulses in the fibres artificially stimulated. But whatever the nature of the stimulus, if we assume that for each nerve cell there is, as with other protoplasmic structures, a period of latent excitation, the block which occurs at each synapse would thereby be accounted for.

It would appear that, while the synaptic mechanism produces only a delay in the passage of nerve impulses which are travelling in the direction which they normally take, it forms a complete block to passage of impulses in the reverse direction ("valve" action). Thus when, after the posterior roots are cut, the mixed nerve is stimulated, no effect whatever is produced upon the spinal cord. This is in marked contrast to the effects got when the anterior roots are cut and the posterior left intact; for stimulation of the mixed nerve under these conditions produces, of course, very pronounced reflex effects. When, under the same conditions (anterior roots cut, posterior intact), the spinal cord is stimulated and the mixed nerve led off to the galvanometer, a decided effect is obtained.³ In the latter case, the course of the nerve impulses is of course the reverse of normal, but since there is no synapse between the peripheral sensory nerves and the fibres which pass up the posterior

¹ Horsley and Schäfer, *Journ. Physiol.*, Cambridge and London, vol. vii.

² The same thing is seen when a movement is produced reflexly by excitation of a sensory nerve or of the skin. The excitation may be very rapid, or it may be continuous, but it is responded to by the muscles with a relatively slow rhythm of contraction. This rhythm must in all probability be set up in the motor nerve cell, unless we are to assume that it is due to a tendency of the muscle itself to contract with this rhythm. It does not do so if its nerve be directly stimulated at a rapid rate, although, if very excitable, it may respond to a continuous electrical stimulation with a prolonged contraction which simulates an irregular tetanus.

³ Gotch and Horsley, *Phil. Trans.*, London, 1891, vol. clxxxii. B, p. 267.

column of the cord, no block is met with, and the nerve impulses can pass freely in either direction.

Refractory period of nerve cells.—When two successive stimulations are applied to the same sensory nerve cell, nerve fibre, or nerve termination, they are only appreciated as two, if a certain small interval of time has elapsed between their application; in other words, the nerve substance only responds to a second stimulus after a certain interval has elapsed since the removal of the first. This is a general phenomenon of living substance, and is quite similar in character to the refractory period of cardiac and of skeletal muscle. The difference is found to be by no means the same for different terminal organs, being very small (0.002 second) in the case of the auditory organ (noise of two successive sparks), much longer (0.017 second) in the case of the eye (image of two successive sparks falling on the same spot of the retina), and still longer (0.0277) in the case of the sense of touch (two successive touches of the skin of the finger). The relative amount of this so-called “minimal difference” in these cases is in all probability merely a measure of the relative inertia of the different kinds of terminal apparatus. This difference of inertia is probably also in a measure responsible for the fact that if stimuli be applied simultaneously to two different sense organs, as when a sound is emitted at the same instant that a spark is rendered visible, or at the same moment that the skin is excited, the two sensations are not appreciated simultaneously; in order that they should be so, the one must operate a certain time sooner than the other. The difference is known as the “differential time” between two senses. In this case, the difference may be partly due to a difference in the time taken by the nerve impulses in traversing the nerve paths, and this, again, is probably mainly due to a difference in the number of synapses which have to be passed in the two cases.

The following measurements are taken from Exner:¹—

Smallest possible interval between two stimuli to produce two distinct sensations.

Hearing (two electrical sparks)	0.002 second.
Retinal excitation (direct application of electrodes to eye)	0.017 ”
Retinal excitation (by optical images on fovea)	0.044 ”
Tactile (two successive touches on finger)	0.028 ”
Sight and touch	0.050 ”
Sight and hearing	0.060 ”

Richet² has attempted directly to determine the refractory period of the nerve cell of the motor cerebral cortex in the anæsthetised dog. He found that, if stimuli succeed one another at a rate of 10 per second,

¹ Hermann's “Handbuch,” Bd. ii. S. 262, where further details regarding the differential time, and also the reaction time, will be found. See also Exner, “Exper. Untersuch. d. einfachsten psychischen Prozesse,” *Arch. f. d. ges. Physiol.*, Bonn, Bd. vii. and xi.; Wundt, “Neuere Leistungen auf d. Gebiete der physiol. Psychologie,” *Vrtljschr. f. Psychiat.*, Neuwied, 1867, Bd. i.; Donders, “Schnelligkeit psychischer Prozesse,” *Arch. f. Anat., Physiol., u. wissenschaft. Med.*, 1868; Kries and Auerbach, *Arch. f. Physiol.*, Leipzig, 1877; Richet, “Dictionnaire de physiologie,” *loc. cit.*, 1899.

² *Rep. Brit. Ass. Adv. Sc.*, London, 1897. Lecture to British Association in *Nature*, Oct. 26, 1899.

there is no longer a (muscular) response to each excitation, as with lower rates; and he concludes that the refractory period of the cerebral cell is 0.1 second. This is in conformity with the experiments of Horsley and myself, already alluded to (p. 613), who found the rate of response to cortical excitation in the monkey to be only about 12 per second, even when the excitation rate was very much more rapid, and with the conclusions regarding the rate of volitional impulses arrived at independently by v. Kries¹ and myself² (about 10 per second).

It would further appear that it is not possible to perform a succession of voluntary movements such as is involved in the movements of the fingers in playing a musical instrument, or the movements of the mouth in speaking, at a greater rate than this, and Richet found from experiments upon himself that he was unable to "think" words at a greater rate than about 10 to 12 syllables per second. Thus the rapidity of neural processes has a physiological limit imposed upon it by virtue of the refractory period of the nerve cell.

THE SYMPATHETIC AND OTHER RELATED SYSTEMS OF NERVES.

BY J. N. LANGLEY.

CONTENTS.¹—GENERAL ACCOUNT OF THE SYMPATHETIC NERVOUS SYSTEM, p. 617—Sympathetic Nervous Supply of the Head, p. 617—Of the Skin, except that of the Head and of the Ano-Genital Region, p. 625—Of the External Generative Organs and of the Skin of the Ano-Genital Region, p. 635—White and Grey Rami ; Some General Features of the Sympathetic Nerve Supply to the Skin, p. 637—Of the Skeletal Muscles, p. 639—Of the Thoracic and Abdominal Viscera, p. 642—Nerve Fibres of the Sympathetic System, p. 648—Degeneration of Nerve Fibres, p. 652—Regeneration, p. 652—Structure of Sympathetic Nerve Cells, p. 655—Duration of Effects caused by Section of Nerves, p. 655—Efferent Pre-Ganglionic Fibres in relation to the Anterior and Posterior Roots of the Spinal Nerves, p. 658—NERVOUS SYSTEMS RELATED TO THE SYMPATHETIC NERVOUS SYSTEM, p. 659—Distribution and Action of Cranial Autonomic Nerve Fibres, p. 660—Distribution and Action of Sacral Autonomic Nerve Fibres, p. 666—The Enteric Nervous System, p. 668—Possible Autonomic Fibres running direct in the Cerebro-Spinal Nerves, p. 668—Local Nerve Centres other than the Cranial, Sympathetic, and Sacral Ganglia, p. 671—QUESTIONS COMMON TO THE SYMPATHETIC AND TO SOME OTHER PART OF THE AUTONOMIC SYSTEM, p. 672—Mode of Action of Inhibitory Fibres, p. 672—Automatism of Peripheral Ganglia, p. 676—The Peripheral Ganglia as Centres for Definite Areas, p. 678—Reflex Action from Autonomic Ganglia, p. 678—The Number of Nerve Cells on the course of a Pre-Ganglionic Fibre ; Commissural Fibres, p. 682—The Size of Nerve Fibres as a Characteristic of the Autonomic System, p. 685—Afferent Autonomic Nerve Fibres ; Referred Pain in Visceral Disease, p. 686—Growth of Pre-Ganglionic Cranial Fibres into Sympathetic Ganglia, p. 691—General Comparison of the Cranial, Sacral, and Sympathetic Autonomic Systems, p. 692.

In this account I propose to treat in somewhat general terms of the course of the sympathetic nerve fibres from the spinal cord to the peripheral ganglia, of the distribution and nature of the fibres given off by the ganglia, and to compare broadly the sympathetic fibres with similar fibres given off by the cranial and by the sacral nerves. Since sympathetic fibres run to all, or nearly all, parts of the body, the sections of this text-book which treat of the several organs and tissues have already given some historical account of many of the facts relating to the connections and functions of the sympathetic fibres ; and in consequence, in bringing the facts together, as is done in the following pages, it will, in many cases, be unnecessary to enter into detail either as to the facts themselves or as to the original authorities.

The relation of the sympathetic to the central nervous system, the relation of its several ganglia to one another, and the function of its ganglia, have been subjects of controversy from the beginning of the

¹ A brief account of the papers relating to the sympathetic system which have appeared since August 1898, the date of the completion of this article, save for verbal corrections, is given in an Appendix, p. 695.

century. A discussion of the various views which have been held, even of those which have been held in recent times, would take more space than it is desirable to occupy here. I shall, then, in the main restrict myself to stating the views which seem to me to rest on the most satisfactory experimental basis.

GENERAL ACCOUNT OF THE SYMPATHETIC NERVOUS SYSTEM.

Vertebral and pre-vertebral ganglia.—The ganglia of the sympathetic system are divided into vertebral or lateral, and pre-vertebral or collateral. The vertebral ganglia are the ganglia of the sympathetic chain or trunk, and I shall include in this also the superior cervical ganglia. The pre-vertebral ganglia are the ganglia of the solar plexus (solar ganglion, epigastric ganglion), the inferior mesenteric ganglia, and some small ganglia peripherally of the main masses. I shall include in this class the inferior cervical ganglion.

The characteristic of the vertebral ganglia is, that they send nerve fibres to the cerebro-spinal nerves. The superior cervical ganglion sends fibres in most mammals to the first three cervical nerves—in man to the first three or four—as well as to the fifth, and to some other cranial nerves. And each ganglion of the sympathetic chain sends fibres to one or more of the spinal nerves. The pre-vertebral ganglia do not, so far as is known, send nerve fibres to spinal nerves; they send their fibres to the thoracic, abdominal, and pelvic viscera. It is true that the inferior cervical ganglion is described in man and in some other mammals as sending strands to the lower cervical nerves; but, as there is at present no experimental evidence that the inferior cervical ganglion exercises any sympathetic action in the region supplied by these nerves, I have provisionally included it in the class of pre-vertebral ganglia.

We will consider successively the sympathetic nervous supply of the head, of the skin, of the trunk and limbs, of the skeletal muscles, and of the thoracic and abdominal viscera.

SYMPATHETIC NERVES TO THE HEAD.

Effects produced by stimulating the cervical sympathetic.—Stimulation of the cervical sympathetic produces on the side stimulated the following effects:—

1. *Dilatation of the pupil.*—This is the result of contraction of the dilatator pupillæ; the contractile substance probably consists, not of ordinary unstriated muscle, but of the processes of the cells covering the posterior surface. The dilatation is more marked in the cat and dog than in the rabbit.

2. *Retraction of the nictitating membrane;* the movement of the nictitating membrane is stronger in the cat and dog than in the rabbit—in man and ape the nictitating membrane is rudimentary. Separation of the eyelids, the movement being greater in the lower than in the upper eyelids. Projection of the eye and direction of its axis straight forwards.

3. *Contraction of the blood vessels of the skin and mucous membrane of the head, and of the salivary and other glands.*—The rapidity and extent of contraction varies in different parts of the head. It is usually very great in the salivary glands and in the ear; it is especially obvious in the ear of the rabbit. It is marked in the conjunctiva, the iris, and in most

animals in the skin and adjoining mucous membrane of the nose and lips, and in the mucous membrane of the hard palate; it is less marked in the gums and mucous membrane of the cheeks, and slight only in the tongue.

4. *Dilatation of vessels in the bucco-facial region of the dog.*—This was first shown by Dastre and Morat.¹ They found that strong and moderately strong stimulation of the cervical sympathetic produced intense flushing in the mucous membrane of the lips, gums, cheeks, hard palate, nose, and in the neighbouring parts of the skin. With weak currents the first effect produced is contraction of the blood vessels. In other animals, primary contraction appears always to be produced, whatever the strength of the current. Thus the occurrence of vaso-dilator fibres—at any rate in sufficient number to overcome the vaso-constrictor fibres—is, so far as we know, peculiar to the dog. In this animal they are probably of use in regulating the temperature of the body.

5. *Secretion*² from the salivary glands, the lachrymal glands, the glands of the mucous membrane of the mouth, nose, and pharynx, and from the sweat glands of the skin where these occur.

6. *Erection of hairs*³ in animals which have erectile hairs. In the cat, erection of hairs is obtained in a triangular area between the eye and ear, the base of the triangle lying in front of the ear; in the occipital region, and occasionally in the whole dorsal region of the head; and in the skin of the back of the neck supplied by the third cervical nerve. In the ape it is obtained on the forehead, on the anterior half or more of the scalp, on the temple and cheek.

In the hedgehog the cervical sympathetic causes erection of quills in the head and upper part of the neck.⁴ The cervical sympathetic causes in the dog slight contraction of the angle of the nostril, and in the ape slight retraction of the pinna of the ear.

All of the above actions are well established. Others have been described, about which opinion is conflicting, and the evidence is not satisfactory. Such⁵ are contraction and dilatation of the vessels of the retina, inhibition of the ciliary muscle and the sphincter pupillæ, and, notably, contraction and dilatation of the arteries of the brain.

Some early observations on the cervical sympathetic.—Petit,⁶ in 1727, described in the dog certain effects of section of the vagus in the neck, and

of the "nerf intercostal" (the cervical sympathetic). As the result of section of the latter nerve, he found decrease in the size of the pupil, projection of the "membrane particulière du grand coin de l'œil" (the nictitating membrane), reddening of the conjunctiva, an increase in the fluid bathing the eye, and a decrease in the convexity of the cornea.

Biffi,¹ in 1846, noticed that stimulation of the cervical sympathetic caused dilatation of the pupil.

Bernard,² in 1852, observed that section of the cervical sympathetic led to the dilatation of the vessels of the ear, and increase of temperature of the skin of the head on the side of the cut nerve. This was soon followed by observations of the effect of stimulating the cervical sympathetic. Bernard,³ Brown-Séquard,⁴ and Waller⁵ all found contraction of the blood vessels of the ear, and decrease of temperature. The two latter observers attributed the contraction of the vessels to the stimulation of vasomotor fibres, and the temperature changes to variations in the amount of blood; whilst Bernard was inclined to attribute the variations in temperature, in part at least, to special calorific and frigorific nerves.

Tonic action; effect of section of cervical sympathetic.—The sympathetic nervous system exercises a tonic action on certain of the structures to which it runs, but not on all of them. In the cervical sympathetic, the vaso-constrictor fibres, the pupillo-dilator fibres, and the constrictor fibres to the unstriated muscle of the eye, are in a state of constant action, only broken by occasional inhibition occurring in the central nervous system; whilst the secretory fibres, the pilo-motor fibres in the cat,⁶ and the vaso-dilator fibres to the bucco-facial region of the dog, are normally at rest, broken only by an occasional excitation. Section of the cervical sympathetic will, then, only cause paralytic effects in those tissues which are in a state of tonic contraction. It causes a dilatation of the blood vessels, and an accompanying rise of temperature in the ear and the skin of the head. The vascular effects in other parts are less pronounced; they are generally marked in the conjunctiva, but slight or absent in the mucous membrane of the mouth. The hyperæmia of the lachrymal and salivary glands leads to a greater secretion than normal, whenever secretion is in any way set up. And, similarly, the hyperæmia of the nasal mucous membrane may lead to frequent sneezing. Section of the cervical sympathetic causes also a considerable narrowing of the palpebral aperture and projection of the nictitating membrane, and some retraction of the globe of the eye.

The duration of the several paralytic effects we shall consider later (p. 655).

Origin of fibres of the cervical sympathetic.—The origin of the fibres of the cervical sympathetic from the spinal cord, by which is meant the spinal nerves which convey fibres from the spinal cord to the sympathetic, can be determined by stimulating the several spinal nerves in the vertebral canal, after removal of the corresponding portion of the spinal cord, and observing which of them cause the effects also caused by stimulating the cervical sympathetic. The effects being noted, the

⁶ In the ape, after section of the cervical sympathetic, the hairs of the head on the outside are somewhat less erect than on the intact side (Sherrington).

cervical sympathetic is cut, and the stimulation repeated, in order to make certain that the effects were due to impulses passing by this nerve. It is thus found that the different classes of fibres have different origins; they differ also, though not very greatly, in different animals.

The pupillo-dilator fibres arise from the first three thoracic nerves. In the cat and dog the third thoracic has much less effect than the other two. On the other hand, in the rabbit, and apparently also in the ape, the third thoracic may have a greater effect than the first, though never so great as the second thoracic nerve.

The nerve fibres for the nictitating membrane, the eyelids, and the muscles of the orbit, arise from a greater number of nerves than those for the pupil, and their origin is on the whole more posterior. They arise in the cat and dog from the first five thoracic nerves; but the fifth thoracic has a very slight effect, and the fourth less than the first three. Of the first three, the second and third are more effective than the first.

The vaso-constrictor and vaso-dilator fibres are again, as a whole, a little more posterior in origin than the fibres supplying the nictitating membrane. They arise from the second to the fifth thoracic nerves inclusive, and occasionally a few from the first; the maximum effect is obtained from the third, or from the third and fourth. In the rabbit the origin of the vasomotor fibres to the ear is more extensive; some pass by the sixth and seventh, and occasionally a few by the eighth thoracic. It is not, however, certain whether these fibres of lower origin run to the cervical sympathetic, or make their way by the ramus vertebralis of the ganglion stellatum (cf. p. 624).

The submaxillary gland of the dog receives fibres also from the second to the fifth nerves inclusive, but the maximum effect is obtained from the second thoracic.

Lastly, we have the pilo-motor nerves. Those in the cat are of much lower origin than the others. They arise from the fourth to the seventh thoracic nerves inclusive, and the maximum effect is obtained from the fifth and sixth.¹

It will facilitate a general view of these facts to put those which are best established in a tabular form:—

Effects of Stimulation of Nerve Roots, indicating Origin of Fibres of the Cervical Sympathetic in the Cat.

Spinal Nerve.	Dilatation of Pupil.	Retraction of Nictitating Membrane, etc.	Vessels of Ear and Conjunctiva.	Hair of Face and Back of Head.
First thoracic . . .	Good.	Moderate.	None or slight.	...
Second ,, . . .	Good.	Good.	Moderate or good.	...
Third ,, . . .	Slight or moderate.	Good.	Good.	...
Fourth ,,	Slight or moderate.	Good.	Slight or moderate.
Fifth ,,	Slight or none.	Moderate or slight.	Good.
Sixth ,,	Good.
Seventh ,,	Slight or moderate.

¹ In the ape, Sherrington found the pilo-motor fibres for the head to issue by the second to the fifth thoracic nerves.

The origin of the other fibres of the cervical sympathetic are omitted, as they have not been studied in sufficient detail. "Good," "moderate," and "slight" in the table indicate the relative effects produced by the several spinal nerves.

It must be remarked that there is some evidence¹ that the vasomotor fibres for the iris have the same origin as the fibres for the dilatator pupillæ, and thus a different origin from that of the vasomotor fibres for the conjunctiva and ear, but not many experiments have been made on the point.

The earliest observations on the origin from the spinal cord of the cervical sympathetic fibres were made by Budge and Waller in 1851, with regard to the dilator fibres for the pupil. They found dilatation of the pupil in the rabbit, on stimulating the second thoracic nerve. The results obtained by various observers are conflicting. The account I have given above is based upon my own experiments; in many respects it agrees with that given by some one or other of the earliest observers; thus the account of the origin of the fibres for the dilatator pupillæ is essentially the same as that given by Bernard. It may be mentioned that a considerable number of observers state that fibres run to the cervical sympathetic from the lower cervical nerves. I append below a list of papers for reference.²

Nerve cell connection of the nerve fibres.—The nerve fibres which run from the spinal cord to the cervical sympathetic and to the superior cervical ganglion all end in connection with the nerve cells of this ganglion,³ for if the ganglion in the cat or rabbit be brushed over with 0.5 to 1 per cent. nicotin, in amount insufficient to appreciably affect the conductivity of nerve fibres, stimulation of the cervical sympathetic will have no effect.

The absence of effects must be due to a loss of conductivity somewhere in the ganglion; and in accordance with what we know generally of the action of alkaloids, as well as in accordance with the results of recent histological inquiry, we may fairly conclude that the break of conductivity occurs in the terminations of the sympathetic fibres around the cells of the superior cervical ganglion. In other words, we may say that the absence of effect on stimulating the cervical sympathetic is due to the fact that all its fibres form nerve-endings in the ganglion, and that

these endings are paralysed by nicotin, just as nicotin in rather larger doses paralyses motor nerve-endings in skeletal muscle.

Occasionally, the cervical sympathetic has a slight effect on the nictitating membrane and eyelid, after application of nicotin to the superior cervical ganglion. In such cases it is found that there are groups of nerve cells in the trunk of the nerve at or centrally of the point stimulated. In fact a few of the nerve cells of the superior cervical ganglion occasionally occur in the trunk of the nerve.

The fibres of the cervical sympathetic, as we have seen, pass through one or more of the upper thoracic sympathetic ganglia, and the inferior cervical ganglion, but the cautious application of nicotin to all of these ganglia does not prevent any one of the cervical sympathetic actions from being obtained by stimulation of the spinal nerve. It follows from this result that no appreciable number of any kind of nerve fibre present in the cervical sympathetic has a relay station in any of the upper thoracic ganglia, or in the inferior cervical ganglion; and one may fairly conclude—and the conclusion is supported by other facts—that all the fibres which pass to the cervical sympathetic from the spinal cord reach the nerve without having nerve cells on their course.

A further question is, whether the nerve fibres given off by the superior cervical ganglion run direct to the various peripheral structures, or end in connection with the cells of some other ganglia. In order to determine this, nicotin is injected into a blood vessel. The injection paralyses the cervical sympathetic, just as application of nicotin to the superior cervical ganglion paralyses it, and with the same occasional restriction we have mentioned above. But, on stimulating the several branches given off by the ganglion, all the normal effects can be produced, and to a maximal degree; that is, the nerve-endings of the fibres given off by the ganglionic nerve cells are not paralysed, and in consequence we conclude that they do not run to other sympathetic nerve cells, but proceed straight to the tissue.

Conclusions similar to these deduced from the action of nicotin may be legitimately deduced from the results of degenerative section of the cervical sympathetic and of the branches of the superior cervical ganglion.¹ Waller and Budge found that on section of the sympathetic in the neck, the part in connection with the superior cervical ganglion showed the microscopical signs of degeneration, but that the part still in connection with the spinal cord and the part beyond the ganglion remained unaltered. They found also that stimulation of the part attached to the superior cervical ganglion no longer caused dilatation of the pupil, but stimulation of the ganglion itself promptly caused dilatation. The microscopical observations have been confirmed, and the experimental results extended to other classes of nerve fibres. Waller observed, further, that on degenerative² section of the internal carotid branches of the ganglia, degenerated fibres could be traced to the

¹ Cf. Papers by Waller and by Waller and Budge in *Compt. rend. Acad. d. sc.*, Paris, 1851-1853; *Ztschr. f. wissenschaft. Zool.*, Leipzig, 1851, Bd. iii. ² I use the term "degenerative section" for the cases in which a nerve is cut, but the animal is not killed until degeneration is sufficiently advanced to stop the passage of nervous impulses.

ophthalmic branch of the fifth nerve, and that stimulation of this nerve—normally producing dilatation of the pupil—no longer had an effect.

That the degeneration, after section of the internal carotid branches, spreads to the periphery, is shown by stimulating the sclerotic before and after the degenerative section. In the former case, there is a double effect—local contraction of the radial muscle leading to local enlargement of the pupil, and local contraction of the circular muscle of the iris; in the latter case, the radial contraction is lacking, the circular takes place as before.

General plan of arrangement.—The general idea of the sympathetic supply to the head, which we gather from the foregoing, is as follows:—The upper part of the thoracic spinal cord sends out fibres by the anterior roots of the spinal nerves of this region. The fibres make no halt at the ganglia until they reach the superior cervical ganglion. This is a relay station for the sympathetic nerve supply of the whole of the head; in it all the nerve fibres form nerve-endings—synapses as they are called by Foster; probably, indeed, as we shall see later, each nerve fibre branches and so forms several nerve-endings, each in connection with a nerve cell. Each nerve cell sends off a nerve fibre, which runs to the periphery, where it branches and supplies a group of unstriated muscle or gland cells. On the course of a nervous impulse from the spinal cord to the periphery, there are, then, two nerve cells, one with cell body in the spinal cord, the other with cell body in the local sympathetic ganglion. The nerve fibre of the first nerve cell we may call a pre-ganglionic fibre, that of the second a post-ganglionic fibre.

In introducing the terms pre-ganglionic and post-ganglionic,¹ I mentioned also the terms pre-cellular and post-cellular. I rejected the latter, since they are less distinctive. A pre-ganglionic fibre is post-cellular in relation to the nerve cell from which it arises. Kölliker,² however, prefers to use either pre-cellular and post-cellular, or “Motorische Eingeweide-Fasern, I. und II. Ordnung.”

Course of post-ganglionic fibres.—A further point that concerns us is the course taken by the post-ganglionic fibres of the superior cervical ganglion on their way to the periphery. Our information with regard to this is not very full or well assured. The majority of the fibres which have been traced, pass to the fifth cranial nerve, and are distributed with its sensory fibres.³ Thus the pupillo-dilator fibres and other fibres to the eye pass to the ophthalmic branch of the fifth, and the long ciliary nerves; the fibres—whether constrictor or dilator—to the blood vessels of the lips and mucous membrane of the mouth and nose, pass by the superior and inferior maxillary branch of the fifth. Broadly

(According to François-Franck, the vaso-constrictor fibres to the iris run in the internal carotid plexus and not in the cervico-Gasserian strand.) Jegorow, *Arch. f. Physiol.*, Leipzig, 1886, S. 149; Luchsinger, Hermann's “Handbuch,” 1883, Bd. v. Th. 1, S. 421 *et seq.* (sweat fibres); Dastre and Morat, “Système vaso-moteur,” Paris, 1884, p. 116 (vaso-dilator); Morat, *Arch. de physiol. norm. et path.*, Paris, 1889, p. 196. I have found that the pilo-motor nerves for the face area accompany the fifth nerve.

speaking, we may say that all parts of the skin and mucous membrane, which receive their sole sensory supply from the fifth nerve, receive their sympathetic supply also by way of the fifth nerve. Sympathetic fibres pass to the posterior part of the tongue, the pharynx, and the larynx, by way of the glosso-pharyngeal nerve, the pharyngeal and superior laryngeal branches of the vagus. The tongue receives fibres by way of the hypoglossal, but they are few, for the superior cervical ganglion has no great influence on the vessels of the tongue.

The ear¹ receives sympathetic fibres by more than one route, and there are considerable differences in different animals. In the cat, the grey rami, running from the superior cervical ganglion to the first three cervical nerves, contain fibres which accompany the cutaneous branches of these nerves, and thus run to the ear, the occipital region of the head, and the upper part of the neck. The anterior branches of the superior cervical ganglion also contain vasomotor fibres for the ear, but by what course they reach their destination is not known. In the rabbit most of the fibres for the ear are contained in the strand which runs from the superior cervical ganglion to the external carotid, and they follow the branch of the artery which runs to the ear. These fibres, on stimulation, cause contraction of the whole of the central artery, but the effect is sometimes slight at the tip of the ear. As in the cat, some fibres run in the anterior strands of the ganglia, chiefly to the basal third of the ear. It may be mentioned that in the rabbit vasomotor fibres commonly run to the ear from the ganglion stellatum² by way of the ramus vertebralis and third cervical nerve; these, on stimulation, cause contraction, chiefly at the tip of the ear,³ though the contraction spreads a variable distance towards the base. In the dog most of the vasomotor fibres for the ear run by the anterior branches of the superior cervical ganglion, their further course being unknown, and some pass by the branch to the external carotid artery.

The sympathetic fibres to the large salivary glands, pass by the strand which runs to the external carotid, and reach the glands by way of their arteries.

Three bundles of post-ganglionic fibres from the superior cervical ganglion remain for mention. There is that which accompanies the internal carotid; it would naturally be supposed to convey vasomotor fibres to the vessels of the brain, but this view, as we have said, is contested. And there are two bundles, one passing to the third and the other to the sixth cranial nerve, these might be supposed to convey vasomotor fibres to the vessels of the eye muscles, but so far experiments have not shown that they do so.

The general scheme of the distribution of the post-ganglionic fibres of the superior cervical ganglion appears then to be, that those which run to skin and mucous membrane accompany the cranial and cervical sensory fibres running to the skin and mucous membrane, and that those which run to deep visceral structures—the salivary glands—accompany the arteries. There is, however, in the rabbit the striking exception, that vasomotor fibres run to the ear by the artery. And this, together

³ The vasomotor action of the great auricular nerve was first described by Schiff, and its local action by Lovén, *Arch. a. d. physiol. Anst. zu Leipzig*, 1866. An anatomical account of the nervous supply of the ear of the rabbit is given in this paper.

with the inadequacy of detailed experiment on the course taken by the post-ganglionic fibres, makes it obvious that the scheme just mentioned is only to be regarded as approximate and provisional.

SYMPATHETIC FIBRES TO THE SKIN, EXCEPT THAT OF THE HEAD AND OF THE ANO-GENITAL REGION.

Effects produced by stimulation.—The actions set going in the skin by the sympathetic nerves, naturally vary in different parts and in different animals, in accordance with the kind of structures which have developed in them. Thus, in rabbits, the only action produced in the skin of the trunk and limbs is a vasomotor one. Sweat glands and erector muscles for the hairs are absent. The effects which can be produced in the skin by stimulation of some part or other of the sympathetic chain are as follows, omitting the effects produced on the skin of the genital region, which will be given in the account of the external generative organs:—

1. *Contraction of the arteries.*—This can be brought about in all parts of the skin, but apparently more easily in some parts than in others. Thus, with equal nervous stimulation, it is said that there is greater contraction in the vessels of the foot than in the vessels of the thigh. The sympathetic fibres have not been shown to cause directly any change in the capillaries. They have been found to cause contraction in the veins of the wing of the bat,¹ and in the superficial veins of the leg of the cat and rabbit.² The former have rhythmic contractions and dilatations, like those which occur in the arteries of the ear of the rabbit; the rhythm depends upon impulses passing from the spinal cord.

2. *Secretion from sweat glands.*—Observations on the distribution of secretory fibres to the sweat glands of the skin, other than that of the head, have only been made upon the cat and dog; and in the cat and dog the glands only occur on the pads of the feet.

3. *Erection of hairs.*—This is also a local occurrence. In the cat it occurs in the dorsal strip of skin which is innervated by the posterior cutaneous branches of the spinal nerves, and in the tail. In the dog and ape the hairs are affected in a similar dorsal strip. In the hedgehog the region in which quills are moved is co-extensive with the region in which quills are found, so that here the sympathetic causes movement in the region of the lateral cutaneous as well as in that of the posterior cutaneous skin branches.

The "goose skin" which occurs in man is a similar phenomenon, and is no doubt also produced by sympathetic nerve fibres.

We may note here that the action of the sympathetic chain is unilateral on the trunk; it is unilateral also on the limbs, except for an occasional very trifling effect on the opposite hind-limb, but it is bilateral on the tail and on the external generative organs, though generally stronger on the same side. The bilateral action is connected with the fact that the vertebral ganglia from the second sacral, and sometimes from the first sacral downwards, are connected together on the two sides, and it is these ganglia, as we shall see, which send fibres to the tail and to the external generative organs.

² Bancroft, *Am. Journ. Physiol.*, Boston, 1898, vol. i. p. 477.

4. *Flushing of the skin*, or a rise of temperature in it, are at times and in certain circumstances produced by stimulation of the sympathetic; and it is generally believed that the changes are due to the presence of vaso-dilator nerves.¹ The evidence, on the whole, is in favour of the presence of such nerve fibres, but it is, I think, premature to regard the question as settled.

Some of the statements made do not harmonise with well-established facts. Thus it has been said that weak tetanising currents stimulate vaso-dilator more than vaso-constrictor fibres, although, as we have already mentioned, the cervical sympathetic in the dog, when stimulated with weak currents, produces contraction, and when stimulated with strong currents, produces dilatation of the vessels of the bucco-facial region.

The strongest evidence for the presence of vaso-dilator fibres in the sciatic is that afforded by the series of well-known experiments initiated by Goltz,² on the effect of stimulating the sciatic nerve some two to four days after cutting it. The thermometric method, the plethysmographic method, and direct observation have given similar results, namely, that the vaso-constrictor action becomes less as time goes on, and that in the last day or two, before irritability completely disappears, the vascular dilatation is out of proportion to the preliminary contraction, or occurs without any contraction at all.

It is not an unfair deduction that the vascular dilatation is due to the presence of vaso-dilator fibres, which become prepotent some days after section of the nerve, in consequence of their preserving their conductivity rather longer than the vaso-constrictor fibres do. But, on the other hand, it has not been shown by experiments in typical dilator and constrictor fibres, that the latter degenerate more slowly than the former, nor is it inconceivable that the changes which take place in the nerve and the tissue after section of the nerve should be of a nature enabling stimulation of constrictor fibres to cause the described degree of dilatation.

According to Dziedziul,³ the vaso-dilator fibres of the submaxillary gland (*chorda tympani*) take eleven days to lose their irritability, and those of the *nervus erigens* nine days. These observations are, I think, untrustworthy. I have found the vaso-dilator fibres of the *chorda tympani* of the cat to be completely without effect in five days. Anderson and myself⁴ found that the sacral nerves seven days after section had no effect of any kind.⁵

There is some evidence also for the presence of vaso-dilator fibres in the sympathetic supply to the skin, in the effects produced by stimulating fresh and normal nerves. Primary dilatation is comparatively rarely obtained with any strength or form of stimulation, but not uncommonly the after-dilatation seems out of proportion to the primary contraction.⁶ When a part only of sympathetic supply to a given region is stimulated, the dilatation may occur during the stimula-

¹ For reference to papers, in addition to those mentioned in this section, cf. article on "Circulation" in this volume.

⁵ For a further criticism of the evidence relating to vaso-dilator fibres of the limbs, and especially of the muscles, see p. 640.

⁶ Cf. Dastre and Morat, *Compt. rend. Acad. d. sc.*, Paris, 1878, tome lxxxvii. p. 880.

tion; indeed, if the vessels are already contracted, there may be no observable primary contraction, but dilatation only. And when, as first shown by Ostroumoff, slowly repeated shocks—about 1 in 2 seconds to 1 in 5 seconds—are used as the stimulus, there may be primary dilatation. The most obvious conclusion from these results is, that the dilatation of the vessels is due to the presence of the vaso-dilator fibres; but it may perhaps be doubted whether the evidence is conclusive that in these cases the stimulation does not lower the irritability and conductivity of the peripheral vasomotor nerve fibres, and thus prevent tonic vasomotor impulses from coming into play. Lastly, we must mention a line of evidence first put forward by Schiff,¹ and adopted by Ostroumoff and others. This consists in showing that the dilatation of the vessels of a given region of the skin which can be produced by impulses from the central nervous system—for example, by excitation of afferent fibres—is greater than that produced by section of the vaso-constrictor and all other nerves to the region. Unfortunately for the conclusiveness of these observations, the reflex dilatation has not—in most cases, at any rate—been compared with the maximal dilatation caused by section, but with the dilatation existing after the vessels have recovered some degree of tone.

Course of post-ganglionic fibres.—The sympathetic fibres which run to the skin leave the sympathetic chain by the grey rami, they run to the spinal nerves, and follow the cutaneous branches to the skin.² It has been generally believed that some sympathetic fibres make their way to the periphery along the sheaths of the arteries. It is easily shown that this is not the case with the pilo-motor nerves, for if the dorsal cutaneous nerves are cut, the sympathetic is no longer able to cause movement of the hairs. Similarly, after section of the sciatic, the sympathetic is no longer able to cause secretion from the sweat glands of the foot. There is some difference of opinion with regard to vasomotor fibres. For it has been found by some observers that, after section of the sciatic, changes take place in the calibre of the vessels of the foot, which can only be due to impulses coming from the central nervous system. But in these cases the crural nerve was left out of account. And it has been shown that sometimes, at any rate, the crural nerve contains vasomotor fibres for the foot.³ In mammals, then, there is no evidence that sympathetic fibres pass to the skin of the trunks or limbs by way of the arteries, and, taking all the facts into account, we may conclude that they all pass by way of the spinal nerves. In the frog, experiments have been made upon the vasomotor nerves to the hind-limb; the general result of which is the same as in mammals, although the statement that the fibres accompany the arteries has been more positively put forward.

In this connection there is one point to keep in mind—the sympathetic sends some fibres direct to the aorta, and these appear to spread some way down the large arteries. It is not unlikely that these nerve

¹ *Schriften d. Berner Naturf. Gesellsch.*, 1856, S. 69.

Physiol.*, Cambridge and London, 1891, vol. xii. p. 368 (sweat fibres); *ibid.*, p. 375 (vasomotor fibres); *ibid.*, 1893, vol. xv. p. 199 (pilo-motor fibres); *ibid.*, 1894, vol. xvii. p. 296 (secretory and vasomotor fibres). Cf. these papers also for origin and nerve-cell connection of the sympathetic fibres to the skin.

³ Lewaschew, *Arch. f. d. ges. Physiol.*, Bonn, 1882, Bd. xxviii. S. 431; Dastre and Morat, "Système nerveux vaso-moteur," Paris, 1884, p. 262; Spallitta and Consiglio, *Arch. ital. de biol.*, Turin, 1897, tomo xxviii. p. 257.

fibres can cause some contraction in the large arteries. In this way a modification of blood supply to the skin, and to the muscles, may take place, without any direct effect upon the peripheral vessels.

Distribution of grey rami.—Broadly speaking, the successive spinal nerves to the neck and the trunk are found anatomically to supply successive bands of skin encircling the deeper lying tissues. These rings are broken where the nerves pass to the fore- and hind-limbs; there the several nerves cease to run separately, but join to form the brachial and the lumbo-sacral plexus. One or more of the nerves in the middle of the series of nerves forming the plexus send no cutaneous fibres to the trunk, but run entirely to the limb. Since each spinal nerve has its grey ramus, and since, as we have seen, the grey ramus contains sympathetic fibres running to the periphery with the spinal nerve, the probability is great, that the distribution of the fibres of the successive grey rami is the same in its general plan as that of the cutaneous branches of the successive spinal nerves.

The question is easily tested as regards pilo-motor fibres, by stimulating the successive grey rami in the cat, and observing the areas of skin in which erection of hairs occur. In this way, it is found¹ that the area of skin innervated by successive effective grey rami are successive, overlapping by a millimetre or two only, and that the areas correspond to the anatomical areas of the successive spinal nerves as nearly as could be expected from the lack of accuracy of the anatomical method. A similar result is obtained by observing the contraction of the small arteries to the skin, although the result is less constant and precise, on account of the variability on the course of the arteries.

I have said that the grey rami which are *effective* supply successive strips of skin with pilo-motor nerves. There are one or more grey rami about the middle of each of the series which form the brachial and lumbo-sacral plexuses, which have no pilo-motor nerves. These rami run to nerves which have no dorsal cutaneous branches. In the cat these nerves are the eighth cervical, often with either the seventh cervical or the first thoracic in the region of the brachial plexus; and the sixth lumbar, often with either the fifth lumbar or the seventh lumbar in the region of the lumbo-sacral plexus. When the sixth and seventh lumbar nerves have no dorsal cutaneous branches, the sixth and seventh lumbar grey rami have no pilo-motor nerve fibres, and send no fibres to the skin over the vertebræ, the dorsal cutaneous branch of the first sacral nerve follows immediately on that of the fifth lumbar, the first sacral grey ramus causes erection of hairs in a strip of skin immediately posterior to that affected by the fifth lumbar grey ramus.

From these and other experiments, it is clear, as regards the skin of the neck and trunk, that the grey ramus running from the sympathetic to a spinal nerve may be regarded as having broadly the same skin distribution as the cutaneous branches of the nerve to which it runs. These branches contain sensory fibres of the skin. Sherrington² has shown that the successive spinal nerves which send sensory fibres to the skin of the neck and trunk supply successive areas, but that these areas overlap considerably, so that in general each area includes a half of the area above, and a half of the area below. On this plan it will be noticed each portion of the skin sends afferent fibres to two nerve roots. As we have said, the efferent fibres of the grey rami do not overlap to this

¹ Langley, *Journ. Physiol.*, Cambridge and London, 1893, vol. xv. p. 199.

² *Phil. Trans.*, London, 1893, vol. clxxxiv. p. 641.

extent; they encroach very little on their neighbour's territory. We must conclude, then, that although the efferent sympathetic fibres accompany the sensory spinal fibres to the skin, they spread out less in the skin than do the sensory fibres. Thus the efferent sympathetic nerve region lies in the afferent spinal nerve region.

Turning now to the distribution of the grey rami which run to the limbs, we have no pilo-motor fibres to serve as indicators, and although the vasomotor fibres afford some aid, we have for accurate observations on distribution to rely upon the sweat glands in the pads of the cat's foot.¹ As a rule, four grey rami send secretory nerves to the foot of the cat, namely, the sixth lumbar to the second sacral; the second sacral grey ramus occasionally has no effect. In a typical case the sixth lumbar grey ramus causes secretion in the inner part of the foot, the second sacral grey ramus causes secretion on the outer part of the foot, the other two cause copious secretion on the whole of the foot, but the seventh lumbar most on the inner part, and the first sacral most on the outer part. Here, then, each part of the skin receives fibres from three grey rami. Some parts, in some cases, receive fibres from four grey rami. Türck² and Sherrington³ have shown that the afferent fibres of the nerves which go to make up the sciatic, overlap very largely. The overlapping described by them is, however, hardly so great as that which occurs in the secretory fibres of the several grey rami. In the limbs, then, unlike the trunk, the sympathetic efferent areas of the grey rami appear to overlap rather more than do the afferent skin fibres of the corresponding spinal nerves.

Origin of grey rami from the ganglia.—Having thus determined the course taken by sympathetic fibres, on passing from the sympathetic chain to the skin, our next step is to determine from what nerve cells the nerve fibres arise. This can be done by the use of nicotin, in the manner already given in treating of the cervical sympathetic. The result of such experiments is, that the great majority of the fibres of a grey ramus, in some cases all of them, arise from the corresponding vertebral sympathetic ganglion, and run to the periphery without having further sympathetic nerve cells on their course. The few fibres which do not arise from the corresponding ganglion arise from the ganglion next above or below, and in the case of the lumbar grey rami from the ganglion next above; in the case of the thoracic and sacral ganglia there appears to be some variation, but the details have not been fully worked out.

Broadly speaking, then, the vertebral sympathetic ganglia are segmental, and each supplies sympathetic fibres to its own spinal nerve.

There is a divergence from this rule, though functionally not a very important one; the white rami not infrequently receive a few fibres from the sympathetic ganglia. Where the white rami run posteriorly before joining the sympathetic chain, as they do in the cat, from the tenth or eleventh thoracic to the fourth or fifth lumbar, a white ramus may receive fibres from the nerve cells of the ganglion of the nerve immediately posterior to it (cf. Fig. 309).

A complication occurs, in that the ganglia may unite with one another and form a compound ganglion. A compound ganglion gives off a grey ramus to more than one nerve. In some places compound ganglia are constant in occurrence, in others they are occasional. The constant compound ganglia are the ganglion stellatum which sends grey rami to the cervical nerves from about the third downwards, and to the

first three, possibly four, thoracic nerves; and when there are coccygeal nerves, the coccygeal ganglion. A compound ganglion will, of course, send sympathetic fibres to (approximately) the whole skin region supplied by the spinal nerves, to which it sends grey rami. Thus the cells of the ganglion stellatum send axons to the glands and blood vessels of the whole of the forelimb, as well as to the hair muscles of part of the neck and thorax.

Origin and nerve cell connection of pre-ganglionic fibres; individual variations.—

Lastly, we have to determine the connection which exists between the spinal cord and the several ganglia, or rather we have to determine with which ganglia the efferent fibres in the roots of each spinal nerve are connected. The fundamental line of experiment is to stimulate each spinal nerve near its exit from the spinal cord, and to observe the area of the skin in which sympathetic effects occur. Since we know, within narrow limits, the area of the skin innervated by each ganglion, we can tell within narrow limits which ganglia are in connection with each spinal nerve—supposing always that the effects are brought about by means of the ganglia.

The spinal nerves which, on stimulation, give rise to sympathetic effects in the skin in the regions we are here considering, are, in the cat, the fourth thoracic (occasionally the third) to the third or fourth lumbar inclusive. The region, it will be remembered, is that of the whole body, except the head and the ano-genital region.

The distribution of the several nerves has been determined by observation on the pilo-motor nerves to the neck, back, and tail in the cat; and on the secretory and vasomotor nerves to the feet and limbs. Some confirmatory observations have been made in the vasomotor nerves to the back and trunk. As we shall see, there are some differences in the distribution of the different classes of nerve fibres, although the differences are inconsiderable.

The pilo-motor nerves present especial advantages in dealing with this question, because the movement of hairs is readily observed. And

FIG. 309.—The variations we have mentioned are represented in the diagrams A, B, and C. In A each ganglion sends its nerve fibres to the corresponding spinal nerve. In B the upper ganglion sends the great majority of its nerve fibres to its own nerve, and a few (represented by the dotted line) to the nerve below in the grey ramus of that nerve. In C each ganglion sends the majority of its fibres to its own nerve, but the lower sends a few (represented by the dotted line) to the nerve above in the white ramus of that nerve.

this allows the area of skin actually supplied with pilo-motor fibres by each grey ramus to be determined without difficulty, after the area supplied by each spinal nerve has been determined. Moreover, the region of skin having erectile hairs receives its nerves from the posterior primary division of the spinal nerves, and this, with the fibres of the grey ramus accompanying it, leaves the anterior primary division close to the posterior root ganglia. Thus, by pulling the spinal nerve a little into the vertebral canal, or by using a strong current—so that it spreads

FIG. 310.—Diagram of course of a grey ramus. A, in a thoracic spinal nerve. B, in a sacral spinal nerve; *Sy. G.*, sympathetic ganglion; *Sp. G.*, spinal ganglion. In A the branch of the grey ramus to the posterior primary division of the nerve is outside the vertebral canal, but can be stimulated if the nerve is pulled a short distance into the canal. In B the grey ramus follows the nerve a short distance into the canal.

down the nerve—the pilo-motor fibres of each grey ramus can be stimulated without opening the abdominal cavity. This will be obvious from the diagram given (Fig. 310).

Before taking the connections of the individual nerves, we must mention a common feature presented by their sympathetic fibres. We have seen that none of the nerve fibres, which pass from the spinal cord to

FIG. 311.

the head by way of the cervical sympathetic, run direct to the periphery, but that they all form nerve-endings (synapses) around sympathetic ganglion cells. The same law holds for the nerve fibres running from the spinal cord by way of the sympathetic to the skin of the trunk and limbs. They all form nerve-endings in one or other of the pre-vertebral ganglia. This is shown by experiments with nicotin.

We may now return for a moment to the stimulation of the spinal nerves in the vertebral canal. I have said that in certain ways the pilo-motor nerve fibres of the grey ramus of the nerve can be stimulated. But these are post-ganglionic fibres, and they are not paralysed by nicotin. So that, after observing the area of the skin in which the hairs move on stimulation of each spinal nerve, we have only to inject nicotin into the blood, and to stimulate the nerves a little past the posterior root ganglia, or to stimulate it with a strong current, to observe also the area supplied by each grey ramus.

Thus, to take an example from an experiment. The thirteenth thoracic nerve roots caused the hairs to become erect from a spot a little below the third lumbar vertebra (fourth spine) to a little below the first coccygeal vertebra (cf. long bracket XIII. in Fig. 311). In the middle part the hairs were strongly erected; in the ends, especially the lower end, they moved slightly only. Then nicotin was injected. After this, stimulation of the thirteenth thoracic nerve had no effect, unless the nerve was stimulated peripherally of the ganglion or with strong currents, in which case a small patch of hairs just above the

FIG. 312.—Diagram to show variation in nerve-origin. M = median arrangement. The upper nerve roots of M pass into the nerve above in the anterior arrangement (A), and the lower nerve roots of M pass into the nerve below in the posterior arrangement (P).

previous limit moved sharply and strongly; and on stimulating similarly each of the following nerves, small successive patches were obtained, as indicated in the lower line of brackets in the figure. In this case the pre-ganglionic fibres of the thirteenth thoracic sent fibres to all the lumbar sympathetic ganglia, sending most to the second, third, fourth, and fifth ganglia. It will be noticed that no area is given for the sixth lumbar grey ramus; as we have said above, this runs entirely to the limb.

On investigation in this fashion, it becomes clear that there are individual variations. In part these can be referred to a difference in the functional activity of the tissues in different individuals; in some, for example, the contractile muscular tissue of the hairs is much better developed than in others, and thus spinal nerves which produce a weak erection of hairs in the one, may have no observable effect in the other. In part, however, they are due to structural variations, which are correlated with a number of other structural differences. The roots of

the spinal nerves leave the grey matter in a continuous band. Adjacent portions of this continuous band are gathered up into bundles and form the spinal nerves. In this gathering up into bundles there is a certain amount of individual variation. The fibres, which in one individual are gathered up so as to make the lowermost fibres of a given bundle, may, in another individual, be taken to form the uppermost fibres of the bundle below. The variation rarely involves more than two-thirds of the fibres of a nerve. It may be represented diagrammatically as in Fig. 312, A, M, P.

The three arrangements may be spoken of as anterior (A), median (M), and posterior (P) arrangement of nerves. This relation of roots to nerves affects a whole series of nerves simultaneously, and to very nearly the same relative extent. Thus, if one lumbar nerve is anterior in arrangement, all the lumbar and sacral nerves will also be anterior in arrangement. On this basis it follows that the relative size of the strands which the several spinal nerves send to the trunks issuing from the lumbo-sacral plexus¹ will be different with each arrangement, and thus the anatomical characters of the lumbo-sacral plexus form a ready means of determining whether the arrangement of nerves is anterior, middle, or posterior. In consequence, instead of saying that in a given individual the arrangement of nerves is anterior, we may say, simply, that the plexus is anterior. The brachial nerves appear to vary much less frequently than the lumbo-sacral nerves.

The variation in the two sets of nerves is not necessarily in the same direction; the brachial plexus may be anterior, and the lumbo-sacral plexus posterior, but the statistics are insufficient to show how frequently this is the case.

The importance of this, for the subject we are considering, is that, in order to state at all accurately the several sympathetic ganglia to which each lumbar nerve sends nerve fibres in any one species of animal, it is imperative to know whether the arrangement of nerves is anterior, middle, or posterior. At the same time, it must be remembered that these variations are very numerous, and that the grouping of them into three forms is purely arbitrary.

The connections of the spinal nerves in relation to these variations have been only worked out in detail in the cat. I shall take the connections with an anterior arrangement of nerves as a basis for description; other forms I shall not deal with in detail; a few illustrations will be sufficient to show the general trend of the variations.

It need hardly be said that the spinal nerves in one species have only approximate homologues in the spinal nerves of another species. But as the structural outlines not only of species but of all mammals are the same, information as to the connections of the sympathetic fibres known for one animal, can, with proper allowance for anatomical peculiarities, be applied to any other.

In this table a number enclosed in brackets indicates that the connection of the spinal nerve with this ganglion has been determined by vasomotor fibres to the limb, or by secretory fibres to the foot. We have already seen (cf. 628) that the fifth and sixth lumbar sympathetic ganglia do not—when the plexus is anterior—send off pilo-motor fibres; nor do the seventh and eighth cervical, but these ganglia are merged in the compound ganglion stellatum.

As we have said, the connections of the several spinal nerves have been chiefly determined for pilo-motor fibres; we may make a brief statement with regard to the other kinds of nerve fibres.

1. The connection of the vasomotor fibres with the dorsal cutaneous branches of the intercostal and lumbar arteries, has not, in the experiments I have made, presented any constant difference from that of the pilo-motor nerves, though sometimes the connection was a little more extensive.

2. The secretory and vasomotor fibres for the hind-foot of the cat arise from the twelfth thoracic to the third lumbar inclusive. The ganglia which give off secretory fibres are the sixth and seventh lumbar, and the first and second sacral. With one or more of these ganglia, then, the twelfth to the third lumbar nerves must be connected. The exact connections have not been determined, but it appears probable that the twelfth thoracic sends a few fibres secretory and vasomotor to the seventh lumbar ganglia, and that the thirteenth thoracic sends a few such fibres to the first sacral ganglion; and this connection has, in consequence, been inserted in the table. The nerve having the maximum effect on secretion is the first or second lumbar.

The eleventh thoracic nerve occasionally sends a few secretory fibres to the foot, so that in these cases the eleventh thoracic must send fibres either to the fifth or sixth lumbar ganglion; this is not represented in the table.

3. The secretory and vasomotor fibres for the fore-foot arise from the spinal cord by the fourth to the ninth thoracic nerves inclusive, and

end in the ganglion stellatum, from which the post-ganglionic fibres are given off to the brachial nerves. The origin of these fibres closely resembles that of the pilo-motor fibres (cf. table), with the exception that the ninth thoracic nerve, whilst sending secretory and vasomotor fibres to the ganglion stellatum, does not send pilo-motor fibres to it. The maximum effect is usually obtained with the seventh nerve, the nerves above and below giving progressively less effect.

Occasionally there is slight secretion and pallor in the fore-foot on stimulating the third thoracic, possibly also from the tenth. Bayliss and Bradford found, in the dog, that the tenth and sometimes the eleventh nerve caused vaso-constriction in the fore-limb, and that the eleventh to the third lumbar caused vaso-constriction in the hind-limb.

4. The vasomotor fibres for the tail have very nearly the same origin and connections as the pilo-motor fibres for this region. They appear, however, to be a little more posterior.

General differences accompanying a posterior plexus.—With a posterior arrangement of nerves, the fourth lumbar nerve in the cat sends fibres to the coccygeal ganglion, and, according to the degree of downward shift, to more and more of the ganglia above up to the fifth lumbar. The posterior arrangement also considerably affects the connection of the seventh to the eleventh thoracic nerves. Of these nerves, four always send some fibres up and some down in the sympathetic chain; the remaining one, the eleventh thoracic nerve, may or may not do so. For details with regard to the variations in ganglionic connection of these nerves, the original papers must be referred to. The connection of the other nerves—except, perhaps, the third lumbar—are comparatively little affected by a shifting in their origin.

SYMPATHETIC NERVOUS SUPPLY OF THE SKIN OF THE EXTERNAL GENERATIVE ORGANS AND OF THE ANO-GENITAL REGION.¹

Effects produced by stimulation.—Stimulation of the lumbar sympathetic chain causes contraction of the unstriated muscles and blood vessels of the skin of the ano-genital region, and of the penis or vagina. The degree of contraction varies considerably in different parts and in different animals. We may mention the effects in the cat, dog, and rabbit in the male. In the female the effects are *mutatis mutandis* the same as in the male, but most of them are much less marked.

In all three animals the lumbar sympathetic causes strong contraction of the blood vessels, of the unstriated muscles of the body of the penis and of the prepuce, and of the retractor muscle of the penis. The retractor muscle is well developed in the dog, and, as in some other animals, it is a thin band of longitudinally arranged unstriated muscle, inserted at the attachment of the prepuce, and continued backwards in the middle line over the ventral surface of the corpus spongiosum and bulbos urethræ. In the cat and dog there is strong contraction of the tunica dartos of the scrotum; but the blood vessels of the scrotum are not strongly affected. In the rabbit the scrotal contraction is very slight. In the cat and dog there is little movement of the skin of the ano-genital region, apart from that of the scrotum. In the rabbit the skin covering the body of the penis contracts strongly.

¹ For list of papers and more detailed account, cf. Langley and Anderson, *Journ. Physiol.*, Cambridge and London, 1895, vol. xx, p. 85.

Course and origin of post-ganglionic fibres.—In the main the sympathetic fibres producing these effects have the same general arrangement as the nerves to the skin—that is, they leave the sympathetic by grey rami, pass to the spinal nerves, and follow the branches of these to the periphery. The branches followed in this case are the pudic nerves, which give rise to the *nervus dorsalis penis*, the genito-anal nerve or nerves, and the scrotal nerve. It must be noticed that the *nervus dorsalis* and the genito-anal nerves cause contraction of one or more of the striated intrinsic muscles of the penis.

The fibres of the grey rami which run to the pudic nerve follow, as regards their origin, the general rule of the fibres of the grey rami which run to the skin, *i.e.* they arise from the nerve cells of the corresponding ganglion. The ganglia in the cat and dog are the three sacral ganglia. But the ganglia in the sacral region often fuse together, so that a grey ramus is less restricted to a corresponding ganglion here than elsewhere; and the first sacral grey ramus not infrequently receives from the seventh lumbar ganglia some fibres for the external generative organs.

The pudic nerves vary in origin, and in correspondence with this there is some variation in the particular sympathetic ganglia, from which the fibres for the external generative organs arise.

Whilst the great majority of the sympathetic fibres for the external generative organs have the same general arrangement as the sympathetic fibres for the skin, a few have a different arrangement, passing by the inferior mesenteric ganglion (*cf.* p. 646), *i.e.* by a pre-vertebral ganglion, and reaching their destination by the hypogastric nerve and the pelvic plexus. The origin of these fibres from the spinal cord is the same as that of the fibres which run by way of the vertebral ganglia, and as they are few in number, we need not enter into any detailed account of them.

Origin of pre-ganglionic fibres from spinal nerves.—We have seen, in treating of the sympathetic fibres which supply the skin of the body generally, that the sacral ganglia receive pre-ganglionic fibres from the thirteenth thoracic and the first three lumbar nerves (*cf.* table, p. 634) in the cat. Since the sacral ganglia send fibres to the external generative organs, we might expect that the spinal nerves which influence the external generative organs, by way of the sympathetic, would be the thirteenth thoracic and the first three lumbar nerves; and we might expect that the second and third lumbar would have a greater influence than the first lumbar, and the first lumbar than the thirteenth thoracic nerve. And this, in fact, is the case. But there is an additional fact, which could not be deduced simply from the connections of the cutaneous fibres of the sacral ganglia, namely, that the fourth lumbar nerve, which has no effect on the hairs of the tail or on the blood vessels or glands of the foot, causes marked contraction of the musculature of the external generative organs. This difference is constant. Thus when, in the cat, the arrangement of nerves is posterior, and the fourth lumbar nerve sends some fibres to the tail and to the foot, the fibres for the external generative organs are shifted also, and the fifth lumbar nerve will cause retraction of the penis.

It is natural enough that the external generative organs should have a more extensive nervous supply than the sweat glands of the foot, or the hairs of the tail. But the fact that it is so, involves a selective arrangement of pre-ganglionic fibres with particular nerve cells, which

presents certain difficulties in considering the whole question. We need not, however, dwell on these. It is sufficient at present to point out that a bundle of pre-ganglionic fibres may run to a single vertebral ganglion, and restrict its connections with cells which supply a given region, entirely passing over the cells which supply fibres to other regions.

The external generative organs and a portion of the ano-genital skin receive efferent fibres from the sacral nerves by way of the pelvic nerve (*nervus erigens*), but these fibres do not belong to the sympathetic system, and will be considered later.

SOME GENERAL FEATURES OF THE SYMPATHETIC NERVE SUPPLY TO THE SKIN.

White and grey rami as paths for fibres from the spinal cord.— It appears from the preceding account that in the cat, the skin of the body receives in all cases sympathetic fibres from the first thoracic to the fourth lumbar nerves inclusive, and from no others,¹ except in those cases in which the nerves have a more posterior arrangement, when the skin receives some sympathetic fibres from the fifth lumbar nerve also. These nerves are the only ones which, on anatomical and microscopical investigation, are found to have white rami connecting them with the sympathetic chain. Since every nerve is connected with a vertebral ganglion by a grey ramus, the conclusion may fairly be drawn that all the sympathetic nerve fibres which run to the skin from the spinal cord, run to the sympathetic chain, on their way to the skin, by the white rami. And the conclusion is confirmed by the entire absence of sympathetic effect, when the roots of a lower thoracic or upper lumbar nerve² are stimulated after section of its white ramus, its grey ramus remaining intact.

The adoption of the view that the efferent fibres of the sympathetic pass to it by the white rami, is due to Gaskell.³ He arrived at his conclusions chiefly from a histological investigation of the white and grey rami and of the nerve roots. He pointed out that since the nerve roots contained very few non-medullated fibres, and since the few present might reasonably be supposed to end in the vessels of the spinal cord, it must be concluded that all the fibres running from the cord to the sympathetic are medullated fibres. Further, since medullated fibres are numerous in the white rami, and very scanty in the grey rami, it must be concluded that the white rami form the channel of communication between the spinal cord and the sympathetic.

This line of argument is satisfactory up to a certain point, but it is only conclusive as regards the great majority of fibres. It does not exclude the possibility of some efferent fibres passing by the grey rami. In fact, some grey rami contain a considerable number of medullated fibres (cf. p. 649).

If efferent fibres run to the sympathetic chain by way of the grey rami, they would degenerate on section of the nerve roots. Some experiments⁴ have been made on the lines thus suggested. As a rule, section of the nerve roots caused no degeneration of medullated fibres in the grey rami. In some

¹ A considerable number of observers have described sympathetic effects as occurring on stimulation of nerves which have grey rami only. As I have been unable to obtain any such effects, I attribute them to experimental errors.

² The uppermost thoracic white and grey rami are too closely associated to be cut separately.

³ *Journ. Physiol.*, Cambridge and London, 1886, vol. vii. p. 1.

⁴ Langley, *ibid.*, 1896, vol. xx. p. 60.

cases one or two degenerated fibres were found; these could be referred either to an implication of the spinal ganglion in the injury, or to fibres passing to the grey ramus from the white ramus of one of the cut nerves.

Limits of white rami in different mammals.—Of the cat we have already spoken. With regard to the white rami in other animals, our knowledge is less accurate than could be wished; but there is more or less evidence for the following statements. The first thoracic nerve is in all animals the first nerve to give off a white ramus. Relatively, as well as absolutely, there are fewer fibres in the first thoracic white ramus of the rabbit than in that of the cat, dog, monkey, and man. In the dog the last white ramus comes from the third lumbar nerve, with anterior arrangement of nerves, otherwise from the fourth. In the rabbit, the last nerve with a white ramus is the fourth or fifth. In man, it is, so far as is known, the second lumbar;¹ whether the second lumbar nerve has always a white ramus, and whether the third lumbar nerve has a white ramus when the arrangement of nerves is markedly posterior, has not been sufficiently investigated.

Course of post-ganglionic sympathetic fibres to the skin.—On reviewing the course of the sympathetic efferent fibres to the skin, we see that the peripheral fibres all arise from the ganglia of the sympathetic chain. The post-ganglionic fibres, almost without exception, pass by grey rami to the cerebro-spinal nerves, and accompany the cutaneous branches of these nerves. And, further, the fibres of each grey ramus have in the main the same distribution in the skin, as the afferent cerebro-spinal fibres of the nerve it accompanies.

General scheme of the connections of the white rami with the vertebral ganglia.—A consideration of the connections of the several spinal nerves given above, shows that they are arranged with a certain symmetry (cf. especially table, p. 634). Each spinal nerve, from the first thoracic to the fourth lumbar (cat, anterior arrangement), sends fibres to a series of ganglia, varying usually from six to nine, and in no case to a single segmental ganglion. Each spinal nerve sends its rays of fibres a little more anteriorly than the spinal nerve behind it, and a little more posteriorly than the one in front of it. Thus, speaking broadly, the successive spinal nerves give off sympathetic fibres to successive largely overlapping portions of the skin of the body.

Although each spinal nerve sends fibres to a series of ganglia, it does not send an equal number to each of them. In each case it sends more fibres to one or two ganglia than to any others; and from this position of maximum supply there is a regular diminution in the number of fibres sent to the several ganglia of the series. The position of maximum supply is not necessarily, or even usually, in the middle of the series, but it would take us too far to give here an account of the details of distribution.

A compound ganglion behaves in some respects like a series of simple ganglia. We have seen that the ganglion stellatum sends grey rami to a series of spinal nerves. The nerve cells giving off these grey rami are connected with the spinal nerves in much the same way as if they formed a series of separate ganglia. Thus, a spinal nerve may be connected with some of the grey rami, and not with the rest, but the former will in all cases

¹ Langley and Latham, *Journ. Physiol.*, Cambridge and London, 1893, vol. xv. p. 242; Harman (*Journ. Anat. and Physiol.*, London, 1898, vol. xxxii.) finds that in man the rami of the second lumbar nerve have about two hundred medullated fibres, and that the rami of the third lumbar have about twenty only.

form a series, as they would if they arose from separate ganglia. So also with the coccygeal ganglion, this sends grey rami to six coccygeal nerves; when the arrangement of nerves is posterior, the pilo-motor connections with the several grey rami may be as follows:—The second lumbar nerve sends a few fibres to the first coccygeal ramus, and none to the rest; the third lumbar nerve sends a considerable number of fibres to the first, second, and third grey rami, and a few to the rest; the fourth lumbar nerve sends fibres to all the grey rami.

A question which naturally arises from the fact that one spinal nerve is connected with a number of ganglia, is whether a single nerve fibre runs to one ganglion only, or whether it divides and runs to some or to all. Since a given spinal nerve does not affect equally all the ganglia of the series to which it runs, it is fairly certain that the constituent nerve fibres in it do not divide into branches equal in number to that of the ganglia, and send one branch to each ganglion. That in some cases the constituent fibres run to comparatively few ganglia, is obvious from a comparison of the innervation with different arrangements of the spinal nerves. In the anterior arrangement, the third lumbar nerve causes strong erection of hairs in the whole of the tail and over the sacrum, *i.e.* it sends fibres to the fourth lumbar and all the lower ganglia, and the fourth lumbar nerve has no effect at all upon the hairs. As, however, the nerves shift downward, some of the fibres of the third lumbar nerve pass into the fourth; these will naturally be the ones contained in the lowermost nerve roots. Thus a certain number of fibres ordinarily contained in the third lumbar nerve become separated from the rest, and pass into the fourth lumbar nerve. On stimulating these, it is found in some cases that they do not affect the hairs in the whole of the region from the sacrum downwards, but in part of it only; for example, only in the latter two-thirds of the tail. Thus these pilo-motor fibres send no branches to the ganglia from the fifth lumbar to the third sacral, but end entirely in connection with the coccygeal ganglion. As the coccygeal ganglion is made up of about six single segmental ganglia, the nerve fibres may still divide and give a branch to each. We may conclude, then, that the ganglionic connection of individual nerve fibres in a spinal nerve is usually less extensive than that shown in the table (p. 634) for the several spinal nerves. We shall later consider a method of determining approximately the number of single ganglia with which individual nerve fibres are connected (*cf.* p. 681).

It will be noticed also that a spinal nerve sending fibres to a ganglion, even when this is a single segmental ganglion, does not necessarily send fibres to all the kinds of nerve cells in the ganglion. Thus the fourth lumbar nerve sends fibres to the sacral ganglia, but these fibres are in connection with the cells which innervate the external generative organs, and not in connection with the cells which innervate the vessels and hair muscles of the root of the tail.

SYMPATHETIC NERVES SUPPLYING THE SKELETAL MUSCLES.

We have seen that the grey ramus running to a spinal nerve contains fibres which accompany the cutaneous branches of the nerve, and which supply various structures occurring in the skin in the region to which the cutaneous branches run. We might, then, naturally expect that the grey ramus would also send fibres to the other branches of the spinal nerve, and thus supply vasomotor fibres to the arteries of the skeletal muscles.

We shall consider separately the evidence with regard to vaso-constrictor and vaso-dilator fibres.

Vaso-constrictor fibres.—According to Grützner and Heidenhain,¹ the abdominal sympathetic trunk in the dog contains vaso-constrictor fibres for the muscles of the limb. They found that stimulation of the abdominal sympathetic trunk causes a slight fall of temperature in the gastrocnemius, and a fall of blood pressure in the veins carrying blood from the extensor group of muscles of the thigh.

Gaskell² observed directly the blood-flow from the extensor group of muscles of the thigh; he obtained a slight, but only a slight, decrease of blood-flow on stimulating the abdominal sympathetic. The result is not convincing as to the presence of vasomotor fibres, since Gaskell obtained only a transient increase of blood-flow by section of the sympathetic, and no decrease by stimulating the fifth lumbar grey ramus. I have not seen any change of colour in the muscles of the limbs in the cat and rabbit, on stimulation of the abdominal sympathetic, though sometimes there appeared to be a slight constriction of the larger arteries. We may conclude that, if there is a sympathetic vaso-constrictor supply for the muscles of the limbs, it is at any rate not well developed.

The circulation in some of the small muscles of the eye and of the larynx can be examined under the microscope. On stimulation of the cervical sympathetic, I have not found any certain change in the size of the small arteries of the muscle; sometimes there was a slight slowing in the blood-flow in the capillaries, suggesting a contraction of some larger arteries outside the muscle.

Vaso-dilator fibres.—The presence of vaso-dilator fibres in the nerves supplying the muscles of the limb has been advocated by Gaskell,³ and by Heidenhain with his collaborators.⁴ Gaskell did not deal with the origin of these fibres. Heidenhain considered that they ran to the muscular nerves from the abdominal sympathetic.

We are here only concerned with the question of vaso-dilator fibres of sympathetic origin, but as there is some ground for believing that if vaso-dilator fibres are present in the muscular nerves they arise from the sympathetic, it is advisable to mention, though briefly, the chief experiments which have been brought forward to show that the muscles receive vaso-dilator fibres.

Gaskell observed the rate of blood-flow from the extensor muscles of the thigh of the dog on stimulation of the crural nerve. Normally, this caused great increase of blood-flow, after a preliminary decrease. When curari was given in minimal amount, just sufficient to paralyse the motor nerves to the muscle, an increase in the blood-flow was sometimes obtained on stimulating the crural. When a larger dose of curari was given, the crural became ineffective.

Now, the amount of curari which paralyses the vaso-dilator action of the crural does not paralyse any known vaso-dilator nerve fibres, neither those of the chorda tympani, nor of the nervus erigens, nor of the dog's cervical sympathetic. In other words, the vaso-dilator fibres of muscle,

⁴ Grützner and Heidenhain, *Arch. f. d. ges. Physiol.*, Bonn, 1878, Bd. xvi. S. 1; Heidenhain, Alexander u. Gottstein, *ibid.*, S. 31.

if they exist, are much more easily paralysed by curari than the other known vaso-dilator fibres. In view of this, it is impossible to avoid the suspicion that the dilatation of the vessels, which was observed when a minimal dose of curari was given, was accompanied by an unnoticed slight contraction of the skeletal muscular fibres.

Heidenhain experimented on the sciatic nerve. He found that when the sciatic nerve was stimulated four days after it had been cut, a rise of temperature was produced in the gastrocnemius. The rise, however, was slow and slight. It was produced on completely curarised animals, and, according to Gaskell, curari paralyses the vaso-dilator nerves to muscle.

It is obvious that the conclusive form of experiment, as regards vaso-dilator fibres of sympathetic origin, is to observe the effects of stimulating the abdominal sympathetic. Gaskell found a slight decrease of the blood-flow through the muscles. Heidenhain found a slight fall of temperature. Neither found, on direct stimulation, evidence of the presence of vaso-dilator fibres. The absence of vaso-dilator action has been attributed to the antagonistic action of the vaso-constrictor fibres. What we know of the antagonism of vaso-constrictor and vaso-dilatation fibres, makes it permissible to assume that a few vaso-dilator fibres may be present in the abdominal sympathetic, but is directly opposed to the assumption that there are sufficient vaso-dilator fibres to produce the very large increase of blood-flow which occurs during contraction of a muscle. It was pointed out by Gaskell that the increase of blood-flow accompanying contraction, however produced, is comparable to the increased blood-flow produced elsewhere by the chorda tympani and by the nervus erigens. If a few vaso-constrictor fibres are stimulated simultaneously with either of these nerves, there is either vaso-dilatation at once or after a preliminary constriction; if many vaso-constrictor fibres are stimulated with either of these nerves, there is complete vaso-constriction, with or without an after-dilatation. In no case are results obtained similar to those so far obtained by stimulating the abdominal sympathetic, namely, with all strengths of stimulus a slight constriction without after-dilatation.

Further, on Heidenhain's view that both the vascular effects in muscle on stimulating a muscle nerve are due to fibres coming from the abdominal sympathetic, it is inexplicable why the muscle nerve and the sympathetic should produce such very different results.

There is, then, no satisfactory evidence that the sympathetic sends vaso-dilator fibres to the skeletal muscle, although it is possible that it sends a few. As a provisional hypothesis, we may suppose that the increased blood-flow which takes place in muscle, on stimulation of its motor nerve, is brought about by changes of some kind in the muscle fibres.

In the frog, it was shown by Gaskell¹ that the branch of the fifth nerve which supplies the mylo-hyoid muscle, contains vaso-dilator fibres for it. This muscle, however, is more related to the muscles of the tongue—to which in mammals vaso-dilator fibres run—than to the muscles of the limbs, so that the behaviour of the mylo-hyoid does not justify us in drawing any conclusion as to the innervation of the limb muscles, or of the skeletal muscles of the body in general. It may be noticed the vaso-dilator fibres of the mylo-hyoid are not paralysed by

¹ *Journ. Anat. and Physiol.*, London, 1877, vol. xi. p. 720.

curari. Whether these fibres arise from a cranial nerve, or reach the fifth nerve from the sympathetic, has not been investigated.

SYMPATHETIC FIBRES SUPPLYING THE THORACIC AND ABDOMINAL VISCERA.

Thoracic viscera.—The relations of the sympathetic nerves to the heart and lungs have been already noticed in previous articles in this volume, so that I need only mention a few points here.

The accelerator fibres for the heart proceed from a rather more anterior series of the spinal nerves than do the vasomotor fibres for the lungs. The accelerator fibres are contained chiefly in the second, third, and fourth thoracic nerves, some fibres also at times being present in the first and fifth.¹ The vasomotor fibres for the lungs arise, according to Bradford and Dean, from the third to the seventh thoracic nerves inclusive.²

The fibres proceed partly by strands leaving the ganglion stellatum, forming what is sometimes called the *nervus accelerans*, and partly by strands leaving the inferior cervical ganglion. The nerve cell connection of the pre-ganglionic fibres has not been worked out, but it is probable that the majority end in connection with the cells of the ganglion stellatum, and the minority in connection with the cells of the inferior cervical ganglion. Assuming that the accelerator fibres do end in the ganglion stellatum, we have the curious fact that, whilst the origins of the nerve fibres supplying the external carotid and the heart are practically the same, the nerve cells with which the nerve fibres are connected have become widely separated, and that the first, second, and usually also the third thoracic nerves are connected with no cells of the ganglion stellatum, except those supplying the thoracic viscera.

Upper abdominal viscera.—The nerve fibres to the upper abdominal viscera run by way of the splanchnic nerves, the solar ganglia and the bundles of nerve fibres accompanying the celiac, the superior mesenteric, and the renal arteries. The splanchnic nerves on each side consist of the main splanchnic, and of two or three smaller nerves. When there are three nerves only, as is generally the case, they are sometimes spoken of as the great, the small, and the smallest splanchnic. Not infrequently the term "splanchnic nerve" is used to include all three nerves.

The solar ganglia, which, it will be remembered, are pre-vertebral ganglia, consist of a group of ganglia joined by nerve strands. These are in close connection with the celiac, superior mesenteric, and renal arteries. From the ganglia proceed nerve fibres, which accompany and innervate the arteries, and innervate also the organs to which the arteries run. The fibres which accompany the arterial trunks arise in large part, though by no means wholly, from different ganglionic masses, so that we may speak of the celiac ganglia, the superior mesenteric ganglia, and the renal ganglia, as sending their fibres in the main to their respective arteries. Certain of the renal ganglia are close to the hilum of the kidney, but it is convenient to include them in the solar ganglia.

The several abdominal organs, with the exception of the kidney,

¹ Cf. *Phil. Trans.*, London, 1892, vol. clxxxiii. p. 107.

² *Proc. Roy. Soc. London*, 1889, vol. xlv. p. 369.

receive fibres from the splanchnic nerves of both sides. And, so far as is known, the fibres proceeding from the corresponding ganglia of the two sides, for example the two superior mesenteric ganglia, have the same peripheral distribution.

The earliest attempts to determine which spinal nerves innervate a given abdominal viscus was made by Bulgak¹ (1877). He obtained contraction of the spleen, on stimulating the third to the tenth thoracic nerves on the left side. No further observations of the kind were made until 1889. Bradford² then investigated the origin of the vasomotor fibres of the kidney by Roy's oncometer method. He found that vasomotor nerves run to the kidney in the dog in the fourth thoracic to the fourth lumbar nerves inclusive; the maximum effect was obtained from the eleventh, twelfth, and thirteenth thoracic nerves, a moderate effect from the sixth to the tenth thoracic, a very slight and inconstant effect from the other nerves.

Bechterew and Mislawsky,³ also in 1889, obtained evidence of the presence of inhibitory fibres for the small intestine of the dog, in the sixth thoracic to the first lumbar nerves inclusive, and especially in the ninth, tenth, eleventh, and twelfth thoracic nerves. In one experiment inhibitory effects were obtained by stimulating the nerves above the sixth thoracic.

In the last few years a considerable number of observations have been made.

Bayliss and Starling⁴ (1894) have found that a rise of portal blood pressure is produced in the dog by stimulating the third to the eleventh thoracic nerves inclusive; a considerable effect being produced by the fifth, sixth, seventh, eighth, and ninth; a less effect by the fourth and tenth; and a slight effect only by the third and eleventh. On general grounds, partly anatomical and partly physiological, I⁵ came to the conclusion (1895) that in the cat (with anterior lumbo-sacral plexus) the sixth thoracic to the second lumbar nerves inclusive send pre-ganglionic fibres to the solar ganglia, and that these ganglia send post-ganglionic fibres to all the abdominal viscera.

Schäfer and Moore⁶ (1896) reinvestigated the innervation of the spleen in the dog, using the plethysmographic method. They found motor nerves to be present in the third thoracic to the first lumbar inclusive (on both sides). The most marked effect was obtained on stimulating the sixth, seventh, and eighth thoracic nerves; a very distinct contraction on stimulating the fifth, ninth, and tenth nerves; a slight contraction on stimulating the third, fourth, eleventh, twelfth, and thirteenth thoracic and the first lumbar nerve.

¹ *Virchow's Archiv*, 1877, Bd. lxxix. S. 181. For other literature, cf. Schäfer and Moore (*op. cit. infra*).

² *Journ. Physiol.*, Cambridge and London, 1896, vol. x. p. 358. I have seen in the cat prompt and great pallor of the kidney and of the upper part of the ureter on stimulating the first lumbar nerve, and slower, though still great, pallor on stimulating the second lumbar nerve. It appears to me unlikely that the third lumbar nerve, and still more unlikely that the fourth lumbar nerve, send fibres to the kidney in the dog.

³ *Arch. de physiol. norm. et path.*, Paris, 1889, Suppl., p. 243.

⁴ *Journ. Physiol.*, Cambridge and London, 1894, vol. xvii. p. 120; the fibres to the portal vein run in the splanchnic nerves. It had already been shown by Mall (*Arch. f. Physiol.*, Leipzig, 1892, S. 409) that the splanchnic contains vasomotor fibres for the portal vein.

⁵ "Short Account of the Sympathetic System," 1895.

⁶ *Journ. Physiol.*, Cambridge and London, 1896, vol. xx. p. 1.

François-Franck and Hallion¹ (1896, 1897) have investigated in the dog the vasomotor supply of the liver, the pancreas, and the small intestine, and the first part of the large intestine. They found that the vasomotor fibres in each case leave the spinal cord by the sixth thoracic to the second lumbar nerve inclusive. The vessels of the large intestine only occasionally receive fibres from the sixth thoracic; the vessels of the small intestine sometimes receive vasomotor fibres from the fifth, and occasionally from the fourth thoracic. The maximum effect on the intestine appeared to be obtained from the twelfth and thirteenth thoracic nerves. The second lumbar had a slight effect only upon the vessels of the pancreas.

Lastly, Bunch² has experimented on the visceromotor and visceroinhibitory action of the spinal nerves on the small intestine of the dog and cat. He finds the innervation to extend from the sixth thoracic to the second, third, fourth, or fifth lumbar. The greatest effect was obtained from the eighth thoracic to the first lumbar.

The several observations given above do not enable us to form a simple and consistent scheme of the innervation of abdominal viscera, and we may consider the matter from another point of view.

By dissection, it is easy to see that a large proportion of the splanchnic nerve fibres arise from the white rami communicantes, running in the sympathetic chain for a variable distance. And there is good reason to believe that all the splanchnic fibres are the direct continuation of the fibres of the white rami (cf. p. 646). If this be so, it follows that if any white ramus can be shown not to send fibres to the splanchnic nerves, the spinal nerve from which the white ramus springs, does not send fibres to the solar ganglia.

In the cat and dog the fibres of the great splanchnic nerve can be traced upwards in the sympathetic chain as far as the sixth thoracic ganglion,³ and this was one of the facts which led me earlier to place the upper limit of connection of the spinal cord with the solar ganglia at the sixth thoracic nerve. But, on examining the course of the white rami, some fibres of the fifth thoracic ramus can be seen to descend in the sympathetic chain. As these fibres do not run to the vertebral ganglia (cf. p. 634), we may conclude that they run to the splanchnics. It is possible that a few fibres also descend from the fourth white ramus. But, so far as I have seen, none of the fibres of the third white ramus (cat) run downwards. We may then conclude that the uppermost nerve to send fibres to the solar ganglia is the fourth or fifth thoracic.

The fibres of the lowest splanchnic strand in the cat usually leave the sympathetic chain a little above the third lumbar white ramus.⁴ There is some variation here, according as the arrangement of nerves is anterior or posterior. On tracing the white rami, it can be seen that the second lumbar white ramus constantly sends fibres to the smallest splanchnic, and that the third lumbar white ramus sends a few fibres to it, if the arrangement of nerves is posterior. Probably, in the dog, the

¹ *Arch. de physiol. norm. et path.*, Paris, 1896, p. 478 (intestine); *ibid.*, 1896, p. 921 (liver); *ibid.*, 1897, p. 661 (pancreas). These authors stimulated the sympathetic chain or the white rami, and not the spinal nerves in the vertebral canal.

² *Journ. Physiol.*, Cambridge and London, 1898, vol. xxii. p. 357.

³ In man, it is said that the splanchnic fibres can be followed up to the level of the second or third thoracic ganglion.

⁴ In man, the smallest splanchnic leaves the sympathetic chain about the level of the twelfth thoracic ganglia.

lowest nerve sending fibres to the splanchnic is, with an anterior arrangement of nerves, the first lumbar, and with a posterior arrangement of nerves, the second lumbar.

It will be seen that the conclusions thus reached agree very closely with the experimental results of François-Franck and Hallion, on the vasomotor supply of the liver, pancreas, and intestine in the dog. The nerves which had a marked effect were the sixth thoracic to the first lumbar; the second lumbar had a slight effect—probably there would have been none if the arrangement of nerves had been anterior; the fifth thoracic had an effect sometimes, and the fourth very rarely.

On the other hand, the third thoracic nerve is stated by Bulgak and by Schäfer and Moore to have an effect on the spleen; the third and fourth lumbar are said by Bradford to cause contraction of the kidney vessels; and the third, fourth, and fifth lumbar nerves are said by Bunch to cause contraction or inhibition of the small intestine. But in all cases the effects were slight, and in none were the nerve fibres producing them shown to pass by the splanchnics. With regard to fibres from the third and fourth lumbar nerves, it is possible that some might pass to the intestine, etc., by way of the inferior mesenteric ganglia, but I think this is very unlikely. It is also to be borne in mind that in the dog, so far as is known, the fifth lumbar nerve never has a white ramus, and that sometimes (anterior plexus) the fourth lumbar nerve also has no white ramus.

We have said that the coeliac artery, the superior mesenteric artery, and the renal artery receive their nerves in large part, but not altogether, from separate ganglia. A comparison of the facts we have learnt with regard to the connections of the vertebral ganglia, does not give us any sure guidance as to the connection of the several pre-vertebral ganglia, but it suggests that a more anterior set of nerves will pass to the coeliac than to the superior mesenteric ganglia, and to the superior mesenteric than to the renal ganglia, and that these sets will overlap considerably. It suggests further that, as regards the connection of the spinal nerves with the several arteries, there will be an additional overlap, due to fibres from one ganglion passing to more than one artery.

It is not worth while to discuss this matter at present, since there are practically no anatomical or histological data, and the experimental data are insufficient. It may, however, be pointed out that the spinal nerves which have the maximum effect on the spleen are the mid-thoracic (Schäfer and Moore), whilst those which have the maximum effect upon the vessels of the intestine (François-Franck and Hallion) and of the kidney (Bradford) are the lower thoracic. It may be expected that further investigation will show that the maximum effect on the intestine is obtained from a more anterior set of nerves than that which gives the maximum effect on the kidney.

Lower abdominal viscera.—The sympathetic nerve strands which supply the lower abdominal and pelvic viscera, are three or four on each side. Since these strands correspond to the splanchnic nerves, we may call them the *inferior splanchnic nerves*.¹

The inferior splanchnic nerves run to the inferior mesenteric ganglia. In the cat, rabbit, and many other animals, there are two on each side, one above and one below the inferior mesenteric artery, connected with one another by nerve strands. As the connecting strands are often short, the whole group is often spoken of as a single ganglion, the inferior mesenteric ganglion.

¹ They have also been called the rami efferentes of, and the spinal branches to, the inferior mesenteric ganglion.

The inferior mesenteric ganglion gives off several strands—the colonic nerves—which accompany the inferior mesenteric artery. They give off also, on each side, a hypogastric nerve which runs downwards to the pelvic plexus, and ascending branches which run partly to the descending colon and partly to the solar plexus.

Stimulation of the colonic branches causes great pallor, with inhibition and sometimes contraction of the descending colon and rectum; and, in the cat and dog, slight contraction and pallor of the internal anal sphincter.

The ascending branches have a similar but smaller effect upon the upper part of the descending colon.

The hypogastric nerves cause great pallor with more or less contraction of the Fallopian tubes and uterus, or corresponding organs in the male; weak contraction of the bladder, chiefly in the region around the ureters, but little or no contraction of the blood vessels; pallor with inhibition or contraction of the rectum and end of the descending colon; slight contraction and pallor of the internal anal sphincter with its mucous membrane, and of the external generative organs.

The inferior mesenteric ganglia in the cat receive nerve fibres from the first to the fourth lumbar nerves, and, when the arrangement of nerves is posterior, from the fifth lumbar nerve also; occasionally they receive a few fibres from the lower thoracic nerves. In the dog the origin of the fibres is a little higher, and in the rabbit it is a little lower, than in the cat.

Taking the matter generally, it may be said that each spinal nerve which sends fibres to the inferior mesenteric ganglion, is capable of producing all the effects which we have mentioned above as produced by stimulating the nerves given off by the ganglia.

The intensity of the effects with an anterior arrangement of nerves is marked with the third or fourth lumbar, moderate or slight with the second lumbar, and slight or absent with the first lumbar.

With a posterior arrangement of nerves the fifth lumbar also produces an effect, the effect becoming greater as that of the third lumbar diminishes.¹

Nerve-cell connection of the sympathetic fibres supplying the abdominal viscera.—It can easily be shown in the rabbit that the very great majority of the fibres running from the spinal cord to the abdominal viscera end in the pre-vertebral ganglia. After injection of a small amount of nicotin in the rabbit, the nerve roots, the splanchnics proper,² and the inferior splanchnics³ have either no effect or a mere trace on the blood vessels or abdominal and pelvic viscera; but all the normal effects can be readily obtained by stimulating the fibres given off by the pre-vertebral ganglia. And on degeneration of the anterior roots of a nerve sending fibres to a splanchnic strand, numerous

¹ For the differences in the innervation of the several organs which occur in correspondence with the arrangement of the spinal nerves, for the slight differences which exist in the innervation of the several organs, and for an account of the literature of the subject, see Langley and Anderson, *Journ. Physiol.*, Cambridge and London, 1895, vol. xviii. p. 67 (lower part of intestine); *ibid.*, 1895, vol. xix. p. 71 (bladder); p. 86 (external generative organs); p. 122 (internal generative organs).

² Langley and Dickinson, *Proc. Roy. Soc. London*, 1889, vol. xvi. p. 424; Langley *Journ. Physiol.*, Cambridge and London, 1896, vol. xx. p. 223; Bunch (*ibid.*, 1897, vol. xxii. p. 357) comes to the same result as regards the motor and inhibitory fibres of the small intestine.

³ Langley and Anderson, *ibid.*, 1895, vol. xix. p. 131.

degenerated fibres can be traced into the strand. In the cat, after degenerative section of the first five lumbar nerve roots, it was found by Anderson and myself¹ that the several inferior splanchnic nerves in nearly every case had no effect when stimulated, although the colonic fibres and the hypogastrics caused contraction of arteries and the remainder of their customary actions.

Occasionally, after injection of nicotin in the rabbit, a rise of 1 or 2 mm. of arterial pressure may follow on stimulation of the splanchnics. Theoretically, I see no adequate reason why some nerve cells which send their fibres to the abdominal viscera, should not be situated in the vertebral ganglia, for it is a probable assumption that the pre-vertebral and the vertebral ganglia have separated from a common mass, and in that case it might easily happen that the separation would not be strictly carried out. In the ganglion stellatum the

FIG. 313.

separation does not appear to have taken place, or only partially. But if the slight rise of blood pressure mentioned above be taken as showing the occasional presence of a few fibres proceeding from cells in the vertebral ganglia, it is clear that they run to the periphery without having nerve cells in their course, unless we suppose that the connection of sympathetic nerve cells with other nerve cells is not paralysed by nicotin, a supposition on which I shall later have something to say (p. 685).

There is, however, good evidence that some efferent fibres run through the inferior mesenteric ganglion, pass down the hypogastric nerves, and end in connection with cells of the pelvic plexus. A sufficient proof of this is the degeneration of nerve fibres which takes place in the hypo-

¹ *Journ. Physiol.*, Cambridge and London, 1894, vol. xvi. p. 432.

gastric nerves after section of the roots of the lumbar nerves.¹ And this is, no doubt, also the case with the solar ganglion; some fibres traverse it and run to small peripheral groups of ganglion cells, such as those which occur in the pancreas. Whether such fibres send a branch to the main pre-vertebral ganglion, as they traverse it, requires experiments of a different kind to determine (cf. p. 679). We may for the present regard the splanchnic and inferior splanchnic nerve fibres as arranged as in Fig. 313; the great majority, as in A; comparatively few, as in B; and possibly, occasionally, a few as in C.

It has long been known that the major splanchnic contains a considerable number of non-medullated fibres, and it is in large part this fact which has led to the unquestioned belief that the ganglia of the sympathetic chain send fibres to the solar ganglia or to the abdominal viscera. It is *a priori* possible that the non-medullated fibres in the splanchnic nerve should arise from the solar ganglion and run to the ganglia of the sympathetic chain, or to their grey rami. But this possibility I put on one side, since I have not observed any pilo-motor, vasomotor, or other similar effect, on stimulating the central end of the splanchnic nerve after removal of the spinal cord. If, then, the view I have given above be accepted, namely, that very few if any fibres pass from the cells of the vertebral ganglia to the splanchnic nerves, we must take the non-medullated fibres to be pre-ganglionic fibres which have lost their medulla (cf. p. 650).

THE NERVE FIBRES OF THE SYMPATHETIC SYSTEM.

Distribution of medullated and of non-medullated fibres.—A striking feature of the sympathetic system is the predominance of small medullated fibres in it. This was pointed out by Bidder and Volkmann² in 1842. The great majority of its medullated fibres vary from $2\ \mu$ to $3.5\ \mu$ in diameter.

Other larger medullated fibres are present to about $12\ \mu$. These vary in number in the different strands, and although all sizes, from 3.5 to $12\ \mu$, occur, they may, broadly speaking, be divided into two classes—medium-sized fibres about $5\ \mu$, and large fibres of about $8\ \mu$. The size of small, medium, and large vary somewhat in different animals. Very large medullated fibres, 15 to $20\ \mu$, which are common in the roots of the spinal nerves, do not occur in the sympathetic system.

The large fibres of the sympathetic occasionally divide. In this case the branches are of somewhat less diameter than the parent fibre. Most of the large fibres in the cat can be traced to Pacinian bodies.

In the trunk of the sympathetic the large and medium fibres are most numerous in the lower dorsal and upper lumbar regions. Here, too, they are somewhat larger than in the lower lumbar region. Most of them pass outwards in the superior and inferior splanchnics. Below the lowest inferior splanchnic strand, there are few fibres larger than $5\ \mu$ in diameter, and they diminish in number in passing downwards. In the cervical sympathetic there are sometimes a few medium and

¹ Langley and Anderson, *Journ. Physiol.*, Cambridge and London, 1894, vol. xvii. p. 183.

² "Die Selbstständigkeit des sympathischen Nervensystems," Leipzig, 1842. Numerous observations of the size of the medullated fibres in the different nerves of vertebrates are here given.

large fibres, and sometimes none; the few which may be present probably arise from the vagus. In the cat, the sympathetic chain—apart from its ganglia—contains few non-medullated fibres. Some of these are fibres we have spoken of above (p. 629) as passing from one ganglion to the ramus of a neighbouring ganglion. In the rabbit, non-medullated fibres are more numerous, and in the sacral region they are the chief constituent, very few medullated fibres being present. These non-medullated fibres I take to be largely pre-ganglionic fibres which have lost their medulla (cf. p. 650).

The non-medullated fibres make up about one-fifth of the transverse section of the great splanchnic nerve (cf. p. 642). There are fewer in the small splanchnics, still fewer in the inferior splanchnics and in the cervical sympathetic.

In the branches proceeding from the superior cervical ganglion and the pre-vertebral ganglia the non-medullated fibres preponderate. Some have but few medullated fibres, and others have many.

The internal carotid branches of the superior cervical ganglion contain in the cat several hundred small medullated fibres, in the rabbit there are a few only, and usually a few only in the dog. The external carotid branches of the superior cervical ganglion contain only a few medullated fibres. A small nerve filament, consisting chiefly of medium and large fibres, runs to these branches from the vago-glosso-pharyngeal nerve. The cardiac accelerator nerve, which runs from the ganglion stellatum, has a few medullated fibres up to about 5μ in diameter. The branches from the solar ganglia vary greatly in the number of medullated fibres they contain. The hypogastric nerve¹ in the cat contains 350 to 900 medullated fibres; of these, one or two only, and sometimes none are large.

In the grey rami the great majority of the nerve fibres are non-medullated. The limit of size of the medullated fibres is about 1.8 to 10μ in diameter; they are scattered amongst the non-medullated fibres. The number of medullated fibres in the grey rami varies considerably in different mammals. In the rabbit there are few, in the cat there are many. Thus in the seventh lumbar grey ramus of the cat there may be more than 300 medullated fibres.

The variation in the number of medullated fibres in the grey rami affects almost entirely the small ones, and the most constant form is the medium fibre. Most of the small medullated fibres of the grey rami are post-ganglionic fibres (cf. p. 650). Others are pre-ganglionic fibres on their way to aberrant sympathetic cells. Others, again, medium and large, as well as small, are afferent fibres which run in the white rami to the sympathetic chain from the spinal ganglia, and after a course of varying length leave the chain and accompany the post-ganglionic efferent fibres. When the grey ramus divides, part running centrally and part peripherally, medullated fibres, small and medium, accompany both branches. Both, then, on stimulation, should produce some reflex effect. This, however, so far, has not been obtained.² There is reason to believe that one or two of the medium and large fibres of the grey rami have their trophic centre in the corresponding spinal ganglia,³ i.e. that not all the afferent fibres run to the spinal cord by the white rami,

¹ Langley and Anderson, *Journ. Physiol.*, Cambridge and London, 1894, vol. xvii. p. 177.

² Langley, *Phil. Trans.*, London, 1892, vol. clxxxiii. p. 120.

³ Langley, *Journ. Physiol.*, Cambridge and London, 1896, vol. xx. p. 55.

but that a few run to it by the grey rami. There is not, however, any definite physiological evidence for the existence of such afferent fibres.

Loss of medulla by pre-ganglionic fibres.—We have already seen reason to believe that some of the pre-ganglionic fibres of the splanchnic nerve lose their medulla on their way to the pre-vertebral ganglia (cf. p. 648). The evidence that pre-ganglionic fibres are not necessarily medullated up to their terminations, is still stronger in the case of the vertebral chain.

By the degeneration and by the nicotin method, it can be shown that in the cat fibres run from the upper lumbar white rami to the sacral and coccygeal ganglia without passing through nerve cells. In the rabbit the nicotin method only has been tried; it gives the same results. We may then conclude that in the rabbit there are pre-ganglionic fibres, stretching from the upper lumbar white rami to the sacral and coccygeal ganglia. But since the sympathetic in the sacral and coccygeal region of the rabbit contains very few medullated fibres, it follows that the pre-ganglionic fibres in this region must be non-medullated, and as they are medullated in the white rami, they must become non-medullated in passing down the sympathetic chain. In other words, pre-ganglionic fibres may become non-medullated some distance from their termination in the vertebral ganglia.

Post-ganglionic medullated fibres.—Although Remak discovered non-medullated nerve fibres (organic fibres) in 1838,¹ their nervous nature was not generally accepted till about 1860. Thus, most of the early observers who believed that the sympathetic ganglia gave off nerve fibres at all, necessarily believed that they gave off medullated nerve fibres (primitive nerve fibres, tubular fibres). Those observers, on the other hand, who accepted the nervous nature of Remak's fibres, were inclined to think that these alone were sympathetic fibres, and that all medullated fibres were of cerebro-spinal origin. As time went on, the observations of Bidder and Volkmann² on the origin of small medullated fibres from sympathetic and spinal ganglia seemed more and more irreconcilable with the results of research, and in consequence less and less attention was paid to them. Thus, some writers passed by the question of the medullation of ganglionic nerves, without even considering it, and others took for granted that no further proof was required to show that all fibres given off by sympathetic nerve cells are non-medullated.

The proof brought forward by Bidder and Volkmann, that in the frog small medullated fibres arise from sympathetic ganglia, was fairly conclusive. The essential part of the proof was the fact that many more small medullated fibres run from the sympathetic ganglia to the periphery, than run to the ganglia from the central nervous system. As at that time there was practically no knowledge of the connection of nerve cells with nerve fibres, or of the finer structure of the ganglia, it might have been objected that the increase in the number of fibres peripherally of the ganglia was merely due to a division of nerve fibres in them. But, in the light of our present knowledge of the ganglia, Bidder and Volkmann's proof must be regarded as conclusive. They showed also, and in the same way, that the ciliary ganglion gives off medullated fibres.

¹ Remak, "Observ. anat. et micros. de systematis nervosi structura," Berlin, 1838.

² "Die Selbstständigkeit des sympathischen Nervensystems," Leipzig, 1842.

The observations of Waller¹ on the superior cervical ganglion of mammals showed that this ganglion also gives off medullated nerve fibres. He did not himself make this deduction, presumably because he, like many others at the time, considered the question to have been settled by Bidder and Volkmann. He found that section of the cervical sympathetic caused degeneration of the fibres up to the superior cervical ganglion, but not beyond it, and that section of the internal carotid branches of the ganglion caused degeneration in the peripheral branches; degenerated fibres were followed as far as the ophthalmic nerve.

These experiments I have repeated,² without at the time knowing of Waller's experiments on the internal carotid strands, and with the same results, except that after section of the internal carotid branches a few sound fibres were found in the peripheral end, and a few degenerated fibres in the end attached to the ganglion.

Kölliker in 1844, in teasing out the fourth thoracic sympathetic ganglion of the cat, found in some cases that one of the processes of the cell could be traced into a medullated fibre. Numerous other similar instances have been recorded in various vertebrates, and in some of the recent observations on sympathetic ganglia by the Golgi and the methylene-blue method, the axons of the cells have been found to become medullated.

By the degeneration method it can also be shown³ that the great majority of the small medullated fibres of the grey rami arise from the nerve cells of the corresponding sympathetic ganglion.

A few of the medullated fibres arise occasionally from an adjoining ganglion, and a few are pre-ganglionic fibres, which are on their way to the aberrant nerve cells of the grey rami. The inferior mesenteric ganglion, and the ganglia of the pelvic plexus, send off very few, and possibly at times no non-medullated fibres.⁴ The same appears to be the case with the ganglia on the cranial nerves,⁵ with the exception of the ciliary ganglion, but the observations are not very complete.

So far as investigation has gone, the efferent medullated fibres which arise from nerve cells are all small.⁶

Summing up, then, we find that medullated post-ganglionic fibres are present in mammals, in amphibia, and probably in all vertebrates. They are relatively very much more numerous in amphibia than in mammals; in amphibia, indeed, non-medullated fibres are fewer than medullated, and they vary in number in different mammals. Thus, few medullated fibres are given off by the sympathetic ganglia in the rabbit, but a considerable number in the cat.

We should naturally expect to find some difference in function between the medullated and the non-medullated post-ganglionic fibres, but there is not at present any evidence of such difference.

⁶ In some cases apparently they are as much as $4\ \mu$ in diameter, that is, in the border line between small and medium.

DEGENERATION OF SYMPATHETIC NERVE FIBRES AFTER SECTION—
DURATION OF IRRITABILITY.

The medullated nerve fibres of the sympathetic undergo the same series of changes in degeneration as other medullated fibres. But the changes are in most cases more rapid; since most of the nerves are small, and the medulla, which has to be absorbed, is less in amount. Thus, after section of the sympathetic trunk, all the fatty portion of the medulla may be absorbed in two or three weeks, and the degeneration which has taken place may only be indicated by a few rows or small clumps of granules.

In non-medullated nerves, section produces extremely little histological change, when the nerves are treated with most reagents¹; but Tuckett² has shown that the core of the non-medullated nerve in about two days ceases in the fresh state to stain with methylene-blue. The conducting core appears to become granular and then to be absorbed, the sheath still remaining.

Broadly speaking, sympathetic nerves lose their irritability in the dog, cat, and rabbit, about the fourth day after section, sometimes a little earlier, sometimes a little later. There is no satisfactory evidence that there is any constant difference in the time after section at which different classes of nerve fibres lose their irritability (cf. above, p. 626). The time is longer in old animals than in young; it varies in different animals, and with the state of nutrition of the animal; it varies also with the size of the nerve cut. In the rabbit, Tuckett found that the branches of the superior cervical ganglion which run to the internal carotid artery, lose their irritability two days after section; but it may be doubted whether early degeneration is characteristic of non-medullated fibres, since the vaso-constrictor fibres of the sciatic of the dog retain their irritability up to about the fourth day.

Waller³ was the first to make observations on the duration of irritability of the cervical sympathetic. He found that, at the end of the third day, stimulation of the peripheral (upper) end no longer caused dilatation of the pupil. Budge,⁴ as the result of experiments on rabbits, stated that the irritability of the pupillo-dilator fibres of the sympathetic lasts four to six days, and occasionally even longer.

REGENERATION OF SYMPATHETIC FIBRES.

Pre-ganglionic fibres.—In the earlier observations on the regeneration of nerve fibres, pre-ganglionic fibres were at times the subject of experiment, but no distinction was made between them and any other nerve fibres. Some attention was directed to observing differences in the time of return of function to nerve fibres of different classes, as motor and sensory, vaso-constrictor and vaso-dilator, but the inherent differences attending regeneration in the pre-ganglionic and post-ganglionic fibres were not even mentioned. Waller⁵ found that, two months after section of the cervical sympathetic, dilatation of the pupil could be obtained by

¹ Langley and Anderson, *Journ. Physiol.*, Cambridge and London, 1894, vol. xvii. p. 183.

⁵ *Compt. rend. Acad. d. sc.*, Paris, 1853, p. 378.

stimulating the cut nerve; and in the subsequent observations of Schiff, v. Beke Callenfels, and others, on the duration of the effects of excision of the sympathetic, it was pointed out that a considerable length of nerve must be excised to prevent regeneration. I have found¹ a return, though not to the full extent, of all the functions of the sympathetic in the cat twenty-four days after section. The return of function probably begins in about a fortnight. Regeneration, then, is fairly rapid in the cervical sympathetic, and hence probably in other pre-ganglionic sympathetic fibres.

We have seen that in the cat seven thoracic nerves send fibres to the superior cervical ganglion, and that each of these produces its own peculiar effects. Hence, no two thoracic nerves send fibres to exactly the same cells in the superior cervical ganglion. Moreover, since the highest of the series of thoracic nerves do not produce any of the effects of the lowest of the series, the highest and the lowest must run to a completely different set of cells in the ganglion.

Now, when the several thoracic nerves in the cat are stimulated after regeneration of the cut cervical sympathetic,² each produces, in the majority of cases, its normal effects.

Thus (usually), the first thoracic nerve causes good dilatation of the pupil, opening of the eye, and retraction of the nictitating membrane, but causes little or no contraction of the arteries of the ear, and no effect on the erectile hairs; the third thoracic nerve causes very little dilatation of the pupil, moderate opening of the eye, and retraction of the nictitating membrane, good contraction of the arteries of the ear, but (usually), like the first thoracic nerve, it has no effect upon the erectile hairs; the sixth thoracic nerve produces none of the effects mentioned above, but causes more or less marked movement of the erectile hairs.

It is conceivable that in regeneration the nerve fibres should grow through the superior cervical ganglion and become directly connected with peripheral structures. But since nicotin, both when applied locally to the ganglion and when injected into the blood, has its normal effect, we must conclude that the nerve fibres have formed new terminations in connection with the nerve cells.

We arrive, then, at the remarkable fact that, in most cases, each spinal nerve becomes connected with nerve cells similar to, if not the same as, those with which it was previously connected, and with no others. It is difficult to account for this, except on the supposition that the regenerating fibres are guided to their appropriate nerve cells by some chemiotactic attraction. The guiding influence might either lie in the remains of the old fibres or in the characters of the nerve cells.

The selective connection of nerve fibres with nerve cells occurs also if a regenerated nerve be cut; and the second regeneration takes place as readily as the first.

It may be mentioned that not infrequently, though by no means always, an upper thoracic nerve, after regeneration of the cervical sympathetic, has not quite so strong an action as normally, as if the regeneration were not quite complete. This is probably due to a failure of some of the nerve fibres to make their way through the

¹ *Journ. Physiol.*, Cambridge and London, 1897, vol. xxii. p. 228.

² Langley, *ibid.*, 1895, vol. xviii. p. 280; and 1897, vol. xxii. p. 215.

cicatricial tissue which forms early between the cut ends of the nerves.

The return of function to the sympathetic takes place before the freshly formed fibres have become medullated. Thus, in the case mentioned above, in which regeneration had occurred twenty-four days after section of the cervical sympathetic, no medullated fibres were found in the peripheral portion.

Seven to eight weeks after section of the nerve, the medullated fibres in the regenerated part of the nerve are still few in number. Even fifteen months after section, the regenerated nerve has fewer medullated and more non-medullated nerves than normal.

Although the fibres from each spinal nerve usually take on during regeneration the functions they possessed before section, they do not always do so. Thus the first and second thoracic nerves may after regeneration cause erection of hairs, and the fourth and fifth thoracic nerves may cause dilatation of the pupil, effects which they do not normally produce. The selective action of the nerve fibres has therefore its limits. And we may conclude that a sympathetic nerve fibre of one class, as pupillo-dilator, is capable of becoming connected with a nerve cell of another class as pilo-motor.

Post-ganglionic fibres.—In the accounts which have been given of observations on the regeneration of the nerves to the limbs, mention is occasionally made of recovery of vasomotor action. Since we have seen reason to believe that the vasomotor fibres in limb-nerves are post-ganglionic, we may conclude that post-ganglionic fibres can regenerate. Extremely few direct observations have, however, been made on the matter. Tuckett¹ found, in a rabbit, that the anterior strands of the superior cervical ganglion regenerated in 259 days. Stimulation of the cervical sympathetic caused dilatation of the pupil, and treatment of the internal carotid with dilute methylene-blue showed the presence of regenerated non-medullated fibres.

The problem already dealt with in relation to the pre-ganglionic nerves obviously occurs also, in a slightly modified form, in relation to the post-ganglionic nerves. The fibres from the several cells run to different tissues. When the fibres re-grow, will they end in connection with the tissue with which they were previously connected? I have, as yet, made one experiment only on this point. The anterior branches of the right superior cervical ganglion were cut in a cat; after nineteen weeks, the upper thoracic nerve roots were stimulated on both sides. On the left side, the usual effects were obtained. But on the right side, the first six thoracic nerves, instead of the first three only, caused dilatation of the pupil. A part of the region of the face in which the hairs are normally strongly erected, by stimulation of the fifth and sixth thoracic nerves, was barely affected by stimulation of any nerve. The explanation of this which at once presents itself, is that some of the fibres which normally run to the hairs of the face, had, in the process of re-growth, been carried out of their way, and had formed new nerve-endings in the pupil. If this explanation is correct, it follows that a nerve cell does not necessarily send its axis cylinder process to a particular kind of peripheral tissue; and it suggests that there is no specific difference between the different classes of post-ganglionic fibres, and that the function which each serves is in a way accidental, depending upon the kind of peripheral tissue with which it first comes in contact.

¹ *Journ. Physiol.*, Cambridge and London, 1896, vol. xix. p. 297.

SOME FEATURES OF THE STRUCTURE OF SYMPATHETIC NERVE CELLS.

Our knowledge of the minute structure of sympathetic nerve cells has been greatly furthered by the use of the Golgi and methylene-blue methods of staining.¹ We need, however, only mention those points which bear upon the experimental results.

In mammals, the sympathetic nerve cell has a single nerve fibre process and a considerable number of dendrons. In this it resembles most of the nerve-cells of the central nervous system; but in most cases, at any rate, a characteristic appearance is given it by the arrangement of the dendrons.

In amphibia and in some other lower vertebrates, dendrons are not always present. Thus the spiral cells, discovered by Beale and Arnold, have no dendrons, the straight process is the nerve fibre.

In such sympathetic ganglia as have been investigated, fine nerve fibres are found penetrating the ganglion and ending in it, in more or less close relation with the nerve cells. In amphibia, such fibres form the spiral "process" of the pyriform cells, and end in fine branches underneath the cell capsule. In some cases the entering nerve fibres divide and end in connection with more than one nerve cell. In the sympathetic chain of birds and mammals a fibre may be seen giving off a branch to end in a ganglion, and then continuing on its way, presumably to end in another ganglion. We may reasonably take the fibres ending in the ganglion to be the pre-ganglionic fibres, and the fibres given off by the nerve cells to be the post-ganglionic fibres, which we have described on experimental grounds. So far, the histological and the physiological results are plainly in harmony.

THE DEGREE OF PERMANENCE OF THE EFFECTS CAUSED BY SECTION OF SYMPATHETIC NERVES.

Speaking generally, it may be said that on section of all, or of the great majority of sympathetic nerves to a tissue, paralytic effects may be observed in a few seconds. But in anæsthetised animals, at any rate, the degree of paralysis immediately following the section differs widely in different cases. It is probable that when the symptoms develop slowly, there is some condition of stimulation, either of the cut ends of the nerve fibres or of their peripheral terminations, which only slowly dies out. When vaso-constrictor fibres are cut, the extent of the flushing will depend in part upon the arterial blood pressure. And in cases of section of the majority only of the sympathetic fibres to a tissue, the degree of paralysis will, of course, depend upon the number and activity of the uncut fibres.

These effects may be maximal in a few seconds after section of the

Neurol.*, 1897, vol. vii.

nerve, or they may only become so in anæsthetised animals after some delay.

In the frog the development of the paralytic symptoms in the eye (and tongue), after section of the sympathetic or extirpation of the superior-cervical ganglion, is usually, if not always, gradual.

In the rabbit there is an early stage in the condition of the pupil,¹ after section of the post-ganglionic fibres, which has not been noticed in the cat or dog. After about twenty-four hours the pupil begins to dilate, slowly enlarges, and on the third to the fifth day again becomes small and remains smaller than normal. This may be taken to be due to stimuli set up in the fibres during degeneration, though it is curious that this reaction of degeneration should not occur, so far as we know, in the vaso-constrictor fibres of the rabbit, or in any of the fibres in the sympathetic of the cat and dog.

Apart from this temporary escape from the effect of section, there is, in all animals, as time goes on, some degree of return to the normal condition. This varies in different animals; there is much difference of opinion with regard to it. The recovery is generally held to be greater and more complete in the rabbit than in the cat and dog.

Section of the cervical sympathetic causes a permanent diminution in the size of the pupil. In the cat and dog this is obvious, in the rabbit it is much less; even a week or two only after section, the difference from the normal pupil may be very slight.

Less attention has been paid to the other effects produced on the eye by section of the nerve. In the cat, the narrowing in the palpebral fissure is for several months more or less obvious on the side of the lesion; the nictitating membrane, which for a few days covers about a half of the cornea, is gradually withdrawn until it projects very little more than the normal one. The increase in the secretion poured on the surface of the eye lasts in the dog two or three weeks only.

The nictitating membrane does not maintain a constant position; a month or more after section, it may at times be almost completely withdrawn, and at times project and cover about a third of the cornea.

As we have said, the great dilatation of the vessels of the ear, which is seen in the first few days after section of the cervical sympathetic, or after excision of the superior cervical ganglion, gradually diminishes, at any rate as a rule.

Not infrequently in the rabbit the vessels of the ear on the side of the lesion return nearly to normal in four or five days. The rapid recovery in these cases we must attribute to the presence of uncut vasomotor fibres, passing to the ear by way of the vertebral ramus of the ganglion stellatum and the great auricular nerve (cf. p. 624).

In the cat and dog the decrease in the flushing is slow, going on for some weeks; and it is doubtful whether the normal tone is ever completely regained. In some cases, indeed, in the rabbit as well as in the cat and dog, it is said that the paralytic effects continue for a very long period—a year and more—without any considerable diminution.

¹This was first noticed by Budge, "Ueber d. Bewegung. d. Iris," Braunschweig, 1855, S. 125.

The principal papers dealing with the duration of the paralytic effects are quoted below.¹ It will be sufficient here to mention the comparatively few instances in which paralysis of a long duration has been described, either after section of the sympathetic or removal of the superior cervical ganglion. Bernard in *one* case, in a dog, found that the paralytic effects on the iris, eyelids, and vessels of the ear, were still intense one and a half years after extirpation of the superior cervical ganglion. Schiff observed *one* case in a dog, in which there was hardly any decrease in intensity in the hyperæmia of the ear for two years after section of the cervical sympathetic. Budge stated that, in rabbits, section of the cervical sympathetic caused a decrease in the size of the pupil, lasting a year after the operation. And Pye-Smith found that the paralytic effects lasted indefinitely in rabbits and cats; in *one* case, indeed, in a rabbit, after section of the cervical sympathetic and of the spinal auricular nerves, the paralytic effects remained maximal or nearly maximal for more than five years.

Observations have also been made upon the duration of paralytic effects on the vessels of the hind-foot in dogs. Section of the sciatic causes a dilatation of arteries, and a rise of temperature in the foot; according to Goltz,² the temperature begins to fall in four or five days, and becomes in three or four weeks the same as that on the intact side.

The recovery of tone in this case may fairly be referred to vaso-motor fibres passing to the foot by the crural nerve, for Lewaschew³ found that, as a rule, section of the crural nerve caused a rise of temperature of the foot, and that stimulation of the peripheral end caused a fall of temperature. Spallitta and Consiglio state that on removal of the lumbo-sacral sympathetic chain on one side, the rise of temperature in the foot, though diminishing somewhat, remains considerable for an indefinite period. Their observations, however, do not seem to have extended over a greater period than three months.

It appears certain that unstriated muscle, when severed from the central nervous system, recovers some degree of tone, and it is reasonable to suppose that inherent vitality and responsiveness to stimuli vary in different tissues. Schiff showed that after section of all the nerves to the ear of the rabbit, the arteries still retained their irritability and contractibility, and that irregular automatic contractions and dilatations of the arteries still occurred. There can be little doubt,

² *Arch. f. d. ges. Physiol.*, Bonn, 1874, Bd. ix. S. 174. Schiff, however, states that if certain precautions be taken, the foot on the cut side is permanently of a somewhat higher temperature than that of the opposite side.

³ *Ibid.*, 1882, Bd. xxviii. S. 431. Cf. also Spallitta et Consiglio, *Arch. ital. de biol.*, Turin, 1897, tome xxviii. p. 257. Dastre and Morat ("Système nerveux vaso-moteur," Paris, 1884, p. 262) observed pallor of the skin of the toes on stimulating the peripheral end of the crural nerve in dogs.

then, that the degree of contraction of arteries having no nervous connection with the spinal cord, will to some extent vary with the temperature, the state of nutrition, and so forth.

Whether an area, the vasomotor nerves of which have been cut, is at any moment warmer than the corresponding area of the opposite side of the body, clearly must depend upon a number of independent variables. Since the vessels on the intact side are still under the influence of the central nervous system, they will at times be fully contracted and at times fully dilated. On the cut side the variation is relatively slight. It follows, then, that the tissues on the uncut side will sometimes be warmer and sometimes be colder than on the cut side. And it was shown by Schiff that, after extirpation of the superior cervical ganglion on one side, the ear on the opposite side—ordinarily the cooler—became the warmer when the animal was placed in a heated chamber, when it became hot from exercise, when a feverish condition was induced, and in certain emotional states. On the cut side there was also an increase in temperature, but comparatively a slight one. Similar facts are known with regard to the limbs.

The more or less complete recovery of tone which we have just spoken of might conceivably be due to a peripheral nervous mechanism, and not, as we have suggested, to the inherent nature of the muscular tissue. This we will consider in a later section (p. 671).

What has been said above for the cat and dog, with regard to the cervical sympathetic and the superior cervical ganglion, holds also for man. The paralytic effects of section of the cervical sympathetic continue indefinitely, but they diminish in intensity; the recovery is greater in the blood vessels of the ear and face than in the dilator pupillæ.¹ The presence of sweat glands on the face allows an additional point to be noticed, namely, the permanent absence of secretion of sweat on the side of the lesion. In some cases it has been observed that, during exercise, when the face on the sound side flushes, the face on the side of the lesion becomes paler. This is probably a mechanical effect, the general flushing causing a lowering of blood pressure.

EFFERENT PRE-GANGLIONIC FIBRES IN RELATION TO THE ANTERIOR AND POSTERIOR ROOTS OF THE SPINAL NERVES.

The efferent fibres which pass from the spinal cord to the sympathetic ganglia and to the pelvic nerve² (*nervus erigens*) form, in mammals at any rate, no exception to the law of Bell and Magendie. They pass outwards in the anterior and not in the posterior roots of the spinal nerves. This is shown both by the absence of effect on stimulating the peripheral ends of the posterior roots, and by the absence of degeneration³ in the peripheral ends of the posterior roots when they are cut.

It is true that Stricker and others have found in the dog a rise of

¹ The recovery of tone in the blood vessels appears often to be complete; this suggests either that partial regeneration of the cervical sympathetic has occurred, or that some vasomotor fibres take a path other than that of the cervical sympathetic.

² Cf. below, p. 666.

³ Cf. Sherrington, *Journ. Physiol.*, Cambridge and London, 1897, vol. xxi. p. 209. References to early work on degeneration in the nerve roots are given in this paper.

temperature in the limbs, on stimulating the posterior roots of the nerves supplying the limbs. The experiments we consider elsewhere (cf. p. 668), but the observations on degeneration in the posterior roots after section, show that the increase of temperature observed cannot be due to the presence in the posterior roots of efferent fibres arising from the spinal cord.

Budge¹ found in the rabbit that dilator fibres for the pupil run in the anterior and not in the posterior roots of the first and second thoracic nerves. In the following year he stated² that section of certain anterior roots in the rabbit causes flushing of the ear, whilst section of the corresponding posterior roots has little or no effect. Since that time numerous observations have been made, cf. Dastre and Morat³ on vaso-dilator fibres to the buccofacial region; Gaskell⁴ on erector nerves of the penis; Bradford⁵ on vasomotor nerves to the kidney; Langley⁶ on pilo-motor nerves; Langley and Anderson⁷ on nerve fibres running to the end of the intestine, the bladder, the internal and external generative organs.

In vertebrates other than mammals the matter is less clear. In the chick the axons of nerve cells in the spinal cord have been traced into the posterior roots, but the function of these axons has not been determined. There are no satisfactory degenerative observations on any lower vertebrate. Experimental observations have been chiefly made on the frog, but the conclusions drawn from them are contradictory.

Pflüger⁸ found that the vasomotor fibres to the mesentery and web of the frog run in the anterior and not in the posterior roots of the spinal nerves.

Steinach and Wiener⁹ state that in *Rana esculenta* electrical and mechanical stimulation of the posterior roots of the second to the ninth spinal nerves causes movements in some part or other of the alimentary canal or in the bladder. They find that the effect on the rectum and bladder is not confined to the posterior roots, but occurs to a varying extent on stimulating the anterior roots. Horton Smith,¹⁰ however, was unable to confirm these results. He readily obtained contraction of the rectum and bladder on stimulating the anterior roots of certain of the lower spinal nerves, but did not obtain contraction from the posterior roots.

SYSTEMS OF NERVES RELATED TO THE SYMPATHETIC.

Nomenclature.—The sympathetic system, as we have seen, supplies nerve fibres to certain structures in all parts of the body. In some parts of the body these structures receive nerve fibres from other sources than the sympathetic. It is, in consequence, convenient to have some term to include the whole nervous supply. The words "organic," "vegetative," "ganglionic," and "involuntary" have all been used, but they have also been used in senses other than that we require. The term "visceral nervous system" has been employed by Gaskell and others, including myself. The word "visceral," however, is obviously

inapplicable to some of the structures brought under it, such as the nerve fibres which run to the skin. I propose, then, following a suggestion of Professor Jebb, to use the word "autonomic," including under that term the contractile cells, unstriated muscle, cardiac muscle, and gland cells of the body, together with the nerve cells and fibres in connection with them.

The autonomic nervous system consists of the sympathetic system, which we have already in large part considered, of the cranial autonomic system, the sacral autonomic system, and the enteric system (the plexuses of Auerbach and Meissner), which we will now pass on to consider. The interstitial cells of Cajal, if they are nervous, also belong to the autonomic system.

DISTRIBUTION AND ACTION OF CRANIAL AUTONOMIC NERVE FIBRES.

Autonomic nerve fibres leave the brain by way of the third, seventh, ninth, tenth, and eleventh cranial nerves.

Third nerve.—The third cranial nerve sends a branch to the ciliary ganglion, and in this the efferent fibres end. The connection is shown both by the nicotin¹ and by the degeneration method.² If the third nerve be cut in the skull, numerous degenerated fibres are found running to the ganglion, but no degenerated fibres are found peripherally of it. The post-ganglionic fibres form—with the addition of a few fibres from the fifth nerve—the short ciliary nerves, which give motor fibres to the sphincter pupillæ and to the ciliary muscle.

Seventh and ninth nerves.—The seventh and the ninth nerves we may to a certain extent consider together, since the autonomic fibres of the seventh are, so far as is known, contained in the intermediate nerve of Wrisberg, and this may be regarded as the continuation anteriorly of the ninth. Moreover, the two together probably supply with autonomic fibres the whole of the mucous membrane of the nose and mouth.

The seventh and the ninth nerves together supply in the dog secreting fibres to the orbital gland, the glands of the lips and cheek, and the salivary glands. The fibres run in the several branches of the fifth nerve supplying the respective glands, for stimulation of these branches causes secretion, and, after section of any one branch, stimulation of the seventh and ninth nerves has no longer an effect in the region to which the cut branch runs.

The seventh and ninth nerves have also been shown to send vasodilator fibres by way of the fifth to the greater part of the region to which they send secretory fibres, namely, to all the salivary glands, to the tongue, to the mucous membrane of the floor of the mouth, and to part of the soft palate. They have not been shown to send vasodilator fibres to the mucous membrane of the cheeks and gums. According to Vulpian, indeed, stimulation of the seventh and ninth nerves intracranially does not cause flushing of the lips and cheeks, but since it does cause secretion from glands in this region, and since in other cases the

¹ Langley and Anderson, *Journ. Physiol.*, Cambridge and London, 1892, vol. xiii. p. 460.

² Jégorow, *Arch. slaves de biol.*, Paris, 1887, tome iii. p. 322. (Jégorow, notwithstanding his results, was inclined to consider the ciliary ganglion as homologous to a posterior root ganglion.) Langley and Anderson, *Journ. Physiol.*, Cambridge and London, 1894, vol. xvii. p. 184.

secretory and vaso-dilator fibres run together, the question can hardly be considered as definitely settled.

The fibres of the seventh nerve, which run by way of the lingual branch of the fifth to the submaxillary and sublingual glands, end in the submaxillary and sublingual ganglia, from which fibres (post-ganglionic), both vaso-dilator and secretory, are given off.¹ We might expect, then, to find similar ganglia on the course of the fibres which the seventh and ninth send to the other branches of the fifth nerve. The ganglia which occur in connection with the other branches occur early on the course of the fifth instead of in or near the peripheral organs. The spheno-palatine ganglion is in connection with the superior maxillary nerve, and the otic ganglion in connection with the inferior maxillary nerve. Since nicotin stops the effects of stimulating the seventh and ninth nerves in the tympanic cavity, and does not stop the effects of stimulating the peripheral branches of the fifth nerve, there is some, though by no means conclusive, evidence that the spheno-palatine and otic ganglia are on the course of the autonomic fibres proceeding from the seventh and ninth nerves to the branches of the fifth, other than the lingual. It is to be borne in mind that the fibres of the seventh and ninth nerves which run to the fifth do not, so far as we know, accompany the branches of the fifth which run to the skin, but only those which run to the mucous membrane and glands. We have, then, only ground for considering that the spheno-palatine and otic ganglion send fibres to the branches of the fifth which run to the mucous membrane and to the glands of the head.

On this basis we should conclude that the spheno-palatine ganglion sends vaso-dilator and secretory fibres to the mucous membrane of the nose, soft palate, tonsils, uvula, roof of the mouth, upper lip and gums, and upper part of the pharynx, and that the otic ganglion sends similar fibres to the mucous membrane of the lower lip, cheek, and gums, the parotid and orbital glands; that the ganglia on the course of the lingual send similar fibres to the anterior part of the tongue, the floor of the mouth, the submaxillary and sublingual glands.

In view of the anatomy of the parts, we should expect to find that the spheno-palatine ganglion receives its pre-ganglionic fibres chiefly from the seventh nerve, the otic ganglion chiefly from the ninth nerve, and this is in general accordance with the result of physiological experiment.

The scheme just given with regard to the arrangement of the cranial autonomic fibres has simplicity on its side, and it is not inconsistent with any well-established facts; it is, however, in large part conjectural, and we must await further experimental evidence for proof or disproof of it.

There still remains to consider the cranial autonomic fibres to that part of the tongue which receives its sensory fibres not by the fifth but by the glosso-pharyngeal nerve. Experiments on this point were made by Vulpian. He found that stimulation of the roots of the glosso-pharyngeal nerve intracranially caused flushing of the posterior part of the tongue; and he considered that the vaso-dilator fibres ran direct in the glosso-pharyngeal. We have no information as to any nerve cell connection of these fibres.

Some account of the observations which have been made upon the cranial origin of the secretory and vaso-dilator nerves of the salivary glands

¹ See art. "The Salivary Glands," this Text-Book, Vol. I. p. 475.

have been given elsewhere.¹ Prevost² was the first to obtain evidence of vaso-dilator fibres in the nasal mucous membrane on stimulating the sphenopalatine ganglion. Vulpian³ found dilator fibres for the vessels of the anterior part of the tongue in the lingual nerve, and for the posterior part in the glossopharyngeal nerves. He traced the fibres to the seventh and ninth nerves respectively.⁴ Jolyet and Laffont⁵ observed flushing in the nasal and parts of the buccal mucous membrane on stimulating the superior maxillary nerve. For further information, see the papers quoted below in the footnotes.

Fifth nerve.—Whether the roots of the fifth nerve have any autonomic fibres must, I think, be regarded as doubtful. They have been said to contain secretory fibres, constrictor and dilator fibres for the pupil, constrictor and dilator fibres for the blood vessels. The view that the fifth nerve has secretory fibres is now practically abandoned. There is no evidence worth considering here that it contains vaso-constrictor fibres.⁶ Many observers have advocated the view that the fifth nerve sends constrictor fibres of a peculiar kind to the iris of the rabbit. The chief evidence alleged is that, after atropin has been given and the cervical sympathetic cut, stimulation of the first and second cervical segments of the cord, of the bulb, and of the fifth nerve, causes constriction of the pupil.⁷ But in the cat and dog the fifth nerve has apparently no action on the iris.

There is, on the other hand, some evidence for the existence of vaso-dilator fibres in the roots of the fifth. Stimulation of the fifth nerve in the skull with a strong current will cause in the dog vascular dilatation of the mouth, lips, and part of the adjoining skin, as well as dilatation of the pupil. Part of the effect is certainly due to an escape of current to the sympathetic filaments which join the fifth nerve at or near the Gasserian ganglion. This is shown by making the current weaker when there is no longer an effect on the pupil or on the skin of the face.⁸ Thus a strong current stimulates the sympathetic grey ramus to the fifth in just the same way as we have seen the grey ramus to a spinal nerve can be stimulated (cf. p. 631). The question then is, whether the flushing of the mucous membrane of the mouth, when it alone is obtained by stimulating the roots of the fifth, is also due to an escape of current or not. According to Laffont,⁹ stimulation of the superior maxillary nerve in the dog causes flushing twenty days after extirpation of the superior cervical ganglion, *i.e.* at a time when the sympathetic fibres in the fifth have degenerated. There still remains the possibility of an escape of current to the sphenopalatine ganglion or to fibres running to it from the seventh or ninth nerve. If Vulpian's statement, that these nerves have no vaso-dilator fibres for the mucous membrane of the cheek and gums, were confirmed, the balance of evidence would be

decidedly in favour of vaso-dilators in the fifth, but in the meantime we may regard the view as still requiring proof.

Tenth and eleventh nerves.—The autonomic fibres of the tenth and eleventh nerves are in their central origin homologous with the autonomic fibres of the ninth and seventh, which we have considered above. The fibres run in the vagus. The vagus¹ supplies motor fibres to the œsophagus, stomach, and probably the rest of the gut, as far as the descending colon, and inhibitory fibres to the heart; it sends also motor fibres to the unstriated muscle of the lungs, and, according to recent observations, secretory fibres to the gastric glands and to the pancreas. There is evidence also that the vagus contains inhibitory as well as motor fibres for the gut, but this is not admitted by all observers.

The presence in the vagus of motor fibres for the spleen is denied.² According to Schiff, the vagus contains accelerator fibres for the heart, and Rutherford found (1869) that stimulation of the vagus caused acceleration of the heart after atropin had been injected. Brown-Séguard (1854) and Porter (1896) state that stimulation of the vagus in the lower cervical region causes contraction of the coronary arteries. These effects on the heart and blood vessels may possibly be due to fibres running to the vagus from the superior cervical ganglion.

So far as the experiments have gone, all the autonomic fibres of the vagus arise from the medulla, and none from the cervical spinal cord. The œsophageal fibres arise from the roots of the tenth nerve, the cardiac inhibitory fibres arise from the medullary roots of the eleventh nerve, and, according to Kreidl, from the uppermost of these.³ According to Vulpian,⁴ both the tenth and the eleventh nerves give motor fibres to the stomach.

The efferent autonomic nerve fibres of the tenth and eleventh are apparently not connected with either the cells of the jugular ganglion or of the ganglion of the trunk of the vagus.

It was found by Waller⁵ that, when the vagus was cut between the jugular ganglion and the ganglion of the trunk, and time left for degeneration, stimulation of the vagus in the neck had no effect upon the "lungs, larynx, etc." He concluded that the motor fibres of the vagus were not connected with the ganglion trunci vagi.

Gaskell⁶ found in the crocodile and alligator that, after degenerative section of the vagus in the neck, stimulation of the nerve peripherally of a ganglion, which occurs at the entrance of the vagus into the thorax, caused contraction of the lower part of the œsophagus and of the stomach, but not inhibition of the heart. As he considered that this ganglion was homologous with the ganglion trunci vagi of mammals, he inferred that the ganglion trunci vagi was on the course of the efferent fibres to the œsophagus and stomach.

Gad and Joseph⁷ repeated Waller's experiment; they found that the motor fibres for the œsophagus were not connected with the ganglion trunci

vagi. In the cat I have made a similar experiment, and come to the same result as regards the fibres to the œsophagus (lower cervical and thoracic portion), the stomach, the intestines, and heart.

We may conclude that the autonomic fibres of the vagus end in connection with peripheral nerve cells, since in the rabbit a small dose of nicotin prevents any effects being obtained by stimulating the nerve in the neck. It is probable that the nerve fibres for each organ end in small ganglia situated in or near the organ itself. This is shown, as regards the cardiac inhibitory fibres in the mammal and frog, by the continued inhibitory power of muscarin, after nicotin injection; and in the frog, also, by the inhibition obtained by local stimulation after injection of nicotin.

Twelfth nerve.—The peripheral part of the hypoglossal nerve has a slight vaso-constrictor action upon the arteries of the tongue. The vaso-constrictor fibres come in part, at any rate, from the superior cervical ganglion. It has been supposed that some issue with the roots of the hypoglossal nerve, but the evidence is not satisfactory. In some animals the hypoglossal nerve has constantly, in others occasionally, a small gangliated root; the ganglion is apparently homologous with the jugular ganglion, *i.e.* it belongs to the system of spinal ganglia, and not to that of the autonomic ganglia.

Characters of the cranial autonomic nerve fibres.—The nerve strand running from the third nerve to the ciliary ganglion consists chiefly of small medullated fibres. The fibres proceeding from the ganglion also consist chiefly of small medullated fibres; they are three to four times as numerous as the fibres running to the ganglion. These facts were pointed out by Bidder and Volkmann¹ in 1842.

The chorda tympani, Jacobson's nerve, the superficial petrosals, have very few medium or large fibres.

One or two medium or large fibres usually run to the submaxillary gland—sometimes branching as they go—by way of the duct; the chorda tympani, after leaving the lingual, has usually no fibre larger than 3.5μ ; in the tympanic cavity it has more medium and large fibres.

The post-ganglionic fibres of the otic, spheno-palatine, and submaxillary ganglion are chiefly, at any rate, non-medullated. The nerve cells on the course of the cranial nerves so far considered have the same general characters as those of the sympathetic system.

The vagus at its exit from the skull contains many large fibres, as well as many small ones. The large fibres pass off chiefly to the pharynx and larynx. The branches of the nerve which run to the œsophagus and to the stomach consist of non-medullated fibres, small medullated fibres, a considerable number of medium, and hardly any large fibres. The branches to the lungs contain more large fibres than those to the œsophagus and stomach.

Bidder and Volkmann² give the proportion of small to large fibres in the branches of the vagus of the cat as follows:—In the superior laryngeal, 2 : 1; in the inferior laryngeal, 1 : 8; in the branches to the lungs, about 2 : 1; in the branches to the œsophagus and stomach, hundreds of small, and hardly any large, with much '*Zellgewebe*,' *i.e.* Remak's fibres.

¹ "Die Selbstständigkeit des sympathischen Nervensystems," Leipzig, 1842.

² *Op. cit.*, S. 62.

The depressor consists chiefly of medium fibres, the other varieties being also represented.

Gaskell¹ pointed out that numerous non-medullated fibres appear in the vagus immediately below the ganglion trunci vagi. If the view given above (p. 663) be accepted, namely, that the nerve cells of the ganglion of the trunk are posterior root cells, it follows either that afferent fibres may become non-medullated a long way from their endings, or that the efferent pre-ganglionic fibres do.

In the sympathetic system it can hardly be doubted that pre-ganglionic fibres may become non-medullated a considerable distance centrally of the cells to which they run (cf. above, p. 650), and, in consequence, we may fairly assume that the same may be the case with the similar fibres of the vagus.

Degeneration.—What has been said with regard to the degeneration of sympathetic fibres (p. 652) holds in general for the autonomic fibres of the cranial nerves. It may be noted that, as the vagus is a comparatively large nerve, the absorption of degenerative products, after the nerve has been cut, goes on much more slowly than in the cervical sympathetic. Clumps and granules and granular cells may be conspicuous for two or three months. The irritability of the vagus is lost, as a rule, at any rate, on the fourth to fifth day after section of the nerve.

Schiff² stated that the vagus in the dog lost its inhibitory power on the heart on the fourth or fifth day after section of the nerve. According to the same observer, acceleration of the heart can in most cases be obtained by stimulating the peripheral end of the cut nerve, five, seven, and even fourteen days after the nerve has been cut.

Arloing,³ who holds, as did Schiff, that cardiac accelerator fibres are present in the vagus, finds that in the dog the accelerator fibres are irritable on the fifth day, but that the cardiac inhibitory and the motor œsophageal fibres have lost their irritability. In the donkey he finds that the accelerator fibres retain their irritability about eight days after section, and that the motor œsophageal fibres may be still effective thirteen days after section. He states also that, in the donkey, the sciatic nerve, eight days after section, may still cause contraction of the blood vessels of the hind-leg.

Regeneration of vagus.—A recovery of function, after section of the vagus, has not been observed so far as regards its autonomic fibres, but not many observations have been made on the matter. We should, of course, expect that the vagus, when cut in the neck, would take a considerable time to regenerate, since the distance from the point of section to the peripheral structures is considerable.

In an experiment on a cat, I⁴ obtained no effect on stimulating the peripheral end of the vagus twelve months after section, although the nerve had largely regenerated, and contained numerous medullated fibres. Tuckett⁵ did not find regeneration of the œsophageal fibres of the vagus in the rabbit 231 days after section of the nerve. According to Vanlair,⁶ the recurrent laryngeal in the dog recovers its functions about eleven months after section of the cervical vagus.

DISTRIBUTION AND ACTION OF SACRAL AUTONOMIC NERVE FIBRES.

The sacral autonomic nerve fibres all run to the pelvic nerve, commonly called the nervus erigens.

The origin of the pelvic nerve¹ varies somewhat in different animals,

FIG. 314.—Left pelvic plexus of cat. The three sacral nerves and the first coccygeal nerve were cut peripherally of the spinal ganglia, and eleven days allowed for degeneration.

The numbers placed opposite each strand show the number of normal and of degenerated fibres present in it,—the number of normal fibres being placed first. Thus 35.0 indicates that the strand contained thirty-five normal fibres and not one degenerated; *m* signifies many fibres (more than twenty-five); *s* signifies some (ten to twenty-five); and *f*, a few fibres (nine or less). Thus 9.*m* signifies that nine sound and more than twenty-five degenerated fibres were present in the strand.

and in each animal varies in correspondence with the origin of the lumbo-sacral nerves (cf. p. 633). In the cat, the second sacral nerve

¹ Langley and Anderson, *Journ. Physiol.*, Cambridge and London, 1896, vol. xx. p. 372.

always sends a considerable number of fibres to the pelvic nerve, and the third generally does; the first sends comparatively few fibres, and none when the arrangement of nerves is posterior. In the rabbit, the pelvic nerve arises chiefly from the third and fourth sacral nerves, the second sacral nerve also sending fibres to it in the anterior and median classes; the first coccygeal nerve sending some fibres to it in the posterior class.

Stimulation of the pelvic nerve¹ causes strong contraction of the bladder, but has no certain effect on the blood vessels of the organ; it causes contraction, varying in strength, of both coats of the descending colon and rectum, the effect being much more constant, and generally greater, in the rabbit than in the cat and dog; strong contraction of the recto-coccygeal muscle and of other special longitudinal muscles of the rectum; dilatation of the vessels of the mucous membrane of the end of the rectum, and of the external generative organs; inhibition of the proper unstriated muscle of the external generative organs, notably of the retractor penis; inhibition in the rabbit of the internal anal sphincter, and of some unstriated muscle in the skin of the ano-genital region.

It has been commonly said that the pelvic nerve contains motor fibres for the uterus. Anderson and myself² in numerous experiments found the pelvic nerve and the sacral nerves to be entirely ineffective on the uterus. Further, section of the sacral nerves³ in the cat or rabbit caused no degeneration in nerve fibres running to the uterus or to the vagina, though it caused considerable degeneration in the strands running to the rectum and bladder, and some in the strands to the urethra and vulva; and we concluded that the sacral nerves do not send nerve fibres to the internal generative organs. It is, however, possible that some of the afferent fibres which run to the vulva may run on past this structure, and it is to be remembered that human anatomists have described filaments as passing from the sacral nerves to the uterus.

The origin from the spinal cord of the nerve fibres to the several viscera supplied by the pelvic nerve, is in correspondence with the anatomical origin of the nerve, stated above, except that the nerve fibres to the external generative organs are rather more anterior than those to the bladder and the end of the intestine.

The pelvic nerve soon breaks up into a plexus of nerve fibres containing numerous small ganglia. In these, the nerve fibres end. Speaking broadly, the ganglia in the neighbourhood of each organ are on the course of the fibres for that organ⁴ (cf. Fig. 314). Thus, in the rabbit, after injection of nicotin, the pelvic nerves have no effect, but on stimulating the peripheral parts of the plexus all the usual effects are obtained.

The pelvic nerve consists chiefly of small medullated fibres, but both medium and large fibres are present; it has near its origin few or no non-medullated fibres.

In the cat, the pelvic nerve contains⁵ about 3500 medullated fibres. Of these, one to two dozen are $7\ \mu$ to $12\ \mu$ in diameter; several hundreds, $4\ \mu$ to

⁵ Langley and Anderson, *ibid.*, 1895, vol. xix. p. 377.

5 μ in diameter. In the rabbit the pelvic nerve has few fibres other than small. The histological characters of the nerve cells in the course of the pelvic nerve are, so far as is known, the same as those of the sympathetic ganglia.

THE ENTERIC NERVOUS SYSTEM.

The plexuses of Auerbach and Meissner are peculiar to the gut; they extend from the beginning of the unstriated portion of the œsophagus to the end of the rectum. They have usually been considered to belong to the sympathetic system, but it appears to me preferable to place them in a class by themselves. We may speak of them as forming the enteric nervous system. The chief reasons for placing the enteric nerve cells in a class by themselves are, first, that they differ in many of their histological characters from the nerve cells of the vertebral and pre-vertebral ganglia; and, secondly, that we do not know whether they are connected with the central nervous system by sympathetic or by cranial and sacral autonomic fibres.

The injection of a certain amount of nicotin into a blood vessel in a rabbit prevents stimulation of the spinal nerves having any effect upon the intestine, so that nicotin paralyses all the pre-ganglionic fibres. The results of local application of nicotin to the inferior mesenteric ganglion gives evidence that the pre-ganglionic fibres for the gut end in the pre-vertebral ganglia. If these impulses pass to the enteric nerve cells from the central nervous system, by way of the sympathetic, they must pass by the post-ganglionic fibres of the pre-vertebral ganglia. But the injection of nicotin does not prevent stimulation of the post-ganglionic fibres from producing their usual effects, so that either the post-ganglionic fibres send collaterals only to the enteric cells, or, if they end entirely in synapses with the enteric cells, the synapses are not paralysed by nicotin. In either case, the arrangement is different in the enteric and in the sympathetic (vertebral and pre-vertebral) ganglia. In view of this, it is natural to suppose that the enteric cells are in the course of the vagus fibres in the upper part of the gut, and in the course of the sacral fibres in the lower part of the gut. The matter has not been sufficiently investigated to allow any decisive opinion to be arrived at. The experiments that have been made have been chiefly on the lower part of the gut; the results have tended to show that the sacral fibres end in cells of the sympathetic type, and not in the cells of the enteric plexuses.

POSSIBLE AUTONOMIC FIBRES RUNNING DIRECT IN THE CEREBRO-SPINAL NERVES.

The view that some vasomotor fibres leave the cord by the roots of a spinal nerve, and accompany the branches of the spinal nerve to the periphery, is an old one, but no definite experiments were alleged in support of it before Schiff's account of the innervation of the vessels of the ear and of the vessels of the limbs.

There are one or two general considerations with regard to these fibres which must be borne in mind.

If such fibres exist in the particular cases mentioned, we should expect to find them in every spinal nerve, for there is nothing in the function of the nerves to the ear or limbs which makes it reasonable to suppose that they have

a special kind of autonomic fibre unrepresented in other spinal nerves. And such fibres, if they exist, must be special forms of nerve fibres, distinct from all others.

We have seen that the fibres running from the central nervous system to the sympathetic, to the cranial and sacral autonomic systems, end in connection with nerve cells. The spinal nerves have no nerve cells of the sympathetic type on their peripheral course, so that, if the alleged direct fibres end at all in cells of the sympathetic type, it must be in the posterior root ganglion. Even in this case they would form a class of nerve fibres distinct from other autonomic nerve fibres. But there is no evidence of the presence of characteristic sympathetic nerve cells in the posterior root ganglia, and if this be so, the fibres must differ widely from other autonomic fibres, for either they are connected with a special form of nerve cell, or they have no nerve cell at all on their course.

We may turn now to the particular cases which have been brought forward. These are—(1) The third cervical nerve (vasomotor fibres); (2) the nerves running to the brachial plexus (vasomotor and secretory fibres); (3) the nerves forming the lumbo-sacral plexus (vasomotor and vaso-dilator secretory fibres).

As we have already said (p. 624), Schiff showed that the great auricular nerve in the rabbit contains vaso-constrictor fibres for the ear, and Lovén that the vaso-constrictor fibres run chiefly to the distal part of the ear. Schiff considered that these fibres issue from the spinal cord in the roots of the cervical nerves, which give rise to the great auricular. He found¹ that degeneration of the fibres which run from the superior cervical ganglion did not diminish the vasomotor action of the auricular nerve. This observation, however, does not touch the question, for it has been shown by Fletcher that in the rabbit vaso-motor fibres run to the great auricular nerve from the ganglion stellatum. In order, then, to show that the cervical nerve roots in the rabbit have vaso-constrictor fibres, the cervical nerves should be stimulated a week or more after extirpation of both the ganglion stellatum and the superior cervical ganglion. This has not been done in the rabbit, but one case has been placed on record by Morat,² in which the operation was performed. Morat stimulated the great auricular nerve, after allowing time for degeneration, and found, as a result, dilatation of the vessels of the ear. The experiment, however, can hardly be regarded as a conclusive one, since normally the great auricular nerve does not cause vascular dilatation.

I have made a few experiments in the cat and rabbit, and have not found any effect on the vessels of the ear when the cat's upper cervical nerves are stimulated close to the dura mater. Sometimes, when the electrodes were shifted up to the end of the nerve from the vertebral canal, there was contraction of the artery at the tip of the ear, from the second cervical nerve in the cat, and the third in the rabbit.

On the whole, I think the evidence is against the view that vasomotor fibres issue in the roots of upper cervical nerves.

The experiments brought forward to show that direct autonomic fibres occur in the nerves to the limbs, fall into two classes—(a) Those which are said to show that vasomotor fibres pass out in the anterior

¹ Schiff, "Leçons sur la physiologie de la digestion," Turin, 1867, Leçon 11.

² *Arch. de physiologie normale et pathologique*, Paris, 1891, p. 93.

roots; and (b) those which are said to show that vaso-dilator fibres pass out in the posterior roots.

Most of those observers who support the presence of one class of fibres, deny the existence of the other.

Schiff was the chief advocate of the view that direct vasomotor fibres are present in the anterior roots. His experiments were solely on the effect of section of the nerves; he did not stimulate them. According to him,¹ section of the anterior roots going to the sciatic in the dog causes lasting and considerable rise of temperature in the foot and the lower third (about) of the limb. Bernard,² on the other hand, cut the lower lumbar and sacral nerves in the spinal canal, so that there was complete paralysis and lack of sensation in the limb, and found no increase of temperature of the foot. And this is in agreement with general experience.

Schiff³ stated also that section of the anterior roots of the nerves running to the brachial plexus causes rise of temperature in the lower part of the fore-limb. This also is opposed to the results obtained by Bernard, by Cyon (1868), and by other observers.

Schiff's view was, that some vasomotor fibres run direct by the spinal nerves, and that others run by way of the sympathetic. If this were the case, stimulation of the anterior roots of the nerves supplying the limbs should cause pallor in the foot. There is little difficulty in making the experiment in a cat or dog with light-coloured feet, curari being given to paralyse the muscles. I do not find that the nerves which supply motor and sensory nerves to the foot have any effect upon the tint of the skin. The result is the more obvious, in that complete pallor and subsequent flushing is produced by stimulating the anterior roots of certain of the upper lumbar nerves (see p. 634), which send no fibres to the foot except by way of the sympathetic. Even if curari is not given, the difference in the action in the two sets of nerves is unmistakable, although naturally some pallor may be caused by the contraction of the muscles of the limb.

A considerable number of observers have arrived at the conclusion, that vaso-dilator fibres pass to the lower limb of the dog by way of the posterior roots of the nerves which supply it with somatic fibres.

The view was first advanced by Stricker.⁴ He found that mechanical irritation of the cut posterior roots of the sixth and seventh lumbar nerves—he spoke of them as the fourth and fifth—caused constantly an increase, and sometimes a very great increase, in the temperature of the foot. He did not obtain constant results if curari or anæsthetics were given, and in consequence found it necessary, as a preliminary to the experiment, to cut the cord in the lower thoracic region, and wait for a week to a fortnight, by which time the vascular dilatation produced by the section had passed off. The experiment could then be made without anæsthetics and without pain. Nor did he obtain satisfactory results by electrical stimulation of the posterior roots, nor when adult dogs were used.

Cossy,⁵ repeating Stricker's experiments, did not obtain constant results, but sometimes found a rise of temperature from stimulating the

⁵ *Arch. de physiol. norm. et path.*, Paris, 1876, p. 832.

posterior roots. On the other hand, neither Vulpian¹ nor Kuhlwetter² found any effect.

Gärtner³ confirmed Stricker, and insisted on the necessity of the precautions pointed out by Stricker, namely, young dogs, no curari or anæsthetics, stimulation by ligature and not by the interrupted current, previous section of the thoracic cord.

Since none of these precautions are necessary in the case of the known vaso-dilator nerves, it follows, so far, that however the rise of temperature is produced, it is not produced by the action of ordinary vaso-dilator nerves.

The question was taken up by Morat.⁴ He observed the colour of the hairless, unpigmented parts of the foot in the dog and cat. According to him, the only precaution necessary is that the animals should be young. Werziloff,⁵ returning to the use of the thermometer and using also the plethysmographic method, again confirmed Stricker's results. He apparently did not find necessary any of the special precautions mentioned by Stricker and Gärtner.

Since in numerous cases in anæsthetised cats I have not found any flushing in the foot, on stimulating the nerves which run to the fore- and hind-limbs, I am inclined to attribute the rise of temperature and flushing, which has been observed by others on stimulating the posterior roots, to some other cause than the stimulation of vaso-dilator fibres in these nerve roots.

One fact which has been overlooked in experiments on this question, is the possibility of an escape of current to the ramus of the nerve. This takes place much more readily in young than in old animals, and it is curious that three out of the four observers who have found positive effects, lay stress on the advantage of experimenting with young animals. It is also more likely to occur the stronger the stimulation, and, according to Morat, strong stimulation is required. On the other hand, we should expect that an escape of current to the grey ramus would take place as readily when the anterior roots are stimulated as when the posterior roots are stimulated. But all observers find slight or no effects with the anterior roots. It may be objected also that an escape of current to the grey ramus would cause a fall of temperature, and not a rise; this is to a certain extent true, but the rise might be due to an after-dilatation of the vessels. There are also other ways in which, in the conditions of the experiments, vascular dilatation might be produced, although there were no efferent vaso-dilator fibres in the posterior roots. It would, however, take up too much space to dwell on the various possibilities. It is sufficient to say that the existence of these fibres has not yet been proved, and that, as the question is one of considerable importance, it is most desirable that further careful experiments should be made.

LOCAL NERVE CENTRES OTHER THAN THE CRANIAL, SYMPATHETIC, AND SACRAL GANGLIA.

Goltz,⁶ in experiments on dogs, found that section of the sciatic nerve did not cause a permanent rise of temperature in the foot, but that the temperature returned to normal in a week or two. He dis-

cussed the several possible explanations of the recovery of tone, and adopted the view that in the foot and in the body generally the tone of the blood vessels was maintained by the action of local ganglion cells. The progress of histological inquiry has shown that the hypothetical local ganglion cells of the type of sympathetic nerve cells do not exist. And unless we fall back upon "interstitial cells," the view of the maintenance of tone by local nerve cell centres must be abandoned. It is very doubtful whether the "interstitial" cells are nerve cells at all. And, on the whole, the most probable explanation of such recovery of tone as occurs is the inherent contractile power of the plain muscular tissue itself.

It must be noticed that the degree of recovery of tone, after section of all vasomotor fibres, is still a matter in dispute (cf. p. 655), and that possibly the rapid recovery in the tone of the vessels of the foot, after section of the sciatic, is due to vasomotor fibres taking the course of the crural nerve (cf. p. 657).

In the stomach and intestine, the nerve cells of the plexuses of Auerbach and Meissner may well act as the local centres, but nothing definite can be said at present with regard to this.

QUESTIONS COMMON TO THE SYMPATHETIC AND SOME OTHER PARTS OF THE AUTONOMIC SYSTEM OF NERVES.

We have considered separately the sympathetic, the cranial autonomic, and the sacral autonomic systems, so far as this could be done conveniently, but a separate treatment is inconvenient for certain questions. These we shall consider in the following pages.

MODE OF ACTION OF INHIBITORY FIBRES.

Claude Bernard was the first to attempt to explain the action of inhibitory nerves. This he did with regard to the vaso-dilator fibres of the chorda tympani. He considered that the fibres of the chorda tympani inhibit the action of a local vaso-constrictor centre. On this hypothesis the local vaso-constrictor centre is in constant action; sympathetic fibres run to it and increase its action; chorda tympani fibres run to it and decrease its action; thus the nerve cells would receive fibres from two sources. This view of the mechanism of inhibition was advocated by Vulpian, and is supported by Dastre and Morat.

There are many facts which show that this view is untenable. We will consider the two chief instances of vaso-dilator fibres, the chorda tympani and the nervus erigens.

The local nerve centre with which the chorda tympani fibres is connected is the submaxillary ganglion in the hilum of the gland. This is shown by the action of nicotin. On Bernard's hypothesis, stimulation of the fibres proceeding from the local centre should cause contraction of the arteries. But, after the chorda tympani fibres have been paralysed by nicotin, stimulation of the fibres past the ganglion causes dilatation of the arteries of the gland, and does not cause contraction; hence the nerve fibres given off from the local nerve centre are not vaso-constrictor fibres but vaso-dilator fibres. So that the chief assumption of the hypothesis is incorrect. Moreover, when the sympathetic fibres are followed by means of serial sections into the gland, it is seen that they

accompany the arteries and run past the submaxillary ganglion without entering it. Further, it is easily shown that the sympathetic fibres are connected with nerve cells in the superior cervical ganglion, and that stimulation of the nerve fibres on either side of the ganglion has the same result, namely, contraction of the arteries.

In the case of the *nervus erigens*, the facts are of the same nature. Nearly all the sympathetic fibres—which are vaso-constrictor—end in connection with nerve cells in the sacral sympathetic ganglia; stimulation on either side of these ganglia causes great contraction of the vessels of the penis—section on either side of these ganglia causes great vascular paralytic dilatation. The fibres given off by the sacral ganglia have no nerve cells on their course to the periphery, for nicotin does not paralyse them. On Bernard's hypothesis, then, the sacral ganglia would be the local centres which are inhibited by the *nervus erigens*, but in fact the *nervus erigens* has no connection whatever with these ganglia. If, then, the *nervus erigens* inhibit local vaso-constrictor ganglia, there must be some such ganglia in addition to the sacral ganglia, and situated more peripherally. All the evidence, however, goes to show that the ganglia in the course of the *nervus erigens* are vaso-dilator and not vaso-constrictor. Stimulation peripherally of these ganglia causes vaso-dilatation, and nicotin annuls the effect of stimulating centrally of the ganglia, but does not annul the effect of stimulating peripherally of them.

Both for the *chorda tympani* and for the *nervus erigens* we have, then, satisfactory evidence that the vaso-dilator fibres run to nerve cells, and that both pre-ganglionic and post-ganglionic fibres produce vaso-dilator effects; further, that the vaso-constrictor fibres run to nerve cells, and that both pre-ganglionic and post-ganglionic fibres produce vaso-constrictor effects; lastly, that if the two systems communicate, it can only be in the region of the post-ganglionic fibres.

The state of things is essentially the same in the case of the vaso-dilator fibres of the bucco-facial region of the dog, the inhibitory fibres of the heart, and the inhibitory fibres of the stomach and intestine. And we may conclude for all cases that the inhibition which we are considering is not produced by a lowering of the activity of sympathetic or similar nerve cells.

We must, look, then, for the mechanism of inhibition either in interference of nervous impulses in the peripheral region of the post-ganglionic fibres, or in a direct action of the inhibitory fibres upon the tissue.

On the one alternative, constant motor impulses would be annulled, and no longer reach the tissue; on the other, the tissue itself would be affected, so that such motor impulses as did reach it would not have their usual effect.

The former is essentially the mode of action suggested by Bernard, but the action takes place in a different part of the nervous apparatus. The peripheral apparatus in which it is conceivable it should take place is either—(a) a nerve cell apparatus, the existence of which we have at present no sufficient reason for believing; or (b) a nervous network, into which both motor and inhibitory fibres run.

But such a network could not of itself keep up a tonic constrictor action, so that, if inhibition is produced after degenerative section of the constrictor fibres, it can only be produced by a direct action on the tissue.

Now, after extirpation of the superior cervical ganglion in the rabbit, and consequent degeneration of the vaso-constrictor fibres to the sub-maxillary gland, vaso-dilatation is still produced by stimulation of the chorda tympani.¹ In this instance, then, the inhibition must be caused by nervous impulses affecting directly the tissue. And we may take it as probable that peripheral inhibition by autonomic nerves is always brought about in this manner.

It must be mentioned that, according to Fletcher,² the rat's retractor penis muscle contains a terminal nervous network, which does not degenerate either when the motor or the inhibitory post-ganglionic fibres to it are cut. His experiments are still in progress.

But, accepting this, we are still far from any real knowledge of the processes involved in inhibition. One *a priori* possibility may be disposed of. The decrease of rigidity in the inhibited muscular tissue shows that inhibition is not caused by the development of a contractile force, acting in a direction opposed to the normal one and overpowering it. We are then brought to the conclusion that certain nerve impulses—the inhibitory nerve impulses—are able to lessen or to stop the chemical change in the tissue which leads to contraction. As this chemical change is accompanied by a setting free of energy, it is spoken of as a dis-assimilatory or katabolic change, so that inhibitory nerve impulses may be said to lessen or to stop some katabolic change in the tissue. Beyond this we cannot at present go safely. Gaskell³ has propounded the theory that inhibitory nerves cause assimilation or anabolism, and that the anabolic process stops for the time the katabolic process. And it appears to be implied that the two processes are mutually antagonistic. Gaskell, however, does not enter into a discussion of the relation which he takes to exist between the two processes.

It does not seem probable that, in general, anabolism interferes with katabolism. The histological changes which take place in the majority of glands during secretion afford good evidence that the two processes go on actively at the same time. No inhibitory nerve fibres have, however, been shown to exist in the glandular tissues; and, so far, the question is left open, whether anabolism does not stop katabolism in the tissues in which inhibition does occur.

It is clear, if inhibition is caused by anabolism, that, as regards the unstriated muscle of the arteries, anabolism goes on up to a certain limit simultaneously with katabolism, for by a proper gradation of the stimulus applied to dilator nerves, all degrees of decrease of tone in the arteries can be obtained.

To account for this, we might suppose that, with increasing strength of stimuli, more and more molecules are involved. On this supposition it follows that a given molecule can only be concerned with one process at a time, and that the predominance of one process in the cell necessarily means a diminution of the other. And, consequently, the more fully contracted an artery, the less should be the assimilative processes going on in it. Here we are met by the serious difficulty that in some

¹ Langley, *Journ. Physiol.*, Cambridge and London, 1885, vol. vi. p. 87.

² "Proc. Phys. Soc.," 1898, p. xxxvii., *Journ. Physiol.*, Cambridge and London, vol. xxii.

³ *Ibid.*, 1886, vol. vii. p. 46.

cases the small arteries can be kept for many hours,¹ and probably for days and months, in a state of strong contraction; and it is not to be believed that the breaking down thereby involved could go on if there were not some corresponding fresh formation.

We seem then driven to suppose, on the lines of the theory, that though anabolism interferes with katabolism, katabolism does not interfere with anabolism. But in such cases it is hard to avoid the conclusion that different molecules are affected. And then we are at a loss for an explanation of how anabolism in one molecule can stop katabolism in another molecule.

What is required, in the first place, is some means of determining whether anabolism is increased, or not, during inhibition; and if it is, to what extent it is increased. It need hardly be said that increased strength of contraction after inhibition is not necessarily a sign of increased anabolism; for the continuance of a previously existing rate of anabolism, unaccompanied by katabolism, would be sufficient to produce this result.

Dastre and Morat² regard the sympathetic ganglia as exercising a tonic action upon the blood vessels; they state that vaso-dilator action diminishes or disappears as nerve strands are stimulated more and more peripherally, and they conclude that the vaso-dilator fibres run to the sympathetic ganglia and inhibit their tonic action. Thus their view of inhibition is essentially that of Claude Bernard. The general question of tonic action we discuss later (p. 676). Here we may consider the particular cases on which Dastre and Morat rest their view. These concern—(1) the vaso-dilator fibres for the ear in the rabbit, cat, dog; (2) the vaso-dilator fibres for the foot of the dog.

1. According to Dastre and Morat, stimulation of the eighth cervical and first thoracic nerve roots causes primary dilatation of the vessels of the ear. Since stimulation of the annulus of Vieussens and of the cervical sympathetic causes nearly always, if not always, contraction of the vessels of the ear, they consider that the vaso-dilator fibres coming from the spinal cord end chiefly in the ganglion stellatum; they consider that this ganglion gives off numerous vaso-constrictor fibres, which run to the ear by way of the cervical sympathetic. In my experiments, stimulation of the eighth cervical nerve had no effect upon the vessels of the ear. In the cat, the first thoracic nerve produced sometimes, but not usually, a slight vaso-constrictor effect; this was sometimes followed by an after-dilatation of the same kind as, though very much less than, that caused by stimulation of the cervical sympathetic. Further, a study of the effects produced by nicotin seems to me to show that the ganglion stellatum sends, at least as a rule, no vaso-constrictor fibres to the ear by way of the cervical sympathetic.

2. Dastre and Morat find that stimulation of the sympathetic, above the second and third lumbar ganglia, causes primary dilatation of the vessels of the digits of the hind-foot, whilst stimulation below these ganglia causes primary contraction. They consider that the second and third lumbar ganglia send vaso-constrictor fibres to the vessels of the foot, and that the tonic action of these ganglia is inhibited by vaso-dilator fibres running to them from the spinal cord. I have not been able to observe such a difference, except in so far that more care is required to avoid reflex dilatation when stimulating above than when stimulating below the ganglion. And the action of nicotin in the cat shows, I think, that the second and third lumbar ganglia send no nerve fibres of any kind to the foot.

AUTOMATISM OF PERIPHERAL GANGLIA.

It perhaps hardly needs to be pointed out that, if the peripheral ganglia are devoid of automatism, no essential difference is thereby established between their nerve cells and those of the central nervous system. For many nerve cells on the central nervous system have, so far as we know, no automatic action; and in other cases in which automatic action appears to exist, it is uncertain how far it is simply apparent, and due in reality to afferent impulses.

The experiments to which we may look to throw light on the question as regards those nerve cells which are normally in tonic activity, fall into three classes:—

1. We may cut the fibres running to a ganglion, and later cut those running from it, and observe if the second section increases the paralytic effects of the first section.

2. We may compare the extent of the paralysis produced, when in one animal the nerve fibres running to a ganglion are cut, and in another animal the nerves running from the ganglion.

3. We may compare the extent of the paralysis when the nerve fibres are cut, as in (2), but on the right and left side of an animal instead of in different animals.

Before dealing with the experiments which have been made on these lines, we may note that the peripheral ganglia, of adult animals do not, so far as we know, depend for their nutrition on receiving impulses from the central nervous system. In some cases, in the central nervous system, removal of the normal impulses to the nerve cells causes them to atrophy. The nerve cells of the peripheral ganglia remain functionally active for a very long time after severance of their pre-ganglionic fibres. It was noticed by Budge¹ that a year after section of the cervical sympathetic, stimulation of the superior cervical ganglion still caused dilatation of the pupil, although the nerve itself had not regenerated. Further, so far as the reagents in use show, the nerve cells retain their normal appearance.

1. It may be doubted whether the first form of experiment mentioned above is one which will give convincing results, unless there is a considerable interval of time between the two operations, for it cannot be said with certainty how long it takes for the stimulating effect of the first section to disappear completely. So far, at any rate, the method has not yielded anything decisive on the question.

Some interesting observations have been made on the effects of removal in the frog² of the sympathetic ganglion which sends fibres to the pupil. They do not, however, allow any well-founded conclusion to be drawn as regards the automatism of the nerve cells.

Dastre and Morat³ state that, in the dog, section of the cervical sympathetic does not cause flushing of the bucco-facial region, whilst excision of the superior cervical ganglion does. I have not been able to find any such constant difference in the effect of the two operations.

Dastre and Morat found a greater dilatation of the vessels of the ear (and

¹ Budge, "Ueber die Bewegung d. Iris," Braunschweig, 1855, S. 125. Budge, however, attributed the effect to pupillo-dilator fibres running to or through the ganglion from the hypoglossal.

² Liégeois, *Compt. rend. Soc. de biol.*, Paris, 1862, p. 71; Vulpian, "Leçons sur l'appareil vaso-moteur," p. 312; cf. also Budge, *Arch. f. physiol. Heilk.*, Stuttgart, 1852, S. 773; Tuwim, *Arch. f. d. ges. Physiol.*, Bonn, 1881, Bd. xxiv. S. 115.

³ "Système nerveux vaso-moteur," Paris, 1884; *Arch. de physiol. norm. et path.*, Paris, 1892, p. 171.

of other parts of the head) on cutting centrally of the ganglion stellatum than on cutting peripherally of it, and on cutting centrally of the inferior cervical ganglion than on cutting peripherally of it. They found, also, a greater dilatation of the vessels of the foot of the dog on cutting the sympathetic chain centrally, than on cutting it peripherally, of the second and third lumbar ganglia. Hence they concluded that these ganglia exercise a tonic action on the parts mentioned. The considerations which lead me to consider the experiments inconclusive are given above (p. 675).

According to François-Franck,¹ section in the dog of the ciliary nerves containing constrictor fibres for the sphincter iridis, causes greater dilatation of the pupil than section of the third nerves.

2. The second method has not given any certain results as regards the superior cervical ganglion, and it is on this that experiments have been chiefly made.

Bernard² stated that excision of the superior cervical ganglion gives greater and more permanent paralytic effects than section of the cervical sympathetic. It is not, however, clear that Bernard excised a sufficiently long portion of the nerve to prevent regeneration, or, indeed, did more than state a general impression. Schiff,³ Callenfels,⁴ and Pye-Smith⁵ found no difference between the result of the two operations.

3. Callenfels made three experiments upon rabbits by the third method, *i.e.* he cut the cervical sympathetic on one side and excised the superior cervical ganglion on the other. In two cases he found the temperature of the ear higher on the side on which the nerve only was cut; in one case the temperature was lower on this side. Twim,⁶ in similar experiments in rabbits, found no difference in the flushing of the ear on the two sides; nor in similar experiments in frogs did he find any difference in the flushing of the two sides of the tongue.

Jegorow,⁷ however, states that, in a series of experiments on the dog, the dilatation of the pupil was markedly greater after excision of the ciliary ganglion than after section of the third nerve a little centrally of the ciliary ganglion.

On the whole, the evidence at present leads us to conclude that autonomic ganglia, after separation from the central nervous system, do not exercise any considerable tonic action on unstriated muscle, but that it is possible they have a slight action.

Apart from tonic action, it is not improbable that peripheral nerve cells, severed from the central nervous system, may at times stimulate the tissues to which they send fibres. The nerve cells and fibres remain responsive to chemical and mechanical stimuli, and it is not unlikely that substances circulating in the blood and the movements of the body now and then serve as stimuli to the local nervous mechanism, and so set in action the peripheral apparatus.

So far, we have considered nerve cells which normally exercise a tonic influence on the tissues with which they are in connection. Of the others, there is little that need be said here. There is some evidence that the submaxillary ganglion passes into a state of slight tonic activity after section of the chorda tympani, for, so far as the experi-

ments have gone, dyspnoea increases and chloroform decreases the paralytic secretion.¹ But the sympathetic ganglia supplying the hairs do not appear to acquire any tonic action after severance from the spinal cord.

Lastly, it remains to mention the belief once held, that the beat of the heart is caused by rhythmic impulses from the local ganglia. This view is now generally abandoned. The discussion of it belongs elsewhere. We may, however, notice the possibility that the local ganglia have even after section of the vagus, a tonic inhibitory action upon the heart.

ON PERIPHERAL GANGLIA AS CENTRES FOR DEFINITE AREAS.

It is conceivable that the peripheral nerve cells should be collected together according to their function, so that all the vaso-constrictor nerve cells which send their axons to a given area should be collected into one ganglion, the vaso-dilator nerve cells in another ganglion, the pilo-motor in a third, and so on. But in fact, within the limits of each division of the autonomic system, there is no instance in which this occurs. It occurs only when a tissue receives fibres from two divisions of the autonomic system; then the ganglia of the two systems are separated, and they may have different functions. What we find is that a ganglion which sends nerve fibres to a particular area sends to it all the varieties of nerve fibres, received by the area from the autonomic system to which the ganglion belongs. When an area receives axons from the sympathetic and from the cranial system, or from the sympathetic and from the sacral system, the axons from the two systems have each their own ganglion, and some variety of nerve cell may be, and indeed commonly is, present in the ganglion of the one, which is not present in the ganglion of the other.

Each ganglion, then, may be regarded as a group of nerve cells supplying fibres of various functions to a definite area. In some cases, and within the limits of each autonomic system, all nerve cells supplying a given area are collected together to make one ganglion, but this simple arrangement is commonly departed from in one, or in both, of two ways. For there is a tendency for the nerve cells supplying an area to be arranged in several small ganglia instead of in one larger one. Thus, instead of a single ciliary ganglion, there may be one main ganglion and several accessory ganglia. So the ganglia for the various abdominal and pelvic viscera usually consist of a main ganglion and of accessory ganglia. And even the vertebral ganglia may be in two parts, a small part occurring in the course of a grey ramus.

Further, as we have seen, there is some overlapping in the areas supplied by the several ganglia. The overlapping may be constant and considerable, as in the case of the ganglia sending axons to the hind-limbs; it may be constant and slight, as in the case of some of the thoracic ganglia sending fibres to the skin of the back; or it may be variable, both in occurrence and extent, as in the case of ganglia which may send fibres by a white ramus as well as by a grey one.

REFLEX ACTIONS FROM AUTONOMIC GANGLIA.

Experimental observations on reflex actions from autonomic ganglia were first made by Bernard with regard to the ganglion called by him

¹ Langley, *Journ. Physiol.*, Cambridge and London, 1885, vol. vi. p. 71.

the submaxillary ganglion. These and subsequent observations we have discussed in the article on "Secretion of Saliva." And we came to the conclusion that the supposed reflex secretion was partly due to stimulation of recurrent fibres and partly perhaps to stimulation of one branch of a dividing fibre.

Sokownin¹ showed that when in the cat the nervous connections of the inferior mesenteric ganglion are severed, with the exception of the hypogastric nerves, and then one hypogastric nerve is cut and its central end stimulated, contraction of the bladder on the opposite side is produced. And it was found by Anderson and myself² that the stimulation causes also other effects, namely, contraction of the internal

FIG. 315.—B and C show the probable mechanism of pseudo-reflexes; B, uncrossed, from the sympathetic chain; C, crossed, from the hypogastric nerves. With the arrangement given in A (some compound ganglia), pseudo-reflexes are not obtained.

sphincter of the anus, pallor of the mucous membrane of the end of the rectum, sometimes slight pallor (very rarely contraction) of the uterus on the opposite side, and occasionally slight pallor and contraction of the external generative organs.

We may for convenience speak provisionally of these actions as reflex actions, and proceed to consider the nervous mechanism by which they are produced. The injection of a small amount of nicotine puts a stop to the reflexes, although it does not stop the effects of stimulating the peripheral ends of the hypogastric nerves, so that we may conclude that the reflexes are normally produced by impulses which pass through

¹ *Arch. f. d. ges. Physiol.*, Bonn, 1874, Bd. viii. S. 600; *Jahresb., u. d. Fortschr. d. Anat. u. Physiol.*, Leipzig, 1877, Bd. vi. Abth. 3, S. 87. Cf. also H. Nussbaum, *ibid.*, 1879, Bd. viii. Abth. 2, S. 64; Nawrocki and Scabitschewsky, *Arch. f. d. ges. Physiol.*, Bonn, 1891, Bd. xlix. S. 141.

² *Journ. Physiol.*, Cambridge and London, 1894, vol. xvi. p. 410.

peripheral nerve cells, and chiefly through nerve cells in the inferior mesenteric ganglion. The same effect is produced by degenerative section of the inferior splanchnics, *i.e.* the nerve strands running from the spinal cord to the inferior mesenteric ganglion. Further, the observations tend to show that the same effect is also produced by degenerative section of the roots of the nerves which send efferent fibres to the various viscera in question. And we may conclude that the reflexes are produced by efferent fibres proceeding from the spinal cord, and having some connection with the nerve cells of the inferior mesenteric ganglion. In this case the method of connection can in principle hardly be other than that shown in C, Fig. 315. Some of the efferent fibres from the spinal cord (pre-ganglionic fibres), instead of sending all their terminal branches to the inferior mesenteric ganglion, send one or more to it, and one or more down the hypogastric of the same side to aberrant, more peripheral, ganglia; of the former, some are in connection with cells which send their axons down the opposite hypogastric. Thus, on stimulation of the central end of one hypogastric, impulses pass up the motor fibres, and spread out in their branches to some of the cells of the inferior mesenteric ganglion of the opposite side.

FIG. 316.

The mechanism of these actions is not that which has been ordinarily understood as the mechanism of a reflex action. In the latter, special afferent fibres form an essential part of the machinery. So that it is clearly advisable to use some other term than "reflex" for those actions which are brought about by stimulating the central ends of efferent fibres. A good term is not very easy to find. I shall speak of them as pseudo-reflex actions.¹

Morphologically, a pseudo-reflex action does not differ in principle from a reflex action which is produced by stimulating a nerve trunk. This will be seen on comparing the diagrams, A, B, and C of Fig. 316. A represents a simple reflex action, and B a pseudo-reflex action, and each of these can be reduced to the form C.

In normal conditions, it does not seem probable that pseudo-reflex actions are often brought into play. So far as the experiments have gone, a nervous impulse set up in a post-ganglionic fibre cannot pass back through the nerve cell, so that the only way of setting up a pseudo-reflex action is by excitation of pre-ganglionic fibres, *i.e.* of nerve trunks and of ganglia, and not of peripheral endings in the autonomic tissues. Fig. 317 will serve to make this point clear.

¹ They might perhaps be called "deflected" or "deflex" actions.

Other instances of the same kind of action occur in the body. We have seen that in the cat no pilo-motor fibres run ordinarily to the sympathetic chain below the third lumbar nerve, and that the pilo-motor fibres from the twelfth thoracic to the third lumbar nerves run downwards. But if any part of the lumbar sympathetic chain be stimulated, erection of hairs takes place in the areas of the skin innervated by two, three, or four of the ganglia above the point stimulated.¹ The action can be produced after destruction of the spinal cord, or after section of the white rami, but is annulled by injection of nicotin; and nicotin applied locally to any one ganglion annuls the effect in the area supplied by that ganglion. As with the hypogastric pseudo-reflexes, so here we may put on one side the posterior root fibres as being concerned with the action, since stimulation of these has no pilo-motor effect. It cannot be due to commissural fibres proceeding from lower ganglia to higher ones, since degenerative section of the sympathetic below the third lumbar white ramus abolishes the action below the point of section, but degenerative section between the ganglia does not abolish the effect of stimulating the upper cut end. It can then only be produced by descending motor fibres, the mechanism being diagrammatically as shown in B, Fig. 316.

Similar pseudo-reflexes occur in the upper thoracic region of the sympathetic chain. We have seen that there are no *descending* pilo-motor fibres in the sympathetic in the region between the ganglion stellatum and (about) the sixth thoracic ganglion. But on stimulating any part of this region, after section of the white rami, erection of hairs is obtained in the areas supplied by the two to six ganglia below the point stimulated, and the action is stopped by injection of nicotin.

The pilo-motor pseudo-reflexes from the sympathetic chain, which we have just described, differ, it will be noticed, from those obtained from the hypogastric nerve, in being produced on the same side of the body as the stimulation, instead of on the opposite side (cf. B, Fig. 315). They are further interesting, as giving an indication of the number of ganglia to which a single nerve fibre sends branches. Generally speaking, there are fewer in the lumbar region than in the upper thoracic region of the sympathetic. Further experiments are required before any very definite statement can be made with regard to this; but, so far as the experiments have gone, it appears that the fibres running to the lumbar ganglia send branches to three ganglia as a rule; and the fibres to the thoracic ganglia generally send branches to four or five ganglia.

According to François-Franck,² stimulation of the central end of one limb of the annulus of Vieussens, after severance of the connections of the ganglion stellatum with the spinal cord, causes dilatation of the pupil. He attributes this to a stimulation of sensory fibres, causing a reflex action in the ganglion stellatum. In the cat I have not found a dilatation of the pupil in these circumstances; usually there was no effect, but occasionally the stimulation caused retraction of the nictitating membrane, and a slight separation of the eyelids. I take these effects to be produced by motor fibres, and to be pseudo-reflex and not reflex effects. They can hardly be due to an excitation of nerve cells in the ganglion stellatum, since the local application of nicotin to

FIG. 317.—Impulse set up in the endings of a branch of the post-ganglionic fibre (*po.g.*), though it may irradiate to the other endings of the same fibre, cannot pass back to the pre-ganglionic fibre (*pr.g.*), and so cannot produce a pseudo-reflex action of the kind described in the text.

¹ Langley and Anderson, *Journ. Physiol.*, Cambridge and London, *op. cit.*

² *Arch. de physiol. norm. et path.*, Paris, 1894.

this ganglion does not stop them. Injection of nicotin, or local application of nicotin to the superior cervical ganglion, does put a stop to them. We may conclude, then, that the nerve cells which are set in action are in the superior cervical ganglion, and that the reflexes are produced by fibres which divide in the trunk of the sympathetic, one division running to the anterior and the other to the posterior limb of the annulus of Vieussens. I have not found any effect on the eye, when the central end of the nerve which is given off by the ganglion stellatum to the heart and lungs is stimulated, although this contains numerous sensory fibres.

François-Franck also describes a reflex contraction of the pupil by way of the long ciliary nerves and the ciliary ganglion. Anderson and myself made one or two experiments on the cat and dog, but were unable to confirm this result.

It has been mentioned above, that after degenerative section of the inferior splanchnic nerves, stimulation of the central end of one hypogastric nerve has no effect; and we have deduced from this, that in all probability nervous impulses in post-ganglionic fibres cannot travel back through nerve cells and affect other nerve cells. It is clear, at any rate, that the impulses cannot excite all the nerve cells in the ganglion, for in that case stimulation of the central end of the hypogastric in the given circumstances would cause inhibition (or contraction) and pallor of the descending colon and rectum, since the nerves for those structures and the hypogastric nerve fibres arise in part from the same ganglia.

The experiment may also be taken as showing that the post-ganglionic fibres do not divide and send a branch to each hypogastric nerve; this makes it probable that post-ganglionic fibres only divide near their terminations, and thus we should not expect to find any wide spreading out of effects by an action on post-ganglionic fibres, analogous to that which may be obtained by an action on pre-ganglionic fibres.

Some other experiments, to observe whether stimulation of the central end of post-ganglionic fibres could cause a reflex effect, were made by Anderson and myself. We found no effect on stimulating the central end of one of the short ciliary nerves, nor on stimulating the central end of any one of the branches of the superior cervical ganglion.

ON THE NUMBER OF NERVE CELLS ON THE COURSE OF A PRE-GANGLIONIC FIBRE, AND ON COMMISSURAL FIBRES.

In the preceding account I have assumed that a nervous impulse, in its passage from the central nervous system to the periphery, passes through one nerve cell only of the sympathetic type, and that such nerve cells are not connected by commissural nerve fibres. Both of these assumptions are opposed to general belief. Those who have considered that the nervous impulses pass through nerve cells at all, have taken for granted that in many cases they pass through more than one nerve cell; and most observers have taken for granted that the sympathetic ganglia are connected by commissural fibres. In this section I shall give some of the reasons in favour of my own view. In doing so; it must be remembered that I consider enteric nerve cells to be of a different type from the sympathetic nerve cell.¹

We have good evidence, in the case of particular ganglia, that all the pre-ganglionic fibres which are able to affect the ganglion run to it direct and end in connection with its nerve cells. This is, for example, the case with the superior cervical ganglion, the ciliary ganglion, and the coccygeal ganglion.

¹ Cf. p. 668.

It is hardly necessary to consider the evidence in detail, its general nature is indicated by what has already been said with regard to these ganglia.

We have good evidence, also, that the fibres given off by these ganglia run to the peripheral termination, without having nerve cells on their course.

Consequently, if a pre-ganglionic fibre has more than one nerve cell in its course, the second or other additional cells must be in the same ganglion as the first nerve cell, and the total number of cells with axons terminating in the ganglion must be great. But such arrangement is entirely unsupported by histological appearances. We may consequently adopt the simpler view, that a nervous impulse, in passing from the central nervous system to the periphery, passes through one nerve cell only.

The two questions, of the number of autonomic nerve cells on the course of a nervous impulse, and of the presence of commissural fibres, are closely connected. For if commissural fibres exist, and if they can be put in action by the pre-ganglionic fibres, it follows that a nervous impulse on its way to the periphery must in some cases, at any rate, traverse more than one nerve cell. The facts which bear on the question of commissural fibres are of several kinds.

1. We may consider, first, some cases in which it can be shown that commissural fibres do not exist. We have seen that the nerve cells of the ganglion stellatum in the cat send vasomotor and secretory fibres to the fore-foot, and vasomotor and pilo-motor fibres to the skin of the lower part of the neck and upper part of the thorax. If the superior cervical ganglion sends commissural fibres to any of these nerve cells, stimulation of the central end of the cervical sympathetic must cause observable changes in the foot and in the skin of the back. In fact, the stimulation has no effect. It is clear, then, that the superior cervical ganglion does not send commissural fibres to the great majority of cells of the ganglion stellatum. And, so far as the experiments have gone, it does not send commissural fibres to any of the cells of the thoracic ganglia.

The inferior cervical ganglion is small and comparatively unimportant, but as it is placed near the ganglion stellatum, it might be expected to send fibres to this ganglion. On stimulation of the central ends of the annulus of Vieussens—the white rami being cut—I have not found any effect on the blood vessels or glands of the foot, or on the hairs of the back; so that the inferior cervical ganglion sends no commissural fibres to those nerve cells of the ganglion stellatum which govern the above-mentioned structures.

Stimulation of the sympathetic chain, just above the first coccygeal ganglion, has no effect on the hairs or blood vessels supplied by the lumbar or by any higher ganglia, so that the first coccygeal ganglion does not send fibres to the vasomotor or pilo-motor cells of these ganglia.

Stimulation of the upper thoracic region of the sympathetic does not affect the lumbar ganglia; nor does stimulation of the lumbar region affect the upper thoracic. These parts of the sympathetic cannot then be joined by commissural fibres.

So far, we have spoken of the ganglia of the sympathetic chain. There are similar facts with regard to the pre-vertebral and the vertebral

ganglia. Stimulation of the central end of the splanchnic nerves—the spinal cord being destroyed—has no effect upon the hairs, *i.e.* the solar ganglia and the inferior mesenteric ganglia do not send commissural fibres to the pilo-motor nerve cells of the vertebral ganglia.

We find, then, that in a considerable number of cases the nerve cells of one ganglion do not send nerve fibres to the nerve cells of other ganglia. And, in consequence, there cannot be any general system of connection of ganglia with one another by commissural fibres.

Moreover, whenever an effect is obtained by stimulating the connecting strand between two ganglia, the effect may always be referred on good grounds to stimulation of fibres other than commissural fibres, namely, either of the peripheral ends of pre-ganglionic fibres,¹ or of the central ends of the pre-ganglionic fibres,² or of post-ganglionic fibres. Since, then, commissural fibres are in no case necessary in order to account for phenomena, and in particular cases it can be shown that they do not exist, we may reasonably adopt the view that commissural fibres are absent from the sympathetic system.

2. It can be shown that the pre-ganglionic fibres, if they excite nerve cells which pass on the stimulus to commissural fibres, can only do so to a very limited degree. From the twelfth thoracic to the lowermost effective spinal nerve (fourth or fifth lumbar), the pre-ganglionic fibres of a given spinal nerve excite the nerve cells of the ganglia below, but do not excite the nerve cells of their own segmental ganglia.⁴ Thus, stimulation of the nerve roots of the third lumbar nerve causes erection of hairs in the region of the fourth lumbar ganglion, but none in the region of the third lumbar ganglion, *i.e.* excitation by pre-ganglionic fibres of the pilo-motor nerve cells of the fourth lumbar ganglion does not set in action commissural fibres passing to any more anterior ganglia above. And similarly with the other ganglia, up to the twelfth thoracic.

In some other cases the limitation of the stimulus to particular nerve cells is still more striking. In all compound ganglia it is obvious that stimulation of certain of the pre-ganglionic fibres running to the ganglia excites some only of the nerve cells, and no increase in the strength of the stimulus can cause irradiation of nervous impulses to the other cells of the ganglion. And the nerve cells which cannot then be brought into action may be nerve cells of the same class as the cells which are in a state of excitation. Of this we may give an example. In the cat, at times, when the arrangement of nerves is posterior, the fourth lumbar nerve causes erection of hairs on the tip of the tail; the nervous impulses pass through nerve cells in the coccygeal ganglion; other nerve cells in the coccygeal ganglia will, on stimulation, cause erection of hairs in the greater part of the rest of the tail; but no stimulation of the fourth lumbar nerve will affect this region. Hence, pilo-motor nerve cells, set in action by the fourth lumbar nerve, send no commissural fibres to the other pilo-motor nerve cells of the coccygeal ganglion.

Occasionally facts of the same kind can be shown in simple segmental ganglia. Thus in the cat the second and third sacral ganglia contain two sets of vasomotor cells; one set send their axons to the ano-genital region, and cause contraction of the arteries in this region;

¹ Cf. p. 634 *et seq.*

³ Cf. p. 679 *et seq.*

² Cf. p. 629.

⁴ Cf. p. 634.

the other set send their axons to the skin over the end of the sacrum, and cause contraction of the arteries there. When the arrangement of nerves is anterior, the stimulation of the fifth lumbar nerve causes contraction in the arteries of the ano-genital region, but not in the arteries of the skin over the end of the sacrum, *i.e.* the two sets of vasomotor cells in these ganglia are not connected by commissural fibres; and it seems safe to conclude that the nerve cells which are excited by pre-ganglionic fibres send their axons to peripheral structures, and in no case send them to other nerve cells.

It is to be noticed that if commissural fibres between ganglia are put in action at all, it is practically certain that they must be put in action by pre-ganglionic fibres, for they are not put in action by afferent spinal fibres, nor are they by the fibres which run from the ganglia to the periphery (cf. p. 682), and there is no other class of fibre present except the pre-ganglionic fibre.

3. After nicotin has been injected into the blood vessels, stimulation of the sympathetic between the vertebral ganglia has in most cases no effect. Such effect as is produced can be referred to post-ganglionic fibres. The action of nicotin, then, only allows us to conclude that commissural fibres, if present, are paralysed by nicotin. It does not directly affect the question of the presence of such fibres.

4. The results of experiments by the degeneration method are in their nature more conclusive, though not many have so far been made. When the lumbar sympathetic is cut below the last white ramus, and time is allowed for degeneration, all the sympathetic chain below the cut passes into a state like that which is produced by injection of nicotin. On stimulating between any two ganglia there is no effect, or only such as is produced by post-ganglionic peripherally running fibres. It might perhaps be supposed that commissural fibres degenerate after severance of the connections of the spinal cord with the sympathetic ganglia, but this hypothesis hardly requires serious consideration, for we have seen that the nerve cells giving off post-ganglionic fibres remain unaffected in function by separation from the spinal cord. We may then take the experiment as showing that there are no commissural fibres in the lower part of the sympathetic chain. And there can be little doubt that similar experiments upon the rest of the sympathetic would lead to a similar conclusion.

THE SIZE OF NERVE FIBRES AS A CHARACTERISTIC OF THE AUTONOMIC SYSTEM.

Bidder and Volkmann divided the medullated nerve fibres of the body into two classes, according to their size and certain other characters. The smaller fibres they called sympathetic, the larger cerebro-spinal fibres. They considered that most if not all the sympathetic fibres arose from the spinal and sympathetic ganglia. Bidder and Volkmann's use of the term sympathetic for all small medullated fibres was not generally adopted, and chiefly because it appeared clear that in mammals many small medullated fibres arose from the central nervous system.

But the statement that the nerve strands connected with the sympathetic and other peripheral ganglia contained many small medullated and very few large medullated fibres, was in the main accepted.

Several subsequent observers pointed out that the medium and large fibres of the sympathetic, so far as they could be followed, ran past the ganglia and did not end in them. But no great attention was paid to the size of sympathetic nerve fibres until Gaskell's work in 1887. He argued that all efferent "visceral" fibres are small fibres. And this view we may accept. The only point that can be urged against it is, that the actual termination of many of the medium and large fibres is not yet known.

The converse of this view, namely, that all small efferent medullated fibres are "visceral," *i.e.* autonomic, cannot at present be affirmed. Thus the anterior roots of the nerves to the limbs, which have not been shown to exercise any autonomic function, contain some small fibres, though but few.

A further matter, on which it is premature to make any dogmatic statement, is as to the size of the afferent fibres of the sympathetic and other parts of the autonomic system. It may, I think, be regarded as certain that the afferent fibres occurring in the sympathetic are not fibres of any one size. Small medullated fibres can be traced into the white rami of the sympathetic from the posterior roots of the spinal nerves; and the *nervus accelerans*, which consists exclusively or almost exclusively of non-medullated and small medullated fibres, gives, on stimulation, all the usual reflex effects. On the other hand, in the cat many of the larger nerve fibres of the sympathetic trunk can be traced into Pacinian bodies. And the depressor nerve, which is especially a nerve connected with autonomic reflexes, consists in great part of medium and of large nerve fibres. It is not unlikely, as regards the sympathetic system, that the medium and large fibres end in the serous membranes, and give rise to local pain, and that the small fibres end in connection with unstriated muscle and glandular tissue, and give rise to referred pain (*cf.* p. 689). But until the actual endings of the several afferent fibres have been ascertained, we cannot even say which are directly connected with autonomic reflexes, and which only indirectly by way of the somatic system.

It may be mentioned that the cutaneous nerves contain numerous small fibres which run to them direct from the spinal nerves.

AFFERENT AUTONOMIC FIBRES. REFERRED PAIN IN VISCERAL DISEASE.

Connection of afferent sympathetic fibres with spinal ganglia.—Some histological observations by Cajal and by Dogiel have been taken to imply that the afferent sympathetic fibres have a special connection with the spinal ganglia.

Cajal has described large nerve fibres as passing from the sympathetic chain, and giving off branches which penetrate between the cells of the spinal ganglia; and he suggests that these fibres form nerve-endings around the cells. Dogiel¹ traces small medullated and non-medullated nerve fibres from the primary ventral division of the spinal nerve into the spinal ganglion. He considers that these fibres arise from "sensory" cells of the sympathetic ganglia. He finds that the fibres divide and form pericellular endings, and as a rule, if not always, in connection with a new

¹ *Internat. Monatschr. f. Anat. u. Physiol.*, Leipzig, 1897, Bd. xiv. In this paper, references to other observations bearing on the question will be found.

type of posterior root cell, namely, one which has the general characters of Golgi's "sensory" type. The cell is small, its axon divides into a number of branches, and each branch ends in connection with typical unipolar cells. Thus Dogiel considers that a few afferent sympathetic fibres can stimulate a considerable number of posterior root cells. It will be noticed that a point of primary importance, namely, the origin of the branching fibres from the sympathetic, rests on wholly insufficient evidence. Dogiel's theory must be regarded as purely provisional, for there are certain facts which are inconsistent with it. Section of the inferior splanchnics,¹ the lower lumbar sympathetic chain,² or of a white ramus³ does not, as a rule, cause degeneration of any medullated fibres in the central ends of the nerves. Sometimes a few degenerated fibres may be followed for a short distance, but these appear to belong to small grey bundles and to pass off to peripheral tissues. This, of course, requires close investigation. The result, however, tends to show that the pre-vertebral ganglia do not send any medullated fibres to end free in the spinal ganglia, and that the vertebral ganglia do not send any by a white ramus. The result does not exclude the possibility of medullated fibres passing from a vertebral ganglion to a spinal ganglion by a grey ramus, but the absence of physiological evidence of the presence of sensory fibres in the grey rami is against it.

We may at any rate conclude that the majority of the afferent sympathetic fibres have their trophic centre in the cells of the spinal and not in the sympathetic ganglia.

It is well to bear in mind that the evidence, that the fibres between the spinal cord and the sympathetic chain are *all* medullated, is not entirely conclusive. The evidence simply establishes a high degree of probability. Beck (1846) describes a few "gelatinous" fibres in both anterior and posterior roots. Gaskell does not find any in the anterior roots, but does find some in the posterior roots. No doubt the probability is, that such non-medullated fibres as occur in the nerve roots run to the blood vessels of the spinal cord, but the proof of this is defective.

Relative number of afferent and efferent fibres.—The number of efferent and of afferent medullated fibres in a nerve strand can be determined by cutting the anterior roots of the nerves which supply it, and counting later the number of degenerated and of sound fibres. By this method, it appears that about one-tenth only of the medullated fibres in the hypogastric nerves are afferent,³ and the proportion of afferent fibres in the several splanchnic nerves is probably not very different from this. In the pelvic nerve, the proportion of afferent fibres is considerably greater, and in the cat approximately one-third of the whole number.⁴

The cervical sympathetic contains no afferent fibres proper to it, for stimulation of its central end does not cause pain, nor any reflex action. Sometimes a few afferent fibres from the vagus join the cervical sympathetic, but they run down the neck, and do not accompany the nerve in its peripheral course. The grey rami of the vertebral ganglia have also few, if any, afferent fibres accompanying the efferent post-ganglionic fibres to their peripheral endings.

² Langley, *ibid.*, 1896, vol. xx. p. 55.

³ Langley and Anderson, *ibid.*, 1894, vol. xvii. p. 185.

⁴ *Ibid.*, 1895, vol. xix. p. 377.

General distribution of afferent fibres of autonomic nerves.—In the sympathetic every white ramus contains afferent fibres, for stimulation of the central end of even the smallest, readily causes a reflex body movement and change of blood pressure. The white rami form the only definitely proved channel for afferent impulses passing by the sympathetic. It is true that, as we have seen, there is histological ground for believing that a few afferent fibres pass to the spinal cord by way of the grey rami, but we may leave these out of account, since, in the experiments made so far, no reflex of any kind has been obtained by stimulating them.

The afferent fibres of the white rami do not run to the head, nor to any appreciable extent to the skin of the body. They run to the thoracic and abdominal viscera.

Such afferent autonomic fibres as run to the skin of the head and body must pass to it direct by the cerebro-spinal nerves. The deeper autonomic structures of the head probably receive afferent autonomic fibres from the seventh and the ninth nerves.

It is probable from the experimental evidence, so far as this goes, that the peripheral distribution in the viscera of the afferent fibres of each white ramus is essentially the same as that of the efferent fibres of the ramus, so that the sensory connection of the various viscera with the spinal nerves differs but little from the scheme given earlier for the motor connection.

At the same time, it must be borne in mind that the observations in man with regard to the cutaneous areas of tenderness and pain, which occur in disease of the several viscera (cf. p. 689), tend to show that the afferent fibres for any one organ arise from fewer white rami than do the efferent fibres. It is possible, however, that the referred tenderness ordinarily occurs only in the areas of those nerves which send a considerable number of afferent fibres to the affected organs, and that wider connections of afferent fibres with the several organs may be found, as clinical attention is more directed to the question. The results obtained so far are not concordant, but it is fairly well established that afferent fibres to the heart and lungs, the stomach, the liver, the intestine and kidney, form successive and overlapping series.

The peripheral distribution of the afferent and of the efferent sacral autonomic nerves appears also to correspond. Thus, on section of the pelvic nerve, degenerated fibres can be traced to the structures in which effects are produced by stimulation of the nerve, but degenerated fibres cannot be traced—according to the observations of Anderson and myself¹—to the uterus, which is unaffected by stimulation of the pelvic nerve.

Sensitiveness of the viscera.—It has been long known that the thoracic and abdominal viscera are very insensitive to certain forms of stimulation, such as handling and cutting, and this fact formed the basis of the theory put forward by Reil in 1811, that the sympathetic ganglia serve to suppress sensory impulses, and were only partial conductors of sensibility. Nevertheless, the splanchnic nerves, superior and inferior, and the pelvic nerve, when pinched or stimulated electrically, are apparently as sensitive as any nerve in the body, and we know that certain diseases of the viscera give rise to exquisite pain. There is

¹ *Journ. Physiol.*, Cambridge and London, 1895, vol. xix. p. 272.

comparatively little localisation of sensation in the viscera, and it is doubtful whether there is any proper sense of touch.

Referred pain.—At times diseases of the viscera give rise to pain in certain parts of the skin. This is spoken of as referred pain. Approximate explanation of its occurrence was put forward by Ross.¹ On his view, the irritation of the visceral fibres of an organ is conducted to the grey matter of the cord, and there diffuses to the roots of the corresponding somatic nerves, and thus causes an associated pain in the area of distribution of these nerves. We may adopt the essential part of this view, namely, that when the afferent autonomic fibres of a nerve are affected, the primary referred pain will be in the area of the cutaneous fibres of the nerve.

It was shown by Mackenzie² and by Head³ that visceral disease also causes areas of the skin to be more sensitive to slight stimuli, *i.e.* it may give rise to referred tenderness as well as to referred pain.

On this basis it is clear that referred pain will occur in the skin areas of those roots which have white rami, of those from which the pelvic nerve arises, and of those nerves, if any, with which the vagus afferent fibres are intimately connected. And there should not be primary referred pain in any others kin areas. Indeed, Ross—influenced by Gaskell's work on the visceral system—brought forward some facts to show that this was the case.

The question was followed up by Head, who has shown that, whilst primary referred pain and tenderness occur in large parts of the body, they do not occur in all. They do not occur in certain parts of the limbs, and we have seen that some of the nerves for the limbs send no fibres either to the cranial, sympathetic, or sacral autonomic system.

From what we have said earlier, with regard to the white rami and the pelvic nerve in man, we should expect the lumbo-sacral nerves, in the areas of which no primary referred pain occurs, to be ordinarily the third lumbar to the first sacral inclusive, sometimes also the second sacral, and possibly at other times the second lumbar. According to Head, the nerves are the second, third, and fourth lumbar. If this is so, either the afferent impulses pass by the grey rami, or the afferent sympathetic fibres of a nerve may cause primary referred pain outside the somatic area of the nerve to which they belong. Referred pain by way of the vagus occurs in part of the region of the fifth cranial nerve and of the upper cervical nerves;⁴ hence, we must suppose that the roots of the vagus have intimate connection with the roots of the fifth and of the upper cervical nerves. Certain deep structures of the head, such as the iris, tooth pulp, tongue, cause referred pain in the skin region of the fifth nerve, and, taken together, in the whole region of the fifth.

Affections of certain of the thoracic abdominal organs frequently cause referred pain both in the body and in the head or neck, *i.e.* both above and below the brachial gap. This is naturally explained by the supposition that the organs receive fibres both from the sympathetic and from the vagus.

¹ *Brain*, London, 1888, vol. x. p. 351.

² *Med. Chron.*, Manchester, August 1892; cf. also *Journ. Path. and Bacteriol.*, Edin. and London, 1893, vol. i. p. 332.

³ *Brain*, London, 1893, vol. xvi. p. 1; 1894, vol. xvii. p. 339. Cf. further on this subject the article by Sherrington on "Cutaneous Sensibility" in this volume.

⁴ Head, *op. cit.*, 1894.

Head finds that each area below the brachial gap, when associated with an area above the brachial gap, is associated with the same one; and, further, that the two associated areas may be the seat of referred pain from disease in different organs, for example, the stomach and the liver. Since each organ receives afferent fibres from more than one white ramus, we might expect that the fibres sometimes of one, sometimes of another, white ramus would be especially affected, and so cause referred pain in a different area of the skin; but it is difficult to see why there should be any correlated variation in the seat of referred pain above the gap, except on the unlikely supposition that the afferent fibres of each white ramus are connected peripherally with the fibres of a particular strand of the vagus. Head suggests that in some cases the correlation occurs by means of the spinal cord. According to Head, the skin of the third and fourth cervical segments does not become the seat of referred pain from disease of any organ of the head or neck; when it is affected from disease of the thoracic or abdominal viscera, it has correlated with it an area of pain in the head.

This correlation of tender areas above and below the brachial gap must, on the view we are taking of the matter, cease when organs are reached which do not receive fibres both from the vagus and the splanchnics. We do not know whether the lowest white ramus to send fibres to the intestines in man is the tenth, eleventh, or twelfth thoracic. All that we can say then, theoretically, is that the tenth, eleventh, or twelfth thoracic segment should be the last to be correlated with a tender region in the head or neck. According to Head, the tenth thoracic segment is the last.

We might also expect that there would similarly be double areas of referred pain, from disease of the descending colon and of such viscera as receive afferent fibres by way of the sympathetic and by way of the pelvic nerve. Of this, however, we can at present say very little.

We have taken, as the first step to an explanation, the view that irritation by disease of the afferent fibres of the white ramus of any nerve causes somehow irritation of the cutaneous sensory fibres of the nerve, and that thus tenderness or pain within the skin area of the nerve is produced.

Some difficulty seems to have been felt in accepting this view, since Head finds that the areas of referred pain and tenderness overlap little or not at all, and Sherrington finds that the sensory areas of the spinal nerves overlap considerably. But that the band of referred pain should be narrower than the band of cutaneous distribution of a nerve, seems natural enough. There is good reason to believe that the edges of the band of cutaneous distribution of a nerve receive fewer fibres than the central portion, and thus the central parts would naturally pass first into a state of over-sensitiveness. In visceral disease, though the fibres of a particular white ramus may be more affected than any other, it can never be affected alone, and it is not unreasonable to suppose that the irritation of other rami reaches the level at which a referred tenderness is produced before the irritation of the first is of such intensity that it causes referred tenderness in the parts of the skin which are but scantily supplied with somatic fibres from the corresponding spinal nerve.

There is nothing to show that if one ramus alone could be irritated, the region of skin tenderness would not coincide with the region of sensory supply of the somatic fibres of the nerve to which the ramus belongs. It must be mentioned, however, that Head, who has done most

valuable work on this subject, considers that the skin areas of the body correspond to segments of the spinal cord, and not to the peripheral distribution of the posterior roots.

Ross, as we said, supposed that the visceral fibres affect the cutaneous fibres by some action on the grey matter of the spinal cord. This supposition does not at present rest on any satisfactory histological basis.

If the arrangement suggested by Dogiel (cf. p. 686) exists, it affords a fairly satisfactory basis for explaining the referred pain in visceral disease, so far as regards the trunk of the body. For referred pain in the head, however, an explanation based on some action in the central nervous system does not seem avoidable.

It must be borne in mind that a transference of impulses might take place in the spinal ganglia in other ways than that just mentioned, for example, by the collaterals which some of the nerve fibres are said to give off to the cells of the spinal ganglion. And it may be noticed that, so far as we know, diseases of the viscera do not cause referred pain in the muscles, and that diseases in the areas of the somatic nerves do not cause referred pain in the viscera.

GROWTH OF PRE-GANGLIONIC CRANIAL FIBRES INTO SYMPATHETIC GANGLIA.

We have seen (p. 652) that the pre-ganglionic fibres of the sympathetic, after section, readily re-form connections with sympathetic nerve cells. We have seen also that the fibres may in certain circumstances form connections with sympathetic nerve cells of a different class. The general similarity which exists between all pre-ganglionic

FIG. 318.

fibres suggested the possibility that cranial autonomic fibres might be able to form synapses with sympathetic cells. And experiment has shown that this is in fact the case.¹ If the central end of the vagus be joined to the peripheral end of the cervical sympathetic (as in Fig. 318), it will in about a month make connection with the cells of the superior cervical ganglion of such nature that stimulation of the peripheral end of the nerve will cause dilatation of the pupil, contraction of the vessels of the ear, and the other effects which are normally produced by stimulation of the cervical sympathetic itself. In this formation of new connections some of the fibres of the vagus must change their function; since there are normally no pilo-motor fibres in the vagus, and some are found in it after union with the cervical sympathetic.

Probably a more striking instance of change of function is afforded by joining the central end of the lingual nerve² with the peripheral end of the cervical sympathetic. The lingual nerve contains vaso-dilator and secretory fibres derived from the chorda tympani. After it has been allowed time to unite with the cervical sympathetic, it is found on stimulation to cause, amongst other effects, constriction of the arteries of the ear. It is difficult here to avoid the conclusion that some of the

² One experiment only of this nature has as yet been made.

vaso-dilator fibres of the chorda tympani have become connected with vaso-constrictor nerve cells of the superior cervical ganglion, and have in consequence ceased to be vaso-dilator and become vaso-constrictor nerve fibres. The experiments point to the conclusion that any pre-ganglionic fibre in the body is capable of forming functional connection with any nerve cell of the sympathetic type wherever found.

GENERAL COMPARISON OF THE CRANIAL, SACRAL, AND SYMPATHETIC AUTONOMIC SYSTEMS.

We have seen that the sympathetic system sends post-ganglionic fibres to the whole of the skin of the body. This distribution is in striking contrast to that of the cranial and the sacral system, which send no fibres to the skin, or only such as spread out into it from an adjoining mucous membrane. In this point, then, the cranial and sacral autonomic systems resemble one another and differ from the sympathetic system.

As I have said earlier, a comparison of the distribution of the post-ganglionic fibres shows, if we take the matter broadly, that while the sympathetic system supplies the whole of the body, the cranial autonomic system supplies (with the exception of the eye) certain structures at the anterior end of the alimentary canal, and the sacral system supplies certain structures at the posterior end of the alimentary canal.

We may put the facts, so far as we know them, in a tabular form. Some are still in dispute.

Autonomic structures having a double nervous supply, sympathetic and cranial or sympathetic and sacral.—The muscular coats of the whole of the gut.

The glands opening into the gut, namely, salivary glands, gastric glands, pancreas, probably liver.

Parts at the mouth end of the gut; blood vessels of mucous membrane of mouth and pharynx; heart; unstriated muscle of lungs.

Parts at anal end of gut; blood vessels of rectum and anus; blood vessels and unstriated muscle of external generative organs; muscle coats of bladder.

Autonomic structures having a single nervous supply only, namely, from the sympathetic system.—The blood vessels, glands, and unstriated muscle of skin.

The blood vessels of the portion of the gut between the mouth and rectum, and of the glands opening into this portion; possibly the spleen.

The internal generative organs.

It has been asserted¹ that in the gut, the internal generative organs, and the bladder, there is an essential difference between the character of the nerve fibres received from the sympathetic and of those received from the vagus or from the pelvic nerve, of such sort that the sympathetic fibres cause contraction of the circular muscular coat and inhibition of the longitudinal muscular coat; whilst the vagus and pelvic nerve cause inhibition of the circular muscular coat and contraction of the longitudinal muscular coat. A considerable number of observations which have been made on the several organs, show that this is not the case. And

¹ v. Basch and Hofmann, *Med. Jahrb.*, Wien, 1877, S. 465 (on uterus); Fellner, *ibid.*, 1883, S. 571 (on rectum); and *Centralbl. f. d. med. Wissensch.*, Berlin, 1887, S. 258 (on uterus); Ehrmann, *Med. Jahrb.*, Wien, 1885, S. 111 (on small intestine); v. Zeissl, *Arch. f. d. ges. Physiol.*, Bonn, 1893, Bd. liii. S. 560 (on bladder).

in the course of an investigation into the innervation of the pelvic viscera by Anderson and myself, results were obtained entirely inconsistent with this theory.¹ Thus, for example, stimulation of the sympathetic causes the most striking longitudinal contraction of the vas deferens, and in the rabbit the most obvious inhibition of the longitudinal coat of the descending colon; and, on the other hand, stimulation of the pelvic nerve causes in the rabbit, in certain circumstances, complete and powerful contraction of the circular coat of the descending colon and rectum. In one case only is there some *prima facie* ground for the theory. The pelvic nerve causes great contraction of the recto-coccygeal muscle; and the sympathetic, if it has any effect at all, which is not quite certain, has an inhibitory effect.

We give in the following table a summary of the chief actions of the sympathetic nerve on the one hand, and of the cranial and sacral autonomic nerves on the other, in the regions of double supply. There are certain points which are still doubtful, but the facts will serve to emphasise some conclusions with regard to the autonomic nerves.

Tissue.	Effect of Stimulating the Cranial and Sacral Fibres.	Effect of Stimulating the Sympathetic Fibres.
Heart	Inhibition.	Increase in rate and strength.
Blood vessels of bucco-facial region of dog	? Dilatation.	Dilatation, and in certain circumstances contraction.
Blood vessels of salivary glands, and most of buccal mucous membrane	Dilatation.	Contraction.
Salivary glands	Secretion.	Secretion.
Muscular coats of alimentary canal .	Chiefly contraction, sometimes apparent inhibition.	Chiefly inhibition, sometimes contraction.
Bladder	Strong contraction.	Feeble contraction.
External generative organs . . .	Inhibition.	Contraction.
Blood vessels of anal mucous membrane and of external generative organs	Dilatation.	Contraction.

A consideration of the facts given in the foregoing table shows that there is no constant contrast between the function of the sympathetic fibres on the one hand, and of the cranial and sacral on the other. In the double supply the fibres from each source may have the same action, or they may have a different action. If they have a different action, either one or the other may be motor, and either one or the other may be inhibitory.

When, however, the fibres of one set arise from several nerves, we never find any difference in function in the fibres from the several nerves. Thus, all the sympathetic white rami which send fibres to a

¹ *Journ. Physiol.*, Cambridge and London, 1895, vol. xviii. p. 104 (on descending colon); vol. xix. p. 74 (on bladder); vol. xix. p. 130 (on uterus and vas deferens).

tissue have an action upon it, which may differ in degree, but does not differ in kind; similarly, a root of the pelvic nerve which has an action on a tissue, whether excitory or inhibitory, has the same kind of action as the other roots of the nerve.

This fact gives some probability to the view that the cranial and sacral autonomic centres in the central nervous system are not simply anterior and posterior parts of the sympathetic autonomic centres—parts separated from the sympathetic main region by the development of the nerves to the limbs—but are distinct centres developed at a different time and under different conditions.

We have, however, seen reason to believe that the sympathetic, the cranial, and the sacral autonomic systems resemble one another in a fundamental point of structure. Their efferent portions consist of a number of similar elements. Each element consists of two parts. One part consists of a nerve cell, which has its cell body in the central nervous system, and sends its axon, the pre-ganglionic fibre, outwards; the pre-ganglionic fibre divides, each division forming nerve-endings in connection with a peripheral nerve cell. The other part consists of the nerve cells in connection with which the pre-ganglionic fibre ends; the axons of these, the post-ganglionic fibres, form nerve-endings in the contractile and secretory tissues. Whilst accepting this as a general scheme, it is hardly necessary to say that the evidence for its universality is very inadequate. And it will be at once recalled, that nothing definite is yet known as to the nerve cell connection of the cranial nerve fibres to the gut.

The relation of the enteric nervous system to those just mentioned is at present only a matter of guess-work.

The experiments on regeneration, recounted above, throw a new, though doubtful, light on the question of the specific difference of nerve fibres having different functions. On the one hand, the experiments suggest that the nerve cells, which normally produce different efferent effects, remake their normal connections more quickly and permanently than abnormal ones, so that we should suppose that some difference exists between the different classes of nerve cells. On the other hand, it seems clear that the processes of both pre-ganglionic and ganglionic nerve cells have the power, within wide limits, of making connections other than the normal ones, and so acquiring non-normal functions. And this makes it possible that the functions of the several autonomic nerves are in part, it may be in very large part, dependent upon the particular structures with which they have an opportunity of coming in contact. Thus the laws of growth may have a larger rôle in the determination of function than physiological differences in nervous structures.

On this, as on many other physiological questions, we must hold suspended judgment. It is, however, hardly less important, and to many minds it is certainly more interesting, to formulate the problems to be solved than to dwell on the facts which are known.

ADDENDA.

Nerve supply to the muscular coats of the gut (cf. p. 693, p. 642 *et seq.*, p. 663).—Recent observations¹ have strengthened the general conclusions arrived at in the text, that the cranial autonomic system sends motor fibres to both coats of the gut, and that the sympathetic system sends inhibitory fibres to both coats. With regard to this, it is to be borne in mind that the motor effect produced by stimulating a particular nerve-strand varies somewhat in different animals in different parts of the gut, and in different circumstances. The observations strengthen also the view that the cranial system sends some inhibitory fibres, and the sympathetic system some motor fibres, to both coats, but it is clear that these fibres vary in number in the nerves to the different parts of the gut and in different animals; and although it is perhaps probable that such fibres occur generally in mammals, further evidence is required to place this view on a sound basis.

Origin of splanchnic fibres supplying the stomach and intestine (p. 644).—In the rabbit I have found the splanchnic inhibitory fibres for the cardiac sphincter of the stomach arise from the fifth to the ninth thoracic nerves inclusive. Bunch² in the dog finds that the vaso-motor fibres for the small intestine leave the spinal cord by the second thoracic to the fourth lumbar inclusive. For reasons indicated in the text (pp. 464–465) I think the origin is probably less extensive. Bunch considers that the same spinal nerves, and especially the upper ones, send vaso-dilator fibres to the small intestine.

Nerve-fibres supplying the coronary vessels (p. 642, p. 663).—Maass³ states that in the cat vaso-dilator fibres pass to the coronary artery from the ganglion stellatum, and that vaso-constrictor and some vaso-dilator fibres pass to it from the vagus.

Nerve supply of the bladder (p. 646, p. 667).—Stewart⁴ gives an account of a careful investigation of the innervation of the bladder of the cat. He confirms the statement that the sacral and sympathetic nerves supply both circular and longitudinal fibres of the bladder, and finds further evidence of inhibitory fibres for the bladder in the hypogastric nerves.

Origin from spinal cord of pelvic nerve (p. 666, p. 689).—Harman⁵ finds that in man the pelvic nerve receives its fibres chiefly from the third sacral spinal nerve; usually it receives fibres also from the second and fourth sacral nerves, but sometimes from only one of them. The number of medullated fibres from the several sources is given.

The enteric nervous system (p. 668).—An important observation

on the small intestine of the dog has been made by Bayliss and Starling. They find, after section of the vagi and removal of the solar ganglia, that mechanical stimulation of the intestine causes contraction above and inhibition below the point stimulated; the contraction passing down as a peristaltic wave, having an inhibited region in front of it. After local application of cocain or injection of nicotin, this effect is no longer obtained. They take the results to show that the enteric nervous system exercises reflex functions comparable to those of the brain and spinal cord, the nerve cells receiving afferent impulses, and sending inhibitory impulses downwards and motor impulses upwards. This hypothesis, however, can hardly be regarded as more than provisional.

THE CEREBRAL CORTEX.

BY E. A. SCHÄFER.

GENERAL FUNCTIONS.¹

THE cerebral cortex is the seat of the intellectual functions, of intelligent sensation or consciousness, of ideation, of volition, and of memory. That this is so is proved by the observation in man of cases of defective cerebral development and destructive disease. An individual with defective cerebral development is idiotic, in proportion to the amount of defect. It has not hitherto been shown that idiocy is associated especially with defect of any one particular region or of one hemisphere more than the other; probably in all cases of marked idiocy the defect is bilateral. Similarly, an individual with extensive destruction of the cortex cerebri, the result of accident or disease, becomes mentally defective, the memory is lost, sensations are no longer rightly appreciated, ideas are confused, and the volitional power is disordered, diminished, or absent. These changes occur, not only as the result of affections of the cortex, but also from lesion of the fibres which connect the cortex with the "lower levels" of the central nervous system.

The term "level" in connection with the central nervous system was introduced by Hughlings Jackson to imply stages of complexity of the sensori-

¹ An admirable historical and critical account of the functions of the brain, including many references to the views and researches of both older and more modern investigators, is given by Professor J. Soury in the article "Cerveau," in Richet's "Dict. de physiol.," Paris, 1897, fascs. 5 and 6. For a fuller discussion of many of the questions raised in the recent rapid progress of research in this branch of physiology, than can well be introduced here, the student may be referred to that article; and the more so because the views which are taken by Professor Soury are, on some questions, different from those which are advocated here. See also "Le système nerveux," by the same author, Paris, 1899, which is an extension of the above article.

motor functions of the organs designated.¹ Thus those portions, such as the spinal cord and bulb and its immediate prolongations, upon which the performance of simple reflex actions, unattended necessarily by consciousness, depend, are regarded as forming the first or lowest level; above these come the centres, the action of which is more complex, and, in the first instance at least, volitional, and necessarily attended or preceded by conscious sensations; these centres form the second level; the third or highest level of Hughlings Jackson is that part of the central nervous system which is conceived to be the seat of memory and ideation. But however probable, it has not yet been proved that the domicile of the highest functions is anatomically separate from that of the functions with which the second level is concerned. Both are unquestionably dependent, in man at least, upon the integrity of the cortex, and it is very uncertain whether any special region of the cortex (*e.g.* the frontal lobe, as Hughlings Jackson supposes to be the case) is especially associated with the functions ascribed to his "highest level." This subject will be further discussed later.

THE RESULTS OF REMOVAL OF BOTH CEREBRAL HEMISPHERES.

The results of experimental removal or destruction of the whole cerebrum in animals vary according to the kind of animal and its position in the scale of organisation. These results, as they have been described by various physiologists, and especially by Flourens and Goltz, have been so excellently summarised by Ferrier² that no apology is needed for quoting part of his description at length:—"Deprived of its cerebral hemispheres" (the corpora striata and optic thalami being included in the removal), "the frog³ will maintain its normal attitude, and resists all attempts to displace its equilibrium. If laid on its back it will immediately turn on its face, and regain its station on its feet. If placed on a board, and the board be tilted in any direction, the animal will make the appropriate movements to throw its centre of gravity within the base of support. If its foot be pinched, it will hop away. If it is thrown into the water, it will swim until it reaches the side of the vessel, and then clamber up and sit perfectly quiet.⁴ If its back be stroked gently, it will utter loud croaks, and this with such uniformity on each application of the stimulus, that, as Goltz indicates, a chorus of brainless frogs might be obtained which would utter their βρεκεκεκεξ κοάξ κοάξ on the appropriate occasion in a manner which would have delighted the heart of Aristophanes.⁵ Indeed, in many respects, it would be difficult to say that the removal of the hemispheres had caused any alteration in the usual behaviour of the animal. If placed in a vessel of water, the temperature of which is gradually raised, it will not quietly submit to be boiled like a frog which has only its medulla and spinal cord, but will leap out as soon as the bath becomes uncomfortably hot. If placed at the bottom of a pail of water, it will

¹ Hughlings Jackson, "On the Relations of Different Divisions of the Nervous System to one another and to Parts of the Body," *Brit. Med. Journ.*, London, 1898, vol. i. p. 65.

² "Functions of the Brain," second edition, 1886, p. 109.

³ Goltz, "Beitr. z. Lehre v. d. Functionen der Nervenentren des Frosches," Berlin, 1869.

⁴ But if lowered gently into the water it will remain motionless (Onimus, *Journ. de l'anat. et physiol. etc.*, Paris, 1870, p. 633; Eckhard, Hermann's "Handbuch," 1879, Bd. ii. Th. 2, S. 117; Goltz, *loc. cit.*).

⁵ The uniformity of this reflex is greater after removal of the thalamus than if the hemispheres and corpora striata only are removed (Goltz, *loc. cit.*; Paton, *Edin. Med. and Surg. Journ.*, 1846, vol. lxxvi. p. 251). If another part of the skin be simultaneously and sufficiently stimulated, the reflex, as is the case with many others, is inhibited.

ascend to the surface to breathe. And not merely so, but if placed in a vessel inverted over a pneumatic trough, and containing a column of water sustained by barometric pressure, it will ascend to the surface as before; but not finding there the necessary atmospheric air, will work its way downwards, and succeed in making its escape out of the vessel to the free surface of the trough. There is a method in its movements. If an obstacle be placed between it and the light of a window, the frog will not spring blindly against it when its toe is pinched, but will clear it or spring to the side. It will alter the course of its leap, according to the position of the obstacle between it and the light. There is, so far, no difference between its behaviour and that of a frog in full possession of all its faculties. But yet a very remarkable difference is perceptible. The brainless frog, unless disturbed by any form of peripheral stimulus, will sit for ever quiet in the same place, and become converted into a mummy. All spontaneous action is annihilated. Its past experience has been blotted out, and it exhibits no fear in circumstances which otherwise would cause it to retire or flee from danger. It will sit quite still if the hand be put forth cautiously to seize it, but will retreat if a brusque movement is made close to its eyes. Surrounded by plenty, it will die of starvation; but, unlike Tantalus, it has no psychical suffering, no desire, and no will, to supply its physical wants."

There is a good deal of difference manifested if care be taken not to injure the optic thalami in removing the hemispheres.¹ Under these circumstances, the frog, after the first effects of the operation have passed off, will show spontaneous movements without any manifest external stimulus,² will feed itself by catching insects and the like, will bury itself on the approach of winter, in order to hibernate, and resume activity with the advent of spring, and in the breeding-season will give evidence of possessing normal sexual instincts. All these manifestations, as well as the power of balancing itself on a tilted board and the reaction on a turn-table, are either abolished or rendered imperfect on removing the optic thalami as well as the hemispheres. The latter are, in the frog, only to a very small degree developed, containing but a single layer of nerve cells; the thalami, on the other hand, are, in this animal, the chief centres for movements which are apparently voluntary, an importance which they probably owe to their connection with the visual organs on the one hand, and the tactile sense on the other, these being the senses by which the movements of these animals are mainly directed.

"The results which have been observed in fishes after similar ablation of the cerebral hemispheres are, *ceteris paribus*, of the same nature as those seen in frogs. A fish so mutilated³ maintains its normal equilibrium in the water, and uses its tail and fins in swimming with as great precision and co-ordination as before. The brainless fish is, however, continually on the move, and there is also method in its movements. It will not run its head against any obstacle placed in its path, but turns to the right or left according to circumstances. Left to

¹ Schrader, *Arch. f. d. ges. Physiol.*, Bonn, 1887. Bd. xli. S. 75; J. Steiner, "Die Functionen d. Centralnervensystem, u.s.w.," Erste Abth. "Der Frosch," Braunschweig, 1885.

² This had already been shown by Desmoulin and Magendie, "Des systèmes nerveux," 1825, tome ii. p. 626.

³ Vulpian, "Leçons sur la physiol. du système nerveux," Paris, 1866, p. 683.

itself in the water, it swims in a straight line, and, unlike other fishes which loiter by the way smelling at this and nibbling at that, it keeps on its course as if compelled by some irresistible impulse, and only stops when it reaches the side of the vessel, or when worn out by pure nervous and muscular fatigue. Apparently there is some essential difference between the frog, which sits for ever quiet, and the fish, which goes on indefinitely, but the same explanation is applicable to both. In the one case there is no external source of irritation; in the other, the contact of the mobile water with the body surface acts as a continual external stimulus to the natatory mechanism. As this is constant, so the fish continues to swim until arrested by some insurmountable obstacle or by pure nervous and muscular fatigue."¹

This description of the brainless fish is, however, only applicable to osseous fishes, and only to those osseous fishes from which the optic thalami have been removed as well as the corpora striata and hemispheres. For if only the hemispheres and corpora striata are cut away, the thalami and optic lobes being left intact, the behaviour of the animal is little, if at all, different from that of normal fishes. It moves to and fro in the water along with its fellows, nibbling at passing objects in the manner characteristic of these animals, distinguishing edible from non-edible material (worms from bits of thread resembling them), and even showing a preference for bait (wafers) of certain colours.² And still less is the description applicable to elasmobranch fishes, although the alteration here is in the opposite direction. For the shark, deprived of its hemispheres and corpora striata, remains perfectly immobile, even although the optic thalamus and optic lobes may be completely intact. The difference is due to the fact that the elasmobranch depends mainly upon its olfactory apparatus as a guide to its movements, and in removing the cerebral hemispheres the olfactory lobes are necessarily also removed. In fact, it has been shown by Steiner that removal of the olfactory lobes alone, in the shark, has an effect similar to the removal of the hemispheres. The osseous fish, on the other hand, mainly depends upon influences reaching it through its visual organs, and the greater part of the central apparatus of vision remains intact. In reptiles also, the development of the cerebral hemispheres goes largely hand in hand with that of the olfactory apparatus.³

"The results of ablation of the cerebral hemispheres in pigeons have been described in great detail by Rolando, Flourens, Longet, Vulpian, and others. A pigeon so mutilated continues able to maintain its equilibrium and to regain it when disturbed. When placed on its back, it succeeds in regaining its feet. When pushed or pinched, it marches forward. Should it happen to step over the edge of the table, it will flap its wings until it regains a firm basis of support. When thrown in the air, it flies with all due precision and co-ordination. Left to itself, it seems as if plunged in profound sleep. From this state of repose it is easily awakened by a gentle push or pinch, and looks up and opens its eyes. Occasionally, apparently without any external stimulation, it

¹ Ferrier, *loc. cit.*

³ See Edinger, *Anat. Anz.*, Jena, 1893, Bd. viii. S. 305.

may look up, yawn, shake itself, dress its feathers with its beak, move a few steps, and then settle down quietly, standing sometimes on one foot and sometimes on both. Should a fly happen to settle on its head, it will shake it off. If ammonia be held near its nostrils, it will start back. Should the finger be brusquely approximated to its eyes, it will wink and retreat. A light flashed before its eyes will cause the pupil to contract; and if a circular motion be made with the flame, the animal may turn its head and eyes accordingly. It will start suddenly and open its eyes widely if a pistol be discharged close to its head."

"After each active manifestation called forth by any of these methods of stimulation, the animal again subsides into its state of repose. It makes no spontaneous movements. Memory and will seem annihilated. When irritated it may show fight both with wings and beak, but it exhibits no fear and makes no attempts at escape. It resists attempts to open its beak for the purpose of introducing nourishment, but, should its resistance be overcome, it swallows as usual. If fed artificially it may be kept alive for months, but left to itself it will die of starvation, like the frog or fish."¹

But in the bird also,² if care be taken to remove only the cerebral hemispheres and basal ganglia without injury to the optic lobes or nerves, not only are spontaneous movements frequently manifested, but the animal (pigeon) gives indication that its movements are guided by visual impressions. Thus in the light or in day-time the animal walks continually about the room,³ avoiding all obstacles,⁴ even if transparent, such as glass objects, but in the dark remains quiescent and apparently asleep. It will even fly a little, so as to surmount small obstacles. There is sufficient understanding of things seen for selection of a sort to be exercised; Schrader found that his pigeons preferred to alight upon a perch to the floor; but they hardly ever flew spontaneously up from the floor on to a perch.⁵ Food, however, is not recognised, nor are enemies nor individuals of the opposite sex, although certain sexual phenomena, e.g. the cooing of the male bird, are retained. The animal manifests no fear. It responds mechanically to stimuli, like an automaton. If placed on a swinging cord, it balances itself perfectly with the to-and-fro movements, and this may be kept up for an hour or more; if then placed on the floor it still continues the balancing movements for a time. H. Munk⁶ found that pigeons deprived of their hemispheres were completely blind, but it would appear that whilst blind, in the sense of failing to comprehend the significance of objects, such animals will react to visual impressions through the medium of the optic lobes. In owls and falcons Schrader⁷ found much more marked disturbances of mobility, especially of the hind-limbs, after ablation of the hemispheres (or even of the anterior part only) than is the case with pigeons. It is noteworthy that these birds of prey employ their feet like hands to seize and hold their food, and their movements are therefore

more truly of a voluntary character than the corresponding limbs of pigeons.

The results in mammals of complete removal of the cerebral hemispheres have been investigated in the guinea-pig and rabbit by many physiologists. The rabbit, after removal of the hemispheres, in a few minutes sits up and begins to move about in an apparently normal manner.¹ Its reflex excitability is increased. If the foot is pressed, it will kick and struggle violently, and may rush forward, as when the corpora striata are destroyed.² But if the thalami be included in the lesion, the movements are much more limited, and, according to Christiani,³ progression is no longer possible. Recently the removal of the hemispheres has been effected in a very complete manner by Goltz in the dog. The following description is founded on Goltz's observations⁴ upon an animal in which both cerebral hemispheres were completely removed in successive operations, the corpora striata and the optic thalami being also partly involved in the lesion.⁵ One optic nerve was also severed, and of course the olfactory lobes were included. The hemispheres were removed in three successive operations. The dog was kept alive for eighteen months after the final operation. After complete recovery from the last operation, the animal was able to walk in a perfectly normal fashion; towards the end of the period, however, its movements became gradually weaker, the hind-legs especially becoming emaciated and suffering loss of power. For the greater part of the day it walked restlessly up and down in its cage, but at night would go to sleep, rolled round in the manner usual with dogs. It then required a loud sound such as that of a horn, or rough shaking to awaken it. When awake it reacted to loud sounds by shaking its ears, to a glare of light by shutting its eyes, and by turning its head away. It reacted promptly and consequentially to tactile impressions. When its skin was pinched, it gave vent to its discomfort by snarling or barking just as a normal dog might do, and attempted to get away from the hand which was the source of discomfort, or failing to do this would turn round and bite at it, but in a clumsy manner and often without coming near it. If its feet were placed in cold water, they were quickly withdrawn. If one of its limbs was placed in an abnormal or uncomfortable attitude, it would never be allowed to remain so, although a dog with a lesion of the frontal cortex only does not replace a limb which has been put into such a position. If its fore-feet were placed upon the flap of a table, which was then gradually lowered, the legs would only be allowed to follow the flap for a short distance; the equilibrium was speedily recovered; a dog with the frontal centres only removed would fall under these circumstances. When one foot was accidentally hurt, the animal limped about for a time on three legs, in the manner usual with dogs.

Like the frog, fish, and bird in a like condition, the animal for months took no food spontaneously but had to be artificially fed by placing food at the back of its mouth, and even then often choked in the

process of swallowing. Eventually, it would itself take food if its head were placed over the dish containing it, and especially if the food came in contact with its snout. Meat which had been rendered bitter by quinine or colocynth was ejected with movements indicative of dislike. It also showed a feeling of satiety by refusing to take more than a certain quantity of food. For its size it required a very large amount of nourishment in order to keep up its weight; the extreme restlessness which it exhibited when awake tending apparently greatly to increase its katabolism. The higher psychical faculties were completely absent. The dog never showed any sign of recognition of persons or of other dogs, showed no fear of threatening movements; never wagged his tail, or showed any sign of pleasure on being stroked or spoken to; when wetted, shook himself vigorously but never attempted to lick himself dry, as a normal dog does; never used his fore-paws to hold a bone or to dig a hole for one (although there was even less paralysis apparent than in animals from which only the sigmoid gyrus is removed); never gave any sign of spontaneous mental activity, unless an increased restlessness and other signs of impatience when food was withheld for longer than usual, are to be in a measure so interpreted. The animal showed absolutely no sign of memory. Although its removal from the cage was the usual signal for feeding, it invariably resisted being taken hold of for this purpose, barking loudly and biting and struggling vigorously. During sleep it never showed any indications, as dogs often do, of dreaming. It exhibited no sexual instincts. Removal of the hemispheres had produced loss of all understanding and memory; the condition, in spite of the complexity of many of the phenomena which were still exhibited, was one of complete idiocy; there was no sign of intelligence, and all the actions of the animal can be explained as reflex responses to immediate excitation.¹

The result of experiments upon animals tends, therefore, generally to corroborate that of observations upon pathological cases in man; but it is clear that the higher the position of the animal in the scale of organisation, the more profound is the effect of removing the cerebrum. And it will presently appear that even partial bilateral lesions in monkeys and in man may, in some respects, and according to their extent and position, produce even more marked symptoms of loss of cerebral function, and especially of volitional movements, than in the animals above described.

There are, as Donaldson points out,² anatomical relations behind this difference of effect produced by lesions of the hemispheres. For the activity of the lower level cells is in all animals brought about by two sets of impulses—the one set derived from the sensory nerves passing from their terminations in the grey matter of the lower level centres, either directly to the motor cells or more probably through intermediary cells which play an important part in effecting the co-ordination required for purposeful movements. The other set of impulses, also in the first instance derived from the sensory nerves, pass to the cortex, and are thence sent down (perhaps along the fibres of the pyramidal tracts) to the motor nerve cells, or rather probably also to the intermediary co-ordinating mechanism. In the lower animals this second set plays an insignificant part in producing the ordinary co-ordinated movements of the animal;

¹ H. Munk, *Verhandl. d. physiol. Gesellsch. zu Berlin, Arch. f. Physiol.*, Leipzig, 1894, S. 355.

² "American Text-Book of Physiology," p. 711.

in the higher animals, an important part, so that in them the cutting of it off from the lower centre cells removes a great part of the impulses by which they are normally stimulated.¹

EFFECTS OF REMOVAL OF ONE HEMISPHERE.

Goltz has published² several accounts of dogs with very extensive lesions of the hemispheres, or from which one cerebral hemisphere has been wholly removed.³ Such animals, if kept a sufficient time after the removal, show in their ordinary movements an extraordinarily slight amount of motor paralysis,⁴ although apparently rendered incapable of performing such a purely volitional acquired action as the giving of the paw. Some of the differences of movement which are observable can be explained by the blindness which is produced on the homonymous half of the retina; but the contractions of muscles of the opposite side are rather less powerful than those of the same side.⁵ Sensation on the opposite side of the body is not lost, although somewhat blunted, and even the muscular sense of the paralysed side appears to be still present. Whether the recovery of movement and of sensation which occurs in such an animal after a certain period, is due to a representation of both sides of the body in each cortex (as is unquestionably the case with the movements of some parts), and a vicarious taking up of the functions of the lost side by the other hemisphere, or whether the movements are merely association movements, which are called into play through commissural fibres in the lower centres, is still uncertain. It has, however, been ascertained in the dog and cat as well as in the monkey, that what is believed to be the volitional tract in the cord (crossed pyramidal tract), although mainly formed of fibres from the opposite hemisphere, also contains fibres which come from the homonymous hemisphere,⁶ and it may be through these fibres that such volitional movements as are preserved are carried on. Unilateral removal of the cerebral cortex, including the corpus striatum, is followed by degeneration and atrophy in specific parts of the lower portions of the central nervous system, which are either *primary*, resulting directly from removal of the nerve cells from which descending fibres originate, or from section of nerve fibres causing degeneration in their cells of

¹ Cf. Sherrington ("Proc. of Physiol. Congress," 1892, *Centralbl. f. Physiol.*, Leipzig u. Wien, Bd. vi. S. 399), who found in the monkey that the reflex flexion of the hallux, which is caused by stimulation of the posterior roots of the sacral nerves, is abolished on cutting through the cervical cord.

² In the *Arch. f. d. ges. Physiol.*, Bonn, Bde. xiii., xiv., xx., xxvi., xxviii., and various other volumes up to the present time. An account of such an animal by Goltz, and a report on the condition of the brain by J. N. Langley and A. S. Grünbaum, will be found in the *Journ. Physiol.*, Cambridge and London, 1890, vol. xi. p. 606. Cf. also Vitzou, *Arch. de physiol. norm. et path.*, Paris, 1892, tome v.

³ For observations upon the frog with one hemisphere and the corresponding thalamus removed, see Kato, "Thesis," Berlin, 1886; upon the pigeon see Lussana and Lemoigne, "Fisiologia d. centri nervosi encefalici," Padova, 1871, and M'Kendrick, *loc. cit.*; on the cat, R. Boyce, *Phil. Trans.*, London, 1895, B, p. 321; and upon the rabbit (anatomical), Münzer and Wiener, *Prag. med. Wchnschr.*, 1895; *Monatschr. f. Psychiat. u. Neurol.*, Berlin, Bd. iii. S. 379. Frogs and pigeons show scarcely any noticeable defects, after recovery from the immediate effects of the operation, and rabbits relatively little. There is normally a tendency in moving to pass towards the side opposite to the lesion.

⁴ Immediately after the removal there is hemiplegia and hemianæsthesia, but this is gradually recovered from.

⁵ Boyce, *Phil. Trans.*, London, 1895, B. This result was obtained with the contractions produced by absinthe, which stimulates the cortical centres.

⁶ See article "Spinal Cord," by Sherrington, in this volume.

origin; or, *secondary*, resulting from disuse of portions of the lower centres, in consequence of the lesion. The secondary changes are best observed when the lesion is performed in young animals, and may not show themselves at all in the adult.

The parts which are *primarily* degenerated or atrophied after removal of the whole cerebral cortex are the fibres of the pyramidal tract along their whole course; fibres passing between the optic thalamus and the cortex; many of the cells of the thalamus and of the corpus Luysii; and many of the cells of the substantia nigra of the mesencephalon, all upon the same side of the brain. Degenerations also cross in the corpus callosum to the cortex of the opposite hemisphere, but how far the cells of that hemisphere are involved has not been ascertained. *Secondarily*, partial atrophy may be produced in the grey matter of the pons Varolii, in the quadrigeminal bodies, in the fillet, and in the red nucleus of the same side; and in the inferior and middle cerebellar peduncles, the hemisphere of the cerebellum, in the arciform fibres, and the nuclei of the posterior columns of the medulla oblongata of the opposite side.¹

THE RESULTS OBTAINED FROM ARTIFICIAL EXCITATION OF THE CORTEX CEREBRI.

Previously to 1870, it was almost universally held that the cortex cerebri could not be excited artificially, that there was no localisation of particular functions in particular parts, that the cortex must act for each and all of its functions as a whole, and that lesions of the cortex produce, according to their extent, only a general depression of the functions of the cerebrum without special symptoms of local paresis.² This doctrine was supposed to be firmly established by the experiments of Flourens, which led him to reject absolutely the localisation of function which had been formulated—on altogether insufficient evidence—by the phrenologists, and it remained for many years in almost undisputed possession of the field. A notable exception had, however, to be made, after it had been shown, by the masterly researches of Broca,³ that one important function of the cerebrum, that of producing articulate language, is intimately associated with the integrity of the posterior part of the third frontal convolution of the left hemisphere of the brain, and doubt had begun to be thrown upon the doctrine, at least in its rigid acceptance, by Hughlings Jackson,⁴ and by Bastian,⁵ the former of whom was led somewhat later, from the study of certain cases of epilepsy, following lesions of the brain in man, to the conclusion that the symptoms could best be explained by the assumption of functional localisations, the epileptiform contractions being regarded as the result of irritative lesions.⁶

⁶ "A Study of Convulsions," *St. Andrews Med. Grad. Assoc. Trans.*, London, 1870, vol. iii.

This was the condition of the subject when, in 1870, were published the experiments of Fritsch and Hitzig,¹ which clearly showed that the doctrine of the non-excitability of the cortex was erroneous. Fritsch and Hitzig found that electrical excitation of the dog's brain, at certain definite points upon the convolutions in the immediate neighbourhood of the crucial sulcus, is responded to by movement of parts on the opposite side of the body, that more prolonged stimulation produces local convulsive movements of the same parts, which may be followed by general epileptiform convulsions, and that removal of the localised brain area is followed by paralytic symptoms in the parts of the body or in the limbs which had previously responded to their excitation. From these experiments it became obvious—(1) That parts of the cerebral cortex can be directly excited to action by artificial stimulation; (2) that excitation of similar points in different animals, or upon opposite sides of the brain of the same animal, produces similar results; (3) that many parts of the cortex are apparently not thus directly excitable; (4) that the movements produced by artificial excitation are similar in their general character to those which are the result of voluntary movements of the animal; (5) that the voluntary movements of the opposite side of the body are interfered with on removal of the excitable areas upon one side of the brain.

These facts, which were established by Fritsch and Hitzig by their experiments upon the dog's brain, were verified and amplified by those of Ferrier² upon the brain both of the dog and monkey, and of many other mammals, and they have been abundantly tested and found to hold good for the human brain, in cases where by accident, disease, or the necessity of operation, the cortex has been laid bare.

Although it is difficult to obtain the movements in question by mechanical or chemical excitation, yet it is possible under some circumstances to do so;³ and, as already stated, similar effects are obtained as the result of irritative lesions of the cerebral surface in man (Jacksonian epilepsy).

It was shown by Burdon Sanderson⁴ that if the cortex cerebri be removed at one of the excitable points, and the stimulating electrodes be placed upon the cut ends of the subjacent fibres of the corona radiata, a movement is evoked which is of a character precisely similar to that which had been previously called forth by excitation of the superjacent cortex itself.⁵ In non-narcotised animals the cortex is more excitable than the subjacent corona radiata, whereas in narcotised animals the reverse is the case.⁶ The brain of new-born dogs does not yield results on stimulation, but animals which are born in a more mature state, e.g. guinea-pigs, give cortical reactions. In the dog the effects of excitation begin to show themselves about the tenth

voluntary contractions of a muscle, the curve which is obtained exhibits waves, irregular in amplitude but fairly regular in rate, and exhibiting

¹ Soltmann, *Jahrb. f. Kinderh.*, Leipzig, 1876, Bd. ix. S. 106; Steiner, *Sitzungsber. d. k. Akad. d. Wissensch.*, Wien, 1895, S. 303.

² Bechterew, Abstract in *Neurol. Centralbl.*, Leipzig, 1888, S. 14; and 1889, Bd. viii. S. 513.

a rhythm of about ten or twelve contractions per second.¹ Fig. 320 shows such a tracing taken on a slowly moving surface, and Fig. 321 another tracing with the excursion more amplified and recorded upon a more quickly moving paper. The rate of rhythm is very constant for the same individual, but varies in different individuals (from 8 to

FIG. 321.—Part of a similar tracing, taken on a faster surface and with the movements more amplified.

13 per second), when the muscle is contracting against a small resistance. According to the observations of W. Griffiths² it may become even more rapid (15 or 18 per second) with increase of the resistance up to a certain point, and then again diminish, and it undergoes similar changes of rate if the experiments be long-continued so as to produce fatigue. The vibration observable in the outstretched arm, when holding a weight, shows the same rate of rhythm as the muscle curve (Fig. 322).

Probably 10 per second may be taken as the average rate of rhythm, and 20 per second as the maximal rate. This would make the average interval between the consecutive nervous discharges from the cortical cells 0.1 second, and the minimal interval 0.05 second. Richet found that in shivering the number of contractions per second in the muscles affected, was about 10 to 11

FIG. 322.—Vibrations of the outstretched arm holding a weight of about six kilos. The tracing was recorded by the apparatus shown in Fig. 319.—W. Griffiths.

per second, and did not exceed 13 per second,³ and that it is impossible to articulate at a rate of more than 11 syllables per second. That this rate originates in the cells of the brain appears probable from the fact, also pointed out by Richet, that it is impossible to *think* the act of articulation at a greater rate

¹ Schäfer, *Journ. Physiol.*, Cambridge and London, 1885, vol. vii. p. 114; v. Kries, *Arch. f. Physiol.*, Leipzig, 1886.

³ *Trav. du lab. de Marey*, 1895, tome iii. p. 17.

than this; and the same statement applies to the thinking the act of singing or of playing a series of musical notes.¹ This would give, as the ordinary duration of the activity of the cortical cell, when involved in the performance of the simplest psychological action, about 0.09 second; but it is probable that with practice, and under other favourable conditions, it might be further reduced.

If the surface of the motor region of the cortex be excited by a faradic current, at a rate of rhythm either below or at about 10 to 12 per second, the muscles of the part with which the portion of the cortex stimulated is in connection respond by contractions, which succeed one

FIG. 323.—Myographic curves from hamstring of monkey. (A) Natural contraction (voluntary); (B) contraction caused by excitation of leg centre of cortex by rapid induced currents.

another at the same rate as the excitation. If, however, the excitation be more rapid than this, the response is no longer at the same rate—as in the case of excitation of the motor nerve fibre—but tends to reproduce the curve of voluntary contraction.² This is illustrated in the tracings reproduced in Fig. 323. Of these A represents a voluntary contraction of one of the hamstring muscles of a monkey, the tendon of the muscle having been detached and fixed to the lever of a myograph; B represents the contraction of the same muscle, as provoked by faradic excitation of the hamstring centre in the cerebral cortex, at a

¹ Richet, "Dict. de physiol.," Paris, 1898, tome ii. p. 10. Richet has also found, as the result of direct experiment upon the cerebral cortex of the dog, that in this animal the refractory period of the cortical cell is about 0.1 sec. (*Rep. of Toronto Meeting Brit. Ass. Adv. Sc.*, London, 1897; *Nature*, London, 4th November 1897).

² Horsley and Schäfer, *Journ. Physiol.*, Cambridge and London, vol. vii. Figs. 323 and 324 are reproduced from the tracings given in this paper.

rate of 60 per second; the two tracings show an identical rate of the waves which indicate successive muscular contractions.

The circumstance that a muscular response is obtained at the rate in question does not, of course, establish the fact that this rhythm is originated in the cortex itself. For excitation of the corona radiata, after removal of the superjacent motor cortex, or even of the cut spinal cord, produces a muscular response which has a precisely similar character and rhythm. Thus, in Fig. 324, A is the result of rapid stimulation of the cortex, B of the corona radiata, C of the cut spinal

FIG. 324.—Tracings obtained from the same muscle of a dog, on stimulation of different parts of the motor path. (A) Leg centre in cortex cerebri; (B) corona radiata, after removal of cortex; (C) cut spinal cord; (D) cut motor nerve. The vertical lines (omitted in D) mark seconds. The teeth on the abscissæ show the rate of excitation. In A the cessation of the excitation is followed by clonic epileptoid spasms of the muscle. All to be read from left to right.

cord, and D of the motor nerve, all in the same individual (dog), the same muscle being employed. The rate of stimulation in each case was at least 30 per second, but the response in A, B, and C was only at the rate of about 10 per second. In B and C this rhythm must have become established in the cells of the spinal cord; in A it *may* have originated in the cells of the cortex. Or the cortical cells may have responded at the same rate as the excitation, and the change of rhythm may have occurred in the cells of the cord. It is, however, probable that the cells of the cortex respond to rapid or continuous excitation at about the same rate of rhythm as do the cells of the lower centres, since the rhythm of epileptoid contractions, which unquestionably originates

in the cortex cerebri,¹ although in itself slower than the normal rate of voluntary contractions, nevertheless shows indications of its curves being formed by the summations of excitation of a rate of about 10 per second.²

Although the character of the curves obtained by excitation of the cortex is similar to that obtained by excitation of the corona radiata, it must not be supposed that the effect is obtained by a spread of the stimulus to the subjacent fibres of the white matter. For there is a distinct delay in the lost time (period of latent excitation) of the muscular response, if we compare the commencements of the two curves; amounting, according to Bubnoff and Heidenhain,³ to about 0.0045⁴ in the unanæsthetised dog (Fig. 325), while with anæsthesia it is more prolonged, and eventually the response of the cortex ceases before that of the corona radiata. Further, as will presently appear, the excitation of the cortex is apt to be followed by epileptiform contractions of the muscles, which is never the case with stimulation of the corona radiata.

Inhibition.—There is another function of the cerebral cortex which is no less important than that of originating movements, namely, that of inhibiting them. The restlessness of Goltz's decerebrised dogs, and perhaps that of the lunatic, may be due to the loss or diminution of this function. It has, moreover, been shown⁵ that in mammals there occurs, as an immediate result of removal of the hemispheres, a condition of tonic contraction of certain groups of muscles of the trunk and limbs, the contraction being brought about by afferent impulses passing along the ordinary sensory channels; if one hemisphere only be removed, the tonus or rigidity only occurs on the homonymous side of the body. An increase of the inhibitory function, on the other

FIG. 325.—Period of latent excitation of a dog's muscle on stimulation respectively of the cortex cerebri, M, and of the subjacent corona radiata, M'. Time tracing, $\frac{1}{10}$ of a second. — François-Franck and Pitres.⁶

¹ As is shown by the experiments of Gotch and Horsley (*Phil. Trans.*, London, 1891, B, p. 267), who found that changes of electrical potential of the same rate as the clonic contractions of the muscles, passed along the spinal cord during the occurrence of an epileptoid attack.

² A similar observation has been made by Wolfenden and Dawson Williams regarding the rhythm of the contractions in cases of disease accompanied by muscular tremors, which frequently show a tendency to fuse, so that the apparent rhythm is only about one-half the normal rate (*Brit. Med. Journ.*, London, 1888, vol. i. p. 1049). See also Herringham, *Journ. Physiol.*, Cambridge and London, 1890, vol. xi. p. 481.

³ *Arch. f. d. ges. Physiol.*, Bonn, 1881, Bd. xxvi. S. 187.

⁴ It is interesting to note that this reduced lost time of the cerebral cortex is precisely the same as the reduced lost time of a simple reflex act, as determined by Wundt, and since in all probability the delay occurs, not in transmission through the nerve cell bodies, but at the synapse or conjunction of afferent fibres with them (see p. 608), it may be concluded that when the cerebral surface is stimulated, the nervous impulses which are started pass to the projection cells from which the descending fibres originate, through the intermediary of synapses formed between these cells or their dendrons and the more superficial cells of the cortex, which are those actually stimulated.

⁵ Sherrington, "Decerebrate Rigidity, etc.," *Journ. Physiol.*, Cambridge and London, 1898, vol. xxii. p. 379.

⁶ François-Franck, "Leçons sur les fonctions motrices du cerveau," Paris, 1887.

hand, may be associated with a total temporary deprivation of volitional power, such as occurs in the condition known as hypnosis.¹ That inhibition is an active function of the cortex, was shown by Bubnoff and Heidenhain,² who occasionally got arrest of action on weak excitation. More recently it has been proved by Sherrington³ that electrical excitation of certain parts of the cortex may not only, as has long been known, produce contraction of definite muscles, but that simultaneously inhibition of tonically contracted antagonists may be also brought about. Thus if, after section of the third and fourth nerves on one side, say the left, so that only the external rectus is left in connection with the nerve centres, any of the parts of the left hemisphere which produce conjugate deviation of the eyes to the right be stimulated, not only does the right eye move to the right, but the left eye accompanies it, as far, at least, as the primary position; and this can, under the circumstances, only be effected by the inhibition of the left external rectus.⁴ The same will occur during voluntary movements, if the animal be kept alive a few days after the section of the nerves. Moreover, it is a familiar fact that we are constantly in the habit of exercising voluntary control over, and arresting reflex movements; and that this function is exercised by the cortex is shown by its absence when from any cause the cortex is in abeyance, e.g. during sleep.⁵

As to the manner in which inhibition is brought about, nothing is definitely known. It has been suggested by Lauder Brunton, that it may be regarded as a phenomenon analogous with that of interference in physics, in which case it would not be necessary to assume the existence of paths separate from those which conduct excitatory impulses. But it is well known that in the case of peripheral inhibition (heart, blood vessels), the paths are altogether different. And it has been shown by Sherrington, that inhibition of a muscle or group of muscles is not obtained by excitation of the same point of the cortex as provokes their contraction, but rather in connection with the point from which the contraction of the antagonist muscles is obtained,⁶ so that it appears certain that for this form of inhibition also there are separate nervous paths from those concerned in causing movement. It is probable that the action, whatever it may be, is exerted upon the lower nerve centres in the cord and bulb. Gad,⁷ with Orchansky, found that

¹ Inhibition through the cerebrum is not, however, the cause of the so-called hypnotism of animals, of which the well-known *experimentum mirabile* of Kirschner may be taken as a type, for Verworn has shown that these effects are obtained equally well after removal of the cerebrum ("Die sogen. Hypnose der Thiere," Jena, 1898).

² *Arch. f. d. ges. Physiol.*, Bonn, 1881, Bd. xxvi.

³ *Proc. Roy. Soc. London*, 1893, vol. liii. p. 407; *Journ. Physiol.*, Cambridge and London, 1894, vol. xvii. p. 27; H. E. Hering and Sherrington, *Arch. f. d. ges. Physiol.*, Bonn, Bd. lxxviii. S. 222; "Proc. Internat. Congress of Physiologists," *Journ. Physiol.*, Cambridge and London, 1898, vol. xxiii. (Suppl.).

⁴ This has been confirmed by aid of the graphic method by Topolanski, *Arch. f. Ophth.*, Leipzig, 1898, Bd. xlv. S. 452. It applies equally to the limb muscles. The fact that when one set of muscles contract the antagonists relax was noted by Charles Bell.

⁵ According to the experiments of Fano upon the dog (*Centralbl. f. Physiol.*, Leipzig u. Wien, 1895, Bd. ix. S. 466, and *Arch. ital. de biol.*, Turin, 1895, tome xxiv. p. 438, removal of the whole frontal lobe, including the sigmoid gyrus, shortens the reaction time of reflexes, while stimulation of that lobe lengthens the time, i.e. tends to inhibit reflex movements. But destruction of the sigmoid gyrus alone produces no such effect.

⁶ See also H. E. Hering and Sherrington, *Arch. f. d. ges. Physiol.*, Bonn, Bd. lxxviii. S. 222.

⁷ "Verhandl. d. physiol. Gesellsch.," in *Arch. f. Physiol.*, Leipzig, 1887, S. 363.

the reaction time for contraction and for inhibition of skeletal muscle (masseter) was practically the same, namely, 0.15 second.

OTHER PHENOMENA WHICH RESULT FROM STIMULATION OF THE CORTEX CEREBRI.

Besides the movements of voluntary muscles which are provoked by excitation of the motor area of the cortex, and which we shall study in detail in a subsequent section, various other phenomena are observed as the result of such excitation, prominent among these being alterations in the respiration, in the circulatory organs, in the pupil, and in some of the secretions. The probability of the production of such effects is clear from the influence which the emotions are well known to produce upon the various functions in question.

Influence of the cerebral cortex on respiration.—Danilewsky was the first to make observations upon respiration in this connection.¹ On exciting the posterior part of the motor area of the dog, he obtained slowing and increase of amplitude of the movements; on applying the electrodes to the base of the brain, acceleration was produced. Bochefontaine² obtained usually acceleration of respiration.

Effects upon respiration were obtained by Franck and Pitres³ on excitation of the motor area only (in the dog), and were not very constant; sometimes the respirations were slowed, sometimes accelerated, sometimes increased in depth, sometimes diminished; sometimes with a tendency to an inspiratory, sometimes to an expiratory, tone; the variations, according to them, being due apparently more to the differences in strength of the stimulus than to the part of the motor area to which it was applied. They obtained no results on stimulation of the cortex outside the motor area. Similar results were obtained by v. Bechterew,⁴ whereas other observers⁵ have described special effects (expiratory or inspiratory) as being obtainable from different and fixed places in the cortex.

The differences described by these several observers appear to largely depend upon whether the animals were anæsthetised or not, and upon the nature of the anæsthetic. Richet,⁶ using chloralised dogs, found excitation of various points of the cortex, especially of the sigmoid gyrus, to suspend the respiration.

Connection of the frontal lobe with respiration.—H. Munk⁷ obtained in the dog, on placing the electrodes at a point on the anterior part of the frontal lobe, arrest of respiration in deep inspiration (often preceded by acceleration), whereas from a point on the under surface of that lobe there was also arrest, but in extreme expiration; sometimes, however, acceleration. In the monkey, also, stimulation of certain points on the frontal lobe produced either inspiratory or expiratory tetanus.

The effects on respiration produced by stimulation of this region have been worked out by W. G. Spencer.¹ He found in the dog, cat, and rabbit, definite spots on the frontal lobe, excitation of which produce respectively (1) slowing and arrest of respiration, (2) acceleration, (3) inspiratory clonus, and (4) inspiratory tonus. The first of these is, in all animals tested, related with the part of the lower surface of the frontal lobe with which the olfactory lobe is connected, and a similar effect on respiration is obtained by stimulating, on the cut section of a hemisphere, the fibres of the anterior commissure. The arrest may occur in inspiration or expiration. When it occurs in inspiration, it is accompanied by a great rise of blood pressure.

Acceleration was obtained in the dog and cat by stimulation of the upper end of the supra-orbital sulcus, and in the rabbit by excitation of a point on the dorsal surface of the frontal lobe close to the longitudinal fissure. Inspiratory clonus was obtained from the junction of the olfactory bulb and tract, inspiratory tonus from many parts of the cortex, but most markedly from the middle of the motor area.

Most of these results are intimately related to the olfactory region of the cerebral cortex, and are probably to be referred to excitation of the tract which conveys olfactory sensations towards the lower centres (*racine moyenne* of Broca). Spencer has himself shown that, except the inspiratory tonus effects (which follow the course of the pyramidal tract fibres), the other effects which he has described are traceable, by the excitation method, to the tegmental region. Probably, therefore, the points enumerated are not to be regarded as specific respiratory centres, but the movements obtained by their excitation are such as are ordinarily associated with stimulation of the olfactory nerve-endings, and are correlated with activity of the olfactory nervous apparatus.

Influence of cerebral excitation upon the circulation.—Schiff² was the first to notice the effects on the circulation produced by excitation of the cortex, and they were subsequently (in 1875) shown by Vulpian to be of constant occurrence. Danilewsky³ obtained, on stimulation in dogs of the suprasylvian gyrus, vaso-constriction and cardio-inhibition. Bochefontaine⁴ showed that general vaso-constriction, usually accompanied by cardiac inhibition, but sometimes by cardiac acceleration, was produced by excitation of any part of the motor area; observations which were confirmed by Richet,⁵ who, however, obtained these results chiefly from the anterior part of the sigmoid gyrus. On the other hand, Brown-Séguard,⁶ using heat as a source of excitation, obtained manifestations of vaso-dilatation. I myself, in some experiments (hitherto unpublished), performed several years since in conjunction with J. R. Bradford, constantly obtained vaso-dilatation as the result of stimulating certain regions of the cerebral cortex in monkeys anaesthetised by chloroform or chloral, notably the mesial surface of the hemisphere anteriorly (*gyrus marginalis* and *gyrus*

fornicatus), while from some other parts of the cortex vaso-constriction was obtained. We did not, however, feel justified from our experiments in concluding that there was a definite localisation for the production of vaso-constriction and vaso-dilatation in the cortex, but supposed that we were exciting sensory regions, and that the difference of the results obtained was analogous to that obtained on stimulating different afferent nerves.

The circulatory effects of cerebral excitation have been very fully studied by François-Franck and Pitres.¹ They obtained, as the results of simple excitations uncomplicated by epileptic after-effects, with quiet and very slightly anaesthetised animals (dogs), only constrictor effects upon the blood vessels, often followed, however, by vaso-dilatation; the latter effect was never obtained primarily under these conditions; the effects were *general, not localised*, and not confined to the opposite side; they were most marked when the electrodes were placed on the motor zone, but were also manifested when the adjacent regions were stimulated, but not if the stimulations were applied at some distance from that zone (unless epilepsy was produced). The effects upon the heart-beat were very variable—sometimes it was accelerated, sometimes slowed—these differences appearing not to depend upon the seat of excitation, but partly upon the strength of current and partly upon the condition of excitability of the cortex.

FIG. 326. — Effects upon the volume of the kidney (*Vol. R.*) and arterial pressure (*P.C.*) of exciting the motor area of the cerebral cortex of a dog. The very great rise of pressure in this experiment is due to the fact that the animal was atropinised, so that the cardio-inhibitory effects which are usually also produced were absent. — François-Franck and Pitres.

Effects upon the pupil.—Excitations which are sufficient to provoke epilepsy are always provocative of dilatation of the pupil, no matter to what part of the cortex they are applied (Franck and Pitres). On the other hand, weaker excitations do not affect the pupil, except when applied over the regions which are connected with movements of the eyes and head. Here it was found, both in the monkey and dog, by Ferrier, that if the electrodes were applied to the anterior part of the motor area, the movements of the head and eyes were usually accompanied by opening of the eyelids and marked dilatation of the pupils. The same is the case when the electrodes are applied over the posterior part of the hemisphere (visual region). On the other hand,

¹ François-Franck, *loc. cit.*

excitation of the superior temporal convolution, which also produces movement of the head and eyes to the opposite side, was found by Ferrier to be accompanied by contraction of the pupils. The probability is, since dilatation of the pupil is ordinarily associated with convergence, and contraction with parallelism of the visual axes, that the pupillary effects of cerebral stimulation vary according as such stimulation tends to produce one or other of those conditions. But the matter is one to which little attention has hitherto been given.

It is noteworthy that, although in birds Ferrier was unable to obtain any movements of the limb or trunk muscles as the result of electrical stimulation of the hemisphere, nevertheless stimulation of a point at the vertex of the hemisphere produced "intense contraction of the opposite pupil, occasionally associated with turning of the head to the opposite side."

Effects upon the secretions and upon involuntary muscular tissue.—The effects of emotions upon the secretions, and especially the secretions of saliva and sweat, and upon the muscular tissue supplied through the sympathetic nervous system, especially that of the skin and hairs of the alimentary canal and of the urinary bladder, render it very probable that artificial excitation of the cortex should also produce similar effects. That excitation of the cortex in the dog produces a flow of saliva, was first shown by Bochefontaine,¹ who obtained it from excitation of points scattered over the greater part of the motor area. The effect was usually most marked upon the gland (the submaxillary was employed) of the opposite side, but there was some secretion from the gland of the same side; the impulses passed by the chorda tympani.² There is also a marked flow as the result of artificially induced epilepsy.³ So far as the secretion of sweat is concerned, simple excitation of the cortex has yielded negative results, but Adamkiewicz has remarked the occurrence of abundant perspiration in partial cortical epilepsy in man, affecting the parts which were thrown into convulsions; and the same has been noted in the foot of the cat as the result of artificially produced epilepsy by Franck and Pitres. A certain number of observations have been made upon other secretions—urinary, gastric, biliary—by Bochefontaine⁴ and others, but these have been quite insufficient to determine whether any direct or localised relation subsists between special parts of the cortex and the secretions. The evidence is, on the whole, unfavourable to the conclusion that there are such localised relations, and the effects which are obtained seem to be produced by the cortex as a whole acting upon the bulbo-spinal centres.

Still fewer experiments have been made upon the influence of the cortex upon the "organic" muscles. The only ones that need here be referred to are those upon the bladder. Bochefontaine⁵ found that excitation in the dog of certain points in the neighbourhood of the crucial sulcus produced evacuation of the contents of the bladder in curarised animals. This observation has been

⁴ *Loc. cit.*

⁵ *Loc. cit.*

confirmed by François-Franck and Pitres,¹ who find that the bladder is far more sensitive to the effects of cerebral excitation (in the motor region) than the vascular system, although the effects produced are somewhat irregular. v. Bechterew and Mislawsky also determined separately the effects of cortical stimulation upon the sphincter vesicæ. They found that this was sometimes contracted, sometimes relaxed, as the result of such stimulation, effects comparable, as they point out, to the two kinds of influence, contraction and inhibition, which the will probably exerts upon that muscle.

Heat centres in the brain (?).—That injuries to the brain produced experimentally in animals cause a rise of body temperature, was shown by Tscheschischin,² Eulenberg and Landois,³ and subsequently Hitzig,⁴ found that injuries of the cortex of the dog's brain in the neighbourhood of the crucial sulcus produce a rise of temperature, which is most marked on the opposite side of the body.⁵ Similar observations were made by Wood,⁶ Richet,⁷ Ott,⁸ and others.⁹ Aronsohn and Sachs¹⁰ found that punctures of the corpus striatum, in particular, cause a rise of temperature, and the same fact was affirmed independently by Ott,¹¹ and has been confirmed by Girard,¹² Baginsky and Lehmann,¹³ and Hale White.¹⁴ The observations of Hale White, which were made upon rabbits, tend to show that it is especially a lesion of the grey matter of the corpus striatum and not of the adjacent white matter of the hemisphere, nor of the optic thalamus, which is followed by the rise of temperature, and that this rise, which may amount to 3° or 4° or even 5° F., lasts from a few hours to several days. Lesions of the crus cerebri and of the septum lucidum were also found by Hale White to be followed by a very considerable elevation of temperature, but injuries to the cortex cerebri to a less degree.

Injuries to various parts of the brain (cortex, corpus striatum, and crus cerebri) in man have also frequently been found to be associated with rise of body temperature.¹⁵ It is, however, very doubtful whether the facts observed warrant the assumption that the parts in question, which are apparently irritated by the lesion, are specific centres to determine the production of heat. For when the experiments

on this subject are examined, it is found that the results are closely dependent upon the establishment of an irritative lesion in parts which are either directly in, or in close proximity to, the path taken by motor impulses, and the resultant rise of temperature may therefore well be due to an increased activity, chemical or otherwise, of voluntary muscles, caused by irritation extending to the motor tract.¹

EPILEPSY FROM CORTICAL EXCITATION.

As already stated, Fritsch and Hitzig obtained, as the result of strong or prolonged stimulation of the excitable points which they had marked out in the dog's brain, after-actions of the muscles which had been called into activity; these after-actions took the form of clonic

A

FIG. 327.—Curves obtained from a dog's muscle as the result of strong excitation (A) of the cortex cerebri, (B) of the subjacent corona radiata. E, E, period of excitation; T, contraction during excitation; Ep (in A), epileptoid contractions. In A the cessation of the excitation is followed by gradually developing epileptoid spasms, which appear to be formed by the fusion of smaller contractions. In B the rapid fall of the muscle lever indicates the entire absence (O) of an after-effect.—François-Franck and Pitres.

spasms, or even in some cases passed into well-characterised epileptic fits, spreading eventually to all the muscles of the body. The character of the after-contractions thus obtained is shown in the annexed tracing (Fig. 327, A), where it will be seen that each clonic spasm of a muscle is formed by the summation of a certain number of contractions, which succeed one another at the ordinary rhythm of discharge of the nerve centres. This summation occurs in the nerve cells of the cortex cerebri and not in the lower nerve centres, for, as already mentioned, it was found by Gotch and Horsley, by the aid of the capillary electrometer,² that the passage of the nerve impulses down the spinal cord is accompanied by an electrical disturbance having the same rhythm as the muscular clonus.

¹ The formation of heat within the cortex itself has been studied by Mosso (Croonian Lecture, *Phil. Trans.*, London, 1892, B). Cf. Hill and Nabarro, *Journ. Physiol.*, Cambridge and London, 1895, vol. xviii. p. 218, and article "Animal Heat," this Text-Book, vol. i. p. 808.

² *Phil. Trans.*, London, 1891, B, p. 267.

Other kinds of irritation of the cortex, and especially prolonged mechanical irritation (such as is liable to be produced by the irritation of a bony splinter from the inner table of the skull) will also produce epileptoid attacks, and the same result may follow experimental lesions of the cortex in animals.¹ Irritation confined to the corona radiata is never followed by epilepsy; and if a portion of the excitable area of the cortex be removed, such, for example, as the centre excitation of which produces movement of one of the opposite limbs, and an epileptic fit be brought about by strong or prolonged excitation of another portion of the cortex, the limb in question remains quiescent.² Epilepsy, therefore, is essentially a functional disturbance of the cortex cerebri. It does not occur if the Rolandic or motor region of the cortex be removed entirely, although it may be provoked by excitation of other portions of the cerebral surface³ than this, but not with the same ease and with a longer interval after the excitation.

Hughlings Jackson showed⁴ that in the pathological condition now named after him Jacksonian epilepsy, the convulsive movements in a fit follow a certain order or "march." Thus, if a fit begin by contraction of the thumb flexors, it first spreads to other muscles of the hand and forearm, next to the shoulder muscles, then to the muscles of the face, trunk, and leg in a definite order in each case, passing, if it begin in the hand, *up* the arm and *down* the leg; if it begin in the toes, *up* the leg and *down* the arm. When the centres for movements which are bilaterally represented in the cortex are involved, the corresponding muscles of both sides are set in action, and in severe fits all the muscles on both sides of the body may be included. Ferrier's experiments⁵ upon monkeys and other animals entirely confirmed the observations of Hughlings Jackson upon man, showing that in each case the epileptoid attack began in the muscles corresponding to the motor centre which was stimulated, and spread thence with a definite "march."⁶ The "march" is apparently dependent in each case upon the relative propinquity of the several centres in the motor region of the cortex, and, when they are equally close, upon their relative excitability; it is, however, not interfered with, according to Unverricht,⁷ by isolating the centres from one another, and the sequence must therefore be brought about—at least under these circumstances—by influences passing from one part to another through lower level centres. Section of the corpus callosum does not prevent the spreading of an artificially induced fit from the one side of the body to the other (Unverricht). In dogs, when the side of the brain opposite to that first set in action is involved, the fits always begin with the muscles of the hind-limb, wherever the excitation producing them might have been originally applied on the other side of the brain.⁸

¹ Hitzig, "Untersuch. ueber d. Gehirn," Berlin, 1874, S. 271.

² It was stated by Munk, and the statement was confirmed by Bubnoff and Heidenhain (*loc. cit.*), that if during the progress of an epileptic attack, artificially produced, the cortical centre which was excited is rapidly extirpated, the attack immediately ceases. But François-Franck and Pitres (*loc. cit.*) and Albertoni (*loc. cit.*) were unable to confirm this statement, and deny that the attack once commenced is modified by the ablation.

³ François-Franck and Pitres (*loc. cit.*); Unverricht, *Arch. f. Psychiat.*, Berlin, 1883, Bd. xiv. S. 175; Rosenbach, *Virchow's Archiv*, 1884, Bd. xevii. S. 369. Albertoni (see *Brain*, London, 1878, vol. i. p. 139) came to a different conclusion regarding the seat of epilepsy, but on apparently insufficient grounds.

⁷ *Loc. cit.*

⁸ François-Franck and Pitres, *loc. cit.*; Unverricht, *loc. cit.*

Landois¹ found that convulsive movements can also be produced, in a regular march, by the application of chemical irritants to the surface of the brain.

The character of the muscular contractions in artificially provoked epilepsy has been studied in dogs by François-Franck and Pitres;² and in monkeys, rabbits, and dogs by Horsley and myself and others.³ François-Franck and Pitres generally obtained in the animals they employed (which were usually allowed to partially recover from the influence of the anæsthetic for the purpose of the observation) an after-effect of a tetanic nature lasting for a few seconds; this was practically a continuation of the contraction which was evoked by the faradic current, but often of a more pronounced character. This "tetanic phase" was succeeded, usually quite suddenly but sometimes gradually (Figs. 327, 328), by the "clonic phase," characterised by the violent spasms of slow rhythm which have already been noticed, and which would last a variable time (from a few seconds to several minutes), slowly passing off but sometimes succeeded by a second or a third fit or even more. They note that the tetanic phase was occasionally absent, and this was the case also in many of the

FIG. 328.—M, Curve of the contraction of a muscle during and after cortical excitation, showing the tetanic and epileptoid after-effect. *Pr.c.*, carotid pressure. E marks the period of excitation.—François-Franck and Pitres.

experiments recorded by Horsley and myself, in which the animals were the whole time completely under the influence of the anæsthetic employed (chloroform or ether). As the attack subsides, the clonic spasms become slower and more irregular, and are often attended by short intervals of quiescence. In some cases the muscles affected pass towards the termination of the fit into a condition of contracture. Similar phenomena have been noted in attacks of cortical (Jacksonian) epilepsy in man. If the cerebral cortex be in a condition of abnormally increased excitability, the excitation of a sensory nerve may serve to provoke an attack of epilepsy.⁴ Likewise, if excitation of a sensory part of the brain (at least of some part other than the Rolandic region) fail to provoke epilepsy, an increase of excitability of the motor area, such as is brought about by exposure and previous stimulation, will render the excitation of the sensory area effective. These facts have some bearing upon the causation of idiopathic epilepsy in man, the fits in which, as is well known, are usually preceded by a sensation known as an *aura*,

¹ *Wien. med. Presse*, 1887, Nos. 7 to 9.

² *Loc. cit.*

³ *Journ. Physiol.*, Cambridge and London, vol. vii.

⁴ François-Franck, "Leçons," p. 119.

which may be associated with any of the special senses, of which the tactile and visual are the most common, or may be of a vague dreamy character. In Jacksonian epilepsy the attack is frequently preceded by a sensation of numbness or tingling in the part in which the convulsions begin. There is, however, an important difference between the two kinds of epilepsy, in the fact that in the Jacksonian type the patient

FIG. 329.—Curves showing the effects of cortical excitation productive of epilepsy upon the blood pressure, the pulse rate, and the size of the pupil. *Pr.*, carotid pressure, the height of the mercury column being marked in millimetres on the left of the figure; *H*, the pulse rate; *M*, curve of muscular contraction; *E, E*, period of excitation, occupying two seconds. —François-Franck and Pitres.

is conscious throughout the attack, whereas in idiopathic epilepsy, even in very slight attacks (*petit mal*), unconsciousness is a prominent symptom.

Certain drugs, notably absinthe, produce, when injected into the vascular system, convulsive attacks which are scarcely distinguishable from the epileptic fits provoked by stimulation of the cortex cerebri. They occur, however, according to the observations of Magnan,¹ even

¹ *Arch. de physiol. norm. et path.*, Paris, 1873, p. 127.

after severance of the brain from the spinal cord: the action cannot, therefore, be only upon the cortex.¹

François-Franck and Pitres (Figs. 328, 329) found that during an epileptiform attack in dogs, the blood pressure, which was raised during the excitation of the motor cortex which produced the attack, remained high, with irregular elevations and depressions as long as the fit lasted; while the pulse rate, which first rose a little and then fell considerably as the immediate result of the stimulation, rapidly mounted up during the commencement of the epileptoid attack until it was far above the normal rate, and again fell gradually during the clonic phase. The rise of blood pressure is independent of the pulse rate, and depends upon an active constriction of arterioles. There is usually a considerable post-epileptic fall of blood pressure, and such a fall occasionally happens during the clonic phase of an attack.²

The effects upon respiration vary with the severity of the attack. In some cases the respiratory movements take on a clonic convulsive character, even during the tonic phase of the attack; in other cases they are altogether suspended during this phase, the thorax assuming an expiratory attitude; this condition being succeeded by one in which the respiratory movements are of a clonic and convulsive character.

The pupil usually dilates widely and remains dilated until near the end of the attack, the secretion of saliva is increased, the excitation operating through the chorda tympani,³ and occurring principally in the clonic phase,⁴ and a secretion of sweat has also been noticed during an attack. The effects upon other viscera are probably wide-spread, but have not as yet been sufficiently studied experimentally.

SPECIAL LOCALISATIONS IN THE CORTEX CEREBRI.

THE MOTOR AREAS AND CENTRES OF THE CEREBRAL CORTEX.

The terms "motor area" and "motor centre" are here used to imply those portions of the cerebral cortex which are directly connected by efferent projection fibres with the lower level centres (spinal cord,⁵ bulb and midbrain) from which impulses producing voluntary muscular action emanate. The use of the term "motor" for these regions does not necessarily exclude the possession in the same part of the cortex of some sort of conscious sensation, and especially of that which is known as the muscular sense, although, as we shall presently see, it is uncertain if this portion of the cortex actually does form part of the sensorium. But it is certain that the region in question is intimately connected with, and its integrity is essential for, the production of voluntary movements; nervous impulses for the production of these movements undoubtedly emanating from some of the cells in that region, which, as shown by Betz and Bevan Lewis, are characterised by

¹ It was found by Horsley and myself (*Journ. Physiol.*, Cambridge and London, vol. vii. p. 103) that an after-effect is *very occasionally* seen to succeed prolonged or strong excitation of the cut spinal cord, which is similar in its character to the epileptoid spasms produced by excitation of the cortex cerebri, and which, like those spasms, may be preceded by a tonic phase (see fig. 6 B, *plats v.*, *loc. cit.*).

² François-Franck, *loc. cit.*, p. 199.

³ Albertoni, "Papers from the Sienna Laboratory of Physiology," 1876.

⁴ François-Franck and Pitres, *loc. cit.*

⁵ Termed also on this account the "cord-area" of the cortex by Sherrington, *Journ. Physiol.*, Cambridge and London, 1885, vol. vi. p. 178; 1889, vol. x. p. 429.

their size and grouping.¹ That such nervous impulses are normally set agoing by impulses derived from the periphery through sensory tracts, or from other regions of the brain through internuncial fibres, is certain, but this acknowledged fact does not justify one in terming the areas in question "sensory," for the typically motor cells of the anterior horn of the spinal cord are also called into activity by impressions reaching them from sensory tracts, and these are by common consent spoken of as motor cells. The application of the terms motor and sensory to cells in the central nervous system must be used rather for purposes of convenience than with a view to a rigid definition of function. If we define a motor or efferent cell as one which discharges towards a "lower level" or towards the periphery, a sensory or afferent cell as one which discharges towards the nerve centres or towards a higher level, it is still difficult, if not impossible, in the present state of our knowledge of the central nervous system, to say with regard to some cells whether they are to be regarded as discharging towards higher or lower levels. Nevertheless, when we find that excitation of the cells in a limited region of the cortex produces movements which are indistinguishable from voluntary movements of the muscles, and that extirpation of the same region produces permanent paralysis of those movements without permanent or it may be without appreciable loss of sensibility in the part affected, it appears not only convenient but imperative to think and speak of the region in question as the centre for the voluntary movements involved.² And the more so because there are other regions of the cortex which, when artificially excited, produce special movements of a voluntary character, the power to execute which is, however, in these cases *not lost* on removal of the cortex of the regions in question, although a definite sensory defect (in the case of the occipital lobe, blindness) results. In spite, therefore, of the fact that movements have resulted from their stimulation, we are not justified in terming these portions of the cortex "motor," but may regard them as "sensory," and may look upon the movements as being set up by a "motor" discharging centre elsewhere, as the result of nervous impulses reaching it from the "sensory" region of the cortex.

In connection with this subject, the "isolation experiments" which have been performed by various observers³ deserve notice. These have consisted in cutting off the motor area from the rest of the cortex by an encircling incision passing through the grey matter and some little way into the white matter. In this manner it is believed that all fibres connecting this area with other portions of the cortex are severed, and only the fibres which pass in the corona radiata to or from the lower centres remain. If these fibres are both afferent and efferent,—sensory

² "If we are to retain the terms sensory and motor cells, it would seem more reasonable to adhere to the designation "motor" for those cells which lie in the region of the cortex in which the first steps in the so-called voluntary motor processes begin."—C. K. Mills, "Nervous System and its Diseases," Philadelphia and London, 1898, p. 342.

³ Exner and Vareth, *Arch. f. d. ges. Physiol.*, Bonn, 1885, Bd. xxxvii. S. 523; *ibid.*, 1887, Bd. xli. S. 349; *ibid.*, 1889, Bd. xlv. ; Marique, "Rech. expér. sur le mécanisme de fonctionnement des centres psycho-moteurs du cerveau," Bruxelles, 1885; see also *Brain*, London, 1885, vol. viii. p. 536. In some of Marique's experiments severance of the motor centres of the dog, by a cut involving only the association fibres connected with the posterior parts of the brain, was found to produce almost as marked a motor paralysis as complete isolation. I have found, however, that this is not the case in the monkey, nor did the cutting off in the same individual of the prefrontal area as well produce paralysis.

and motor,—there seems no reason why the motor centres should not continue to act in response to tactile impressions. They do not, however, so act (although they are still capable of being excited by direct electrical excitation), but the isolation produces a paralysis as complete as if the centres in question were excised. The inference is that the motor centres are not themselves directly provided with sensory excitomotor fibres, but that they are set in action by impulses received by means of association fibres from sensory parts of the cortex.

Although this is the obvious inference, it must be pointed out that the results are open to another interpretation, namely, that the cutting off of the innumerable impulses which the motor centres are constantly receiving from the rest of the cortex, has rendered them less liable to respond to afferent impulses reaching them by the corona radiata. Such an explanation presupposes the maintenance of a kind of tonus in the motor centres of the cortex by impulses received through association fibres.

It must also be pointed out that these experiments are open to the criticism that the circumsection of an area very materially interferes with the blood supply of its cortex, and may thereby interfere also with its functional activity.

While there can be no objection, if it is preferred, to the employment of the term "psycho-motor" in place of the more simple term "motor," to denote the excitable centres in the Rolandic region of the cortex cerebri, the use of the term "sensori-motor" is to be deprecated, because it assumes, what has not yet been shown to be the case, that the region in question possesses, besides the faculty of receiving impressions from other portions of the cortex, and transmitting them as voluntary impulses to the lower level efferent stations in the bulb and cord, also that of perceiving sensory impressions directly received from lower level afferent stations; in other words, that it also functions as a region devoted to general (tactile) sensibility. This view has, it is true, been taken by Bastian, Dana, Flechsig, Mott, H. Munk, Schiff, Soury, and other distinguished neurologists,¹ but as appears to me on insufficient evidence. It has found its strongest expression in H. Munk's division of the Rolandic area into so-called "sensory spheres"² (Fig. 330). Munk regards the movements which are evoked by excitation of the Rolandic region of the cortex as due entirely to the calling up of the sensations which ordinarily accompany those movements, and that the paralysis which results from extirpation of the parts in question is a paralysis of sensation; just as when all the sensory nerves (posterior roots) of a limb are cut, the power of voluntary movements, which are guided by sensations derived from the periphery, is greatly impaired, or in some cases appears to be entirely lost. In support of this view Munk asserts that removal of the part of the cortex, excitation of which produces

¹ Schiff was the first physiologist to regard the Rolandic zone as a purely sensory region, but he afterwards saw reason to give up this idea, and in an addendum to his collected papers (published in 1895) he definitely states that experiments have shown that motor centres must exist in the cerebral cortex. The view originally taken by Hitzig was that the paralysis obtained is caused by loss of muscular sense or of loss of the consciousness called up by the imagining of movements; later he admitted that loss of sensibility of tendons, ligaments, and articulations might also be a cause (*Neurol. Centralbl.*, Leipzig, 1888).

² Munk has enunciated his views upon this question in a series of articles in the *Arch. f. Physiol.*, Leipzig, 1877 to 1889 (*Verhandl. d. physiol. Gesellsch. zu Berlin*), republished with notes in book form in 1890; and more recently in the *Sitzungsb. d. k. Akad. d. Wissensch. zu Berlin*, 1892 and succeeding years.

movements of a limb or other part of the body, is followed by entire loss of sensibility in that limb.¹

Even if this assertion of Munk's were true, it would by no means justify the exclusion of the expression "motor" from the designation of a part of the cerebral cortex which is directly functionally connected with the motor apparatus of the spinal cord and bulb.² It is, however, not the case that sensibility is lost in the paralysed part, and it is difficult to comprehend that the assertion should have been made and that it should be reiterated. It is certain that in the monkey the careful and complete removal of the whole of the region of the cortex, excitation of which produces movements in the opposite hind-limb, may not be followed by any discoverable sensory paralysis of the limb in question;³ although the limb is absolutely devoid of the power of executing any true voluntary movements, and although the entire removal of its cortex may be proved by the fact that it does not participate in an epileptic fit, induced by artificial stimulation of other

FIG. 350.—Brain of monkey, marked out into the so-called "sensory areas". *A*, visual sphere; *B*, auditory sphere; *C* to *J*, tactile spheres. *C* of leg; *D* of arm; *E* of head; *F* of eyes; *G* of ear; *H* of neck; *J* of trunk.—After H. Munk.

¹ "After total extirpation of the arm and leg area, tactile sensibility of the opposite extremities is permanently lost; a touch or light pressure is without any effect, neither tactile reflexes nor eye nor head movements are produced. The same is the case if the whole of the arm or leg region is removed in monkeys; tactile sensibility is permanently lost in the opposite arm or leg" (H. Munk, "Ueber die Fuhlsphäre der Grosshirnrinde, Fünfte Mittheilung," *Sitzungsber. d. k. Akad. d. Wissensch. zu Berlin*, November 5, 1896). Further, "Schiff was right in affirming the existence of sensory disturbances, local anaesthetics. The parietal lobe is therefore the tactile sphere, as the temporal is the auditory and the occipital the visual sphere. One can roughly say that, as the retina is projected on the visual so is the skin on the tactile sphere." "The affirmation that lesions of the cortex in the region of the parietal lobe produce purely motor disturbances, without accompanying sensory defects, has been shown to be erroneous" (!).

² Although as a matter of fact the fibres of the pyramidal tract do not terminate amongst the cells of the anterior horn of the spinal cord, as has hitherto been supposed, but amongst the cells of Clarke's column and of the base of the posterior horn (Schäfer, "Proc. Physiol. Soc.," 18th March 1899, *Journ. Physiol.*, Cambridge and London, vol. xxiv.), and their connection with the motor cells must therefore be indirect, it is none the less the case that the impulses they convey must be efferent, but whether motor or inhibitory, or both, is not known. Perhaps the fibres which go to the homonymous lateral column are inhibitory; while those to the heteronymous side are motor.

³ Schäfer, *Journ. Physiol.*, Cambridge and London, 1898, vol. xxiii. p. 310.

parts of the cortex, which throws all the other muscles on the same side of the body into contraction. If the area, excitation of which produces facial movements, be cut away, there is paralysis of the cheek-pouch, but after recovery from the immediate effects of the operation the monkey still shows consciousness of the presence of food within the pouch, and occasionally empties it by pressure with the hand from outside or of the cheek against the shoulder.¹

When there is paralysis of sensation produced by a lesion of the Rolandic region, it is not necessarily localised to the limb the muscles of which are deprived of voluntary motion, nor is it ever so complete as it would be if the paralysis of motion were due to sensory paralysis.² Charles Bell obtained paralysis of the facial muscles on cutting the trigeminal nerve; Exner and Pineles,³ paralysis of all the muscles of the larynx of the horse on cutting the superior laryngeal nerve; and Mott and Sherrington,⁴ paralysis of the upper limb of the monkey, on cutting all the posterior roots of the nerves supplying the limb. Mott and Sherrington found that if only one posterior root of the nerves proceeding to the upper limb were left, all the other sensory fibres being cut, the paralysis which they obtained from severance of all the posterior roots did not occur. Bastian⁵ has suggested that this effect is probably due to a diminution of excitability of the cells of the spinal cord, consequent on the absence of the advent of peripheral impressions; thus there would be a diminution of tonus of the muscles concerned. These cells and muscles are still capable of being excited to action by electrical excitation of the cortex cerebri, and are also brought into action in violent voluntary movements.⁶ Nor does sensory paralysis ever occur, as asserted by Munk, if the cortex connected with the movements of a *limited part of the body, such as one limb*, be alone removed. I have found⁷ that if *in successive operations even the whole of the motor cortex be removed* in the monkey, there may be no appreciable effect upon the sensibility of the opposite side of the body, yet voluntary paralysis is complete. v. Bechterew⁸ makes a similar statement for the motor cortex of the dog and monkey. Mott⁹ came to the conclusion, from his experiments upon monkeys, that there was sometimes, after an *extensive lesion* in the Rolandic region, a certain amount of deficiency in the sensibility of the paralysed limb. But the method of testing this upon which he chiefly relied was one on which reliance cannot be placed. He fixed a "bull-dog" clip alternately to the skin of the sound and the paralysed limb, and found that it was usually at once removed from the sound limb but was frequently left on the paralysed side; he concluded that this showed a loss of tactile sensibility on the paralysed side. That this conclusion is erroneous is shown by the fact that

¹ E. Flood, *Brit. Med. Journ.*, London, 1894, vol. ii. p. 189.

² It is an ascertained fact that voluntary movements are directed by sensations and cannot be performed without the guidance of some sort of sensation.

⁷ Schäfer, *loc. cit.*

⁸ *Neurol. Centralbl.*, Leipzig, 1883, S. 409. This statement has, however, been somewhat modified by Bechterew, see *ibid.*, 1898, S. 139. See also "Die Leitungsbahnen im Gehirn u. Rückenmark," Leipzig, 1894, S. 146; and *Anf.* 2, 1899, S. 429. Bechterew regards the parietal lobe as being especially associated with all forms of cutaneous and muscular sensibility.

⁹ *Journ. Physiol.*, Cambridge and London, 1894, vol. xv. p. 464.

animals display consciousness of and clearly localise a slight touch or gentle stroking of the paralysed limb, upon which a fairly strong clip will be left unnoticed. The reason why the pressure of the spring clip is felt upon the non-paralysed side is probably to be found in the fact that the muscles of that side are constantly in slight activity, and the variations in tension which this produces upon the skin converts the constant stimulus of the clip into a variable stimulus which is at once appreciated. On the paralysed side this of course does not occur.¹

That the above is the correct explanation of the results with the "clip" test, is probable also from the fact that as soon as the "associated movements" of the paralysed limb return, the difference of behaviour of the two limbs to the clip is no longer apparent.² Even where there appears a slight defect in the localisation of sensory impressions after removal of a localised portion of the Rolandic cortex, this by no means shows that the region in question is sensory, any more than defects of olfaction or vision after lesions of the trigeminal prove that olfactory and visual impressions are conveyed by this nerve.³ For after such lesions there invariably follows, as the result either of inactivity of the muscles or of vasomotor changes, a general swelling of the limb due to the accumulation of lymph; there is usually also dryness of the epidermis, and vaso-dilatation; any of which conditions would tend to affect its sensory functions. This will be further discussed when the clinical evidence has been alluded to.

The conclusion arrived at, therefore, so far as we can interpret experiments upon animals, is that removal of the part of the cortex with which the volitional movements of a limb are connected, either does not at all affect the tactile sensibility of the limb, or if a slight effect is produced it is in an indirect manner; *the paralysis of motion cannot be the result of loss of tactile sensibility.*⁴

It is difficult to determine in an animal questions which involve differences in general sensibility, and quite impossible to determine questions involving what has been called "muscular sensibility," or appreciation of muscular contraction through the position of the limbs. It is necessary, therefore, to turn to clinical experience to assist us in determining whether a lesion of the Rolandic region of the cortex, which in man as in monkey produces according to its extent paralysis of voluntary motion, is accompanied by loss of sensibility in the paralysed parts. The reply which clinical medicine has furnished to this question is not uncertain. Very many cases have been recorded in which sensibility has been most carefully tested, and in which not only has

¹ The same explanation holds good for the results obtained by Mott from hemisection of the cord. He came to the conclusion that the paralysed limb in this case also was deficient in sensibility, because there was as a rule no tendency to remove a clip from it. I have found, however, in monkeys with hemisection of the cord, that although these animals may not remove a clip from the paralysed side, they will react, by looking round or otherwise, to a touch or stroking of the paralysed foot, so that Mott's conclusion, which was based wholly upon the "clip" phenomenon, cannot be accepted without reservation in either case. Mott himself, in his hemisection experiments, got evidence of reaction to touch (*Phil. Trans.*, London, 1892, vol. clxxxiii. B, p. 1).

² Mott, *ibid.*

³ Cf. on this subject, v. Bechterew, *Neurol. Centralbl.*, Leipzig, 1894, S. 252, 297.

⁴ Schäfer, *Journ. Physiol.*, Cambridge and London, 1898, vol. xxiii. p. 310. On the other hand, the tactile and general sensibility of a part may be completely abolished by cocaine, but the action of the muscles in no way affected. This is stated to be the case with the larynx by Beaunis (*Bull. Soc. de psych. exp.*, Bordeaux, 1888, tome iii. p. 14).

there not been loss of sensibility in the paralysed limb, but in which no trace of deficiency in sensibility, as compared with the opposite side, could be detected. The fact that in numerous other cases defective sensibility has been found, in no way affects the argument. For a single case of cortical lesion, accompanied by muscular paralysis, careful examination fails to detect any loss or affection of tactile sensibility, is quite sufficient to invalidate the hypothesis that cortical muscular paralysis must have its origin in tactile paralysis. The position as based upon clinical observations is admirably summarised by Charcot and Pitres¹: "Les paralysies d'origine corticale s'accompagnent parfois des troubles de la sensibilité cutanée ou musculaire; mais ces troubles sensitifs éventuellement associés aux paralysies motrices, n'ont aucun rapport constant et nécessaire avec les lésions de la zone motrice. Les centres moteurs corticaux de la région rolandique ne sont donc pas des organes sensitivo-moteurs." C. K. Mills² states that "innumerable cases have been reported of lesions of the motor cortex without the slightest impairment of sensibility. In several cases of excision of the human cortex in the Rolandic region by surgical operations, careful studies of the patients, by the writer and others, failed to show any impairment of sensation."³

This being so, how then are we to explain the occurrence of a certain number of cases (amounting, according to Charcot and Pitres, to about one-third of those which have been carefully recorded), in which the lesion of the Rolandic area is accompanied by a certain amount of sensory disturbance? This question is discussed by Charcot and Pitres as follows:—

"Not only are the sensory disturbances not exactly coterminous with the parts deprived of movement, but they also do not persist as do the motor paralysees. They are almost always fugitive and changeable. Would they be susceptible of alteration from one moment to another, of disappearing and reappearing under the influence of slight causes, if they actually depend on the destruction of corresponding perceptive centres? This is very improbable. Further, it is impossible, as some authors have attempted to do, to explain motor paralysis of cortical origin by primary or concomitant disturbances of the muscular sense, of tactile sensibility, or of the aggregation of sensations to which the term 'kinæsthetic'⁴ has been applied."

¹ "Les centres moteurs corticaux chez l'homme," Paris, 1895. Abundant statistics are here given as well as a succinct account of the history of the subject up to the date of publication. See also the cases quoted by Ferrier in "Cerebral Localisation," pp. 139-144.

² "The Nervous System and its Diseases," Philadelphia and London, 1898.

³ I have lately had the opportunity of carefully testing a case in which, as the result of a gunshot wound of the mesial surface of the right hemisphere of the brain, was produced motor paralysis of the upper arm, trunk, and leg muscles (but not of the hand or face). Although the left foot was completely paralysed, the slightest touch could be felt upon it, and no difference in delicacy of discrimination of two points could be detected between it and the right foot. Localisation of the exact position of the point touched was imperfect upon the outer side of the leg and the dorsum of the foot only, but was perfect upon the inner side of the leg and the plantar surface of the foot, although every part was equally and completely paralysed for voluntary motion. Such slight defect in localisation of tactile sensations as did exist was therefore independent of the muscular paralysis, and was perhaps due to the fact that a part of the cortex other than that involved in the production of the motor disturbance (or perhaps part of the thalamus opticus) was included in the area of disturbance.

⁴ The term "kinæsthesia" or sense of movement has been introduced by Dr. Charlton Bastian, to denote all those impressions which are evoked by muscular movements, including "cutaneous impressions, impressions from muscles, fasciæ, tendons, and articular surfaces, and in addition a set of unfelt or but little felt impressions which guide the activity of the brain by the information (unconscious) which they afford us as to the different degrees of

"As a matter of fact, clinical medicine teaches in an unmistakable manner that anæsthesia of the limbs, whether superficial or deep, is not in itself a cause of motor failure. In anæsthetic hysteria the patients do not by reason of their anæsthesia lose the faculty of freely moving their limbs, even when their muscular sense is abolished and all forms of cutaneous and deep sensibility are lost. And it is equally true that the faculty of movement can be completely preserved in cases of hemianæsthesia, resulting from destructive lesions in the posterior part of the internal capsule. To us it appears that these facts are conclusive."

"There remains, however, to be explained why alterations of the motor zone are accompanied in almost a third of the number of cases where they occur by disturbance of sensation either cutaneous or muscular."

"Legroux and de Brun¹ connect these sensory symptoms with circulatory disturbances affecting points in the cerebral substance beyond those involved in the paralyzing lesion. Ferrier regards them as being produced by co-existing lesions of sensory centres (elsewhere in the cortex) or of sensory tracts. But this combination of two lesions . . . is certainly exceptional."

"In our opinion the anæsthetic conditions which sometimes accompany motor paralyses of cortical origin are most frequently functional anæsthesias, analogous if not identical with hysterical anæsthesias; . . . they are super-added and accidental phenomena, not depending directly on the lesions of the Rolandic region, nor playing any pathogenic part in the production of the paralytic symptoms."

Besides this "functional" explanation, perhaps in correlation with it contraction of all the muscles concerned in the production of any movement"; and he considers that the Rolandic region is a special seat for the ultimate reception of such impressions, and for their revival as an antecedent to the excitation of the motor centres of the spinal cord and bulb.

Bastian's view has been developed in a highly philosophical manner in a series of important articles, dating from some twenty-five years back up to the present time, and has been accepted, sometimes with and sometimes without acknowledgment, by many neurologists. As it has been often misapprehended, it may be as well to point out that Bastian has not postulated that voluntary movements are *produced by* kinæsthetic impressions, but merely that the performance of such movements is *guided by* them; and considering that in order properly to perform their functions the centres in the Rolandic area must receive such impressions, Bastian regards this area as a sensory area and its centres as sensory centres. By the same mode of reasoning, however, the centres in the anterior horns of the spinal cord from which the motor nerves originate, must also come under the same category. Bastian has not committed himself to the opinion that the Rolandic area is the sole portion of the cortex where kinæsthetic impressions are perceived, but merely that part where these impressions or the memory of previous similar impressions are concentrated for the *guidance* of volitional impulses; which last are themselves originated by immediate or earlier sensory impressions, whether visual, auditory, tactile, gustatory, or olfactory. The difference, therefore, between Bastian's view of the Rolandic centres and that taken in the text, largely resolves itself into one of terminology. For full information regarding the kinæsthetic theory of voluntary action, the student will do well to consult Bastian's original works, and especially "The Brain as an Organ of Mind," p. 543; "Paralyses, Cerebral, Bulbar, and Spinal," p. 108; "Hysterical or Functional Paralysis," Appendices A and C; "The Muscular Sense," *Brain*, London, 1887, vol. x. p. 1; "On Attention and Volition," *ibid.*, 1892, vol. xv. p. 1. ¹"L'encephalon," 1884.

there is more than one physico-anatomical explanation possible of the occurrence in some cases, especially where a lesion is large, of sensory disturbances affecting the paralysed side. For, first, the occurrence of a large lesion may undoubtedly, as suggested by Legroux and de Brun, affect the vascular supply of portions of the brain even remote from the part where the lesion itself occurs; or, in the case of a tumour, the pressure of the growth may make itself felt in remote parts. It is unquestionably the case that in extensive removals of cerebral cortex the effect of such removal may influence—temporarily if not permanently—even the whole of the same side of the brain; so that, for example, removal of the frontal lobe in the monkey has been found to produce both general hemianæsthesia and hemianopsia,¹ and removal of the whole motor area at one operation the same combination of sensory disturbances.² Secondly, defects of sensibility in a paralysed limb may be produced by the local effects of lymph accumulation, due to the loss of activity of the muscles of the part (see p. 727). And there is yet another way in which sensory defects indirectly following lesions of the motor region may be explained,—one which also offers an explanation of the fact that excitation of the Rolandic region of the brain is sometimes found to produce slight sensory symptoms,³ and also perhaps of the sensory “signal” which in some cases heralds the approach of an epileptiform fit originating in the same region. For since the volitional movements are guided and governed by afferent impressions received from all parts—from the skin, the muscles themselves and their tendons, and the other structures in the limbs which are affected by their action, the eye, the ear, and other special sense organs—it is certain that the parts of the cortex from which the volitional impulses emanate must by means of association fibres be in intimate connection with those parts of the cortex—some of which are known and others still unknown—which are involved in the perception of such sensory impressions. These association fibres must be assumed to be derived from cells in the sensory parts of the cortex, and since when a nerve fibre is stimulated conduction is in either direction, stimulation of the endings of these association fibres in the motor region may affect the sensory parts of the cortex through them. Further, it is a well-established fact that the severance of a nerve fibre, not only produces the Wallerian degeneration in its peripheral part, but also causes degenerative changes in the cell from which it takes origin; and especially is this the case with sensory cells, where these degenerative changes may proceed to complete atrophy.⁴ We should therefore expect that even

¹ Ferrier and Turner, *Phil. Trans.*, London, 1898, vol. cxc. B, pp. 35, 36.

² Mott, *Journ. Physiol.*, Cambridge and London, 1892, vol. xv. p. 483, Exp. v.

³ W. B. Ransom (*Brain*, London, 1892, vol. xv. p. 440) produced with a slight strength of current in a patient who had been trephined, and whose brain was stimulated by needle electrodes passed through the skin, a *tingling sensation* in the part, which would contract when the strength of the current was increased. No effect was observed on tactile sensation. The effect may have been a vasomotor one. Cf. also C. L. Dana, *Med. Rec.*, N. Y., 1893, p. 578, who in a similar experiment found that, simultaneously with the movement, a sensation of numbness and heaviness was produced in the limb moved (opposite arm), similar to the sensation experienced when a peripheral nerve is pressed. It is noteworthy that in neither case was the “idea of movement” called up, nor even such sensations as ordinarily accompany movement. The movements produced in Dana’s case were very extensive, and with stronger stimulation were followed by general epileptic convulsions and loss of consciousness; prior to this the same numbness was felt in the opposite arm and shoulder, which were the parts first moved.

⁴ Cf. article “Nerve Cell,” this volume, p. 601.

if a lesion be confined to a part of the cortex which is purely motor, there would be produced indirectly but at no long interval of time both functional and organic changes in parts which are purely sensory, and the extent to which these would be perceptible would probably depend largely upon the extent of the lesion in the motor region.

Redlich¹ has collected and analysed 132 cases of cerebral hemiplegia, with especial reference to the question of the condition of the muscular sense. In only twenty-eight out of the 132 was there any clear deficiency, and in all these there was defective general sensibility as well, although not always proportional to the defect of muscular sensibility. The large number of cases in which no defect of muscular sense can be determined, speaks strongly against the idea that cerebral hemiplegia is merely due to loss of that sense.²

Contracture.—There sometimes results after removal of the motor centres of the limbs in the monkey, and after lesions of the corresponding part of the brain in man, a condition of permanent contraction of some of the muscles, to which the term "contracture" has been applied. It is not found in other animals besides monkeys, and not always in these, being most frequently met with in those animals which are kept closely confined. According to H. Munk,³ contractures are of two kinds, namely—(1) those due to irritation of the cortical substance as the result of injury with incomplete removal—these are rare; and (2) those which occur after complete removal, and which are associated with the complete disuse of the limb. The condition appears to be due to the existence of a state of hypertonicity in the muscles affected, and has been compared by Soury⁴ to that which obtains in the congenital malady known as Thomsen's disease, in which the voluntary movements are characterised by prolonged tonic contractions of the muscles, the cause of the disease being in all probability due to some defect of the cells of the cortex.⁵ But, on the other hand, the hypertonicity may be due to a totally different cause, namely, the cutting off from the lower centres of the inhibitory impulses which they habitually receive from the cortex cerebri, while excitatory impulses which reach them from the cerebellum are still passing. Hence also it is found in man (and to a less degree in the monkey), that whereas in hemiplegia due to cerebral lesions, both contracture and exaggeration of spinal reflexes is liable to occur, in total transverse lesions of the spinal cord contracture never occurs, and the spinal reflexes are diminished or altogether abolished.⁶

¹ *Wien. klin. Wchnschr.*, 1893, Nos. 24–30.

² Legroux and de Brun, *loc. cit.*, and *Brain*, London, 1885, vol. viii. p. 554, classify the disorders of sensation met with in cerebral hemiplegia into five groups—(1) Sensation unaffected, the paralysis purely motor; (2) anæsthesia affects the whole side; (3) anæsthesia is absolute in one extreme segment of a limb, less in the middle segment, and still less in the other extreme segment (*e.g.* absolute in foot or thigh, less in leg, still less in thigh or foot); (4) external (lateral) half of a limb, normal sensation, mesial half anæsthetic; (5) anæsthesia is in patches, which may shift from day to day. They find that the anæsthesia, when it occurs, has no constant relation either of time or place to the motor paralysis, and are inclined to refer it to alterations in the cerebral circulation.

⁶ That this is the true explanation of many of these phenomena was first shown by Bastian (*Med.-Chir. Trans.*, London, 1890, p. 151). See further on this subject, Bruns, *Arch. f. Psychiat.*, Berlin, 1893, Bd. xxv. S. 759 (literature); and in *Neurol. Centralbl.*, Leipzig, 1897, S. 72.

DETAILED RESULTS OF STIMULATING THE MOTOR CORTEX IN ANIMALS.

The results which were obtained by Fritsch and Hitzig (Fig. 331) in the dog have already been alluded to. Their experiments showed that there are certain definite points or centres, mostly situated on the convolution bounding the crucial sulcus—stimulation of which constantly produces (a) movements of the head (contraction of neck-muscles); (b) of the opposite forearm, extension and adduction; and, at an adjacent point, flexion and rotation (? supination); (c) of the opposite hind-leg; (d) of the facial muscles and eyes. They also obtained from intermediate but less circumscribed points contractions of the muscles of the back, tail and abdomen.

FIG. 331.—Diagram showing the chief results obtained by Fritsch and Hitzig (in 1870), on stimulation of the cerebral cortex of the dog. (a) Contraction of neck muscles; (b) of arm muscles; (c) of leg muscles; (d) of facial muscles and eye movements.

Many other physiologists¹ have confirmed and extended the observations of Fritsch and Hitzig upon the dog. Ferrier was one of the first, and his results, which were obtained by an improved method, that of faradic excitation (whereas Fritsch and Hitzig employed for the most part the galvanic current), were on the whole confirmatory of those of the two German observers, which they materially extended. They are embodied in the accompanying diagram, to the explanation of which the reader is referred. Ferrier obtained similar results in the jackal, and with slight modifications in the cat (Fig. 333). In rodents (rabbit, guinea-pig, rat), in which the hemispheres are smooth, stimulation of certain points of the external surface, in front of and above the fissure of Sylvius, gave the results which are shown in Fig. 334, and very similar results have

been arrived at for insectivora,² for marsupials,³ and for monotremes.⁴ In birds only a single limited region at the vertex of the hemisphere was found by Ferrier to be responsive to excitation, and this caused contraction of the opposite pupil, occasionally associated with turning of the head to the opposite side.⁵ In the frog⁶ and fish,⁷

excitation of the hemisphere produces contraction of muscles of the opposite side of the body, but the parts are too small to determine any exact localisation.

Of great practical value and interest were the observations which were made by Ferrier upon the brain of the monkey, in which the chief features of the conformation of the cerebral surface are so closely similar to those of the human brain, that it is possible to draw conclusions as to localisation of function in man, such as cannot well be done from experiments upon carnivora. The advantage of the

FIG. 332.—Diagram showing the results obtained by Ferrier on stimulation of the cerebral cortex of the dog. A, Sylvian fissure; B, crucial sulcus; with sigmoid gyrus curving round it; O, olfactory lobe; I, II, III, IV, first, second, third, and fourth external gyri;¹ of these the first is continued anteriorly into the sigmoid (see Fig. 331); the second, third, and fourth blend in front to form the anterior composite gyrus.² 1, Opposite hind-limb advanced; 3, tail moved laterally; 4, retraction and adduction of opposite fore-limb; 5, protraction of opposite fore-limb with elevation of shoulder; X, between 4 and 5, flexion of paw; 7, closure of opposite eye and movement of eyeballs; 8, retraction and elevation of opposite angle of mouth; 9, opening of mouth and movements of tongue (sometimes accompanied by barking); 11, retraction of angle of mouth on both sides, and ear drawn forwards; 11' (same as 7), closure of opposite eye; 12, eyes open, pupils dilate, eyes and head move to opposite side; 13, eyes (and head) move to opposite side; 14, pricking, or sudden retraction, of opposite ear; 15, torsion of nostril on same side; 16, elevation of upper lip and dilatation of nostrils.

selection of monkeys as the subjects of experiment upon the brain, was immediately made evident by the precise results which were obtained as the result of stimulation of the cortex, and by the far-reaching effect which such experiments have had upon the diagnosis and surgical treatment of brain affections in man. The results obtained by Ferrier from stimulation of the Rolandic area of the monkey's brain are shown in Fig. 335. Ferrier's main results have been confirmed by many observers,³

¹ This is Ferrier's nomenclature; by Leuret and Gratiolet the enumeration was taken from below up.

² Langley, *Journ. Physiol.*, Cambridge and London, vol. iv. p. 248. In this paper will be found a full account of the fissures and convolutions of the dog's brain, and of the nomenclature which has been adopted by various authors.

³ E.g., H. Munk, various papers in *Verhandl. d. physiol. Gesellsch. zu Berlin, Arch. f. Physiol.*, Leipzig, collected in *Ges. Abhandl.*, 1890; also in *Ber. d. k. Akad. d. Wissensch. zu Berlin*; Horsley and Schäfer, *Proc. Roy. Soc. London*, 1884; *Phil. Trans.*, London, 1888, B; and *Festschr. z. Carl Ludwig*, 1887; Beavor and Hersley, *Phil. and indeed are so easily obtained that it is almost impossible to fail in eliciting the response which he marked out as connected with certain

areas of the Rolandic region. Apart from points of detail, the chief addition to our knowledge of the movements which he found to be provoked on stimulation of the cortex of this region, was the discovery that the excitable area extends to the mesial face of the hemisphere, to include the so-called marginal gyrus. Ferrier himself failed to obtain any definite response from this, but it was subsequently shown¹ to contain extensions of the adjacent excitable areas of the external face of the hemisphere, including an important part

FIG. 333.—Diagram showing the results obtained by Ferrier from stimulation of the cerebral cortex of the cat. The numbers and letters have a similar meaning to those in the last figure, but all are not included, owing to the fact it was not found possible to differentiate so many distinct actions as in the dog. At the point marked *a*, there was produced a clutching action of the paw with protrusion of the claws.

of the areas for the trunk and lower limb (Fig. 336, *B*). Ferrier also found that removal of the portion of the cortex which on excitation

produces movements of a particular part or limb, is immediately followed, unless the movement is of a bilateral character, by paralysis of that part or limb: this had already been noted by Fritsch and Hitzig in the dog. But in the monkey the paralysis is, as a rule, much more marked and permanent, and in the case especially of the upper limb may proceed, as in monoplegia in man, to the development of a condition of contracture of the muscles and permanent immobility of the limb (see p. 731). In the leg, contracture does not as a rule occur, but after a time movements begin to reappear, until eventually it is difficult to determine that any motor

paralysis exists; the same may also be the case with the arm. If, however, the whole portion of the Rolandic region which is connected with the particular limb has been removed or destroyed, unilateral movements of a truly voluntary nature do not reappear; the movements

FIG. 334.—Diagram showing the results obtained by Ferrier on stimulation of the brain of the rabbit. O, Olfactory lobe; X, shallow sulcus running parallel with median longitudinal fissure. 1, Advance of opposite hind-limb; 4, retraction and adduction of opposite fore-limb; 5, protraction of opposite fore-limb and elevation of shoulder; 7, retraction and elevation of angle of mouth (obtained over a large area); 8, closure of opposite eye; 9, on orbital aspect—opening of mouth with movements of tongue; 13, protrusion of opposite eyeball, and occasionally turning of head to opposite side; 14, sudden retraction and elevation or pricking of opposite ear; 15, torsion or closure of one or both nostrils (often associated with movement of ear).

¹ Horsley and Schäfer, *Proc. Roy. Soc. London*, 1884, vol. xxxvi. p. 437.

which are eventually manifested are those which are "associated" with the movements of the side of the body opposite to that which is paralysed, and appear to be brought about by the action of the other side of the brain acting through commissural fibres in the lower level centres.¹ The more delicate movements of the fingers and toes, which are never thus associated on the two sides, never reappear.

It is especially after removal of the leg area of the cortex that the associated movements become so completely restored, that, on superficial observation, it is almost impossible after a few weeks to detect any motor paralysis. But if the animal be held by the upper part of the body and swung gently forward towards the wire-work of a cage, or lowered rapidly towards the ground, the leg on the same side as the lesion will be put forward or downward to catch hold of the cage or touch the ground, but never the leg on the opposite side, however long the animal may have been kept after the lesion. This is, in fact, a true voluntary movement, and it is not recovered, while all the associated movements which are used in ordinary progression have resumed to all appearance their normal characters.

In the same way it was shown by Hitzig that a dog from which the left sigmoid gyrus had been removed would, if suspended in the air by a cloth round its body, its legs being left free, immediately withdraw the left limbs, on a needle being brought near them as if for the purpose of pricking them; but although, on approaching the right limbs with the needle, the animal showed signs of apprehension, these limbs were never moved away by themselves, nor except as a general movement and in association with those of the opposite side.

The areas, excitation of which on one side of the brain produces in the monkey movements involving muscles on both sides of the body, are—(1) The area for movements of the head and eyes; (2) the area concerned with movements of the tongue and cheeks, and movements of mastication and swallowing; (3) the larynx area; (4) the area

FIG. 335.—Diagram showing the results obtained by Ferrier from electrical excitation of the cerebral cortex of the monkey. 1, The opposite hind-limb is advanced as in walking. 2, Flexion with outward rotation of the thigh, rotation inwards of the leg, flexion of the toes. 3, Movements similar to 1 and 2, and in some cases also the tail is moved. 4, The opposite arm is adducted, extended, or retracted, the hand pronated. 5, Extension forwards of opposite arm. *a, b, c, d*, Flexion of the fingers and clenching of the fist. 6, Flexion and supination of forearm. 7, Retraction and elevation of the angle of the mouth. 8, Elevation of the ala of the nose and upper lip. 9 and 10, Opening of the mouth with protrusion of tongue at 9, and retraction at 10. 11, Retraction of the angle of the mouth. The action is that of the *platysma myoides*. 12, The eyes open widely, the pupils dilate, and head and eyes turn to the opposite side. 13, 13', The eyes move to the opposite side with an upward or downward deviation, according as the electrodes are on 13 or 13' respectively; normally also the pupils become contracted. 14, 14', Pricking of the opposite ear, head and eyes turn to the opposite side, pupils dilate widely. 15 (not shown in diagram), on the hippocampal gyrus (anterior and inner aspect), torsion of the lip and semiclosure of nostril of same side.

¹ Broadbent, *Brit. and For. Med.-Chir. Rev.*, London, 1866, p. 477.

concerned with closure of the eyelids. On the other hand, stimulation of the leg area, of the arm area, of the trunk area, and of most of the upper part of the face area, produces movements which are generally strictly confined to the muscles of the opposite side of the body. But in the dog and rabbit, according to Exner and Paneth,¹ excitation of the whole of the cortical field of the facial produces

bilateral effects. And in the dog, according to v. Bechterew,² excitation of the centre for the platysma myoides, and of the centre for lateral flexion of the trunk, produces contraction chiefly of the muscles of the same side of the body instead of those of the opposite side.

Details of the representation of muscular movements within the principal portions of the motor or Rolandic region of the monkey.—It is convenient for purposes of description to distinguish five areas of the motor cortex (Fig. 336), as follows—(1) The area connected with movements of the head and eyes; (2) the area connected with movements of the face, including those of the mouth, throat, and larynx; (3) the area connected with movements of the upper limb; (4) the

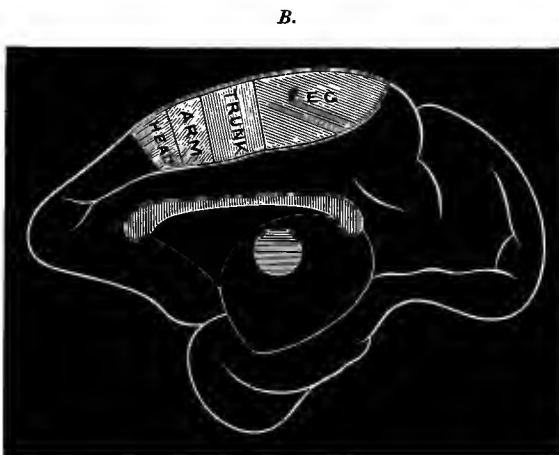

FIG. 336.—Diagrams of the motor zone of the monkey's brain, showing the five areas into which it is divisible. *A*, lateral or external surface; *B*, mesial surface.

area connected with movements of the trunk muscles, including those of the tail; and (5) the area connected with movements of the lower limb. These areas are not marked off from one another by fissures or other anatomical boundaries, nevertheless their limits, as determined by the excitation method, are sharp, and although, on exciting exactly at the boundary between any two areas, movements of both parts may result,

¹ *Arch. f. d. ges. Physiol.*, Bonn, 1887, Bd. xli. S. 349.

² *Neurol. Centralbl.*, Leipzig, 1888, S. 15.

a very slight shifting of the electrodes to one or other side of the boundary will cause the movement to be limited to one part only, provided the excitation be of minimal intensity. If, however, the stimulus be strong or be too prolonged, a spread of effect is at once produced.

Within the limits of the several areas above enumerated, varieties of movement are obtained which indicate a still further differentiation, or in other words an intra-areal localisation.¹ It is obvious that these intra-areal localisations are likely to be most marked within the larger areas, and we should further expect the best differentiation in connection with those parts which are concerned with the more complex and precise movements directed by the will. These in the monkey are chiefly the movements of the upper limb, and especially the hand, and movements concerned with facial expression. Further, it is found that for many movements, if not for all, there is in each case a sort of focal point within the area, from which on the average of a large number of experiments the movement is more readily or more frequently obtained than elsewhere. This

is illustrated in the accompanying diagram from Beevor and Horsley, in which each dot represents an instance in which a movement of the hallux was primarily obtained in a large number of experiments, and in which therefore the point about which the greatest number of dots are accumulated has been termed the

FIG. 337.—Diagram from Beevor and Horsley, showing by relative shading the effect, in a number of individuals of *Macacus sinicus*, of stimulation within the area where movements of the opposite hallux are elicited.

focal point for that movement. It is possible that its focal point does actually represent an absolutely localised centre of representation of each movement, but the fact that the movement is in many instances also got with extreme readiness in a circumjacent area of greater or less size, and that in many individuals it may be produced even more readily from other parts of such circumjacent area than the average focal point, seems to point to the conclusion, which is that usually accepted, that localisation of particular movements is rather connected with small areas of cortex than with mere points on the cerebral surface; in a few cases only do these areas seem to be so extremely limited in size as to merit being spoken of as points. It is further rare to find that the movement which is provoked is simple and uncomplicated by other movements, although occasionally this is so. Thus it is often possible by stimulation at the upper end of the Rolandic fissure to obtain a simple flexion or extension of the hallux, or by stimulation of the middle of the ascending parietal convolution to obtain simple flexion of the fingers, or at a little lower level simple opposition of

¹ The intra-areal localisations have been largely worked out by Beevor and Horsley, *Phil. Trans.*, London, 1887 and 1888, B.

the thumb. Much more commonly, however, the movements provoked are complicated by others. Thus in some individuals even minimal stimulation of what has been termed the hallux centre produces movements, not only of the hallux but also of other toes, and even of the foot and leg; and stimulation of the middle of the ascending parietal may cause not only flexion of the fingers but also extension of the wrist. Such movements may succeed one another, or they may be simultaneous. It has been usual to speak of the movement which is most often or most readily obtained on excitation of a particular localised area, as the "primary" movement, and the others as "secondary."

Undoubtedly the most striking character of many of the movements which are provoked by cerebral excitation is their co-ordinated and purposeful nature. In conformity with this, we find that they are rarely produced by contractions of a single muscle or group of muscles, but it is frequent for a succession of movements to occur, and these are very closely imitative of natural voluntary movements of the animal. Thus the successive movements involved in prehension are very easily called into play by excitation of certain portions of the arm area, and a series of complicated masticatory movements by excitation of the lower part of the face area.¹ But if the excitation is only momentary, it is sometimes possible, as already mentioned, to obtain the contraction of only a single muscle, such as the *opponens pollicis*; nevertheless the movement produced in this case may be perhaps regarded as purposeful. On the other hand, it must be admitted that it is frequently difficult to recognise any purpose or any approach to the natural actions of the animal in some of the movements and combinations of movements which are provoked by artificial excitation of the cortex; but this is more especially the case when the cerebral surface is in an abnormally excitable condition, in which case the effect of the excitation appears to spread to areas which are not naturally involved.

These general remarks may serve as preface to the following details of the results obtained by stimulation and localised lesion respectively, within the limits of the motor sphere of the cortex, as previously defined. The results obtained by stimulation are shown in Figs. 337 and 338.

1. **The area connected with movements of the head and eyes and of the ear.**—This area lies in front of a line which runs from below upwards, either coincident with or parallel to and just behind the lower limb of the precentral sulcus, at the top of which it turns sharply forward to reach the mesial surface of the hemisphere. It is bounded anteriorly by a line which runs nearly vertically through the anterior end of the precentral sulcus. It extends over on to the mesial aspect of the first frontal gyrus (marginal convolution). The part of the frontal lobe in front of this line (prefrontal region) is inexcitable,² and the area itself is

¹ Fürstner (*Arch. f. Psychiat.*, Berlin, Bd. vi. S. 719) notes that in the rabbit chewing movements are especially easy to obtain over a relatively large surface, and Ferrier showed that in monkeys a protraction, followed by retraction of the arm and leg, as in climbing, is very readily got over an extensive area. From this it would appear that the voluntary movements which are most habitually performed are usually those which are most easily obtained on artificial excitation.

² Ferrier is of opinion that the inexcitable prefrontal region is nevertheless a part of the same centre as the excitable post-frontal area, for he finds that after a lesion of the prefrontal area alone there occurs descending degeneration in the mesial bundles of the

most excitable in its middle and posterior part, and becomes less excitable as it is traced towards the prefrontal region. Its action is bilateral, excitation producing a movement of the head and both eyes towards the opposite side (conjugate lateral deviation), which may be simple or may be combined with an upward or downward inclination. Although the head and eye movements are usually obtained together, it sometimes happens that only the eyes are moved, and in other cases only the head as a whole; the latter appears to be especially the case if the part of the area which is close to the longitudinal fissure or the adjacent portion of the gyrus marginalis is stimulated.

The area in question has been the subject of special investigation by Mott, in conjunction with the writer. In our experiments¹ we found that in the monkeys which have generally been used for stimulation experiments (*Macacus rhesus* and *Macacus sinicus*), it was difficult to obtain any definite results other than the simple lateral conjugate deviation of the head and eyes to the opposite side, together with opening of the eyes and dilatation of the pupil, which had already been described by Ferrier and others.² But by using a large species of *Cercopithecus*, in which this portion of the brain appears to be better displayed than in the macaque, we were able to show that excitation of the upper part of the area usually leads to downward as well as lateral deviation of eyes and head, of the lower part of the area to upward as well as lateral deviation; whereas excitation of a middle, narrow, wedge-shaped portion produces simple lateral deviation: sometimes the downward and upward results were almost unmingled with any lateral deviation (Fig. 337). The greatest effect for all the movements was obtained close to the angle of the precentral sulcus, which may therefore be regarded as the focus of the area. Stimulation of the posterior margin of the area, especially near the focal point, usually also elicits a sharp movement (either pricking or retraction) of the opposite ear or of both ears. The pricking or forward movement is especially caused by stimulation towards the upper part of this margin; retraction of the ear, by stimulation towards the lower part.

Risien Russell³ endeavoured by a special method to differentiate the points on this area in the bonnet monkey, by stimulation after previous division of the lateral recti. He obtained in this way simple upward and downward movements of both eyes, from points situated close together and near the focus of the area; and by employing the same method in the dog and cat, in which animals stimulation of the head and eyes area only produces normally a simple lateral deviation, he was also able to elicit both an upward movement and a simple downward movement.

Inhibition effects.—Sherrington has shown⁴ that if in the monkey the third and fourth cranial nerves have been severed upon one side, say the left, so that the rectus externus remains the only unparalysed ocular muscle,

internal capsule and crista, although not extending down to the pyramids of the medulla oblongata; and he interprets this to mean that the fibres from the prefrontal region pass to the nuclei of the motor nerves governing the eye movements. But if this were the case the prefrontal region should not be inexcitable.

² Ferrier, *Proc. Roy. Soc. London*, 1876; Horsley and Schäfer, *Festschr. f. C. Ludwig*, Leipzig, 1887; and *Phil. Trans.*, London, 1888, B; Horsley and Beevor, *ibid.*

³ *Journ. Physiol.*, Cambridge and London, 1894, vol. xvii. pp. 1 and 378.

⁴ *Proc. Roy. Soc. London*, 1893, vol. liii. pp. 411-420; *Journ. Physiol.*, Cambridge and London, 1894, vol. xvii. p. 27.

excitation of the frontal (and of the occipital) cortex produces conjugate movements of *both* eyes towards the opposite side, *i.e.* from left towards right. Similarly by an appropriate experiment, the internal rectus can also be inhibited after section of the sixth nerve, so as to produce an outward movement of the globe. Inhibition of the tonus of the antagonistically acting eye muscles can thus be elicited from the cortex. The same may occur volitionally. The action does not take place necessarily through the opposite cortex, for it will occur if the area on the opposite side be removed, nor does it occur through the occipital area when the frontal is stimulated. And *vice versá*, on stimulation of the occipital area it does not occur through the frontal area, for these two areas can be severed from one another by a vertical incision through the brain, and the inhibition is still found to take place. The action is therefore directly on the lower centres. This is known also to be the case with the contraction effects,¹ so that it would appear that the inhibitory phenomena follow the same paths as the excitatory.

Equal and simultaneous excitation of two similar points in the focal part of this frontal area in both hemispheres produces visual fixation, with the eyes either in the primary position or slightly convergent. If the electrodes are placed on the upper part of the area, the movement may be simply downwards; if on the lower part, simply upwards.² A similar convergence is got, even if both right and left third and fourth nerves are previously divided.³ This effect must be due to inhibition of the tonus of both external rectus muscles.

In rare instances stimulation of the area on one side causes movements of the head and eyes to the *same* side, even if none of the nerves are severed. This may be due to the stimulus to inhibition being, under the immediate conditions of the experiment, more effectual than that to contraction.

Removal of the area on one side of the brain causes the head and eyes to be turned towards the side of the lesion, due doubtless to muscular paralysis. The effect passes off after a day or two, a statement which also applies to other bilateral movements. Nor is there any obvious permanent paralysis, even on removing the area on both sides. This is not to be wondered at, considering that movements of the head and eyes are elicited from other considerable areas of the cortex (occipital, temporal).⁴

2. **The area connected with movements of the face, mouth, throat, and larynx.**—This area embraces rather less than the lower half of the two central convolutions (Fig. 336). It is bounded above by a line joining the angle of the precentral sulcus with the lower end of the intraparietal sulcus, and extends below to the Sylvian fissure.⁵

¹ Schäfer, *Brain*, London, 1888, vol. xi.; Mott and Schäfer, *ibid.*, vol. xiii. p. 169.

² In *Cercopithecus*, Mott and Schäfer, *loc. cit.*, p. 170.

³ Sherrington, *loc. cit.*

⁴ Extirpation in the dog of the centre for movements of the ocular muscles (7 in Fig. 332), also does not appear to have any permanent effect upon those movements. See Eckhard, *Centralbl. f. Physiol.*, Leipzig u. Wien, 1898, No. 1; R. du Bois-Raymond and P. Silex, *Arch. f. Physiol.*, Leipzig, 1899, S. 174. This last paper also contains an account of observations on the effects of excitation of the centre in the dog (see also on this subject, v. Bechterew, *Arch. f. Physiol.*, Leipzig, 1899, S. 500). The extensive paralytic phenomena described by Groszbeck as resulting from ablation of the frontal lobes (*Arch. f. Physiol.*, Leipzig, 1895, S. 98), are probably due to an implication of other regions in the lesion.

⁵ Beevor and Horsley described (*Phil. Trans.*, London, 1887, B, Plate vii., Figs. 7 and 8) primary movements of the thumb over the upper two-thirds of this area, but there must have been some unrecognised source of error in this observation.

A considerable amount of differentiation is obtained within the area, as was observed already by Ferrier in his first experiments. Thus he got, on stimulation of the upper part of the area over the ascending frontal gyrus, retraction and elevation of the opposite angle of the mouth, due to the action of the zygomatic muscles, and from a part

FIG. 338.—Diagrams of the lateral and mesial surfaces of the monkey's brain, showing the effects obtained from stimulation of the excitable areas.

just below this, elevation of the opposite ala of the nose and upper lip associated with depression of the lower lip. These movements when performed bilaterally produce a snarl, fully exposing the canine teeth; an expression very characteristic and frequent in monkeys when alarmed. Excitation of the part of the ascending parietal gyrus on a level with the two regions just described, produced "retraction of the angle of the mouth. The action is that of the platysma myoides, and

when this is strong the head is drawn slightly to the side."¹ This muscle is also called into action in expressing sudden terror.

Stimulation below the centres above described produced, in Ferrier's experiments, opening of the mouth with protrusion and retraction of the tongue, the protrusion being obtained more anteriorly, the retraction more posteriorly. The movements were bilateral, and occasionally repeated even some time after the electrodes were withdrawn.

Subsequent observers have for the most part corroborated these statements of Ferrier, and have added the following facts:—(1) Stimulation of the upper part of the area, close to its upper boundary, produces, besides the movement of the opposite angle of the mouth, also closure of both eyes,² but especially the opposite one.³ (2) Movement of the tongue may be obtained even from the upper part of the area (thus showing a very extensive representation of this organ); here it takes the form of protrusion towards the opposite side, and may be combined with bilateral movements of the cheeks,⁴ whereas, over the lower part of the face area, retraction of the tongue is more common. In producing the lateral movements of the tongue, the same muscles on the two sides are not called into play; so that, although there is bilateral contraction it is not symmetrical. The cheek movements are more generally and easily obtained over the lower part of the area, and especially over the posterior part of the lower end of the ascending frontal, and over the lower end of the ascending parietal gyrus. They are there combined with rhythmic masticatory movements of the lower jaw and tongue, and with movements of the throat such as are made in deglutition. (3) Stimulation of the anterior part of the lower end of the ascending frontal convolution produces strong adduction of both vocal cords,⁵ but abduction of the cords is not obtainable from cortical stimulation in the monkey, although it can be obtained in the cat and dog.⁶

Destruction or removal of the facial area⁷ produces paralysis of

⁴ Horsley and Schäfer, *loc. cit.* Beevor and Horsley, *loc. cit.*, also obtained a peculiar rolling movement of the tongue, with the dorsum turned to the opposite cheek.

⁵ Semon and Horsley, *Brit. Med. Journ.*, London, 1889, vol. ii. p. 1383; and *Phil. Trans.*, London, 1890, B, p. 187.

⁶ Risien Russell, *Proc. Roy. Soc. London*, 1895, vol. lvii. p. 237; cf. also J. Brockert, *Flandre méd.*, tome xi. p. 769; and Klemperer, *Arch. f. Laryngol. u. Rhinol.*, Berlin, 1894, vol. ii. S. 329. Adduction of the vocal cords from cortical excitation was first obtained in the dog by H. Krause, on stimulation of the base of the precrucial gyrus, where this is connected with the anterior composite gyrus (*Arch. f. Physiol.*, Leipzig, 1884). Bilateral removal of the part in question was found by H. Krause to produce marked alteration in or even abolition of the bark, growling or whining sounds only being produced. This confirms the prior observations of Soltmann (*Jahrb. f. Kinderh.*, Leipzig, 1875, Bd. ix. S. 106). Masini ("Sui centri motori cort. d. larynge," Napoli, 1888) got unilateral effects from stimulation and ablation of Krause's centre, but his results have not been confirmed by others. Ferrier occasionally found that in the dog stimulation at the point marked 9 in Fig. 332 produced a loud bark, *West Riding Lun. Asyl. Rep.*, London, 1873. Duret, *Compt. rend. Soc. de biol.*, Paris, 1877, and "Études expér., etc.," Paris, 1878, found loss of the bark to result from bilateral extirpation of the region 9 of Ferrier (see Fig. 332), while mechanical excitation by pressure upon this region caused a succession of barks. In connection with this, it is interesting to note that the bark of the dog has been acquired as the result of domestication, and may be said to answer in a measure to "speech" in man.

⁷ Everett Flood, *Brit. Med. Journ.*, London, 1894, vol. ii. p. 189.

those muscles of the opposite side which act unilaterally on stimulation, but not of the bilaterally acting muscles. The opposite cheek-pouch is paralysed and fills with food, but is occasionally emptied by pressure by the hand. Eventually the paralysis is recovered from, and it is emptied by its own muscular wall. If a second lesion is now established upon the intact side of the brain, this first cheek-pouch does not show renewed paralysis.¹ With a bilateral lesion there is marked difficulty in swallowing and mastication, but the voice is not lost. The actions of the muscles are ultimately recovered. This may be due to parts of the grey matter in the depth of the fissures within the area having been left, or it may be that the recovered movements are reflex, and not truly volitional.

3. The area connected with movements of the upper limb.— This is an extensive area (Fig. 336) occupying the upper half of the central gyri (except their uppermost ends), and extending forwards in the first frontal gyrus, to the edge of the hemisphere, where it reaches the marginal part of that gyrus (Fig. 338). It is bounded in front by the area for the head and eyes, below by the facial area, behind by the intraparietal sulcus, and above by an imaginary line separating it from the leg area at about the level of a small horizontal sulcus, which is very constant in the monkey's brain. Various complex movements of the arm and hand were described by Ferrier by stimulation within this area (Fig. 335). From the upper part, extending over both central gyri, the opposite hand was struck backwards, the arm being adducted, extended, and retracted, and the hand pronated. Further forwards (base of first frontal gyrus), extension forwards of the arm from the shoulder, as if trying to reach or touch something in front. Along the ascending parietal gyrus, clenching of the fist, beginning with the thumb and index finger, associated with action of the wrist. On the ascending frontal gyrus, in front of this, flexion and supination of the forearm.

The retraction of the limb described by Ferrier is most readily got from the ascending parietal near the upper limit of the arm area. From the corresponding part of the ascending frontal it is more usual to obtain, as a primary movement, a forward movement of the whole arm with raising of the shoulder, and this and other movements of the shoulder, combined secondarily with movements of the more peripheral parts of the arm, and especially with extension of the elbow, is found over the whole of the upper and anterior part of the area, merging in front into combined movements of the head and shoulder. This upper and anterior part of the arm area is therefore primarily concerned with shoulder movements, although, secondarily, other parts of the upper limb may be set in action by its stimulation. Below the shoulder region is a part of the area, occupying the expanded part of the ascending frontal gyrus just above the level of the angle of the precentral sulcus, which, as Ferrier showed (Fig. 335, 6), gives on stimulation a marked flexion of the arm at the elbow, combined with supination (biceps action). This is often combined as a secondary action with extension at the wrist and flexion of the fingers and thumb.

The primary effects obtained from stimulation of the ascending parietal in the lower two-thirds of its extent within the arm area are, as Ferrier stated, movements of the fingers and thumb. These, how-

¹ E. Flood, *loc. cit.*

ever, are not confined to the ascending parietal, but extend to the corresponding margin of the ascending frontal, where indeed they may be alone represented. The thumb movements are most marked near the lowermost limit of the area, where, with a very weak excitation, a simple movement of the thumb, or one combined with that of the index finger (opposition), may readily be obtained.¹

4. The area connected with movements of the lower limb.—This (Figs. 336, 338) occupies the upper end of the ascending frontal and ascending parietal gyri (including the parietal lobule) above the arm area,² and the corresponding parts of the marginal convolution.³ Immediately in front of it is the area connected with movements of the trunk and tail, which in fact merges gradually into it. Stimulation over the posterior part of the area, namely, the upper end of the ascending parietal gyrus and the parietal lobule, and the adjacent part of the marginal gyrus, produces primarily movements of the opposite toes, which may or may not be associated with that of other parts of the limb. The movements of the hallux are especially represented close to the Rolandic sulcus at the upper end of the ascending frontal gyrus.⁴ It will be seen, therefore, that a large part of the leg area of the monkey is mainly connected with toe-movements, which indeed, as Ferrier found, are also readily, although not as a primary effect, elicited by stimulation even of the most anterior part of the area.

The movements of the ankle, knee, and hip are by no means sharply differentiated from one another in the leg area, being generally obtained in association, as indeed is the case in most voluntary movements of the limb. But it will be found that, on the whole, the representation of movements of toes, ankle, knee, and hip is from behind forwards; hip movements being most readily obtained from the front of the area, toe-movements from the back, and knee- and ankle-movements from the middle part, the hip-movements being frequently combined with movements of the tail and of the pelvis. The analysis by stimulation of the leg centre by Beavor and Horsley⁵ gave uncertain results as to the focal points for the representation of these movements. They found that in by far the majority of cases the primary movement produced was that of flexion of all three joints, such, it may be added, as occurs when the limb is advanced in climbing. It is often followed, as in that action, by general extension. Extension of the hip, produced by contraction of the gluteal muscles, is more frequently got as a primary movement from excitation of the marginal gyrus near the anterior limit of the leg area, and flexion of the knee produced by contraction of the hamstrings a little behind this.⁶ Extirpation of the leg area is followed by, at first, complete paralysis of the limb, which hangs down limp in climbing, is dragged behind in walking, and in sitting is thrust passively forward. In the course of a week or two, however, the condition begins to show

¹ Horsley and Schäfer in *Festschrift f. C. Ludwig*, Leipzig, 1887, S. 286; Beavor and Horsley, *Phil. Trans.*, London, 1888, B, p. 232.

² Ferrier, *Proc. Roy. Soc. London*, 1875, vol. xxiii.

³ Horsley and Schäfer, *ibid.*, 1884, vol. xxxvi. p. 437.

⁴ Beavor and Horsley, *Phil. Trans.*, London, 1888, B. Both flexion and extension may be excited from the same spot. Sherrington found (in the monkey) that when flexion of the hallux was obtained, if the nerve passing to the flexors was cut, excitation at the same part of the cortex now produced extension.

⁵ *Phil. Trans.*, London, 1888, B.

⁶ Horsley and Schäfer, *Festschrift f. C. Ludwig*, Leipzig, 1887, S. 278; and *Phil. Trans.*, London, 1888, B, p. 10.

improvement, and movements return, so that after a few weeks the animal climbs and runs about apparently as usual. Probably, however, the movements are now "associated" with those of the opposite side, and not truly voluntary; for if such an animal, apparently completely recovered, be held by the upper part of the body and lowered suddenly to the ground, or swung towards a cage, the leg which was paralysed is never put down to meet the ground or forwards to catch hold of the cage, a movement which is always made by an unparalysed leg. Sherrington¹ has shown that in the monkey stimulation of a point in the posterior part of the lobus paracentralis, on the mesial surface, causes contraction of the sphincter ani.

5. The area for movements of the trunk and tail.—This is a comparatively small area, lying chiefly on the marginal convolution (Fig. 338)² in front of the leg area, but coming to the external surface (Fig. 336) and extending over a small portion of the superior frontal gyrus³ as far as the limit of the arm area, which here bounds it laterally and anteriorly.⁴

Its excitation is followed by a bending of the tail to the opposite side, combined with a bending of the trunk or a rotation of the pelvis. The area is too small to give any well-marked differentiation on analysis by stimulation, but, on the whole, it is noticeable that the posterior part is especially connected with the movements of the lower part of the trunk and pelvis, associated with hip and leg movements; the anterior part with movements of the upper part of the vertebral column, associated with shoulder and arm movements. The trunk movements are occasionally bilateral, the tail or vertebral column being extended. Extirpation of the trunk area on one side produces, unless the lesion involve the adjacent areas (which it is somewhat difficult to avoid), very little obvious effect. If, however, it be removed on both sides simultaneously, there is for a time complete inability to sit erect, power over the trunk muscles being entirely lost.⁵

The motor centres in the anthropoid apes.—These have only been determined in a single case (orang-utan),⁶ and by the method of faradic excitation, but since the configuration of the brain in the anthropoids approaches still more closely to that of man than does that of the monkey, the evidence afforded is of great value and interest. It

³ Ferrier, *ibid.*, 1875; Horsley and Schäfer, *Phil. Trans.*, London, 1888, B, p. 9.

⁴ On the centres for the trunk muscles in dogs, see Unverricht and Kusick, *Ges. Abhandl. d. med. Klin. zu Dorpat*, Wiesbaden, 1893; and H. Werner, *Allg. Ztschr. f. Psychiat.*, etc., Berlin, 1895, Bd. lli. S. 134. These authors failed to confirm Munk's statement, that the centre for the trunk muscles is in the frontal lobes. They find that it lies between the centres for the muscles of the fore- and hind-limbs, and that its excitation provokes movements of the trunk muscles of the same side. Rothmann (*Neurol. Centralbl.*, Leipzig, 1896, S. 1105) states, however, that the trunk movements described by those authors are really passive, and are due to contractions of hip and shoulder muscles of the opposite side. Rothmann, who examined the brains of four dogs from which Munk had removed the prefrontal lobe of one side, was unable to find any descending degeneration in the pyramidal tract either at or below the medulla oblongata. It is therefore highly improbable that the centre for the trunk muscles is in this part of the dog's brain, as taught by Munk.

⁵ Horsley and Schäfer, *Phil. Trans.*, London, 1888, B, p. 13. This condition was not recovered from in the animals we operated on, but they were not kept under observation for more than three or four weeks.

⁶ Beever and Horsley, *Phil. Trans.*, London, 1890, B, p. 129.

was noticed by Beevor and Horsley—(1) That instead of the excitable sphere of the cortex being continuous, as in the monkey, it is, in the orang, interrupted here and there by spaces from which no effect could be obtained even by strong excitations; (2) that the amount of cortex which is excitable is relatively smaller in the orang than in the monkey. Thus the first frontal gyrus was found to be inexcitable, and most of the upper part of the ascending parietal. Indeed, with the exception of an

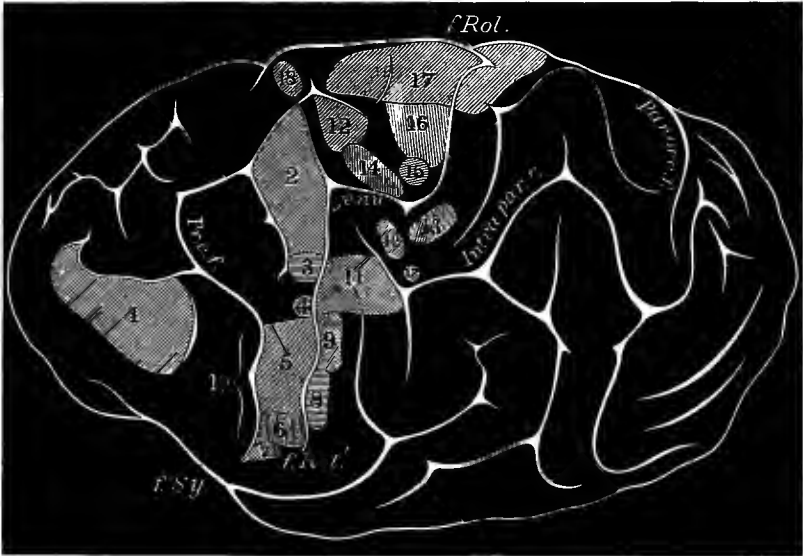

FIG. 339.—*f. Rol.*, *f. Rol.*', fissure of Rolando, with well-marked *genu*; *Pr. c. f.*, precentral fissure; *f. Sy.*, fissure of Sylvius; *Intra par. f.*, intraparietal fissure; *Par. occ. f.*, external parieto-occipital fissure. 1, Both eyes move conjugately to opposite side; 2, Eyes open, eyes and head to opposite side; 3, Closure of eyelids, those of opposite side most; 4, Eversion of lower lip on opposite side; 5, Retraction of opposite angle of mouth; 6, Rolling in of both lips, also opening of the mouth—this latter movement is obtained a little further back than the former; 7, Pursing of both lips; 8, Pouting of both lips; 9, Elevation of upper lip on opposite side; 10, Movements of the tongue—these occurred over almost all the facial area; 11, Twitching of orbicularis oris of opposite side; 12, Movements of the thumb, generally extension—it will be noticed that these were got at three several spots isolated from one another; 13, Extension of index finger; 14, Extension of all the fingers, with pronation or ulnar adduction of wrist; 15, Flexion of elbow; 16, Adduction of shoulder; 17, Area for movements of lower limb. Movements of hallux, small toes, ankle, knee, and hip all occur at various points in this area (which extends over to the mesial surface), but movements of the hip and knee were not got quite as high as movements of the toes and ankle, and, on the other hand, their area of representation extended a little lower; 18, An outlying spot where extension of toes was obtained.

area for eye-movements in front of the precentral sulcus, almost the only parts of the fronto-parietal lobe found to be excitable were the ascending frontal gyrus, the lower two-thirds of the ascending parietal gyrus, and the marginal gyrus opposite the upper end of the ascending frontal; (3) the tendency to provoke a sequence or march of movements from stimulation of one point only, which is so often met with in the monkey, is very much less marked in the orang. The

accompanying diagram (Fig. 339) gives the main results of Beever and Horsley's investigation.

The motor centres in man—Experimental evidence.—A few

A.

B.

FIG. 340.—Diagrams indicating the probable localisation of the chief motor and sensory areas of the cerebral cortex of man. A, lateral surface; B, mesial surface.

experimental observations have been made upon man, the cortex having been on several occasions stimulated over a limited area exposed for the

purpose of operation.¹ The results, as far as they go, conform with those made upon the monkey and orang.² Both in the orang and in man a much greater strength of current than that employed for lower animals is needed to provoke movements, a result which appears to indicate that they are caused by excitation, not of the superficial but of more deeply lying parts of the cortex, which is much thicker than in the monkey. The convolutions are also more excitable near their convexity than near the bounding fissures. Both in the orang and in man it is difficult to provoke epilepsy by electrical excitation; and it may be added, it is easier to produce this condition in the dog than in the monkey, and in the rabbit than in the dog. Thus the lower the animal in the scale of intelligence the more easy is it to provoke epilepsy, which is characterised by a condition of abnormal excitability of and spread of excitation over the whole cortex.

Clinical evidence.—Abundant confirmation is forthcoming regarding the situation of the motor areas in man, as the result of clinical observation. On this subject a very large number of cases have been collected and published by Charcot and Pitres,³ to whose book the reader is referred for the details and diagrams by which the cases are illustrated. They show that the motor zone in man includes only the convolutions adjacent to the fissure of Rolando, namely, the ascending frontal, the ascending parietal, the paracentral lobule, and the Rolandic operculum.⁴ Lesions of any of these gyri, even if quite small, always cause permanent paralysis in one or several muscular groups of the opposite side of the body, and are followed by degeneration in the pyramidal tract. The areas are disposed in the following order from above down (Fig. 340, *A* and *B*):—

That for the lower limb.—In the paracentral lobule and the upper fourth of the two central gyri. The area for the trunk muscles is closely associated with this one.

That for the upper limb.—In the middle part of the central gyri, extending from the leg area as far as the sharp downward bend of the fissure of Rolando.

That for conjugate movements of the eyes and head.—Occupying the ascending frontal gyrus just below the genu of the fissure of Rolando, and extending forwards into the base of the second and third frontal gyri.

That for the face, mouth, tongue, and throat.—In the lower third of the central gyri, and in the Rolandic operculum.

The motor area in man does not include Broca's convolution, *i.e.* the base of the third frontal gyrus, lesions of which, although productive of

¹ See the cases quoted by Mills, *Brain*, London, 1889; Beevor and Horsley, *Phil. Trans.*, London, 1890, B, pp. 152-156; and Ferrier, "Croonian Lectures," 1890, p. 34. Cf. also v. Bechterew, *Arch. f. Physiol.*, Leipzig, 1899, S. 543.

² Gotch (*Brit. Med. Journ.*, London, 1893, vol. i. p. 1102) got movements of the head (to the same side) on stimulating a point on the ascending frontal gyrus a little below the genu of the bend of the Rolandic fissure. This is also got here in the orang, but not in the macaque.

³ "Les centres moteurs corticaux chez l'homme," Paris, 1895.

⁴ Whether the head and eye movements are represented here only or in a more advanced portion also, as in the anthropoid, does not appear clear as the result of clinical observations; these movements are rarely if ever wholly lost in cases of cortical paralysis.

defects of speech, do not produce actual paralysis of the organs of speech (larynx, tongue, etc.).¹

THE SENSORY AREAS OF THE CEREBRAL CORTEX IN THE MONKEY AND MAN.

Besides the areas which have just been described, it is found that excitation of certain other regions of the surface of the hemisphere also produces definite movements. Thus, excitation of the superior temporal convolution of the monkey causes the animal to turn its head and eyes to the opposite side and to prick its ear,² and a similar movement of the head and eyes is provoked by stimulation of the posterior part of the hemisphere. Ferrier also obtained "torsion of the lip and semiclosure of the nostril on the same side," when he excited a small area on the anterior and inner aspect of the uncinatè gyrus; and he further states that sometimes, on exciting the lower extremity of the middle temporal convolution, "movements of the tongue, cheek-pouches, and jaws were induced, very like those which are characteristic of tasting."

Extirpation of the above areas is not, however, in any case followed by motor paresis, nor does there occur any long descending degeneration, like that down the pyramidal tract, as is always the case with a lesion of the excitable part of the parietal and frontal regions. On the other hand, there is indubitable evidence—at least in the case of the occipital region—that extirpation or lesion is productive of marked and permanent sensory disturbance (hemipopia). It has therefore been assumed by Ferrier and others, probably with reason, that in this case the movements which are produced are the result of and secondary to ideas of sensation which are called up by the stimulation, and it is inferred that the areas in question—at least those which have been most fully investigated—are portions of the cortex which are connected with the perception of, and response to, sensations derived from the organs of special sense, and differ in their mode of action from the "motor" areas by producing the movements in question in a more indirect manner. Other neurologists, on the other hand, have taken up the position that in all cases, whether the excitation is applied to the Rolandic or to the other areas, the movement produced is the result of subjective sensations, or ideas evoked by the excitation; by some it has been held that, in the case of the Rolandic area, the sensation thus excited is the sense of movement or muscular sense. If the result is brought about in a similar manner, the period of latent excitation of the muscles which are set in action should be about the same in both cases, whereas, if in the one case the transmission of impulses is more direct, there

¹ Amongst papers dealing with the subject of the localisation of motor centres in man, the following may be cited, in addition to those already referred to:—Séguin, *Trans. Am. Neurol. Assoc.*, N. Y., 1877; *Journ. Nerv. and Ment. Dis.*, N. Y., 1881; Gowers, *Brain*, London, 1878, vol. i. p. 388 (congenital absence of hand, associated with atrophy of middle part of ascending parietal); Bastian and Horsley, *Brain*, London, 1880, vol. iii. p. 113 (a similar case to the above); Exner, "Local. d. Funct. in d. Grosshirn. d. Menschen," Wien, 1881; and in Hermann's "Handbuch," 1879, Bd. ii.; Starr, "Localised Cerebral Disease," *Am. Journ. Med. Sc.*, Phila., 1884; Keen, *Am. Journ. Med. Sc.*, Phila., November 1888; *Phila. Med. News*, 1890, p. 381; Ferrier, "Cerebral Localisation," 1890; M'Bride, *Journ. Nerv. and Ment. Dis.*, N. Y., 1890, vol. vii. p. 512; C. K. Mills, *Brain*, London, 1899, vol. xii. pp. 233, 358.

² Ferrier, *Proc. Roy. Soc. London*, 1875, vol. xxiii. p. 426.

should be a difference in the latency periods of the two. I have accordingly put this point to the test by the following method:¹—Two pairs of flat electrodes, carefully guarded with paraffin, are applied through trephine openings, the one to the frontal area, the other either to the occipital lobe or to the superior temporal gyrus. The wires from the electrodes (Fig. 341, *Fr.*, *Occ.*) pass to a switch (*Sw.*), by turning

FIG. 341.—Diagram of the arrangement of apparatus for determining the comparative latency periods of two parts of the cerebral cortex. *G*, Grove battery working the Ruhmkorff coil; *D*, Daniell cell working the du Bois coil, *D.B.*; *S.C.*, short circuit for du Bois coil. *H*, Helmholtz key arranged so that the Ruhmkorff circuit is made at the same instant that the short circuit of the du Bois coil is broken. which the areas under investigation can be alternately stimulated. The lateral movement of one of the eyes is recorded by attaching it by a thread (*T*) to an aluminium lever (*L*), through which sparks at the rate of 250 per second can be transmitted from a Ruhmkorff coil (*R*) to the smoked paper on a rotating brass cylinder (*Cy.*). The sparks are

FIG. 342.—Curves showing the comparative periods of latency for the ocular muscles, on stimulation of the frontal and occipital cortex respectively.

only allowed to commence from the moment of stimulation, and serve to mark the time as well as the curve described; for the lever is not allowed to touch the cylinder, differences in friction against the paper being thus eliminated—an important point when dealing with the latency of comparatively weak muscles.

The accompanying figure (Fig. 342) shows some of the tracings thus obtained from alternate stimulation of the frontal and occipital cortex;

In these Tables, F denotes excitation of frontal area; O, of occipital lobe; T, of first temporal gyrus. The periods of latent excitation are given in seconds. The observations recorded along each horizontal line are immediately consecutive.

It will be observed that the periods of latency from the temporal and occipital regions are identical (Table III.), whereas, in the course of the same experiment, that from the frontal is markedly shorter than from either the temporal or occipital regions.¹ In the latter case, therefore, there must be at least one other nerve cell (neurone) interpolated, if not more. One's first idea would be, that the action of the posterior (temporal and occipital) areas is through the frontal region. But both frontal regions may be completely removed, and the action will still be

¹ The variations in different experiments may be due to differences in the depth of anæsthesia.

produced from the temporal and occipital regions.¹ The extra cell or cells through which they operate must probably, therefore, be looked for in lower centres (thalamus² or superior corpora quadrigemina?). It may therefore be concluded that the disposition of the tracts by which the nervous impulses which produce motion operate, is different in the case of the Rolandic areas and of the areas connected with visual and auditory sensations—a conclusion which has a far-reaching effect in connection with the question of the supposed sensory functions of the Rolandic cortex. It also militates against the hypothesis of Flechsig,³ that each sensory sphere is like the cortex of the Rolandic region, in having its own special mechanism for producing movements of the particular peripheral sense organ, and only of this one, and that each such sphere is therefore a motor area in the same sense as is the cortex of the Rolandic region.

We may next proceed to consider more in detail the several sensory areas which have been mentioned.

FIG. 343.—Brain of a monkey from which one occipital lobe had been entirely removed but the angular gyrus left intact. This animal was rendered permanently hemipic.

Visual area.—The parts comprised within this area are, in the monkey, the occipital lobe and the immediately adjacent portions of the temporal lobe, including the cuneus, lingual lobule, and posterior parts of the temporal convolutions upon the inner and under surfaces.

Ferrier was the first to describe in various animals (dog, jackal, cat, rabbit, monkey) the existence of an excitable zone in the posterior part of the hemisphere, stimulation of which causes movement of the eyes to the opposite side. In carnivora he placed this zone on the posterior part of the second convolution, in the monkey on the angular gyrus; and both alone and in conjunction with G. F. Yeo he subsequently

found destruction of the angular gyrus to produce loss of vision in the opposite eye, and of both angular gyri complete blindness in both eyes. Hitzig described blindness of the opposite eye as the result of removal of the cortex of one occipital lobe in dogs,⁴ but later was led to conclude that a similar result might follow lesions of the anterior part of the brain also.⁵ On the other hand, Luciani and Tamburini⁶ asserted

¹ Schäfer, *Internat. Monthly Journ. Anat. and Physiol.*, Leipzig, 1888, vol. v. This has been confirmed by other investigators, e.g. Danillo, Rosenbach, Steiner and Obregia (*Arch. f. Physiol.*, Leipzig, 1890, S. 260). The last observer also found that extirpation of the occipital lobes had no effect on the movements obtained from the excitation of the frontal lobes.

² Various observers have described centrifugally conducting fibres as passing from the cortex of the occipital lobe, and terminating in the thalamus.

³ *Neurol. Centralbl.*, Leipzig, 1894, Bd. xiii. S. 674.

⁵ *Arch. f. Psychiat.*, Berlin, 1883, Bd. xv. S. 270.

⁶ "Sui centri psico-sensori corticali," Reggio-Emilia, 1879. See also on the effects of ablation of the occipital lobes in dogs, Vitzou, *Arch. de physiol. norm. et path.*, Paris, 1893, p. 678.

that destruction of the cortex of the angular gyrus and occipital lobe of one hemisphere produces not amblyopia but hemiopia, *i.e.* not blindness of the whole of the retina of the opposite eye, but blindness of the same side of the retina in both eyes. It was, however, shown by H. Munk¹ that removal of the occipital lobe alone, in the monkey, produces homonymous hemiopia (blindness of the corresponding half of both retinæ), and that removal of both occipital lobes causes complete blindness, even although the angular gyri are intact; by Munk, therefore, the visual centre was located in this lobe alone. Subsequently the subject was investigated by me in conjunction with Sanger Brown² by the method of extirpation. The result of our experiments was to show that, as stated by Munk, removal of one occipital lobe causes homonymous hemiopia, and of both lobes at first complete blindness; but the blindness was not permanent, unless the lesion extended somewhat in advance of what is generally taken to be the limit of

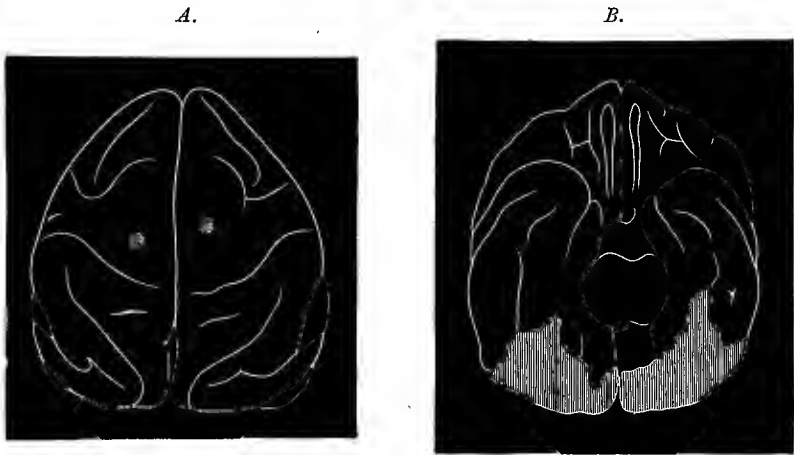

FIG. 344.—Views from above, *A*, and from below, *B*, of the brain of a monkey, from which both occipital lobes, and, on the under surface, part of the temporal lobes had been cut away. This animal was completely blind for several months, although both angular gyri were intact.

the lobe, on the inner and lower surface. The explanation of the difference between these results and those of Ferrier and Yeo is probably to be found in the fact that in their cases the removal is less complete—this is manifest from their figures. And the same remark applies to some experiments of Horsley and myself on this region.³ With regard to the angular gyrus, the experiments with Sanger Brown were entirely contradictory to those of Ferrier and Yeo. In animals in which the grey matter of this convolution was destroyed on one or both sides we could discover no defect of vision. If it were done on one side, there was neither blindness of the opposite eye nor hemiopia; if the eye of the same side were bandaged, the animal saw perfectly well with the opposite eye. In one case only, in which we scooped the whole of the convolution away, after opening up the fissures

³ *Phil. Trans.*, London, 1888, B.

which bound it, we produced hemiopia, which lasted for a few days, gradually passing off. But in this case a considerable disturbance must have been mechanically produced in the occipital lobe by the operation, and this would be quite sufficient to explain the hemiopia. In no single instance in which I have performed a lesion in this, or any other part

FIG. 345.—Diagram showing the connection between several parts of the retina and occipital lobes in the dog.—H. Munk.

of the hemisphere, has the visual disturbance which resulted been confined to the opposite eye; it is invariably of a hemiopic character, producing partial blindness of both retinae.¹ Removal of the angular gyrus has no effect upon the sensibility of the opposite eyeball.² After removal of the occipital lobe in a monkey, all optical reflexes, except the pupillary reflex, are abolished, so far as the blind side of the retina is concerned (Munk).

M'Kendrick³ found that destruction of the occipital lobe in the pigeon did not produce blindness of the opposite eye; it was necessary to remove the whole hemisphere.

Localisation within the visual area.—H. Munk attempted to determine this in the dog and monkey by effecting large partial extirpations of the occipital cortex.⁴ As the result of these experiments, he came to the conclusion that in the dog the upper zone of the retina corresponds with the anterior part of the visual

¹ As already stated, temporary hemiopia may be produced by extensive lesions of almost any part of the hemisphere, the cause being doubtless the vascular and mechanical disturbance which the removal occasions. It is, however, more apt to occur from these causes when the lesions are in the neighbourhood of the occipital lobe.

area, the lower zone with the posterior part, the mesial or internal zone with the mesial or internal part, and the lateral zone of the retina with the lateral part of the area, and that the part of the retina concerned with most distinct (central) vision is represented upon both visual spheres over an area which lies near the apex of the occipital lobe (in the monkey rather nearer the mesial surface); and he finds confirmation of these conclusions from the results of excitation performed in conjunction with Obregia.¹ These results of Munk are embodied in the diagram on the previous page (Fig. 345). I myself, in conjunction with Sanger Brown,² found in the monkey that bilateral injury of both mesial surfaces of the occipital lobes appeared to cause loss of central vision, peripheral vision being intact, and came to the conclusion, partly from this but mainly from the results of excitation of the occipital cortex,³ that the scheme given by Munk for the dog will not apply to the monkey's brain, in which it is more than probable that central vision is represented upon the mesial surface of the brain at the anterior part of the visual area, which would be in the neighbourhood of the anterior part of the calcarine fissure. And this appears certainly to be the part where visual perceptions are most obviously located in man (see p. 757).

Electrical excitation of the visual area.—As already remarked, it was stated by Ferrier that electrical excitation of the angular gyrus produces conjugate lateral movement of the eyes to the opposite side; with an upward deviation if the electrodes are placed on the anterior limb of the gyrus, with a downward deviation if placed on the posterior limb.⁴ These experiments were subsequently repeated by other observers, who for the most part failed to obtain the same result.⁵ I was myself never able to produce such movements on excitation of the anterior limb of the angular gyrus, but occasionally got the movement described by Ferrier when the electrodes were placed on the posterior limb and on the upper end of the middle temporal gyrus, which is continuous with the posterior limb. In both these cases there may have been a spread of current to the adjacent upper surface of the occipital lobe. If the electrodes are applied directly to the upper surface of the occipital lobe, conjugate deviation to the opposite side with downward direction of the visual axes is extremely well marked, and it is also produced by excitation of the upper part of the mesial surface of that lobe, and of the quadrate lobule immediately in front of the internal parieto-occipital fissure. If, on the other hand, the posterior extremity of the occipital lobe, its lower or tentorial surface, and the posterior and lowermost part of its mesial surface, be stimulated, the lateral deviation is combined with an upward movement. In both cases the downward or upward movement may be almost uncomplicated by lateral deviation; this depends upon the position of the electrodes. On the other hand, there is an intermediate zone, narrow on the mesial surface of the lobe, and broader upon the outer or convex surface, excitation of which is productive of

⁵ Luciani and Tamburini obtained in dogs conjugate deviation to the opposite side, both from the angular gyrus and from the convexity of the occipital lobe, but without any upward or downward deflection, "Centri psico-sensori corticali," Reggio-Emilia, 1879.

simple lateral deviation. All the effects are strongest upon the mesial surface, especially towards the anterior limit of the lobe; it is here that the focal point for the movements is located.¹

The movements are usually accompanied by dilatation of the pupils, but I have occasionally obtained, from stimulation on or near the quadrate lobule, marked contraction of the pupils, such as is produced when a strong light is thrown directly into the eye. Equal bilateral excitation produces, as with the frontal areas (p. 740), fixation of the

FIG. 346.—Diagram showing the probable relations between the parts of the retina and the visual area of the cortex.

visual axes, with an upward or downward inclination according as the electrodes are placed on the lower or upper zones above described.² If we assume that these various movements of the eyeballs are the result or concomitants of subjective visual sensations set up by the excitation,

¹ Schäfer, *Brain*, London, 1888, vol. xi. p. 1. These observations have been confirmed in dogs by Obregia (with Munk), *Arch. f. Physiol.*, Leipzig, 1890 (see also H. Munk, *Sitzungsber. d. k. Akad. d. Wissensch.*, Berlin, 1890, S. 53, translated in *Brain*, London, 1890, vol. xiii. p. 45), and in the cat and rabbit by Steiner, *Arch. f. d. ges. Physiol.*, Bonn, 1891, Bd. I. S. 603; also in the monkey, by v. Bechterew, *Neurol. Centralbl.*, Leipzig, 1897, S. 720, who affirms that similar movements of the eyes and pupils are obtainable by stimulation of the parietal lobe.

² Mott and Schäfer, *Brain*, London, 1890, vol. xiii.

and that the movements take the direction towards which those sensations are projected, then the above facts, especially if taken in connection with the results of destructive lesions of the area, indicate a certain connection between the parts of the cerebral visual area and the retina. This connection may be stated as follows:—

1. The whole of the visual area of one hemisphere is connected with the corresponding lateral half of both retinae.

2. The upper zone of the visual area of one hemisphere is connected with the upper zone of the corresponding lateral half of both retinae.

3. The lower zone of the visual area of one hemisphere is connected with the lower zone of the corresponding lateral half of both retinae.

4. The intermediate zone of the visual area is connected with the middle zone of the corresponding lateral half of both retinae.

5. The focal point of the visual area, which is placed on the anterior part of the mesial surface of the occipital lobe, is connected with rather more than the corresponding half of the macula lutea of each retina.

These probable connections, in so far as they can be shown in a horizontal plane, are illustrated in the appended diagram (Fig. 346). They can be easily understood, if we imagine the visual areas of the two hemispheres to be joined together (with a little overlapping) at their mesial surface to form a single hemispherical cup of the size of the retina, and if we then imagine the two retinae to be placed one inside the other in their natural position in contact with the cerebral cup thus formed. All corresponding points, both of the two retinae and of the cerebral visual area, will be in contact with one another (Fig. 347).

If we compare the scheme thus represented with that which is given by H. Munk for the dog (Fig. 345), we observe that the main point of difference is that Munk locates the focal point of each visual area at the apex of the occipital lobe. In accordance with this, he finds that destruction of this point on both sides causes loss of central vision. Whether this is the case with dogs or not I cannot certainly say, but my experiments upon monkeys do not agree with this conclusion, nor does it find support from observations upon man. On the other hand, there is abundant clinical evidence to show—

1. That lesions of the occipital lobe produce disturbances of vision which are invariably of a hemiopic character.

2. That lesions of the mesial surface of the lobe in the immediate neighbourhood of the calcarine fissure are those which for their size produce the most serious visual disturbances. On the other hand, lesions of parts near to but not involving these parts of the occipital lobe have not infrequently been associated with defective appreciation of visual objects, and particularly with word-blindness.

3. Perimetric observations in man show that in cases of hemiopia, produced by lesions of the cortex (of one hemisphere), the line of demarcation between the blind and functional parts of the retina usually passes, not through the middle of the fovea but on the homonymous side; in other words, the fovea is not involved in the hemiopic condition.

The visual area in man appears to be relatively less extensive than in the monkey. Séguin found that in by far the greater number of cases of hemiopia examined, the cortical lesion was in the neighbourhood

FIG. 347.—Diagram to indicate the corresponding points of the two retinae and of the two halves of the visual cortex.

of the cuneus. Monakow¹ limits the visual area to the cuneus, the lingual lobule, and (probably) the two occipital gyri. The cuneus and lingual lobule are especially connected with the corpus geniculatum laterale, from which they receive fibres which run in the ventral part of the medullary centre of the occipital lobe; on the other hand, fibres pass from the cells of the visual area by way of the optic radiations to the superior corpora quadrigemina. All parts of the macula lutea are in man, according to Monakow, represented in both hemispheres, and over the whole visual cortex; hence, if the whole visual area of one hemisphere is destroyed, or even if the optic tract is completely degenerated, the macula lutea is not completely blind in any part.

According to Henschen,² the cortical centre for vision in man (inclusive of colour vision) lies exclusively in the grey matter bounding the calcarine fissure,³ the upper lip of that fissure being connected with the upper quadrant of the retina, the lower lip with the lower quadrant, the macula lutea with the most anterior part of the area, and each macula being represented in both visual areas. Henschen describes the "visual" fibres of the optic tract as ending exclusively in the lateral geniculate body, the destruction of which produces hemiopia. From this fibres run in the ventral part of the optic radiations of Gratiolet to the cortex at the calcarine fissure. The remainder of the occipital cortex and the angular gyrus are considered by Henschen to be probably connected with special visual apperceptions, as is instanced by word-blindness accompanying lesions of these parts.⁴

Flechsig⁵ has shown that in man the fibres of the optic nerve become myelinated later than those of most of the other senses, viz. in the course of the first month of post-uterine life. Tracing them backwards, he finds the fibres of the optic tract passing directly to the lateral geniculate body, and thence to

³ The grey matter of the calcarine fissure, together with the immediately adjacent parts of the cuneus and lingual lobule, is characterised by the development of a stratum of white fibres in the middle of its thickness, which is known as the band of Gennari, as well as by the thickness of the molecular layer, and the appearance of a very large number of stellate nerve cells, which form a layer of considerable thickness in connection with the band of Gennari. This layer corresponds with the layer of granules in other parts of the cortex. This part has been termed by Henschen the "cerebral retina"; he supposes that visual impressions are projected and received here, but are perceived elsewhere in the occipital lobe, and perhaps also in the parietal lobe. The structure of the visual cortex in man has been recently dealt with in a special treatise by Ramón y Cajal ("Die Schrinde," Leipzig, 1900), who draws especial attention to the presence of many stellate cells in the granule layer having descending instead of ascending axons. The fibres of the stripe of Gennari constitute, in all probability, according to Cajal, the eventual endings of the optic nerve fibres.

the superior corpora quadrigemina, but none directly to the thalamus. From the lateral geniculate body a stout bundle passes to the pulvinar thalami, but the fibres for the most part pass through this to join the optic radiations of Gratiolet and to pass in these to the margins of the calcarine fissure. Other fibres of the optic radiations, the origin of which is somewhat uncertain, spread out into the whole of the cuneus and lingual lobule, and extend over the posterior pole of the hemisphere to the basal surface (occipito-temporal region). No fibres of the optic radiations go to the gyrus angularis, which is therefore entirely excluded by Flechsig from the visual area of the cortex.

Steiner found that in the cat and rabbit the visual area does not begin to respond to electrical excitation until about the fourteenth or fifteenth day after birth, whereas response is obtained from the Rolandic area about the tenth day. In the dog the response of the visual area is obtained still later (thirtieth to fortieth day). It is noteworthy, in connection with this observation, that puppies do not appear to recognise objects by sight until after about the twenty-third day after birth, and do not appear to recognise objects the images of which fall on the periphery of the retina until about the thirty-fourth day.¹ It would appear from the observations of Ræhlmann upon infants, that these do not recognise objects the images of which fall upon the centre of the retina until the fifth week after birth, and those which fall upon the periphery of the retina not until the fifth month.

The view has been taken by Ferrier, as the result of his experiments, that while the occipital lobe may be concerned with visual perceptions due to nervous impulses derived from the homonymous part of the same retina, the angular gyrus is especially connected with central vision of the opposite eye; and this view has been adopted by several other clinicians. His statement that blindness of the opposite eye, of a transient character, is caused by destruction of that gyrus, has, however, been confirmed only by one other observer, namely, Lannegrace,² and is denied by all others who have experimented upon the subject; nor has it been shown in any animals with bilateral vision that lesion of one hemisphere only is productive of complete blindness of the opposite eye or of loss of central vision. It is true that cases of amblyopia, involving one eye only, accompanying cerebral lesions, are not unknown clinically, but they are not specially connected with lesions localised to the angular gyrus, and the symptom is always combined with anæsthesia of the globe.³ It appears certain that monocular defects of vision, when not due to injury of the optic nerve, are caused by a disturbance in the nutrition of the retinal elements (perhaps produced indirectly by an alteration in the blood supply), and are on a par with the defects in taste and smell which are brought about by lesions of the trigeminal nerve.⁴ The monocular defects which are observed in cases of functional or hysterical amblyopia may, according to Knies,⁵ be due to vasomotor disturbances (vaso-dilatation) affecting the conduction of the fibres of the optic nerve, where these pass through the foramen opticum. That the disturbance in these cases is not retinal, is shown by the fact that the ophthalmoscopic image is normal.

In progressive pathological lesions of the occipital lobe, loss or affection of

⁴ Defective vision in the opposite eye has been experimentally obtained by section of the ascending root of the fifth nerve in the medulla oblongata, and is ascribed by v. Bechterew to vasomotor and trophic disturbance of the retinal elements (*loc. cit.*).

⁵ *Neurol. Centralbl.*, Leipzig, 1893, S. 570.

colour vision upon the homonymous side of the two retinae may precede the hemiopia; but it has not yet been determined that colour vision is dependent upon the integrity of a different part of the cortex than appreciation of form.

Occasionally hallucinations—in perfectly sane subjects—are present in hemiopia, the sensations originating on the blind side of the brain. In these cases either the lesion producing hemiopia is subcortical, or if cortical must be assumed to be incomplete. Such unilateral hallucinations, with or without hemiopia, are also sometimes seen in attacks of hemicrania.¹

Cases of localised bilateral lesions of the internal surface of the occipital lobes, producing complete blindness, have been published by various observers.² In some of these cases both lobes were affected simultaneously, in others first one lobe was affected, and a condition of hemiopia was produced, and then after an interval of time the other lobe, the condition being converted into double hemiopia or total blindness. In Forster's case central vision was still possible, although of a very imperfect character; it was found by Sachs, who made the examination of the brain, that a small portion of the grey matter of the cortex bounding the right calcarine fissure had not been involved in the destruction; but whether this was sufficient to account for the persistence of some central vision, cannot be definitely affirmed, especially since there have been several other cases of double hemianopsia in which some amount of central vision has persisted.³ In this patient colour vision was absent, although the appreciation of form persisted, as shown by the fact that he could recognise common objects and even read and write. There was, however, a marked loss of memory of locality, and lack of power to appreciate the relative positions of objects, such as the position of countries and places on a map, the position and direction of the paths in a garden, or even the position of furniture and accustomed objects in his own room; although there was no such loss of memory of position of objects the appreciation of which was ordinarily determined by the sense of touch, such as parts of his own person, clothing, etc. In fact, although this patient still had some central vision, he was able to find his way about with far less facility than persons who are totally blind from destruction of the peripheral visual organs, and whose other senses have become sharpened by disuse of the visual sense. An animal (monkey, dog) rendered blind by removal of the occipital lobes is unable for an indefinite time to find his way freely about even the most familiar place without bumping against objects, and shows a great disinclination to move about; whereas it is a familiar fact that an animal which is blind in consequence of a peripheral lesion, speedily accommodates itself to the altered circumstances in which it is situated, and has no difficulty in finding its way about places with which it is familiar (H. Munk). Sachs⁴ attempts to explain some of the phenomena which were observed in Forster's case, by supposing that the appreciation of the quality of light coming from objects is effected in a manner different from that of the form and relative position of objects, that the perception of form and relative position involves motion of the eyes, and is associated with sensations produced by such motion, and that this perception is localised in other parts of the occipital lobes than those concerned in the appreciation of colour. Wilbrand finds it necessary, in consideration of various phenomena which have been observed clinically, to assume three centres of visualisation—one for the mere appreciation of luminosity, one for appreciation of colour, and one for appreciation of form and relative position of objects (space); he supposes that these may all be situated in the same region of the brain, but in different layers of the cortex. Holden⁵ noticed that partial loss of

conductivity in the optic tract led to partial colour blindness, combined with a diminution of the power of appreciating the relative intensity of light, and interprets this observation as indicating the non-existence of a separate centre for colour appreciation. This interpretation cannot, however, be conceded, for the results may be explained by assuming that the nervous impulses for these qualities are conducted along different nerve fibres, which are differently affected by the conditions disturbing their conductivity—a phenomenon well known to occur in other mixed nerves. There is not sufficient evidence as yet to enable an authoritative opinion to be pronounced upon this matter. It has been suggested that the fact that in unilateral lesions of the cortex central vision is often unaffected, may be explained by supposing that the vascular conditions of the part of the cortex which is connected with the macula are more favourable, so that this particular portion of the centre is more resistant to pathological changes than the rest, without the necessity of assuming that the whole macula is represented upon both sides of the brain, but there is no evidence in favour of this suggestion.¹

The auditory area of the cerebral cortex.—It was originally stated by Ferrier,² and the statement has been confirmed by all subsequent observers, that stimulation in the monkey of the upper two-thirds of the inferior temporal convolution causes pricking of the opposite ear, turning of the head and eyes to the opposite side, and dilatation of the pupils.³ This was taken by Ferrier to indicate that this convolution is connected with the function of hearing (by the opposite ear), and in conformity with this view he found that if it was destroyed on one side, and the ear of the same side was stopped with wax, the animal was rendered deaf; and that if it was destroyed on both sides the animal became absolutely and permanently deaf. Ferrier therefore concluded that this gyrus, and this alone, is the cerebral seat of the auditory function.

I have elsewhere, however, shown that this deduction of Ferrier was founded upon an insufficient basis.⁴ On repeating his experiments, in conjunction with Sanger Brown, it was found that monkeys entirely deprived of the superior temporal gyri on both sides, and even of a very considerable additional amount of the temporal lobe, are by no means deaf, but still show signs of hearing quite distinctly, and of understanding the nature of the sounds heard.⁵ Even in the case upon which Ferrier chiefly relied in support of his opinion, the notes which he has published show that the monkey undoubtedly reacted to sounds.⁶

It is certain, therefore, that the function of sound-perception is not entirely localised to the superior temporal gyrus, although the focal point for it is probably there. Luciani and Tamburini⁷ extended it to the second temporal gyrus, because excitation of the upper end of this also gives the head- and eye-movement. H. Munk, chiefly from experiments on dogs,⁸ ascribes the function to the whole of the temporal lobe. Luciani,⁹ in a later communication, says: "Our results tend to show

¹ W. Harris, *Brain*, London, 1897, p. 307.

² *Proc. Roy. Soc. London*, 1875.

³ I have myself generally got retraction of the ear instead of pricking. Baginsky (with H. Munk) obtained raising of eyelids combined with movements of the opposite ear on stimulating the lowermost point of the temporal lobe in the dog (*Neurol. Centralbl.*, Leipzig, 1890, Bd. ix. S. 458). Steiner (*op. cit.*) in the rabbit also obtained movement of the opposite ear, on excitation of the same part of the temporal lobe.

that not only the whole cortical area of the temporal lobe, but probably also the *cornu ammonis*, forms an integral portion of the auditory sphere." With bilateral extirpation (in dogs) "at first the auditory troubles may amount to absolute deafness, but soon pass into a condition of obtuseness of hearing." In five monkeys the superior temporal gyrus was destroyed or removed on both sides by Sanger Brown and myself, and in one both temporal lobes were completely removed. In the last case there was produced for a time a condition of idiocy, due probably to the extent of the lesion, but in none of the cases was hearing abolished; whether it was impaired it is quite impossible to say, since even normal monkeys will frequently take no notice of noises.¹ At any rate these experiments, as well as those of Luciani, afford conclusive

FIG. 348.—Diagrams of brain of a monkey, showing complete removal of the superior temporal gyrus on both sides. Even when this was effected the animal retained a delicate sense of hearing.

evidence that in animals the function of auditory perception is not entirely confined to the temporal lobe, although it has not been experimentally determined into what other portions of the cortex it extends. That its focal point is to be found in the superior temporal gyrus, and especially the upper part of that gyrus and the gyrus transversus anterior (which is concealed within the fissure of Sylvius, and is very early in making its appearance in man, Heschl), is probable, partly from the result of electrical excitation and partly from the observations of Flechsig (see below) on the time of myelination of the fibres; and also as the result of clinical and pathological evidence in man; in whom cerebral lesions productive of disturbances of auditory perception are generally found closely associated with the neighbourhood of the superior temporal gyrus.²

It has been shown by v. Monakow³ that the cortex of the temporal lobe, and especially of the first gyrus, is directly united with the mesial geniculate body, which again is connected directly with the inferior corpus quadrigeminum, and

¹ Since the publication of our experiments, Ferrier has given an account of a monkey on which he had performed the same operation, namely, removal of the superior temporal gyrus on both sides. Although he found that for a few days it appeared to take no notice of sounds, yet after a time (two or three weeks) it showed recovery of the sense of hearing, and even showed appreciation of the meaning of certain sounds, which it responded to by characteristic cries. It is therefore impossible to suppose that audition is localised to this gyrus in monkeys.

² Ferrier, "Croonian Lectures," 1890, p. 80.

³ *Arch. f. Psychiat.*, Berlin, Bd. xxvii. S. 428.

this again by the lateral fillet and by some fibres of the reticular formation with the cochlear nerve. Flechsig¹ finds that in the child of two months, fibres are found undergoing myelination within the temporal lobe, connecting the mesial geniculate body almost exclusively with the transverse convolutions of the temporal lobe which are concealed within the Sylvian fissure. He regards these as the only corticopetal fibres concerned with audition, and is on this account disposed to locate the auditory area of the cortex in man exclusively in this situation, although apparently willing to admit that corticofugal (motor) fibres, set in activity by auditory impressions, may emerge from a larger area. He describes a bundle of such fibres as passing from the temporal lobe by way of the lateral fourth of the crista to the pons Varolii (temporo-pontine tract), and regards these as motor, carrying impulses for the movements of the ears, head, and trunk. The opinion that the fibres in question are respectively corticopetal or corticofugal rests, however, wholly upon the fact that those regarded as centripetal are developed at a relatively earlier period than the others. According to Held, although most of the fibres of the cochlear (auditory) nerve are interrupted in the dorsal and ventral auditory nuclei, the superior olivary nuclei of the same side, and the nuclei of the trapezium, of the fillet, and of the inferior quadrigeminal body of the opposite side, some fibres may pass directly to the cortex of the temporal lobe of the opposite side.²

Localisation within the auditory area.—Clinical evidence appears to point to the fact that the *appreciation of words heard* is intimately associated with the integrity of the first temporal gyrus of the left side, numerous cases having been recorded of "word-deafness" resulting from lesions of this convolution, especially of its posterior two-thirds.³ Luciani and Sepilli⁴ collected twenty cases of word-deafness, and of these fourteen were associated with lesions more or less extensive of the first and second temporal gyri on the left side of the brain.⁵

Munk states that in dogs in which the anterior part of the auditory area is destroyed there is deafness for tones of high pitch, while destruction of the posterior part of the area is attended by deafness to tones of low pitch. These statements are confirmed and amplified by v. Bechterew and Larionoff,⁶ who divide the auditory area into three zones, for high, medium, and low-pitched notes respectively. But the difficulties of such experiments are so great, that it would be wise to suspend one's judgment before accepting them as evidences of intra-areal localisation.

The olfactory and gustatory areas of the cerebral cortex.—As Ferrier remarks: "The position of the olfactory centre may with great probability be inferred from anatomical considerations alone, apart from actual experiment." If with Broca we divide animals into those with a highly developed olfactory sense (*osmatics*, including the great majority of mammals) and those with feebly developed olfactory sense (*anosmatics*, including the monkey, man, and a few amphibious or marine mammals), we find that the parts of the brain which vary in development directly with this sense are—(1) The olfactory lobe (olfactory bulb and tract); (2) the posterior portion of the inferior surface of the frontal lobe; (3) the anterior portion of the hippocampal region, including the uncus, the

¹ "Localisation der geistigen Vorgänge," etc., 1896.

³ Naunyn, *Verhandl. d. vi. Cong. f. innere Med.*, Wiesbaden, 1887, S. 132.

⁴ Quoted by Laquer (*Neurol. Centralbl.*, Leipzig, 1888, S. 337), who also gives the details of a well-observed case in which the lesion was strictly limited to the first gyrus. For other cases hearing on this subject, see Ferrier, "Cerebral Localisation," 1890.

⁵ Manouvrier found the right superior temporal gyrus to be small in a man who was from infancy deaf in the left ear (*Bull. Soc. de psychol. physiol.*, Paris, 1890, tome v.). See also a case related by C. K. Mills in *Brain*, London, 1891, vol. xiv. p. 465.

⁶ *Arch. f. Physiol.*, Leipzig, 1899, S. 391.

hippocampal gyrus, the hippocampus major, and the dentate convolution¹ (but not the amygdala); (4) a convolution termed the "bordering gyrus,"² which closely encircles the corpus callosum, and is connected at both ends with the olfactory lobe. Very little of this convolution is present in primates, the dorsal part only being represented by the "nerves of Lancisi," and the ventral part by the lamina of the septum lucidum, the peduncle of the corpus callosum, the fornix, and the fimbria; (5) the anterior part of the callosal convolution (gyrus fornicatus);³ (6) the anterior commissure.

The main connection of the olfactory nerve fibres is with the cortex of the same side of the brain. On physiological grounds, it appears to be doubtful whether there is any crossed connection between the two olfactory lobes, but anatomically such has been affirmed through the medium of some of the fibres of the anterior commissure (Meynert). This commissure is stated to be chiefly a means of connection between the hippocampal gyri, especially their anterior parts, and it also appears to connect the olfactory tracts with one another.⁴ According to the observations of Flechsig,⁵ the nerve fibres of the olfactory tract, which begin to be myelinated towards the end of the ninth month of foetal life, pass (1) partly to the whole of the hinder border of the base of the frontal lobe and to the front part of the gyrus fornicatus; (2) partly to the uncus and to the adjacent inner pole of the temporal lobe, these two regions coming together below the island of Reil. From the frontal olfactory region, fibres pass by way of the stria tecta to the middle segment of the gyrus fornicatus, others into the septum lucidum, and then by way of the cingulum to the cornu ammonis. From the temporal olfactory region a strand of association fibres also goes into the cornu ammonis. From both regions, tracts (corticifugal) pass to the globus pallidus of the lenticular nucleus and to the thalamus.

Rámon y Cajal⁶ has traced fibres of the external auditory root, which arise as axons of the mitral cells of the olfactory bulb, into the uncus, where they terminate by arborising in the grey matter. Cajella⁷ describes the fibres of the mesial root as passing to end in the trigonum olfactorium by arborising amongst peculiar groups of pyramidal cells which are found in this region, and to which the name "olfactory islands" has been applied. According to the observations of Elliot Smith in monotremes,⁸ the axons of the mitral cells pass partly direct to the fimbria and fascia dentata, arborising amongst the cells of the fascia dentata (the axons of these cells ultimately go to the hippocampus); partly to the septum lucidum and peduncle of corpus callosum (gyrus subcallosus of Zuckerkandl; precommissural area of Elliot Smith), where they

¹ Hill, *Phil. Trans.*, London, 1893, vol. clxxiv. p. 389, states that in anosmatics the fascia dentata varies directly with the development of the olfactory organs.

² See Quain's "Anatomy," vol. iii. pt. 1; also Zuckerkandl, "Ueber das Riechcentrum," Stuttgart, 1887.

³ There is, however, as Broca pointed out, an exception in the case of Cetacea, "in which, although the sense of smell is rudimentary or absent, the anterior portion of the callosal convolution is specially well developed" (Ferrier, "Functions of the Brain," p. 314). According to Ferrier, it is only the uncinate (anterior) portion of the hippocampal gyrus (hippocampal lobule) the development of which is correlated with that of the sense of smell. In man and in the dolphin (both anosmatics) the hippocampus is comparatively well developed. In reptiles, which have a strong olfactory sense, the cerebrum is almost entirely represented by the hippocampal region (Etinger, *Anat. Anz.*, Jena, 1893, Bd. viii. S. 305).

⁴ Ganser, *Arch. f. Psychiat.*, Berlin, 1878, Bd. ix. See also Dana, "On the central tracts of the olfactory nerves," *New York Med. Journ.*, 1889.

arborise around the dendrons of the pyramidal cells, the axons of which also then pass to the hippocampus to end in arborisations amongst the dendrons of its pyramidal cells (Fig. 349). If this be so, both the gyrus subcallosus and the fascia dentata are receptive areas of the second order for olfactory impressions.

Broca¹ was of opinion that the whole of the limbic lobe (consisting of olfactory lobe, hippocampal lobe, and lobe of the corpus callosum) is related to the sense of smell, although he fully admitted the probability of its having also another unknown function, as shown by its development in some anosmatics. It has an intimate connection with the frontal lobe, and in Broca's opinion this last-named lobe owes its supposed importance as a special organ of intelligence to its connection with the olfactory region; since in most

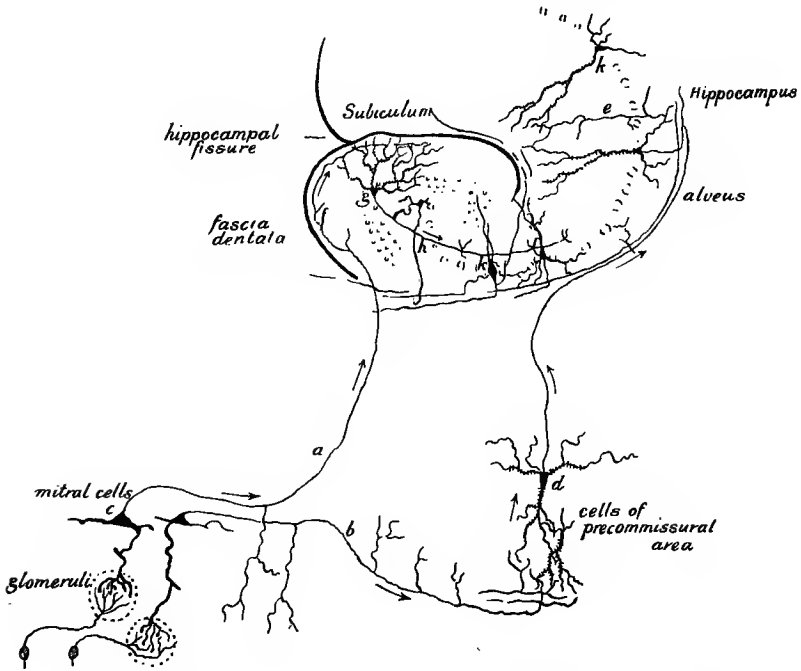

FIG. 349.—Diagram to show the connections of the olfactory organ with the hippocampal region.—Elliot Smith.

mammals the chief impressions derived from the external world are obtained through the medium of the olfactory sense.²

Ferrier found that "the effects of electrical irritation of the hippocampal lobule in the monkey and other animals are such as may be most reasonably interpreted as being indicative of subjective olfactory

¹ "Mém. sur le cerveau," Paris, 1888. Broca's distinction of these regions of the brain (*rhinencephalon*, Turner) from all the rest of the cortex (*pallium*) has been followed by all subsequent writers (Schwalbe, "Neurologie"; Zuckerkandl, "Ueber das Riechcentrum," 1887; Turner, *Journ. Anat. and Physiol.*, London, vol. xxv.; Retzius, "Das Menschenhirn," Stockholm, 1897. The rhinencephalon is phylogenically and ontogenically the oldest, and in many vertebrates remains throughout life the most important part of the cortex.

² P. Broca, "Local. cérébrales." "Rech. sur les centres olfactifs," "Mémoires," 1888, pp. 424, 429.

sensation, namely, a peculiar torsion of the lip and nostril on the same side. Occasionally, however, the reaction is bilateral, and especially so in the rabbit. The reaction is that actually induced in these animals by the application of an irritant, such as a pungent odour, directly to the nostril. . . . But while we can be more or less certain, from the outward reactions, that subjective olfaction is aroused by stimulation, it is an exceedingly difficult problem to determine whether smell is lost by destruction of the same region."¹ In Ferrier's earlier experiments by this method, which were admittedly not very exact, he found, with destruction of the lower temporal regions on both sides, indications of impairment or abolition of the senses of smell and taste. In monkeys operated upon by myself, in conjunction with Sanger Brown,² we were unable to detect such impairment, even when the whole of both temporal lobes was removed. We did not, it is true, remove the hippocampus major as well, and in some animals small pieces of the hippocampal convolution were left. Nevertheless, in spite of the very extensive lesion in this region, the animals unquestionably gave very distinct indications of still possessing both smell and taste. Ferrier has since repeated the operation upon another monkey, and obtained evidence of the loss of both senses for a period of about two months, after which time both senses appeared gradually to undergo recovery.³ There is, therefore, not complete localisation of those senses to these parts of the brain. Munk⁴ has recorded the case of a dog, rendered blind by destruction of the occipital cortex, which seemed also to have lost the sense of smell, and in which it was found post-mortem that the whole of the hippocampal gyrus upon each side was converted into a thin-walled cyst. Luciani⁵ got no evident deficiency of smell after extirpation of the temporal lobe in dogs, but found olfactory disorders to follow lesions of the gyrus hippocampi and of the hippocampus major combined.

A case of tumour in the right gyrus hippocampi has been recorded by Hughlings Jackson and Bevor, in which the patient suffered from subjective sensations of smell.⁶

It is probable, for various reasons, that the centre for the sense of taste is anatomically in close association with the olfactory centre, but neither experiments on animals nor clinico-pathological observations in man have thrown much light upon its localisation. Ferrier got occasionally movements of the lips, tongue, and jaws in the monkey and cat, on electrical excitation of the lower extremity of the temporal region,⁷ and interprets this as indicative of the calling up of subjective sensations of taste.

The localisation of tactile sensibility.—Ferrier was led by the results of his experiments upon the hippocampal region of the hemisphere,⁸ to the conclusion that tactile sensibility is in every case impaired or abolished, in proportion to the destruction of the hippocampal and inferior temporal region. It was, however, found by

⁶ *Ibid.*, 1889, vol. xii. p. 340. For other cases, see Ferrier, "Cerebral Localisation," p. 126.

⁷ Flechsig has supposed, but without presenting any convincing evidence, that the sense of taste is connected with the anterior part of the gyrus fornicatus.

⁸ Ferrier, *Phil. Trans.*, London, 1875, pt. 2; Ferrier and Yeo, *ibid.*, 1884, pt. 2.

Horsley and myself that extensive lesions might be made in the hippocampus major without producing hemianæsthesia, although in other cases, when the lesion was more extensive and involved the greater part of the hippocampal gyrus, and a large part of the adjacent under surface of the temporal lobe, hemianæsthesia was very marked. The same result was obtained on destruction of the gyrus fornicatus, so that we were led to the conclusion that these convolutions, which form the greater part of the limbic lobe (especially the gyrus fornicatus) were the seat of perception of cutaneous sensations, and especially of tactile sensibility. Our experiments upon the gyrus fornicatus were confirmed by Munk,¹ who was, however, of opinion that the anæsthesia is the effect of unavoidable injury to the neighbouring Rolandic (motor) region of the cortex, in which alone he localises tactile perceptions. Neither did we ourselves, however, nor Ferrier, ever obtain anæsthesia on directly injuring the motor cortex solely. Nevertheless, it must be borne in mind that in endeavouring to excise such deeply lying portions of the cortex as the gyrus fornicatus and hippocampal gyrus, it is necessary to raise up or draw aside the whole mass of the brain, and it is possible that the hemianæsthesia we obtained in the experiments upon the hippocampus and gyrus fornicatus were due not to the actual injury to those parts, but to a general disturbance in the functions of the whole hemisphere (perhaps of the optic thalamus), which the manipulation of the brain might produce.

In order to test this point, I have recently² performed experiments on the monkey in the following manner:—In a preliminary operation, the whole of the leg area of the cortex, together with the greater part of the remainder of the marginal convolution, was severed by a sharp knife passed vertically into the cerebral substance parallel with the longitudinal fissure. The only symptom produced was motor paralysis of the opposite leg; no anæsthesia could be detected; the animal responded, after the first day or two, to the slightest touch, both on the paralysed and on the non-paralysed side. After two or three weeks the brain was again exposed, and a cut was made along the same line as before, but deep enough to sever the fibres passing to and from the gyrus fornicatus. No additional symptoms whatever followed this second operation, although in two cases at least, from one-third to one-half of the gyrus fornicatus was severed from the rest of the brain. The experiment was, in one case, varied by removing the gyrus marginalis altogether in the first operation, and scooping away the middle part of the gyrus fornicatus in the second, but the result was the same.

These experiments are not conclusive, because the destruction of the gyrus fornicatus was not by any means complete, but, so far as they go, they are not in favour of this convolution being regarded as especially the seat of tactile sensibility; at least they tend to show that sensation is not localised to it. It is, however, possible that the *whole of the limbic lobe*, with the exception of the antero-inferior parts (which are probably devoted to smell and taste) may be the seat of cutaneous perception. It is natural to expect the senses of smell and taste to be in relation with that of cutaneous sensibility, since the organs of smell and taste are modifications of integumental structures. It has already been shown that the view of Munk, that tactile sensibility of the

¹ *Sitzungsb. d. k. Akad. d. Wissensch. zu Berlin*, 1892.

² *Journ. Physiol.*, Cambridge and London, 1898, vol. xxiii. p. 810.

various parts is located in the motor areas of the Rolandic region, cannot be substantiated. This no doubt lands us in the unsatisfactory position that we are unable certainly to say in what part we are to localise cutaneous sensibility, or even if it is localised at all in the cortex. This difficulty may, however, arise from the great extent of cortex to which the tactile projection fibres are distributed. It is, I think, quite certain that the sensory projection of any part of the general surface of the body is not localised, as Munk teaches and as is believed by many neurologists, to the part of the Rolandic cortex stimulation of which produces movements of that part.¹

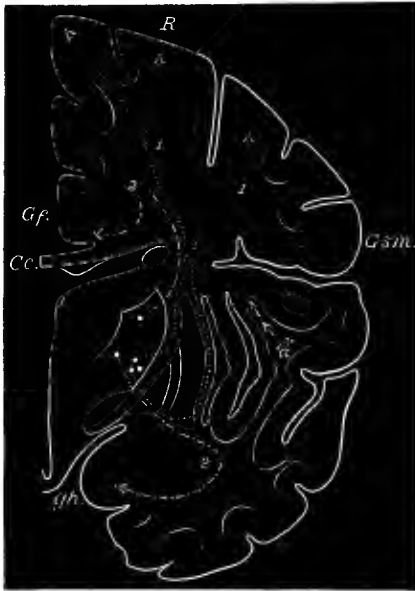

FIG. 350.—Diagram of a frontal section through the brain of a new-born child, to show the course and destination of fibres from the optic thalamus to the cortex. *Cc*, Corpus callosum; *Gf*, gyrus fornicatus; *gh*, gyrus hippocampi; *Gsm*, gyrus supramarginalis; *R*, Rolandic region; 1, 1, fibres belonging to the first system; 2, 2, fibres belonging to the second system; *a*, fibres passing to the superior and transverse temporal gyri.—Flechsigs.

month of foetal life) are situated in the part of the internal capsule immediately behind the pyramidal fibres, and pass almost entirely to the two central or Rolandic gyri (but some go to the visual sphere); the second (Fig. 350, 2, 2), which appear about a month after the first, go partly to the Rolandic region, partly to the gyrus fornicatus and the cornu ammonis (the latter by way of the cingulum),

¹ *Journ. Physiol.*, Cambridge and London, 1894, vol. xv. p. 469.

⁴ "Die Localisation der geistigen Vorgänge insbesondere der Sinnesempfindungen des Menschen," Leipzig, 1896.

and partly to the gyrus hippocampi; the third (which appear from one to several months after birth) go partly to the third frontal gyrus (by way of the fasciculus subcallosus), partly into the frontal lobe, almost to its apex; not ending here, however, but bending sharply backwards to the middle third of the gyrus fornicatus, to the anterior part of the first frontal gyrus, and to the foot of the second frontal gyrus. Almost all these fibres come from the lateral nucleus of the thalamus opticus, which constitutes, in Flechsig's opinion, a special station on the course of the afferent tracts towards the cortex, and which receives from below the chief part of the fillet layer, the superior peduncle of the cerebellum, the longitudinal bundles of the reticular formation, and part of the posterior longitudinal bundle.¹ It appears obvious that these three systems, which are developed at considerable intervals from one another, cannot be regarded as having an identity of function, although it is not easy, in the present state of our knowledge, to indicate exactly what their several purposes may be. The fibres of the first system being distributed almost exclusively to the motor regions of the cortex, and becoming developed very early (a month before birth), may perhaps be regarded as excito-motor fibres for cerebral reflexes; they perhaps represent the fibres which convey impressions of muscular sense. Those of the second system, which are developed at about the time of birth, may well be those for the conveyance of cutaneous perceptions; their existence affords strong confirmation of the view that the limbic lobe is intimately connected with this sensory function.² It is still more difficult to conjecture the special function of the third system of Flechsig, which is developed so much later than the others, and the myelination of which apparently extends over a considerable period of time, but it may perhaps be constituted merely by reinforcing fibres for the other two systems.³

THE INEXCITABLE REGIONS OF THE CORTEX. ASSOCIATION AREAS OF FLECHSIG.

It will be seen that if we mark off upon the surface of the cerebrum the areas from which a response to stimulation is obtainable, and to which we can with some probability ascribe a definitely localised function, whether motor or sensory, a large proportion—relatively much larger in man than in monkey,⁴ and becoming progressively smaller in descending the scale of intelligence in mammals—remains over. With regard to those portions of the surface which for the sake of brevity we may

¹ According to Flechsig and Hösel, part of the main or upper fillet goes *directly* into the internal capsule and is connected with the central gyri, but this statement has not been confirmed by any other observer. Mott, after lesions of the fillet in the monkey, could trace no degeneration beyond the thalamus (*Brain*, London, 1895, vol. xviii. p. 1).

² There are also a certain number of published clinical cases which tend to favour the view that the limbic lobe, and especially the gyrus fornicatus, is especially related to tactile sensibility (see Savill, *Brain*, London, 1891, vol. xiv. p. 270, and *ibid.*, vol. xv. p. 448), but the importance of this evidence is diminished by the fact that extensive lesions of the gyrus fornicatus, which do not involve important neighbouring structures, are practically unknown.

³ Flechsig appears to regard all these systems of fibres as connected with cutaneous sensibility, and considers that their distribution indicates exactly the extent of the area for cutaneous sensibility, which he accordingly locates in the several regions to which they pass, namely, the Rolandic region (including the two central gyri, the gyrus marginalis, and the bases of the first, second, and third frontal gyri), the gyrus fornicatus, cornu ammonis, and part of the gyrus hippocampi.

⁴ Amounting, according to Flechsig, to two-thirds of the whole cortex in man.

speak of as the inexcitable or latent portions, since they are distinguished from the rest by the fact that their excitation produces no obvious response, and their excision no definite paralysis, their function is at present a matter of conjecture.¹ What appears clear is, that any

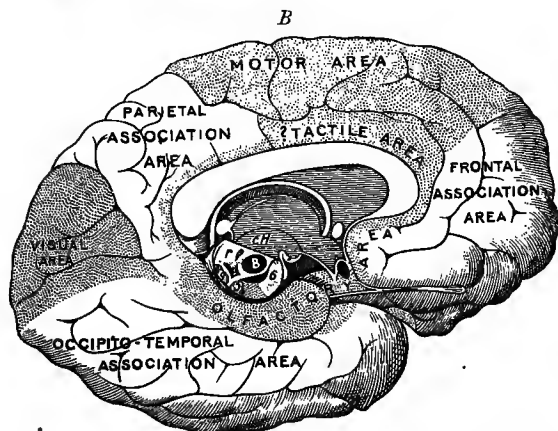

FIG. 351.—Diagrams to show the supposed division of the cerebral cortex into projection and association areas, the former being shaded with dots. A, lateral; B, mesial surface.—Modified from Flechsig.

¹ An anatomical distinction between the excitable and latent areas consists in the fact that whereas the latter all belong to the five-layered cortical type of Meynert, the excitable regions, and to these must be added the gyrus fornicatus and hippocampal lobe, all possess, either in addition to or in substitution for the usual five layers of cells, certain peculiarities of structure, e.g. the giant cells of the Rolandic area, the small stellate cells of the visual area, the special features of the hippocampal region, etc.

² It must, however, be observed that this statement is probably true of the excitable regions also.

³ Dejerine, however, finds that the prefrontal lobe is united to the internal nucleus of the thalamus by numerous fibres (*Compt. rend. Soc. de biol.*, Paris, 1897, p. 178); and other authorities have come to a similar conclusion ("Versl. Deutsch. Naturf. u. Aerzte," *Neurol. Centralbl.*, Leipzig, 1896, S. 995). Flechsig, *ibid.*, 1897, S. 290, finds that the internal nucleus of the thalamus is developed proportionally with the development of the so-called association centres.

⁴ Article "Brain" in Stricker's "Handbook"; also "Psychiatrie," Wien, 1884, and "Neue Studien ueber die Associationsbündeln des Hirnmantels," *Sitzungsber. d. k. Akad. d. Wissensch.*, Wien, 1892, Bd. ci.

extensive lesion, especially bilateral, of these portions, leads to alterations in the intellectual condition of the patient, alterations which appear to vary directly with the amount destroyed.² These inexcitable portions of brain surface are chiefly massed in the prefrontal, in the post-parietal, in the temporal, and in man in the occipital, regions; to which must be added the cortex of the island of Reil.

According to Flechsig, the fibres of the corona radiata of all these parts become myelinated far later than those of the excitable areas, and very few of the fibres pass downwards as projection fibres,³ but nearly all belong to that class of inter-nuncial fibres which were termed *association fibres* by Meynert,⁴ from the fact

that they connect either neighbouring or more distant parts of the cortex.

Most of the association fibres are comparatively short, but there are some well-known long tracts of this description, such as the *superior longitudinal bundle* passing between the Rolandic region and the parieto-occipital region; the *perpendicular bundle* passing between the parietal lobule and the temporo-occipital region; the *anterior association bundle* connecting the frontal and temporal lobes and passing across the bottom of the Sylvian fissure; and the *inferior association bundle* connecting the temporal and occipital lobes and the fibres of the fornix and cingulum (see Fig. 352).

According to Flechsig, the association fibres, which are both centrifugal and centripetal, serve largely to connect the inexcitable or association

FIG. 352.—Diagram of the association fibres of the cerebral hemisphere. *s.*, short fibres, connecting adjacent gyri; *f.l.s.*, fasciculus longitudinalis superior; *f.l.i.*, fasciculus longitudinalis inferior; *f.u.*, fasciculus uncinatus; *ci.*, cingulum; *f.p.*, fasciculus perpendicularis; *fo.*, fornix; *f.*, fimbria; *v.d.A.*, bundle of Vicq d'Azyr.

areas with the excitable or projection areas, and through them also the various projection areas are indirectly interconnected and coagitated. Flechsig regards, therefore, these inexcitable regions of the cortex as constituting a great association centre, or rather three association centres, which he designates respectively the *frontal*, the *parieto-occipito-temporal*, and the *insular* centre, the chief function of these centres being to associate together impressions received from the adjacent sensory or projection areas. Dependent upon them is the due appreciation of the impressions recorded upon the several parts of the sensory cortex, and he also regards them as the seat of memory.¹ Hence their lesion, although

¹ The portions of the association areas which lie immediately adjacent to the excitable areas (which latter, according to Flechsig, are really sensory) are termed by Flechsig the "marginal zones." They receive from the excitable areas innumerable fibres of association; and according to Flechsig are concerned especially with the memory of sensory impressions.

not productive of paralysis nor of any actual loss of sense, yet leads to inability to appreciate the impressions which are received through the sense organs, to loss of memory, and to a diminution of the intellectual faculties.¹ It has often been supposed that the frontal lobe is the special seat of the intellectual faculties;² chiefly on the ground that this lobe—at least the non-excitabile anterior part (pre-frontal)—is much more developed in man than in the lower animals. But this is also true for the region which Flechsig terms the parieto-occipito-temporal association area;³ and although cases in man are cited of lesions of the frontal lobes which have been followed by considerable mental and intellectual disturbance, this is equally a consequence of extensive lesions, especially bilateral lesions, of any part of the cortex. It is in fact more easy to produce a condition of semi-idiocy in monkeys from extensive bilateral lesions of the temporal lobes, than from complete severance of the pre-frontal region; an operation which may indeed be effected without producing any very obvious symptoms.⁴

It is important, in effecting an extensive lesion of any part of the brain, to avoid if possible removing the cerebral substance, or interfering more than can be helped with its vascular connections. It is sufficient to cut off the part to be removed by a subcortical incision, so as completely to sever all its nervous connections with the rest of the brain, leaving the piece thus isolated *in situ*. In this manner much of the shock of the operation, and the mechanical and vascular disturbance of the whole hemisphere, which results from entire removal of a large piece of brain, and which may lead to erroneous conclusions being arrived at,⁵ are in some measure avoided. Operating in this way, I have in several cases completely removed in the monkey the whole of the inexcitable area of both frontal lobes without producing the slightest sign of the mental and intellectual dulness and alteration of character which has been regarded as pathognomonic of a lesion of this region.⁶ Many cases have also been described in man in which lesions of the frontal lobes have not been followed by any marked symptoms of this kind, and, on the other hand, they are apt to supervene with extensive bilateral lesions of other parts of the cortex.⁷

So much has been made of certain clinical cases in which an extensive lesion of the frontal lobes was followed by diminution of the intellectual

¹ For a criticism of Flechsig's views see Dejerine, *Compt. rend. Soc. de biol.*, Paris, 1897, p. 178, who insists that numerous fibres pass from *all parts of the cortex* to the basal ganglia, or, in other words, that the association areas of Flechsig are in fact also projection areas. It must not be overlooked that the association of action of different parts of the cerebral cortex may equally well be carried out through fibres passing vertically in the corona radiata to and from the thalamus as by fibres passing tangentially from one portion of the cortex to another.

² See below.

³ The parietal lobe, rather than the frontal, has been especially found to be developed in some men of genius. This has been the case with great musicians, such as Bach and Beethoven, and also with men eminent in science and philosophy, such as Dollinger, Gauss, Liebig, and Kant (cf. Rüdinger, "Ein Beitr. z. Anat. d. Affenspalte, u. s. w.," Bonn, 1882).

⁴ Horsley and Schäfer, *Phil. Trans.*, London, 1888, B; Schäfer, *Trans. Internat. Cong. Psychol.*, London, 1893.

⁵ Ferrier and Turner, for example, obtained on extirpation of the left frontal lobe in front of the precentral sulcus, deviation of both eyes to the left, paresis of the right arm and leg, left hemiopia and impairment of cutaneous sensibility over the whole of the right side, a dull, sleepy condition being also observed (*Phil. Trans.*, London, 1898, B, p. 365). It is impossible to suppose that all the functions which were impaired by the lesion had their seat in this lobe.

⁶ Compare with these the results obtained by Bianchi, see *Brain*, London, 1895, vol. xviii. p. 498; also Groszbeck, *Arch. f. Physiol.*, Leipzig, 1895, S. 98. Such examples of a markedly contrary result are probably due to neglect of the above-mentioned considerations.

⁷ Cf. Bruns, *Neurol. Centralbl.*, Leipzig, 1898, S. 770, 848; Williamson, *Brain*, London, 1896, vol. xix. p. 346; Bernhardt, "Symptomologie u. Diagnostik der Hirngeschwülste," Berlin, 1881; Oppenheim, "Die Geschwülste des Gehirns," Wien, 1896.

faculties, and by a change for the worse in the general disposition of the individual, that it is important to ascertain what the clinical evidence on this point really amounts to. Welt¹ has collected fifty-nine cases of lesions confined to the frontal region in man; of these, forty-seven (or about 80 per cent.) showed no changes in intellectual capacity or in character; and only twelve of the total number (or 20 per cent.) had such changes recorded against them. It is clear, therefore, that the doctrine of special localisation of the intellectual faculties in the latent or inexcitable portion of the frontal lobe rests on no sufficient basis.

We cannot, therefore, say that the intellectual faculties reside in this part more than in another; they are apparently bound up with the integrity of the whole organ. But what part of the changes of which they are the manifestation take place in the "sensory areas," what part in the "motor areas," and what part in what Flechsig has termed the "association areas," there is no evidence to show. That there is, however, some localisation in connection with the expression of intellectual processes in the association areas, is evidenced by the phenomena of aphasia to which attention will immediately be directed.

It must be borne in mind that although the inexcitable regions of the cortex yield no obvious result on stimulation, at least in the direction of the production of movement, they may nevertheless be concerned in the production of inhibitory phenomena, which are no less important in neural physiology than the phenomena of movement. For, after they are extirpated, and especially is this said to be the case with the prefrontal lobes, the time and intensity of spinal reflexes is stated to become shortened; while, on the other hand, stimulation of these regions, and especially of the prefrontal, is said, in the dog, to cause prolongation of latency and diminution in intensity of spinal reflex responses.² It is further stated that these inhibitory influences travel both by the lateral and the anterior columns of the cord. Fano found that much more influence was exerted upon the reflex movements of the anterior than of the posterior limb, but that strong induced currents had in any case to be employed to obtain the inhibitory results. Very little effect was got by stimulating the occipital region, and none from the parieto-temporal. Neither ablation nor excitation of the *motor* region appeared to influence the spinal reflexes. This last statement appears improbable, and there can be little doubt that before drawing inferences of a general nature from these experiments they should be repeated, with every precaution to avoid fallacy, upon the monkey.³

It is noteworthy, confining our attention to the primates, although the statement appears to be one of general applicability to mammals, that as we ascend the scale of organisation we find the projection areas (both sensory and motor) of the cortex becoming relatively smaller and more concentrated, and the non-excitable or association areas occupying a larger proportion of the surface. This concentration is very obvious if we compare the Rolandic or motor areas of the monkey with those of the anthropoid ape and of man (Figs. 336, 339, and 340), and it applies not only to the whole motor area, but also to its individual components. It is also manifested in the auditory projection area,

¹ *Deutsches Arch. f. klin. Med.*, Leipzig, 1888, Bd. xlii. S. 339.

² Fano, *Atti d. r. Accad. d. Lincei*, Roma, 1895, tomo cccii., Rendiconti, p. 115; Oddi, *ibid.*, p. 118; Libertini, *Arch. per le sc. med.*, Torino, 1895, tomo xix.

³ Goltz had long previously noted that dogs with the anterior half or fronto-parietal regions of the brain bilaterally removed, became much more excitable and restless, and showed a complete absence of self-control and an exaggeration of many reflex movements; but there was of course much more than the prefrontal lobes lacking in these cases.

which in man appears, as the result of clinical and anatomical observation, to be confined to the upper part of the first temporal gyrus and the transverse temporal gyrus, whereas in the monkey it certainly extends far beyond this limit (indeed, extirpation of the whole of both temporal lobes is not in the monkey sufficient to produce complete deafness). And the same principle is illustrated in the case of the visual projection area, which in man appears, from clinical evidence, to be confined to the convolutions bordering on the calcarine fissure; while in the monkey it undoubtedly extends over the whole of the occipital lobe, which is relatively large in this animal. As regards the olfactory sense, the peripheral organ is so insignificant in all the primates that it is not to be expected that the cortical projection would be at all extensive in any. We have not sufficient knowledge of the exact localisation of the centres for taste and touch to draw a similar comparison.

APHASIA.

This term¹ is used to express not only a loss or defect of articulate language, but also "a loss or defect in symbolising relations of things in any way."² It occurs as the result of lesions upon the left side of the brain, and especially of the base of the third left frontal convolution. Three degrees may be distinguished, namely—(1) Defect of speech (*partial aphasia*); (2) loss of speech (*complete aphasia*); (3) loss of gesture language, *i.e.* of pantomime (*amimia*) as well as of speech (*asemasia*,³ Hamilton). In complete aphasia the patient does not speak intelligibly. He can only utter words without sense, or mere jargon.

Motor aphasia may show itself simply as a defect in or complete loss of utterance of spoken words (*aphemia*⁴), or simply as a defect in or complete loss of the ability to write intelligibly (*agraphia*), or as both these conditions combined.

The patient may understand what is said or read to him, and remember things told him. "This is important, for it proves that although speechless, the patient is not wordless." Apart from speech his articulatory and vocal organs may be unaffected. He may be able to sing. He smiles, laughs, frowns, and varies his voice so as to express emotions correctly. Although he has lost speech, he has not lost the images of things; he will point to any object which we name, and recognises drawings of objects. He may retain the propositional use of "yes" and "no," and either by these or by pantomime may intelligently assent or dissent to simple statements; he may have the interjectional or emotional use of certain words, such as oaths, which are uttered under appropriate circumstances, but cannot be repeated at will; in rare cases a proposition is stated or a question is asked intelligibly, but always under the influence of emotion. Some of these instances "show that there is not only retention of some words but of some speech, by the right side of the brain." In point of fact, as Gowers insists, "the left hemisphere has by no means a monopoly of speech function. The right hemisphere contains structures of similar position and similar connections. These structures can supplement those in the left hemisphere. Loss of speech due to permanent destruction of the speech region in the left hemisphere, has been recovered from; and that this recovery was due to the

¹ *á* and *φάσις*, speech.

² Hughlings Jackson, *Brain*, London, 1878, vol. i. p. 311. The quotations and descriptions which follow are chiefly from the same source.

³ From *á* and *σημαίνω*, an inability to indicate by signs or language.

⁴ *á* and *φῆμι*, I speak.

supplemental action of the corresponding region of the right hemisphere, is proved by the fact that in some of these cases speech has been again lost when a fresh lesion occurred in this part of the right hemisphere. This supplemental action occurs in the sensory as well as in the motor functions. It occurs far more readily in children than in adults . . . Hence it is probable that speech processes go on more equally in the two hemispheres in childhood than they do in adult life. It is also highly probable that there are individual differences in this respect among adults."¹ Two processes are involved in speech as in other forms of volitional expression, the one involving sensory, the other motor regions of the cortex. Thus the idea of words may be aroused through the senses of hearing, sight, or touch, and the parts of the brain where these perceptions occur are connected with the speech centre proper, which is an association centre, situated mainly if not entirely in the posterior part of the third left frontal convolution.² Accordingly, we may have aphasia of certain kinds from inability to express words heard or words seen, produced by lesions in the sensory areas ("word-deafness," "word-blindness"). This is spoken of as "sensory aphasia" (Wernicke). Such forms of aphasia occur from lesions of the temporal region (especially the superior gyrus), and of the occipital region respectively, or both motor and sensory aphasia may be combined.

There may be inability to *recollect* words, to revive the word images (*verbal amnesia*). Patients with this affection can repeat words after you when hidden, which is not possible in cases of so-called motor aphasia.

Further, lesions producing aphasia or amnesia may occur in the fibres connecting the several centres³—sensory and motor; this is illustrated by the appended diagram (from Gowers), in which *S* is the speech centre;

A the centre for movements of the hand; *SC* fibres from the speech centre to the corpus callosum and opposite hemisphere; *Sm*, *Am*, fibres to the internal capsule. A lesion at *x* must cause permanent aphasia, since it involves both the fibres to the internal capsule and those to the corpus callosum, but would not cause *agraphia* (inability to write intelligibly), for impulses can still pass from *S* to *A*; one at *y* might cause only transient aphasia, the impulses from *S* being able to pass through the corpus callosum to the opposite speech region.

There is abundant evidence that amnesia and even complete aphasia may be produced by lesions of the cortex of the left hemisphere elsewhere than in Broca's convolution. Thus, as has already been stated,⁴

FIG. 353.—Diagram to show the manner in which lesions of inter-nuncial fibres may produce aphasia.—Modified from Gowers.

it has been found that lesions of the temporal region, especially of the first and second temporal gyri and of the gyrus supramarginalis, are causative of the condition known as word deafness,¹ *i.e.* words although heard are not understood, not "perceived," nor can words be recalled to memory. An individual with such a defect is unable to speak or to write intelligibly, although, if the visual centre is intact, he might be able to comprehend written language. And, as Bastian has pointed out, a lesion in the association fibres which connect the auditory word centre with the speech centre, would be equally productive of the same condition.²

Similarly, word-blindness (*alexia*) has been found to result from lesions in or near the left occipital region, written language becoming unintelligible, although spoken language may be comprehended. There is in these cases necessarily a condition of *agraphia*. Further, in the production of such acts as reading aloud or writing from dictation, both the visual and the auditory word centres as well as Broca's centre and the motor centres of the left hemisphere must all come into action, and a lesion of any one of these or of the association fibres connecting them one with another must be fatal to the proper performance of these actions. The cortex of the island of Reil of the left hemisphere has been supposed by Meynert to be a special association centre for language; it is better developed in the primates than in other animals, and has very few callosal fibres uniting it with the cortex of the opposite island.

Sensory aphasia may show itself as a defect in or loss of recollection of words, especially of names of people or things, although the idea of the thing is represented in consciousness (verbal amnesia), or it may show itself as word-blindness or word-deafness, or as a combination of two or more of these conditions.³

THE CONNECTIONS OF THE CORTICAL CENTRES WITH ONE ANOTHER AND WITH THE LOWER CENTRES.

Connections of the frontal lobe and Rolandic area.—The Rolandic

¹ Wernicke, "Der aphasische Symptomencomplex," 1874. Bastian appears to have been the first to point out that aphasia may result from disturbance in an auditory centre of the cortex ("On the Various Forms of Loss of Speech in Cerebral Disease," 1869), although the position of such centre was at that time unknown, and its very existence purely hypothetical.

² It is held by Herbert Spencer and by Bastian that words are revived in the cerebral hemispheres, as remembered sounds or visual impressions. This view appears more probable than that of Wundt and Bain, which considers that words are revived as faint impressions of the processes occurring in motor cells during their articulation.

³ The subject of aphasia is far too large and the literature much too voluminous to be dealt with here otherwise than in the briefest possible manner. The student is referred, for an account of all the varieties which occur and a full discussion of the conditions under which the different forms are produced, to the works of Bastian, "On the Various Forms of Loss of Speech, etc.," 1869; "Brain as an Organ of Mind," "Paralyses, Cerebral, Bulbar, and Spinal," London, 1886, and especially, "On Aphasia," etc., 1898; Wernicke, "Der aphasische Symptomencomplex," Breslau, 1874, and *Fortschr. d. Med.*, Berlin, Bde. iii. and iv.; Ogle, *St. George's Hosp. Rep.*, London, vol. ii. p. 83; Kussmaul, Ziemssen's "Cyclopædia," London, 1877, and "Störungen der Sprache," 1885; Lichtheim, "On Aphasia," *Brain*, London, 1885, vol. vii.; Grashey, *Arch. f. Psychiat.*, Berlin, 1885, Bd. xvi. S. 654; J. Ross, "On Aphasia," London, 1887 (which includes a brief and clear account of the various views that have been taken to explain the several forms of aphasia); Gowers, "Diseases of the Brain," London, 1893; Charcot, reported by Marie in *Progress méd.*, Paris, 1888, No. 5; Allen Starr, *Brain*, London, 1889, vol. xii. p. 82; Bateman, "On Aphasia," London, 1890; Dejerine, *Compt. rend. Soc. de biol.*, Paris, 1891; Shaw, *Brain*, London, 1893, vol. xvi. p. 492; Byrom Bramwell, "Morison Lectures," Edinburgh, 1900. In several of these works the principal literature of the subject will be found referred to.

(motor) areas of the cortex are connected with the mesencephalic, the pontine, the bulbar, and the spinal motor centres by means of the fibres of the pyramidal tract, which constitute the projection fibres of this portion of the cortex. These fibres take origin in some of the cells of the motor cortex—perhaps in the “giant cells,” which were described there by Betz and by Bevan Lewis—and pass in the corona radiata directly to the middle two-thirds of the internal capsule. This middle two-thirds is the only part of the capsule which is directly excitable by artificial means; the anterior and posterior sixths being apparently inexcitable. The anterior sixth is largely composed of fibres which come from the prefrontal region of the hemisphere, while the posterior sixth appears to be chiefly composed of afferent (sensory) fibres, which probably have their origin for the most part in the thalamus. As the fibres of the pyramidal tract course downwards through the internal capsule they show a tendency to be arranged in such a way that the fibres which come from the region for the head and eyes and from that subserving movements of the tongue, are chiefly accumulated in the anterior half of the excitable region; those from the face, from the upper limb, from the trunk, and from the lower limb in the posterior half.¹ There is, however, as the study of the detailed results obtained by Beever and Horsley shows,² a considerable overlapping of the representation of the several parts above enumerated, and this overlapping and intermingling tends to increase as the fibres are traced downwards, and becomes even more marked in the crusta. Here such arrangement as can be detected by localised stimulation shows that the order of fibres from within out is also face, upper limb, trunk, lower limb.³ The intermingling which obtains is strikingly exemplified by the results of degeneration after localised lesions of the cortex, since after lesions which are strictly limited to one of the excitable areas of the Rolandic cortex, degenerated fibres are found scattered over almost the whole of the excitable part of the capsule (although more numerous in some parts than in others), and over the whole of the excitable part of the crusta.⁴ Diagrams, therefore, representing the excitable (motor) part of the internal capsule, as divided up into segments, each of which contains fibres subserving only the movement of a particular part of the body, convey an erroneous impression of the actual distribution of the pyramidal fibres in the capsule. All that can be definitely stated is, that there is a greater accumulation of the fibres subserving the movement of this or that part in one section than in the others.

The pyramidal fibres, after arising from the cortical cells of the Rolandic area, first give off collaterals which pass into the adjacent grey matter, and perhaps others which pass into the corpus callosum, and are then continued into the internal capsule, the middle part of the crusta, and the pyramidal bundles of the pons, to be collected in the medulla oblongata into the distinct masses which are known as the pyramids. Many fibres belonging to the pyramidal system end in the substantia nigra and in the grey matter of the pons and medulla oblongata. Arrived at the lower part of the medulla oblongata, the fibres of the pyramids enter the spinal cord in three tracts. By far the larger number pass directly at the decussation of the pyramids into the opposite lateral column of the spinal cord, forming the *crossed lateral pyramidal fibres*. A certain number pass into the lateral tract of the same side of the cord,⁵ and become intermingled with the fibres of the crossed

pyramidal tract which have been derived from the opposite pyramid of the medulla oblongata (*uncrossed lateral pyramidal fibres*). And lastly, a certain number remain in the anterior or ventral part of the cord, and are continued down for a variable distance in the anterior column of the same side close to the anterior median fissure (*uncrossed ventral pyramidal fibres*). This direct or ventral pyramidal tract is not present as a distinct tract in the lower animals, not even in monkeys;¹ it is not known whether it occurs in the anthropoid apes. The fibres of the lateral pyramidal tract terminate amongst the cells at the base of the posterior horn, in the neighbourhood of the lateral horn, and amongst the cells of Clarke's column,² not amongst the cells of the anterior horn as has generally been assumed.

Besides the connection with the lower centres, by means of the fibres which the pyramids form, there appears to be another path of communication between the motor cortex and the nuclei of the motor nerves, by way of fibres which pass in the corona radiata and internal capsule to the nuclei of the pons, and perhaps to the substantia nigra, and thence by fibres which go either at once to the motor nuclei by way of the posterior longitudinal bundle and anterior descending tract of the cord, or indirectly with intercalation of the cerebellum. This second path of connection between the Rolandic area and the lower centres has not, it is true, been absolutely proved, but its existence would be very probable if the statement of Starbinger³ is correct, that section of the pyramids (in the dog) produces no persistent loss of voluntary power over the muscles.

Cajal⁴ describes axons of many of the pyramidal cells of the frontal lobe as passing to the corpus striatum. After destruction of the frontal lobe in dogs and monkeys, Marinesco⁵ found numerous degenerated fibres in the corpus striatum and especially in the caudate nucleus.⁶ On the other hand, the corpus striatum receives numerous fibres from the thalamus and the sub-thalamic region, and probably sends out centrifugal fibres downwards, along the motor tract; but these have not hitherto been satisfactorily traced; some appear to go to the substantia nigra. The corpus striatum is generally believed to act as a centre for the higher reflex movements, and to be in close association with the Rolandic area, but the experimental grounds for this belief are still lacking.⁷ Morphologically, the corpus striatum is regarded as a part of the cortex.

Corticopetal tracts pass, as shown by Flechsig,⁸ to the Rolandic area from the lateral nucleus of the thalamus (see p. 768). Monakow further found that after extirpation of this part of the cortex in young animals, there was atrophy in the fillet and in the nuclei of the opposite posterior columns of the medulla oblongata.⁹ Flechsig and Hösel¹⁰ state that part of the fibres of the

fillet, and some perhaps also of the superior cerebellar peduncle, pass directly to the same area, chiefly to the ascending parietal gyrus, but this direct connection of fibres of the fillet with the cortex could not be found by Mott, and is also denied by Dejerine.¹ The Rolandic areas are further commissurally connected with one another through the middle part of the corpus callosum, and by stimulation of these commissural fibres the grey matter of both sides can be simultaneously set in activity.² If one hemisphere be cut away and electrodes applied to the cut surface of the corpus callosum, the motor centres in the remaining hemisphere may be excited through the fibres of this commissure as readily as if the electrodes were applied directly to the grey matter, and the effects produced are similar, but not so easily isolated. That the movements which are produced by excitation of the callosal fibres are brought about through the cortex, and not by fibres which have been described as passing from the cortex of the one side across the corpus callosum directly to the internal capsule of the opposite side,³ is shown by the fact that they are not obtained if the Rolandic cortex is destroyed, although the connection between corpus callosum and internal capsule may not thereby be interfered with. Nor is degeneration set up in the opposite internal capsule by removal of portions of the cortex of one hemisphere, although localised degenerations are thereby produced in the corpus callosum, and can be traced to the corresponding part of the Rolandic area of the opposite cortex.⁴ The fibres connecting the different motor centres of the two hemispheres through the corpus callosum, although massed together at certain places so as to give specific results on exciting these places, nevertheless show a certain amount of scattering, as can be ascertained by following the degenerations which result from localised cortical lesions (Sherrington). The corpus callosum also contains other fibres serving to connect the parts of the brain in front of and behind the Rolandic region. It is constituted, in fact, by a great mass of fibres, which must serve to effect an association of action between the two hemispheres. But the exact purpose of such association is by no means clear. Association of movement between the two sides can, and does, occur in the lower level centres, and although it is very probable that there is also association through the corpus callosum, it is nevertheless the case that this commissure can be completely divided in animals without any distinct symptoms being manifested. Many cases have been recorded of congenital absence of the corpus callosum in man. These are generally associated with a condition of greater or less idiocy, but this may be the result of a general lack of cerebral development, which usually accompanies absence of the commissure. In one or two cases of its complete absence, which have been published, no symptoms were noticed during life.⁵ The Rolandic area further receives numerous association fibres from other regions of the cortex.

The prefrontal (non-excitabile) region of the cortex sends corticifugal fibres down in the anterior part of the internal capsule and in the mesial bundles of the crusta, to end in the grey matter of the nuclei pontis.

¹ *Compt. rend. Soc. de biol.*, Paris, 1895, p. 285.

² Brown-Séquard, *Compt. rend. Soc. de biol.*, Paris, 1879; Mott and Schäfer, *Brain*, London, 1890, vol. xiii. p. 174.

³ Hamilton, *Proc. Roy. Soc. London*, 1884, p. 349. The fibres described by Hamilton appear to be really corticifugal fibres passing from the optic thalamus of one side across the corpus callosum, to the cortex of the opposite side (Ferrier and Turner, *Phil. Trans.*, London, 1898, B, p. 31).

⁴ Muratoff, *Arch. f. Anat. u. Entwicklungsgesch.*, Leipzig, 1893, S. 97. Tschermak, however, found it to obtain in the cat, *ibid.*, 1898, S. 291. But Mellus (*Proc. Roy. Soc. London*, 1895, vol. lviii. p. 206) found in some cases, in the monkey, after lesions of the cortex of the one side, degenerated fibres in considerable numbers, running (presumably after having crossed by the corpus callosum) to the opposite internal capsule.

⁵ For abstracts of a large number of cases recorded by others, and an account of a case observed by himself, see a paper by Alexander Bruce in *Brain*, London, 1889, vol. xii. p. 171; see also Dunn, *Guy's Hosp. Rep.*, London, 1889, vol. xlvi. p. 117.

According to Dejerine,¹ lesions of this prefrontal region are also followed by degeneration in the stratum opticum of the thalamus, with subsequent atrophy of the mesial nucleus. Lesions of the parietal lobe and angular gyrus, on the other hand, cause, according to the same author, degenerations in the pulvinar and posterior part of the lateral nucleus. From the base of the third frontal convolution, and from the operculum, fibres pass into the mesial fasciculus of the crista.

Connections of the visual area.—To the occipital lobe both corticifugal and corticipetal fibres can be traced. The corticifugal fibres pass chiefly to the pulvinar thalami and anterior quadrigeminal body of the same side,² and are scattered as they pass from the cortex amongst the other fibres of the optic radiations. The occipital lobe also sends fibres to the crista.³ The corticipetal fibres (optic radiations) arise from the lateral geniculate body,⁴ and also from the pulvinar thalami. They are traceable, according to Ferrier and Turner, not only to the occipital lobe, but also to the angular gyrus, whereas, according to Henschen and to Flechsig, they pass chiefly, if not entirely, to the cuneus and the lips of the calcarine fissure. M. and Mme. Dejerine have also described connections of the lingual and fusiform lobules with the posterior and inferior parts of the thalamus.

The occipital lobes are said to be commissurally connected with one another through the splenium of the corpus callosum;⁵ according to Ferrier and Turner, the same statement applies to the angular gyri. The occipital lobe of one side is also connected with the temporal lobe of the opposite side by some of the fibres of the corpus callosum which form part of the tapetum (Sachs). There is, further, a well-marked tract of longitudinally coursing association fibres which passes forwards to connect the occipital with the frontal lobe, and shorter association fibres connecting it with nearer portions of the hemisphere.

The corticipetal tract for visual perceptions passes from the peripheral sense organs by way of the optic nerves and tracts to the corpora geniculata lateralia, thence as just stated by the optic radiations of Gratiolet to the visual area in the occipital lobes. According to Monakow, 80 per cent. of the fibres of the optic tract pass to the corpus geniculatum laterale and pulvinar, where they terminate, new fibres arising in these nuclei and continuing the optic path to the occipital lobe. Here these (corticipetal) fibres terminate mainly in the cuneus and the lips of the calcarine fissure. But, according to Flechsig, it is from the macula lutea that fibres pass—at least indirectly—to the calcarine fissure, not from the retina generally.⁶ v. Monakow has shown that extirpation of the occipital cortex in young animals leads to atrophy of the cells of the lateral geniculate body, whereas section of the optic tract does not affect the cells, but the grey matter in which they lie.

The manner in which the fibres pass from the lateral geniculate body to the visual cortex has been studied by Cajal, who finds that they are collected into a bundle situated at the upper and outer part of the cerebral peduncle, and continued into the internal capsule, whence they radiate into the occipital lobe; here they are continued into the grey matter, where they appear to form the stripe of Gennari.⁷ Other fibres of the optic tract go to the anterior corpora

quadrigenina; these probably chiefly serve to carry impulses for reflex movements of the eye.

Loss of the eyes in a new-born pup is followed by diminished development (atrophy) of the optic nerves and tracts, of the occipital lobes, of the superficial white matter of the anterior corpora quadrigenina, of the corpora geniculata lateralia, and of the pulvinare thalami,¹ but not of the mesial corpora geniculata nor of the posterior corpora quadrigenina.

Connections of the auditory area.—Lesions of the first and second temporal gyrus are followed by descending degenerations in the part of the internal capsule which lies ventral to the lenticular nucleus and in the outermost part of the crista.² These fibres terminate in the nuclei pontis. There are also commissural fibres passing by way of the corpus callosum to the temporal and to the occipital lobes of the opposite hemisphere (Sachs), and association fibres passing into the angular gyrus, and into the occipital lobe of the same hemisphere, and probably also into the Rolandic area and towards the speech centre. The course of these last has, however, not as yet been definitely traced. Ferrier and Turner found no degeneration in the posterior quadrigeninal bodies, nor in the fillet, after lesions of the first temporal gyrus; v. Monakow, in experiments upon young animals, found atrophy of the mesial geniculate body to follow destruction of this convolution.

The corticopetal tract from the peripheral sense organ to the auditory area of the cortex, passes by the cochlear nerve to the auditory nucleus; other fibres arising thence probably terminate in the superior olive, the nucleus of the fillet, the posterior corpus quadrigeninum, and the mesial geniculate body of the opposite side; and others again, starting from these nuclei, carry the tract on to the cortex of the temporal lobe.

Connections of the olfactory region of the cortex.—The olfactory lobe (including the olfactory bulb and tract, and the part of the frontal lobe near the attachment of the olfactory tract)³ is connected with the two extremities of the limbic lobe. Fibres from the olfactory lobe pass by means of the outer root of the tract to the anterior part of the hippocampal gyrus, and other fibres have been traced from it into the fascia dentata. The inner root is connected with the anterior end of the gyrus fornicatus. Some of its fibres were described by Meynert as passing by way of the anterior commissure to the temporal lobe and hippocampal region of the opposite side, but the evidence of this "olfactory chiasma" is insufficient. There is, however, as Ganser has shown, a commissural connection between the two olfactory regions of the cortex by means of the anterior commissure. These connections have been already noticed (see p. 764). There is, further, an important association bundle in connection with this region in the cingulum, which courses in the white matter of the gyrus fornicatus and gyrus hippocampi; its fibres probably connect those gyri with the cortex of the outer surface of the hemisphere (Beavor).⁴ Zuckerkandl⁵ has described a bundle of association fibres in the body of the fornix connecting the cornu ammonis with the temporal and olfactory lobes.⁶ The hippocampi of opposite sides are said to be connected commissurally by the "lyra." The fornix further carries fibres from the hippocampus to the corpus albicans. Most of these end here, but some are said to pass to the opposite side and to end in the grey matter of the third

ventricle.¹ On the other hand, the axons from the cells of the corpus albicans (its mesial nucleus) bifurcate soon after leaving the cells, and while one set of branches pass by way of the bundle of Vicq d'Azyr to the anterior nucleus of the thalamus, the other set go to the tegmentum, and are ultimately traceable to the region of the trapezium in the pons Varolii; these form the *pedunculo-maxillary fasciculus* of Ramón y Cajal,² or the *tegmental bundle* of v. Gudden. From the lateral nucleus of the corpus albicans, other fibres, constituting the so-called *peduncle of the corpus albicans*, pass to the tegmentum, to end apparently in the central grey matter.

The hippocampus also sends fibres by way of the fornix and stria medullaris thalami to the nucleus habenulæ, whence other fibres arise and pass to the interpeduncular ganglion by way of Meynert's bundle (*fasciculus retroflexus*).³

REFLEX ACTION.

SPONTANEOUSLY arising conversions of internal into external energy, such as characterise the life of certain cells, for instance those of cardiac muscle, are not apparent in the life of spinal cells. All purely spinal reactions seem reactions to environmental change. They are reflex in the sense that the environment is causally related to them, and that to the environment they return again. The initiation of some is less directly and demonstrably traceable from the environment than that of others. The former are by a convenient usage often termed "spontaneous." The latter or obviously reflex comprise for the most part the relatively simpler. The distinctions drawn between reflex and spontaneous reactions naturally alter from time to time. The tendency with increasing knowledge of physical and chemical agents has been for an increasing number of reactions to be included as reflex.

Among the properties of living matter (bioplasm), those which by their high development in the nervous system may be said to characterise the physiological qualities of that system, are excitability to certain kinds of stimuli, spatial transmission of the excited state, and ability to control the liberation of energy in tissues adjoind to them-

selves. Hence the nervous system links together and co-ordinates the activities of the various organs. Its power of spatial transmission is technically known as its "conductivity."

In the physiological analysis of the reactions of the spinal system the unit reached is "the reflex." Upon it as basis our existing notion of the reactions of the nervous system is built. The whole neural system may be regarded as a superstructure resting upon two nerve cells, the two root cells, one afferent the other efferent. The afferent root cell is the alpha of every functional series of units in the system; the efferent root cell is the omega to which every series immediately or mediately leads. In every functional series of units there is a place or there are places where conduction involves change in quantity of the state of excitement transmitted, and alteration of its distribution both in space and time.

The places where such modification of the nerve impulses occur are spoken of as "nerve centres."

Stephen Hales first proved the spinal cord to be a seat of "reflection" as against other places where nerves seem to unite (for example, the nerve plexuses). Grainger¹ later indicated that in the spinal cord the grey matter is the seat of the reflection. It was then inferred that the essential element of the centre must be the nerve cell body (perikaryon); later, an inextricable net of nerve cell branches was found surrounding and continuous with the bodies of the cells (J. Gerlach); to these together were attributed the reflecting and distributing properties of the nerve centre. More recently, from evidence that goes to show that the branches of the individual nerve cells do not anastomose into a continuum, but retain morphological individuality, although functionally linked, stress has been laid on the possible properties of the places of linkage or *synapse*. The places where nerve cells thus "hold hands" with each other are not necessarily near to the cell body, although usually so. It is as the, with few exceptions, exclusive seat of modification and redistribution of nerve impulses that brain and cord play such pre-eminent part in the functions of the nervous system. Comparable seats of modification occur also at places of linkage outside the central nervous system, e.g. the places of linkage of the spinal nerve cells with the sympathetic nerve cells in the sympathetic ganglia, and of the linkage of spinal nerve cells with muscle cells and epithelial cells in motor end-plates, glands, and sense organs. These seem the nearest approach outside the brain and cord to anything of real likeness to a nervous centre.

Afferent is the term applied to nerve cells, considered as conductors, along which the waves of change normally excited pass in a direction away from the extrinsic, i.e. non-nervous tissues. *Efferent*, conversely, is applied to nerve cells which conduct normally towards extrinsic, i.e. non-nervous tissues. The afferent root cells taken together form one great pathway into an intricate congeries of nerve centres which the cerebro-spinal organ encloses. The efferent root cells conversely together form one great pathway out. And within the cerebro-spinal organ the nerve centres are not only very numerous but are of very various rank. The cerebro-spinal organ is fundamentally a chain of segmental centres, each segmental centre primarily a seat of reflection and distribution connected with the local conducting paths between sense cells and muscle cells of its own segment. The segmental centres have in the course of evolution of the nervous system come to be more and more put *en rapport* one with another by nerve cells overlying them, and dealing with them in groups. By means of these intermediate and overlying conductors, a nerve impulse may, besides embouching upon its own segmental muscle cells, travel over a concatenation of central nerve cells. The reactions which occur along nerve cell chains of a single link

¹ "Observ. on the Struct. and Functions of the Spinal Cord," London, 1837.

or of few links only are characterised by "monotony"; the reactions which employ long chains traversing many synapses are immensely variable. It is a cardinal feature in the architecture of the nervous system that the longest chains all include cerebral links. By rank in regard to nerve centres is understood such position as relieves from local or merely segmental work and involves general responsibility, *i.e.* for a series of segments or even for the whole body. A touchstone for rank of centre in this nervous hierarchy is the degree to which paths from separate loci and of differing sensual modality are confluent thither. A low centre lies at the focus of afferent paths from a limited locus and of one modality, *e.g.* from touch-spots in a small field of skin. A high centre receives widely divergent multi-sensual paths, *e.g.* from organs for touch, heat, cold, pain, and muscular sense for the hand as a whole.

In addition to its power to modify the distribution of nerve impulses, both in space and time, the nerve centre exhibits a valve-like function, allowing conduction to occur through it in one direction only.¹ This is called the "law of forward direction" in the central nervous system. That the direction of nerve impulses is not reversible along the neural chains, may be a function of the "synapse." This seems a bridge open to traffic from nerve cell A to nerve cell B, but barred to passage in the opposite sense. That this valve action of the nerve centre is attributable to the synapse, is rendered likely by the similar valve-like connection between motor nerve fibre and muscle cell and between an efferent nerve and sense cell. How securely the circuits of the nervous system are valved against regurgitation, is shown by the Bell-Magendie law of the reactions of the spinal nerve roots.

In reflex action at its simplest, it is difficult to demarcate between functions of nervous and those of muscular or other contractile tissue. Muscular tissue, like nervous, transmits a state of excitement induced in it at one point to others,—and even across extracellular boundaries.

The reaction in which a local irritation of some point of the Stanniused heart induces co-ordinate contraction of the whole myocardium, is akin to reflex action. It is not yet clear whether the nervous or the contractile tissue is really responsible for the reflexes of the medusa bell or of the manubrium of *Tiaropsis indicans*,² though cells resembling nervous have been demonstrated in the *Medusæ* (O. and R. Hertwig,³ Schäfer⁴), as in the heart ventricle (Heymans).⁵ In the Ascidian, *e.g.* *Ciona*,⁶ there is a characteristic "reflex" nexus between oral and aboral vents. When one aperture is touched, both shut. The musculature controlling each is of somewhat similar arrangement. The main ganglion of *Ciona* lies between the apertures, and is the nervous tie between the musculature of both. Yet, after ablation of the whole ganglion, the reflex, although the threshold stimulus required is heightened, is still elicitable. The nerve-path facilitates the reflex, but is not essential for it. The "reflex" activity of the striped muscle of the intestine of the tench⁷ seems altogether independent of the spinal cord. In the dog recent observations by Goltz and Ewald⁸ show persistence of the "reflex" opening and closure of the rectal and vesical sphincter, after complete removal of the corresponding region of the spinal cord.

The simplest reflex arc imaginable would be one in which a single nerve conductor passed from some tissue recipient of environmental stimuli to some other tissue responsive to the nervous excitement in

the conductor. Such an arc, formed by the intermediation of a single nerve cell between, for instance, a sensory tissue and a motile tissue, may exist in simple organisms, *e.g.* medusa, hydra, and perhaps in the viscera of vertebrates; but the reflex arc upon which the whole complex vertebrate nervous system is founded is less simple, and involves at least two nerve conductors and a linkage or synapse between them, as well as the recipient and the responsive tissues from which and to which respectively the two conductors carry. The peripheral part or path of the afferent conductor is one and the same, whether the arc employed be simple or complex. It forms the only channel of entrance into the whole nervous system. Similarly, the peripheral efferent conductor is the only channel out. Hence these two ways in and out must necessarily be treated introductorily to the reactions of the central nervous system.

It was in the seventeenth century that an idea truly allied to that which "reflex action" now denotes entered physiology. Some who then wrote on animal physiology express it, and among them, not earliest but most notoriously, Descartes. Previous to that century, certain "sympathies" between parts of the body had been noted, and had latterly been referred to communion established by nerves. In Cartesius' time (1650) the argument had become more precise. He pointed out that many of the nerves connected with the brain elicit, without affecting consciousness, involuntary movements. The involuntary closure of the eyelids in result of a threatened blow was one of various instances he gave. Such a process he designated a "reflected" one. Boyle brought to the question the Baconian touch-stone of experiment. He found the body of a viper for three days after decapitation "to be manifestly sensible of punctures, being put into a fresh and vivid motion, when it lay still before, upon being pricked." There is no evidence that Boyle thought such movements unaccompanied by sensation.

As to the seat of the reflexion, Descartes said the pineal gland, Willis the brain, nerve plexuses, and ganglia. Next century opinion came to be grouped into two camps, one maintaining the cerebro-spinal organ (Astruc, Hales, Perrault, K. Boerhaave, Haller, v. Swieten, Monro, and Whytt) to be the only seat of reflex action, the other the nerve plexuses and ganglia (Vieussens, H. Boerhaave, Vater, Meckel, and Gasser). Hales, rector of Teddington, contributed what is known as the fundamental experiment. He showed that the movements evoked by stimuli applied to the skin of the decapitated frog are lost irrevocably by destroying the spinal cord. Whytt's observations widened the notion "reflex," making it include salivation and contraction of the pupil. Muscular reactions he classified as—(1) produced by direct stimuli applied to muscles, (2) vital and involuntary, (3) voluntary. Each of these he considered accompanied by sensation. To Hales' fundamental observation he contributed a fundamental one on inhibition, noting that the reflex movements are inelicitable for the interval immediately succeeding the decapitation. Here again he invoked sensation, attributing the arrest to pain or fright. The part that Prochaska took in the development of the study appears over-estimated; his experimental contributions are negligible; he held, however, like Descartes, that some reflex actions do not involve sensation.

The Bell-Magendie experiment was the next step, and its importance can hardly be overstated. The localisation of the ingoing channel in one root, and the outgoing in the other, was followed by the discoveries by Mayo (1823) of a small circumscribed segment of the brain, which of itself, and alone, sufficed for the pupil reflex, and by Legallois (1826) of a small circumscribed portion of the bulb, injury of which at once paralyses the respiratory movements, whereas other injuries do not. The "localisation" was carried further by Flourens and Longet. Prior to the work of these last, Marshall

Hall's studies began, apparently in ignorance of much preceding knowledge. New points he ascertained are the tonic closure of the sphincters by reflex action, the cessation of strychnia convulsions on destruction of the spinal cord, and the easier excitation of reflexes by stimulating the end apparatus of nerves, than by stimulation of the nerve trunks themselves. In his own estimation, Hall's chief advance lay in the finding of evidence of separate nerve paths for reflexes unaccompanied by sensation, and apart from paths subserving sensation and volition. His evidence was not very satisfying, but it led to work by Grainger (1837), in which good proof was given that in the cord the sole seat of reflex centres is the grey matter; and, further, that each afferent root sends some fibres direct into the grey matter for reflex action, and some fibres upwards as a strand in the white matter, subserving the elaboration of sensation. Valentin suggested two years later that the nerve cells in the grey matter are structures for transferring impulses from the afferent to the efferent channels. Lastly, with the elder Waller's¹ discovery of degeneration of nerve fibres after section, came demonstration of the functional and morphological continuity between the conducting channels and their respective groups of nerve cells. The question of the action of ganglia as reflex centres was, for the spinal ganglia, answered in the negative in Johann Müller's text-book (1837). For the ganglia of the sympathetic an answer in the affirmative was declared by Henle,² Stilling,³ Claude Bernard,⁴ and others⁵; but except in a modified sense of the term "reflex centre," such as is afforded by the interpretation offered by Langley,⁶ its substantiation seems unlikely. The ganglia of invertebrata were at first supposed—chiefly owing to Newport's⁷ conclusions—to be like the spinal ganglia, not seats of reflexion; but Carpenter⁸ later proved them to have reflex powers, and pointed out their analogy with the spinal centres and brain, a view to which Newport subsequently gave adherence.⁹

THE WAY IN.

The peripheral afferent channel consists always of an elongated nerve cell, which by one of its ends extends to points accessible to the environment, including in the environment the "material me," and by the other end lies deeply embedded in linkage with other nerve cells of various rank, composing the machinery of the central nervous system. These nerve cells together form, therefore, the first part of the path travelled by waves of change constantly poured into the nervous system by the world of changing energy around it. These are the "primary afferent neurones" or the "afferent root cells." Their cell branches are as nerve fibres much commingled in most places with those of efferent and other nerve cells, but their cell bodies (perikarya) are collected apart into ganglia, which they thus form.

Assuming the whole organisation to consist of a fore and aft series of

segments, then the perikarya of the afferent root cells of each segment lie uncommingled with other nerve cells, and form the spinal ganglia (right and left) of that segment. And the branches thrust by the cells composing each spinal ganglion into the spinal cord, remaining unmixed with others, form a pure collection of afferent nerve fibres, known morphologically as the dorsal spinal root. This collection contains all the fibres from the sense organs in a segmental area of the body surface, which may be called a segmental skin-field (Fig. 354). It contains also all the fibres from the sense organs in the muscular and visceral apparatus belonging to the same segment. Similarly, the afferent root cells of the fifth and eighth and *intermedius* cranial nerves intrude nerve fibres as unmixed afferent roots into the brain. In a few but important exceptions, *e.g.* the vago-glosso-pharyngeal roots, the afferent fibres are commingled with efferent. The primary afferent path

FIG. 354.—Diagram of the arrangement of segmental skin-fields in the hind limb of the monkey. The numbers indicate the fields of the spinal nerves, thoracic and post-thoracic. *a.t.*, the axial line of the trunk, whether dorsal or ventral; *a.l.*, the axial line of the limb, whether dorsal or ventral. The "overlapping" of the fields is not represented.

for olfaction is peculiar, in that the bodies of its nerve cells are not aggregated, but, maintaining a very primitive disposition,¹ lie scattered severally among cells of non-nervous type in the olfactory region of the body surface.² Their proximal branches are, however, before entering the central nervous system, collected into pure afferent roots, the olfactory nerves.

Recurrent sensitivity.—Magendie's later experiments led him to the view that the ventral root has some sensory fibres in it, derived from those comprising the dorsal root. Denied by many,³ this has been upheld by Bernard and Schiff, and the place of rebending of the sensory fibres has been referred to a region of the peripheral nerve, some little way beyond the place of union of the two roots in the nerve trunk. Severance of the dorsal root or of the neighbouring dorsal roots excludes the phenomenon. Schiff noted,

³ J. Müller, Tiedemann, Van Deen, Stannius, Retzius, and Backer, early repeating the Magendie experiment, do not mention it; Longet, Chauveau, and others mention it to deny it.

after destruction of portions of the spinal cord (in birds), that the ventral roots were still found, when examined by the microscope, to contain a few undegenerated myelinate nerve fibres; these could be traced to the arachnoid and pia mater. Schäfer discovered that in the cat there are in the lumbar ventral roots a few nerve cells; these cells resemble the smaller of the cells of the spinal root ganglion; the number of these cells and the number of sound fibres remaining in the ventral spinal root, peripheral to its place of section, do not in many cases tally. A phenomenon somewhat similar to the slight sensitivity exhibited by the peripheral end of a severed ventral root, is met with on stimulating the peripheral ends of certain motor peripheral nerves after severance of the nerve nearer its origin. The branches of the facial of the dog, when examined in front of the parotid gland, exhibit it, unless the trigeminus is severed. The phenomenon is the more marked, the more peripheral the region of the nerve examined. Fibres can be traced by the degeneration method to loop back from the fifth nerve into these branches of the seventh.

Bell's¹ and Magendie's² observations, in so far as they dealt with the afferent channel, dealt with it only as a channel for exciting signs of sensation. Volkmann,³ later, showed that the dorsal root is also the channel for evoking reflex action after decapitation, and under circumstances, therefore, which there is reason to think exclude sensation. The discrimination between the functions of the roots was discovered, as above stated, in mammals. Wagner,⁴ Stannius,⁵ and Moreau⁶ found it to apply in fish; J. Müller⁷ and Panizza⁸ established it for the frog; and Panizza⁸ and Schiff⁹ for the bird.

The dorsal spinal root has been stated above to be a purely afferent tract of fibres. It does appear to be so in most animals; in some forms, however, it contains a few fibres which have origin in intraspinal cells, perhaps of efferent function. v. Wijhe¹⁰ holds that the ventral spinal roots of *Amphioxus* contain some afferent fibres. I¹¹ have brought forward some evidence in the same direction regarding the roots of the third, fourth, and sixth cranial nerves of mammals.

The histologists Ramón y Cajal¹² and v. Lenhossék¹³ have, by use of the method of Golgi, discovered in the dorsal (afferent) spinal root, nerve fibres arising from cells in the grey matter of the spinal cord itself. This discovery made in the chick has been extended to the cord of certain teleosteans.¹⁴ The nerve cells which give origin to these fibres of the dorsal root lie for the most part in the dorsal portion of the ventral grey horn. They are multipolar, and the microscopists describe them as "motor." This suggests exception of the Bell-Magendie law of direction of transmission in the spinal nerve roots, and calls to mind the recent account¹⁵ of peripheral effects following excitation of the distal ends of the dorsal spinal nerve root of the frog. Steinach and Wiener detected visceral effects, Horton-Smith detected effects on skeletal

muscles only. The visceral effects have been confirmed by another observer,¹ those on skeletal muscles have also been confirmed,² though it is stated they must be regarded as the individual exception and not the rule.³ Stricker⁴ affirmed the demonstration of vaso-dilator fibres in the mammalian dorsal (posterior) roots. Veias⁵ and Joseph⁶ state, in contradiction to the original observations by Waller,⁷ that in the cat and rabbit injury to the dorsal root, proximal to its ganglion, causes peripheral degeneration of a number of nerve fibres, which can be followed into the distal nerve trunk. On the other hand, the original observations by Waller have been confirmed by many,⁸ both in the spinal region of outflow of fibres for the sympathetic system⁹ and in other regions. The position arrived at is therefore as follows: In *Amphioxus*, where all the nerve cells of both spinal roots are intraspinal, some of the fibres of the dorsal root may be efferent, though the majority of them are certainly afferent.¹⁰ In *Petromyzon* some¹¹ of the fibres of the dorsal root spring not from cells of the spinal ganglion, but from intraspinal cells. These may be efferent. Also, in *Pristiurus* some of the fibres of the dorsal root arise from intraspinal cells, but in *Myxine* all arise from the extraspinal cells of the root ganglion. In the chick a few fibres of the dorsal root arise from multipolar intraspinal cells beyond all doubt, and in *Rana* peripheral effects result on exciting the peripheral ends of the dorsal root. In the mammal, efferent fibres appear to exist in certain dorsal nerve roots.

The total entrant path furnished by the whole collection of the afferent root cells is conveniently divisible by functional qualities into eight groups. These are—(1) from the retina; (2) from the olfactory surface; (3) from the cochlea; (4) from the vestibule and semicircular canals; (5) from the integument; (6) from the skeletal muscles (including their tendons) and from joints; (7) from the gustatory surface; and (8) from viscera.

The conditions attending the initiation of nerve impulses in the fibres of this entrant path are examined in the articles on the several sense organs. These fibres appear amenable to the same general stimuli as are other nerve fibres. Though afferent, they are quite indistinguishable in their electro-motive reactions and microscopic structure from efferent fibres. Certain differences, probably quantitative rather than qualitative, are, it is true, found between the excitability of afferent and efferent nerve fibres. The main laws of "double conduction," rate of transmission, etc., treated of in the section on general physiology of nerve, apply, however, to them as to other peripheral nerve fibres.

The total number of separate channels composing the spinal entrant path is probably always greater than the number composing the total spinal efferent

path. In two frogs, Birge¹ found 3781 and 5335 fibres in the afferent roots, and 3528 and 4283 respectively in the efferent roots. When the cranial roots are included, the excess of inferent channels over efferent channels becomes, of course, immensely greater still. It has been pointed out that, so far as examined, no spinal peripheral nerve trunk² of macroscopic size is made entirely of efferent fibres, whereas nerve trunks entirely composed of afferent fibres are numerous enough.

Probably the nerve impulse travelling by the afferent root cell of the adult, with its T-shaped process, does not traverse the perikaryon but sweeps tangentially past it. That the perikaryon might be indifferent for conduction in such cases, was urged in 1889 by Cajal³ from the histology of cells of the mesencephalic roof of the bird. An experimental observation by Bethe⁴ (1896) seems to have placed this hypothesis beyond doubt for certain cells of *Carcinus* (second antenna). Observations by Steinach⁵ confirm the same view for the cells of the spinal ganglion. The conduction is, of course, ultimately dependent on the cell body, since the cell branches cannot maintain their vitality in its absence.

The application of nicotin⁶ to the spinal ganglion does not hinder the conduction of impulses through it, as in sympathetic ganglia; in the latter there is a synapse⁷ or linkage between two cells. There is a difference in the answer obtained by different observers as to the question of alteration of speed of travel of nerve impulses traversing a ganglion. Wundt⁸ found the reflex time markedly shorter from the spinal root than from the nerve trunk peripheral to the ganglion. Exner⁹ found the negative variation travel with unaltered speed through the spinal ganglion. Gad¹⁰ found a longer delay in the development of a respiratory reflex, when excited from the far side of the vagus ganglion, than could be accounted for by the greater length of nerve cord traversed. Moore and Reynolds¹¹ have recently obtained on the spinal ganglion results confirmatory of Exner.

A nerve impulse traversing the afferent root cell passes when once within the spinal cord to various distances and in various directions, without leaving the root cell, and before impinging upon other nerve cells at the first intraspinal synapses. It is not known in many cases whether one afferent root cell may serve as entrant channel from sense organs of different kinds, e.g. whether one afferent nerve fibre from the skin is peripherally connected with tactual and with "cold" and "pain" organs. Probably each fibre is connected only with one species of sense organ. Similarly, it is not known whether one afferent root cell embouches intraspinally into only one or into a number of functionally

different intraspinal nerve paths. It seems likely that some afferent root cells do lead into spinal paths of various functional quality, e.g. into tactual, dolorific, and subconscious reflex.

The axon of the afferent root cell sometimes gives a "side-fibre" near its origin which recurves to apply itself to the perikaryon.¹

In all the spinal nerves the ascending stems from the afferent fibres seem to be longer than the descending, but in the case of some of the cranial nerves, e.g. trigeminus, the descending are the longer. In each of the spinal nerves the ascending stems from certain of the root cells pass to the dorsal column nuclei of the bulb; thus, from the lowest nerves, these ascending stems extend through the whole length of the spinal cord. What proportion of the root cells of any particular afferent root possess, by means of long ascending stems, direct connection with the bulbar nuclei, is not known; the large afferent roots belonging to the limbs seem to furnish a larger number than the small afferent roots of other regions. The total region of embouchment of any one afferent root in the cord is therefore wide. It extends from probably a couple of spinal segments behind the surface attachment of the root anteriorly to the bulb itself.

It appears pretty certain that in front of (above) the segments composing the particular region abutting on the segment to which the ganglion of the root belongs, the ascending stem passes most of the segments without sending collaterals into them, and unconnected with them enters the dorsal nuclei of the bulb. Nine collaterals have been counted from one root fibre in the *funiculus cuneatus*. v. Lenhossék has not found any collaterals to fibres in the *funiculus gracilis*.

When, after transection of the bulb close to the *calamus scriptorius*, the extreme top of the dorso-median column is faradised,² movements of the homonymous leg are evoked; in the monkey, movements of the foot. When the mesial part of the extreme top of the dorso-lateral column is similarly stimulated, movements of the homonymous hand result. In the same way, from the top of the dorso-mesial column, movement over the lowest intercostal spaces can be evoked. These movements appear to be reflexes, involving antidrome conduction down the ascending stems, and so, *vid* collaterals given off near the entrance of the root cell fibres, into the cord. The reactions indicate that the long ascending fibres are given off by thoracic as well as by limb roots, and that under the circumstances the collaterals by which reflexes are particularly facile are those given off by the stem fibres near the entrance of the root into the cord.

The date at which a nerve fibre completes its development, by acquiring a myelin sheath,³ indicates the time at which it becomes functionally active. The long ascending stems (*fun. gracilis*) of the afferent root cells do not become myelinated⁴ until much later than the medium and short fibres, except of Lissauer's *marginal zone*. The long ascending fibres would therefore pertain to a system characterising a more highly developed phase of existence than do the short intraspinal. The long ascending stems form, however, a very well-developed spinal column in systems even as low as that of the frog.

Besides the dorsal column nuclei of the bulb, the "column of Clarke" forms a nucleus of ending for many of the collaterals from ascending stems of afferent root cells in the lumbo-sacral region. And the lateral division of

⁴ Flechsig, *op. cit.*, and especially Trepinski, *Arch. f. Psychiat.*, Berlin, Bd. xxx. S. 54.

the nucleus cuneatus seems to stand in similar relation to fibres from the roots at the top of the cord.

The cell-processes of the Gasserian ganglion, on entering the bulb in its pontine portion, bifurcate into long descending and short ascending stems. Some of the latter join the middle cerebellar peduncle; most, however, end in the front (upper) part of the grey matter in the bulb called the sensory nucleus of the fifth. The former descend close outside this and give collaterals into it; the descending stems, grouped just lateral to the substantia Rolandi, course backwards, some of them even so far as the level of the second cervical segment. The petrous and jugular trunk ganglia of the glosso-pharyngeal vagus nerves are equivalent to spinal ganglia. The descending stems, resulting from the dichotomy of their fibres, run back as a circumscribed bundle, fasciculus solitarius, into the hindmost fourth of the bulb. Both they and their shorter ascending stems give off and end in collaterals to the grey nucleus of ending of the glosso-pharyngeal vagus in the floor of the fourth ventricle.

The transverse extent of the region of intraspinal ending of the spinal afferent root includes in the uncrossed half of the cord the whole of the spongiosa, and some end in the substantia Rolandi of the dorsal horn.¹ The root-collaterals traceable far across the spongiosa into the region of the efferent root cells in the homonymous ventral horn are often called the "reflex collaterals"; they perhaps constitute the ending of the afferent path for some of the simplest and most direct of spinal reflex movements. Root-collaterals form almost entirely the dorsal commissure especially in man (v. Lenhossék), and end in the crossed grey matter; but none contribute to the ventral commissure.

THE WAY OUT.

The efferent root cells are intraspinal in position. They lie in the grey matter, chiefly in its ventral region. Each possesses numerous dendrons, and a single axon.

The grouping of the efferent root cells is segmental, in the sense that they lie in the cord at the same segmental level as the segmentally arranged nerve roots to which they contribute. But in some regions there is very considerable overlapping of the contiguous segmental fields to which they are peripherally distributed. In the limb and neck regions of the cord the root cells in the ventral horn are very distinctly collected into subgroups. These groups are probably assemblies of cells, that collectively innervate particular groups of muscles. Probably all the largest of the efferent root cells conduct to skeletal muscles. The axons of the vast majority of the motor root cells pass to muscles of the homonymous side.² The medio-ventral group of the ventral horn is perhaps distributed to the muscles lying along the vertebral axis. It seems, however, to include *mediate cells*, the "commissure group" of v. Lenhossék, besides *root cells*. In the brachial and lumbo-sacral enlargements there is added to the grey matter of the ventral horn a huge lateral region, in which lie several subgroups of large efferent root cells. Of these there is one which, from its position in the frontal plane of the grey horn, is called the dorso-lateral subgroup. To it has been attributed the innervation of hand (and foot) muscles, especially of palmar (and plantar). The topography of this subgroup along the length of the cord agrees with the latter view, and with its atrophy after amputation of the end of the limb. After amputation even at shoulder or hip, or after the limb has been rendered apæsthetic by severance of the sensory roots, it is the group which suffers most severe regressive change. In the limb thus rendered apæsthetic one move-

¹ v. Lenhossék, "Der fein. Bau d. Nervensystems," 2te Aufl., Berlin, 1895.

² A. S. F. Grünbaum, *Journ. Physiol.*, Cambridge and London, 1894, vol. xvi. p. 365; Paladino, *Arch. ital. de biol.*, Turin, tome xxii. p. 1.

ment, the closure of the hand or foot, is, as a volitional movement, lost. The nutrition of this group seems therefore to be especially dependent on the maintenance of the local reflex arc (and perhaps reflex tonus). It is said¹ that the reflex collaterals are more numerous traceable to this part of the ventral horn than to others. The efferent root cells innervating any one muscle do not seem to be collected into a definite group in the frontal planes of the cord. In the limb regions the root cells innervating each single muscle extend throughout the length of two, three, or more segments of the cord.

In the higher vertebrates each of the segmental spinal nerves which supplies the musculature of the limb leaves the spinal cord in the form of a row of rootlets, which together build up the motor root of the nerve. Excitation by electric currents of any one of these rootlets or filaments, that contribute to the formation of the motor root, produces a movement in the limb which

FIG. 355.—Diagram showing arrangement of the root filaments of two spinal nerves. *c.a.* The ventral white column of the cord; *c.l.* the lateral white column; *c.p.* the dorsal white column; *s.m.l.a.* the median ventral fissure of the cord; *r.a.* the ventral root; *r.p.* the dorsal root; *g.g.* the ganglion of the dorsal root.—From van Gehuchten.

resembles closely the movement produced by excitation of the whole root. The same muscles are thrown into contraction as when the whole root is excited; but the action of each muscle is feebler. The collection of nerve fibres contained in the rootlets is therefore, in miniature, a collection like that contained in the whole root. This fact must be taken together with the fact that, as can be shown by degeneration experiments, the fibres contained in each rootlet represent the axis-cylinders of the motor nerve cells lying in that particular transverse plane of the cord, from which the rootlet makes its emergence.

The two observations

together show that nerve cells which innervate the different muscles belonging to any one myotom in the limb lie commingled, so that any one section through the spinal cord at right angles to its length will meet nerve cells belonging to all the muscles represented in that segment. This is the same as saying that the nerve cells belonging to any one limb-muscle lie not gathered together at any one particular level of the spinal segment, but scattered throughout its length. And inasmuch as each muscle is innervated from several segments, the nerve cells for each muscle are scattered in a continuous series through the length of a series of spinal segments; and throughout this extent are commingled with the cells of a great number—in some cases as many as forty and more—of other muscles. It is therefore evident that no traumatic injury of the spinal cord can ever paralyse a single

¹ G. Mingazzini, *Riv. sper. di freniat.*, Reggio-Emilia, 1892, tome xviii. Nos. 3-4; Lugaro, *Riv. di patol. nerv.*, Firenze, 1896, tome i. p. 1.

muscle alone and apart from its fellows. Even the severance of a whole single motor nerve root cannot paralyse a single limb-muscle; the effect of such an injury is to partially impair a large number of the muscles.

The individual extrinsic eye muscles innervated by the oculo-motorius have been assigned to certain groups of cells in the nucleus of that nerve. The evidence is, however, conflicting. A demonstrably segmental grouping of the efferent root cells in the human spinal cord has been assumed by some anatomists;¹ the statement rests on some evidence of such a grouping in the eel² and snake.³ Waldeyer assumes a similar arrangement in the cord of the gorilla. The careful examinations of the mammalian (including human) cord by Kaiser⁴ and v. Argutinski⁵ have shown that no segmental⁶ grouping of any of the cell columns is detectible; this conclusion stands in harmony with the results of the examination of the relation of the reflex movements to spinal segments. The results of an analysis of the spinal nerve supply of the muscles of the limbs show that the muscular tissue of the limb is arranged in a number of rays, a ray for each metamere contributing to the limb. It shows that of these rays the ones which lie tailmost in the fore-and-aft series are the longest, that is, extend to the extreme free apex of the limb, whereas the foremost, the most rostral, pass only, in the fore-limb, as far as the upper arm, the next only as far as the elbow, the next only as far as the wrist. The four last, or most aboral rays, all contribute to the musculature of the hand in the common macaque monkey (*Macacus rhesus*).

When we come to inquire how these units of the segmental architecture of the limbs, these muscular rays, are related to the physiological or functional units of the limb musculature, it is at once obvious that the extent and boundaries of the two do not coincide. The individual muscles of the limb are functional elements of its structure as a physiological machine. But each of these functional elements is compounded of portions of several rays or myotoms. Moreover, the boundaries between the myotoms do not correspond with the intervals of muscles, or even between muscle-groups.

The same want of segmental separation is evident when we examine the location of the nerve cells which innervate the individual muscles. In experiments on the plexuses, it is rare to find two consecutive individuals of the same species that possess a similar root distribution. The plexus in any species requires for description to be grouped into classes. For most purposes it suffices to distinguish a class in which the plexus is *pre-fixed* and a class in which it is *post-fixed*. Thus, in some individuals, the supinator brevis is innervated from the sixth and fifth cervical nerves, in others from the sixth and seventh. In the former case the plexus is of pre-fixed type. When one muscle or one part of the plexus is pre-fixed, all the rest are pre-fixed; and conversely, when one part is post-fixed, all are post-fixed. In the second instance given above, the supinator brevis is post-fixed, that is, its nerve cells are fixed in segments further aboral in the series than in the individuals with pre-fixed plexuses. Presumably, the muscle itself therefore is built of myotoms more aboral in the series than in the muscle in the pre-fixed individuals. Between the extreme cases of post-fixed type and the extreme examples of pre-fixed type extend a numerous series of intermediate individuals; in fact, any and every intermediate degree of type seems to exist. The extreme of post-fixed type passes over into the comparatively rare individual

⁶ The cells of the columns, especially of that of the lateral horn, are collected into groups along the length of the cord, but the groups are much more numerous than are the segmental nerves.

with an additional segment, e.g. the cat with fourteen ribs. This frequency of individual variations exhibits in an almost ludicrous aspect the view held, that each motor spinal root is a collection gathered together for a functional purpose, and representing a particularly highly co-ordinated movement of the limb. Contrary to any such hypothesis, it shows that for the functional mechanism of the limb it is immaterial whether this or that particular group of muscles is represented in a particular spinal root or not represented in it. The *absolute* segmental level is variable over the range of nearly a whole segment's length; the *relative* segmental position is inviolably preserved. Thus *flexor carpi ulnaris* may get fibres from as high as the sixth cervical segment, or it may not, but it never extends so well forward, so far rostrally, as *flexor carpi radialis*, and this latter never extends so far aborally as *flexor carpi ulnaris*, even when it is most post-fixed; that is, the region of outflow for the spinal nerve fibres to *flexor carpi ulnaris* lies rather more aborally than that of the outflow to *flexor carpi radialis*, and this mutual segmental position of the muscles is maintained whether the plexus be post-fixed or pre-fixed.

In reflex movements, and in movements evoked from the cortex of the brain, the discharge of motor impulses to a pluri-segmental muscle of the forearm or wrist or hand, is probably always pluri-segmental, and involves the whole length of the serial group of intraspinal nerve cells which innervates the muscle extending through its full number of segments of the cord. The afferent and cerebral channels of the cord treat the pluri-segmental motor stations or nuclei of these limb-muscles as entities of homogeneous structure, as, in fact, physiological units.

This serves to emphasise the physiological homogeneity of limb-muscle and nerve trunk, and the physiological heterogeneity, in spite of morphological unity, of the spinal nerve roots in the limb region of the body. The spinal nerve roots of the thoracic region are, from the physiological point of view, less heterogeneous. The peripheral nerve trunk is the *physiological* collection of nerve fibres, e.g. flexors collected together, vaso-dilators included with motors to muscles, etc. The *nerve root* is the *morphological* collection; it contains, commingled into one, such heterogeneities as adductors of the hallux with protrusor muscles of the pelvic floor.

Not all the efferent root cells are large. Many among the smaller intraspinal cells probably innervate the vascular and visceral musculature. A numerous set of such cells lies in a special lateral ridge of grey matter, extending in the cord (man and monkey) from second thoracic segment to second lumbar inclusive. This is the intermediate lateral cell-group lying in the lateral horn of spongiosa. Gaskell first pointed out the correspondence between the longitudinal spinal extent of this cell-group and the preponderance of minute myelinate fibres in the efferent roots, and the existence in those roots of pressor paths to the vascular musculature. The inference is, that the cell-group of the lateral horn is composed not of *mediate* (or column) cells but of the root cells innervating the musculature of the vessels (and viscera). The upper end of the group has close topographical correspondence with the upper limit of outflow of nerve fibres to the dilatator pupillæ. The direct demonstration that a lateral horn-cell gives an axon into the efferent spinal root has, however, not yet been supplied. But it has been proved¹ that the minute nerve fibres passing by the efferent roots into the sympathetic do come from cells lying very strictly in the same segmental frontal level of the cord as the surface origin of the root filament which contains them. They in this point resemble the relation of the skeletal fibres to their cells of origin.

It has been laid down as a law, that the muscles of a given part of the limb and the sense organs in the overlying skin are supplied by the same spinal segment, the afferent root cells being included as belonging to a spinal

¹ Sherrington, *Journ. Physiol.*, Cambridge and London, 1892, vol. xiii.; A. S. F. Grünbaum, *ibid.*, 1894, vol. xvi.

segment. But there are so many and such wide exceptions to this, that the rule as a law can hardly be said to exist. In respect to the proximal joints of the limbs, the muscles producing the chief movements in opposite directions are mainly represented at different segmental levels of the cord. Thus in the macaque the motor root cells for flexion at the elbow lie mainly in the fifth, sixth, and seventh cervical segments, those for extension at the elbow, chiefly in the seventh and eighth cervical and first thoracic segments. The motor root cells for opposite movements of the small joints at the free ends of the limb are, however, not thus segmentally separate, but lie commingled in the same segments of the cord. There are reasons for thinking, moreover, that the motor root cells for antagonistic movements, whether as in the latter joints segmentally commingled, or as in the former segmentally apart, are contemporaneously influenced by any reaction that, *e.g.* from brain or cord, initiates a co-ordinate movement in which they take part, the one set of cells being subjected to pressor, the other to inhibitory influence.

The fact that the ventral spinal roots and certain analogous cranial nerve roots form the only channels by which nervous impulses pass out of the cerebro-spinal organ to the extrinsic tissues, allows the efferent root cells, taken together, to be considered as one great efferent path for all nervous reactions. The telencephalon and diencephalon (primary cerebral vesicle) are the only portions of the nervous system whose root cells are solely efferent. The whole path is made up of the third, fourth, sixth, eighth, eleventh, and twelfth cranial nerves, of the unganglionated root of the fifth cranial and of all the ventral spinal roots. There are some minute nerve fibres in the sheath of the ventral root, which do not take origin from intraspinal cells; these fibres may be sympathetic. As already mentioned, in the ventral roots of the lumbar region of the cat, Schäfer discovered nerve cells, and similar have been seen in the same region in man. Whether these are afferent or efferent, and if the latter, whether sympathetic, is not certain.

Golgi discovered that from the axons of some spinal efferent root cells "*side fibres*" are given near its origin. The function of these is still unknown, though probably important. They may conduct centripetally into the axon.¹

Restoration of movement after "nerve-crossing."—When two mixed nerve trunks (A and B), supplying antagonistic groups of muscles, are cut and "crossed," so as to secure union of the peripheral end of A with the central of B, and *vice versa*, Flourens² concluded that full control and co-ordination was regained by some central adjustment. R. H. Cunningham³ has, in the case of the fore-limb of the dog, re-examined this question carefully, and finds that on cortical excitation, and also in intentional co-ordinated movements, the co-ordination of the muscular contractions is not regained.

RELATION OF AFFERENT TO EFFERENT ROOTS.

Besides the fact that excitation of the ventral spinal root excites contraction of the muscles directly through motor fibres, Bell and Magendie and their followers showed that its excitation evokes no signs of sensation and no reflex actions, and in this respect offers a second difference from the ganglionated root. This "law" of Bell and Magendie sheds light on the quality of the intraspinal arc connecting the afferent nerves and roots with the efferent nerves and roots. It is evident that the nexus between afferent channel and efferent is of a kind allowing

¹ See v. Lenhossék, "Der feinere Bau d. Nervensystems," 2te Aufl. S. 129. He terms them "axo-dendrites."

² "Recherches expér. sur propriét. et fonct. d. système nerveux," 1824, p. 272. Cf. Rawa, *Arch. f. Physiol.*, Leipzig, 1885, S. 296.

³ *Am. Journ. Physiol.*, 1898, vol. i. p. 240.

conduction in the direction from dorsal root to ventral root, but not conversely. This is the special case which gave the foundation of the law of conduction in the neural system termed the "law of forward direction," which has been already referred to (p. 785).¹

The practically universal spinal irradiation obtained under strychnia bore out the view of a conducting network continuous in all directions throughout the grey matter. But when the property of "double-conduction" by nerve fibres had been ascertained, the "Bell-Magendie law" of the roots became more instructive. Since the dendritic processes of the efferent root cells join the general network, the Bell-Magendie law must indicate either that these dendrons are non-conductive, or that they, although conductive from the network into the motor cell, are not conductive back from the motor cell into the network. Gad (1884)² especially insisted on the latter view; Golgi (1882)³ on the former, considering the dendritic processes to be simply nutrient. Since the recent more general rejection of the theory of a continuous intraspinal network, Cajal (1889) and van Gehuchten (1891)⁴ have argued a "dynamical polarisation" of the nerve cell so that the sense of conduction is solely from dendron toward axon, never the reverse. They suggest the importance in this connection of the "articulation" between axon of one cell and dendron of next. The "valved" condition of the circuits may result from properties belonging to these places of "*contact utile*" or "synapse." The "dynamic polarisation" of the cell seems to find expression in certain morphological characters of the cell, so that the two ends are in many cases recognisable by inspection. In accord with the constant failure to provoke reflex actions or signs of sensation by stimulation on the proximal side of the transection of an efferent spinal root, all attempts⁵ to similarly provoke from that root action currents in other nerve tracts have failed.

An immediate influence exerted by the efferent root cells on the motor root cells, as indicated by the skeletal muscles, is demonstrable in various ways. The posture of the hind-limb of the spinal frog, when the limbs are allowed to hang freely (Brondgeest's phenomenon),⁶ shows that the lengths of the flexor muscles of the limb are, under those conditions, slightly shorter than when the afferent roots of the sciatic plexus have been severed. Early experiments failed⁷ to show any lengthening of the muscles on section of their nerves, but the muscles were examined after arrest of the circulation and under extension by not inconsiderable weights. With lighter weight and intact circulation Wundt⁸ observed a lengthening after section of the muscular nerves, but, confronted by a somewhat similar lengthening, resulting as an after-effect of simple contraction of the muscle, he hesitated to accept the lengthening consequent on nerve section as due to anything more than

⁸ "Lehre v. d. Muskelbewegung," Braunschweig, 1858.

the contraction caused by the stimulus when the nerve was cut. Cyon¹ and Tschiriew² obtained a lengthening after nerve section, the former also after section of the afferent spinal roots; and both, from their experiments, concluded in favour of a demonstrable reflex slight tonic contraction of muscle. v. Anrep's³ experiments discriminated between the two instances of lengthening observed by Wundt, and seem to conclusively establish a reflex tonus of the adductor magnus and semi-membranosus muscles of the frog. Curari breaks the tonus down through the motor-end plate, morphia through the afferent spinal channel.

Cyon⁴ early insisted on the occurrence of a fall in the excitability of the motor root, as tested by faradisation and muscular contraction, ensuing upon severance of the afferent root. Harless⁵ had previously stated that the excitability of the sciatic nerve of the frog is lowered by section of the afferent spinal roots connected with it. Cyon's facts were disputed,⁶ but other observers have confirmed them,⁷ and they have been reaffirmed by himself.⁸ They have been extended to the mammalian roots,⁹ and the phenomenon seems well observable after cocainisation or section of the sacral roots of the dog.

Any interference with the nervous system which paralyses a skeletal muscle delays the onset of rigor mortis in it (Hermann¹⁰). Section of the motor spinal roots thus delays onset of the rigor; and so also does section of afferent roots,¹¹ even if practised a short time only before destruction of the animal. It also causes some wasting of adult and some interference with growth of young muscles.¹² When a limb has been rendered apæsthetic by severance of all its afferent roots, the muscles feel peculiarly limp and flaccid,¹³ and the passive mobility of the joints is greater than normal. The same condition is met with in many cases of tabes dorsalis;¹⁴ the hip can, with the limb extended at the knee, be flexed to abnormal extent. This increased passive mobility is due no doubt to loss of tonus (hypotonia) in the limb muscles. At the same time it may be that not *all* skeletal muscles habitually possess such a tonus, and certain muscles appear at least to possess it in higher degree than others. A slight degree of tension of the muscle is a necessary condition for the elicitation of the knee-jerk, and any damage which breaks the reflex arc

maintaining the normal tonus of the vasti-crureus extinguishes the knee-jerk. The particular afferent channels on which the tonus and jerk depend in this case, have been traced to arise in the muscle itself.¹ Cutaneous nerves seem not to be the constituents of the afferent spinal root which in respect to muscular tonus are of chief importance.² There is no asymmetry of facial expression, after section of the sensory root of the trigeminus, though in the rabbit the pinna drops³ on the side homonymous with the facial anæsthesia; but there is facial asymmetry after section of one facial nerve. The myogram obtained when the intact nerve of the quadriceps cruris is excited by a break shock shows a relaxation line much slower and more prolonged than when the cut nerve is similarly excited, and the relaxation line in the former case never, as in the latter, dips below the base line with an inertia fling.⁴ It is the inertia fling attaching to the movements, that is so characteristic of an ataxic limb. This has been admirably analysed by H. E. Hering⁵ in the case of his "Hebe-phenomen." in the frog. The contraction of the muscle when its afferent path is intact seems to set into activity some mechanism, lost after rupture of the arc, that damps the inertia swing of the muscular movement. It may be that the tension developed in the muscle by its contraction excites reflexly in it a condition of tonus. Not every muscle seems, under all normal conditions, to conform to the statement that there is a constant neural tonus of reflex origin in it. When the elbow is well flexed, the biceps is so slack as to feel toneless. When the frog's leg is fully flexed at knee and extended at ankle, the exposed gastrocnemius can be seen to lie actually in slack folds; on being cut it does not gape. It may be that the neural tonus of skeletal muscles is only present in them so long as they are stretched, and only in such as are to a certain degree under stretch. The tonus will obviously be of chief advantage in such muscles as have to be in readiness to contract; the reflexly maintained spinal "sitting" posture of the frog entails, by passive stretch, tonus in the extensors, and holds them ready for the next movement—a spring. Not only is the posture of the pendent limbs of the spinal frog altered from normal by section of the afferent roots of the limb, but the sitting posture of the apæsthetic limb in the otherwise normal frog is abnormal, in the sense that the limb is less flexed at hip, and knee, and ankle.⁶ The apæsthetic fore-limb is, on the other hand, more flexed at elbow, and the digits are often bent under. The excitability of the cord and centres, under the influence of convulsants, is much depressed by section of the afferent roots;⁷ it seems that in the spinal frog strychnin and picrotoxin⁸ fail to produce convulsions if all the afferent spinal roots be severed. Certainly, however, asphyxia can excite spinal convulsions when all the afferent roots of the cord or portion of cord under examination have been severed.⁹ The peculiar condition of extensor spasm of the limbs characterising *decerebrate rigidity*, after transection between diencephalon and mesencephalon, does not ensue in a limb the afferent spinal roots of which have been previously severed, and disappears at once in a limb on the severance of the afferent roots of the limb.¹⁰ The severance of other afferent roots does not destroy the rigidity of the limb. On the other hand, the section of an afferent root seems to make but slight change in the excitability of the motor cells of the corresponding efferent root; when tested by

stimulation of the part of the cortex which produces movement through those cells, they seem slightly more excitable.¹ It was noted above that excitation of the dorsal columns of the cord close to the bulb produces movements in the homonymous limbs. The section of the afferent roots of the limb renders this reaction much more difficult for that limb,² though it is still as easy as before to evoke movements of the limb from the pyramidal tract. The significance of this result may be that the severance of the axon from the cell body and its cellulipetal processes, detaches the collaterals from their synapses with the motor cells. That the change induced is not located in the motor root cell itself, seems evident from the openness of the cortico-spinal synapse.

Panizza,³ who was the first after Magendie to fully confirm the Bell-Magendie law of the roots in warm-blooded animals, drew attention to the fact that though his experiments showed the dorsal (posterior) roots to be wholly afferent, yet the section of a number of the afferent roots brought marked impairment of the local motility. The movements of the apæsthetic limb are clumsy. The hind-limb in walking is lifted too high and set too far. Stilling⁴ reaffirmed these observations after experimenting on the afferent roots of the frog. He wrote —

“The posterior roots have the following important functions:—(1) They maintain continuously the tonus of the muscles, or that action whereby even in time of rest a ceaseless readiness for movement, a ceaseless tension of the muscle fibres, is maintained. (2) The posterior roots transmit continuously the sensation of the condition of the muscles themselves. Each unsuitable, uncomfortable pose of the muscle is thereby brought to consciousness, and, as a result, corrected by the will or by reflex action.”⁵

Claude Bernard⁶ and Schiff⁷ simultaneously later drew attention to the disturbance of movement produced by the section of the roots. Bernard pointed out that when the frog is held up by the body, the animal uses the apæsthetic hind-limb far less than the sound one to release itself, and that the creature springs with difficulty. He cut the afferent roots to one hind-limb in young puppies, and noted that the animal could no longer support its weight on that limb.

H. E. Hering⁸ has given a clear objectively written description of the postures and movements of the apæsthetic limb in the frog. When the animal is first approached—the day after operation—the apæsthetic limb is moved up closely to the body, the normal limb moving much less. In the execution of a small spring there is no obvious difference between the limbs; in execution of a longer spring the animal alights so as to have its head facing somewhat towards the side of the apæsthetic hind-limb. If both hind-limbs are apæsthetic, the spring is higher, but carries less far than normal; the turn with the one apæsthetic limb seems due to enfeebled extensor stroke. As the hind-limbs are drawn up into the sitting posture again, after the spring, the apæsthetic one is seen to be the later, and to be tilted up in so doing. This latter act constitutes Hering's “tilt-phenomenon,” and he has shown by various

lesions of the muscles and nerves of the leg that it results when the tension of the antagonist muscles is abnormally low. He regards it as due to the loss of a reflex inhibition of muscular contraction, arising in afferent nerves of the "muscular sense" order. It is therefore an ataxic effect. In swimming, although synchronous bilateral strokes are sometimes taken, the frog usually swims with the apæsthetic limb in permanent active extension. When both hind-limbs are apæsthetic, the frog does still occasionally swim with synchronous extensor strokes. Apæsthesia of the fore-limbs in the frog causes the frog to sit supported, not on the fore-feet, but on the fore-arm, often with the digits bent underneath. The spring is less high than usual, and for that reason less wide. When all four limbs have been rendered insensitive, the animal can still spring, but only a short distance, and often in attempting to spring upsets itself, rolling over sideways. Bickel¹ has made observations on combination of apæsthesia of one or more limbs with removal of one labyrinth. The forced postures regularly assumed after removal of a labyrinth were, as a rule, far less marked in the apæsthetic than in the normal limbs. Baldi² in Luciani's laboratory observed dogs for long periods after severance of afferent roots of one or both limbs. When one hind-limb is apæsthetic, it is not at first used for walking; it seems unable to bear the weight of the body; it is kept more or less flexed at hip and knee, and full extension is rarely executed by it. Later, it is used for walking, but is lifted too high, and sometimes set too far. With both hind-limbs apæsthetic, the fore-limbs at first simply drag the hind-limbs after them, these trailing with the dorsal aspect of the foot to ground. Later, as the hind-limbs are trailed, they make alternate movements of extension and flexion, and ultimately they may to some extent support the body, crawling as it were with very flexed knees, so that the rump droops too low. When the lowest three cervical and the first thoracic are the afferent roots cut, the animal limps, lifting the apæsthetic fore-limb from the ground. Later it comes at times to be used for progression, but the dorsum of the foot frequently doubles under, causing a fall or stumble. Baldi considers the ataxy the most marked symptom, and refers the chief grävamen of the lesion to rupture of the afferent channels from the peripheral organs of muscular sense. Combination of extirpation of one labyrinth with apæsthesia of the hind-limbs in the dog leads, when the latter operation precedes the former at a long interval, to a recrudescence of symptoms from which the apæsthetic limbs had partly recovered. After extirpation of both labyrinths, there appears far less power to compensate the disturbance of motility of apæsthetic limbs.³ An important observation by Bickel is that extirpation of one labyrinth causes the apæsthetic tail to be twisted 90° on its axis, and that this twist at once disappears when, weeks later, the other labyrinth is removed. Hering⁴ and Bickel have pointed out that the residual disturbance of motility, due to apæsthesia of both hind-limbs, is much increased by excluding retinal sensations, by bandaging the eyes or placing the animal in the dark.

Observations on the symptomatology of apæsthesia of the limbs in the monkey⁵ show even more striking defects of motility. When the whole series of afferent roots of a limb are divided, the limb is useless for progression. The animals never use the apæsthetic limb in climbing either down or up a rope. The limb is chiefly moved in association with vigorous movements of the fellow normal limb. In climbing, while the normal movements are being executed by the normal arm, the apæsthetic, semiflexed at elbow, is often flung up behind the head.

Hering¹ made the following observations on such ataxic animals. When all the afferent brachial roots, except the last cervical, which I have shown to supply the skin of the whole hand, are severed, the monkey, in taking a piece of fruit offered him, exhibits zig-zag swaying of the out-thrust arm. If a maize-corn be placed on the ledge of the cage between the bars, the arm swaying, the more obviously the further it is extended, often fails to make its grasp between the right bars, and misses the object altogether. In picking small objects such as rice-corns out of the observer's hand, the normal monkey exhibits perfection of precision. He uses generally but finger and thumb, and rarely touches the hand on which the corn is lying. The monkey with its one afferent brachial root grasps clumsily with the whole hand, and often meets the observer's hand and not its content.

It has been pointed out that the movements of the proximal joints of the limb suffer less impairment of movement than those of the distal. It must be remembered that the number of nerve roots supplying the musculature of the proximal joints is greater than the number of roots supplying the distal.² The posture of the apæsthetic hind-limb is an almost continuously maintained strong flexion at hip and knee; that of the fore-limb, which swings helplessly, flexion at elbow and wrist, with adduction at shoulder. Warrington has shown that severance of the afferent roots causes degeneration in certain of the motor root cells of the corresponding spinal region.

Charles Bell³ found that in the ass, after section of the supra-maxillary divisions of both trigemini, the upper lip was no longer lifted in feeding, and the same phenomenon has been observed in the rabbit and cat.⁴ Bell questioned in consequence whether the nerve might not be motor. Experiments in Exner's laboratory⁵ led to the conclusion that in the horse a "paralysis" of the laryngeal muscles of one side follows section of the corresponding sensory nerve of the larynx. This observation has, it is true, been disputed, but a most striking example of this kind is furnished by the ape.⁶ After section of all the afferent roots of the limb, the movement of grasp by hand or foot respectively is permanently lost. If even only one of the sensory roots of the three belonging to the hand and foot respectively is left to the limb, the loss of the grasp does not ensue, although there is marked ataxy. Under the most inducive and favourable circumstances, the wholly apæsthetic limb is never used for grasping. Yet, if the appropriate region of the cortex is excited, the grasp is elicited with apparently perfectly normal facility, and in the absinthe convulsions the closure of the hand and foot is as equally exhibited as by the fellow normal limb.⁶

Electrical change in the opposite afferent root has been in some cases found to accompany electrical excitation of the sciatic nerve of one side.⁷ In experiments on the frog, the electrical effect produced

in the opposite afferent root is very slight, inconstant, and whether significant of discharge of impulses appears doubtful.¹

REGENERATION OF THE AFFERENT ROOT FIBRES.

Leaving aside the old question of the regeneration of peripheral ganglia as presenting no observations with methods adequate to settle it,² there is the related one concerning regeneration of the afferent spinal roots. Eichhorst and Naunyn,³ after transection of the spinal cord, found nerve fibres traversing the cicatrix, which they considered traceable to an afferent root adjacent, being able to follow them to a spinal ganglion. After extradural section of the afferent root, a partial regeneration has been observed.⁴ Chipault⁵ has obtained in three puppies regeneration of the severed roots when they were sutured together immediately after section, the times elapsing between severance and suturing and the autopsy being from three to six months. The dorsal spinal columns, since they consist of afferent root fibres almost entirely, should show evidence of regeneration. There is, however, none such recorded. I⁶ looked for signs of regeneration in a monkey's cord, in which the dorsal columns alone had been transected four months previously, but found no evidence of regeneration, although the scar was very limited in the longitudinal extent of the cord. Thirty-three days after section of the lumbar afferent roots proximal to their ganglia, I was surprised to meet, in the spinal stumps of the severed roots, numbers of minute myelinated fibres, less than $4\ \mu$ in diameter, presenting the same appearance as the young nerve fibres in regenerating peripheral nerves. The ganglia had been excised, so that the new fibres could not be due to out-growth from them. The question of the regeneration of the afferent root is not without practical importance. Regeneration of the peripheral fibre—the cellulipetal conducting fibre—of the afferent root cell is a well-established fact, and is found to occur quite well in even advanced adult life. As tested by functional results, it takes place more quickly than the regeneration of the axon of the motor root cell.⁷

SKETCH OF THE FUNCTIONAL ANATOMY OF MEDIATE SPINAL SYSTEMS.

Although the two root cells, afferent and efferent, may suffice for certain reflex actions, it is probable that for most, even purely spinal, reflexes they are by themselves an insufficient apparatus. It is therefore convenient, before dealing with spinal reflexes in general, to consider other elements in the neural mechanism of the cord. Among the spinal cell systems, including in the word "cell" not only the cell body (perikaryon) but also all the nerve fibres which are its branches, there can be distinguished on the one hand the *root* systems and on the other the *medicate* systems. It is possible that the two root systems are themselves connected together, and that the simplest reflex arc is formed by their direct linkage. But in many cases the reflex reaction seems to occur through one part of the afferent root system acting on a distant

part of the efferent root system through a "mediate" cell system. Such mediation may be *via* one link-cell, or *via* a chain of link-cells. The spinal mediate cell systems may be classed as (1) intrinsic or purely spinal, and (2) extrinsic or spino-encephalic and encephalo-spinal.

Mediate cells of the spinal cord.—1. Intrinsic mediate systems.—

These probably form a large proportion of the fibres of the cord, especially of the zone of white matter nearest to the grey. They contribute probably especially to the minute nerve fibres filling the area between the ventral horn and the base of the dorsal horn (*lateral limiting layer*).¹ It seems that the fibres of the ventral part of the layer arise from cells of the ventral horn (Bruce).² As a rule, the longer the course of a nerve fibre in the cord, the nearer its place, except at its immediate beginning or ending, to the periphery of the cord.³ (In the periphery of course is included the dorsal median septum.) Of the short fibres some pass tailward from their cells of origin, some pass headward. Certain that ascend far lie near the lip of the ventral-median fissure.

A number of descending intrinsic spinal fibres are commingled with the pyramidal fibres in the pyramidal area of the lateral column. After complete degeneration of the pyramidal system, many sound fibres are left in the dog in that area,⁴ and in that area many fibres in the dog are myelinated before the fibres of the pyramidal tract.⁵ Münzer,⁶ after semisection of the cord of a new-horn rabbit at the nineteenth vertebra, performed total transection two vertebræ lower when the animal was grown, and found about as many fibres degenerate below the lesion on the semisected as on the intact side; the fibres omitting decussation must have been of intraspinal origin. I (with E. E. Laslett) have by semisection subsequent to total transection similarly found evidence, in the dog, of abundant spinal fibres descending in all regions of the ventro-lateral columns and extending through many segments. Münzer also in the new-born rabbit excised one hemisphere, and after spinal semisection in the grown animal found many degenerate fibres in the lateral column behind the lesion. He did not find injury of the anterior corpus quadrigeminum, nor of the cerebellum, produce spinal degeneration, and therefore many of the fibres degenerating are probably intrinsic spinal.⁷

Some intrinsic spinal nerve fibres, *fasc. dorsalis proprius* (Barker), probably both ascending and descending, lie among the root fibres of the dorsal column. (Flechsig's "oval centre" respected in *tabes dorsalis*; Schultze's "comma"⁸

⁸ Schultze's "comma tract" was first noted and figured by Charlton Bastian, *Med.-Chir. Trans.*, London, 1867. Kahler and Pick, *Arch. f. Psychiat.*, Berlin, 1880, also drew attention to it before Schultze, *ibid.*, 1883. It is difficult to sunder it from the descending limbs of the dorsal root fibres. On the question of endogenous dorsal column fibres, see Daxenberger, *Ztschr. f. Nervenheilk.*, 1897, S. 136; Gombault et Philippe, *Arch. de méd. expér. et d'anat. path.*, Paris, 1894, tome vi.; S. Bruce, *Brain*, London, 1897, vol. xx.; also P. Marie, Redlich, Dejerine and Spiller, and Dufour, L. Mann, and others.

tract,' similarly intact in tabes, and a long descending tract noted by Hoche, the *septo-marginal* of Bruce and Muir; the tract found by Wiener and Münzer ascending but of intraspinal origin.) Some of the descending fibres extend through seven and even twelve segments of the cord. Cajal has noted column cells contributing fibres to the dorsal columns. As a rule the long fibres are of larger diameter than the short.

Some of the mediate cells give off axons which cross from one lateral half of the cord to the other, while others do not. The former seem to be quite numerous,¹ and their main passage of crossing to lie in the ventral white commissure. The median ventral cell group of the ventral horn of grey matter is probably a group of these mediate cells.² Some mediate cells have been described as giving a bifurcating axon, one stem from which crosses the median sagittal plane, whereas the other does not. The number of mediate cells appears to be very great, affording a basis, therefore, for very various possibilities of direction of conduction in the cord. But it is impossible at present to say whether the majority of the mediate cells belong to the intrinsic (simply spinal) system, or to the spino-encephalic system, which is certainly very large.

2. **Extrinsic mediate systems.**—(a) **Spino-encephalic.**—(i.) *Spino-cerebellar.*—Some intraspinal cells possess branches which extend headwards into the superior vermis of the cerebellum. One set of these forms an uncrossed spino-cerebellar system, the axons of which ascend in the dorsal part of the margin of the lateral column and in the restiform body. These cells of origin exist perhaps throughout the whole length of the cord, but are most numerous along the region between the first thoracic segment and the second lumbar (man). There the cells lie grouped together, forming the vesicular column of Clarke.³ A small subgroup, probably belonging to the same system, lies in the upper cervical region, and as scattered cells in the lower brachial and other segments. It is more doubtful whether the group in the sacral region (Stillings) is part of the system. Spinal lesions in the sacral region of man do not cause degeneration of the dorsal cerebellar tract. There is some reason to think that the lateral division of the *nucleus cuneatus* belongs to the same system.⁴ This system, called the *dorso-lateral* or *restiformal spino-cerebellar*, is remarkably developed in man, and in the monkey more than in other mammalian types examined, especially in its more posterior portion. Clarke's column forms a nucleus of ending for collaterals from the afferent roots of the lower limb,⁵ and for the pyramidal tract.⁶

Another spino-cerebellar system, mainly crossed (heteromeric), lies in the ventro-lateral edge of the lateral column.⁷ The cell-bodies whence these fibres

⁷ The existence of ascending fibres here was first noted by C. Bastian, *Med.-Chir. Trans.*, London, 1867 (with figure). In 1879, Gowers called general attention to the degeneration

rise are not with certainty identified; some may be contained in Clarke's column,¹ but some lie at levels more caudal than the most caudal part of Clarke's column,² and therefore more caudal than the main mass of the dorso-lateral spino-cerebellar system. The fibres pass into the superior vermis³ of the cerebellum. The system is often called the *ventro-lateral* or *conjunctival spino-cerebellar*, because its fibres wind back into the cerebellum by the *brachium conjunctivum*.

(ii.) *Other spino-encephalic systems*.—Some spinal cells thrust branches up, it is said, into the mesencephalon, forming a spino-quadrigenal⁴ system. The fibres of this system lie among the fibres of the ventro-lateral column in the region of the ventral root-zone. Many of them decussate to run forward through the bulb close to the ventro-lateral spino-cerebellar system; they reach the fillet. Instead of winding backwards and upwards to the cerebellum, they pass into the roof of the mesencephalon, and end more in the anterior than in the posterior *corpus quadrigeminum*. Others, it is said, proceed farther still, and enter the diencephalon, ending in the ventro-lateral nucleus of the optic thalamus, forming a spino-thalamic system.⁵ Throughout the dorsal longitudinal bundle of the cranial floor fibres exist, probably derived from the cells of the ventral grey horn of the contra-lateral side of the spinal cord, though probably only from the headmost region of the cord. Some ascending spinal fibres seem to end in the grey matter of the ventro-lateral region of the bulb. The ventro-lateral spinal column seems therefore to contain branches from intraspinal cells that reach each of the main divisions of the brain except the telencephalon, unless it be the *n. lenticularis* (Rossolymo).

(b) *Encephalo-spinal*.—Nerve cells of the formatio reticularis of the bulb and of the pons possess, there is reason to think, branches that pass back into the spinal cord.⁶ These are some of them direct and some crossed. The former run partly in the longitudinal bundle and partly in the reticular formation to the cord, forming a system which extends into the cord, the fibres in their spinal course lying in the ventral column to the median side of the motor root-zone. The crossed part of the system passes the median raphe near its origin, and descends in the lateral field of the reticular formation. Its spinal portion consists of fibres in the dorsal part of the lateral column where the fibres of the crossed pyramidal tract lie; this system seems to extend through the whole length of the cord.

A system of fibres is found in the ventro-lateral parts of the cord, which are stated to be derived from a group of bulbar cells (Deiter's nucleus) that forms

of the tract ("Diagnosis of Diseases of the Spinal Cord"), and it is often called *the tract of Gowers*. Singer examined it by experimental degenerations (*Sitzungsb. d. k. Akad. d. Wissensch.*, Wien, 1881, Bd. lxxxiv. Abth. 3). He considered it a spino-cerebellar tract, so also Schultze. Löwenthal (*Bull. Soc. vaudoise d. sc. nat.*, Lausanne, 1885, tome xxi. p. 92, and "Diss.," Genève, 1885) was the first to prove its termination upward in the cerebellum, a result confirmed by Auerbach, *Virchow's Archiv*, 1890, Bd. cxxi.; Mott, *Phil. Trans.*, London, 1891; Tooth, *Brain*, London, 1892, vol. xv.; Schäfer, "Quain's Anat.," 1893, vol. iii. p. 1, and others.

an end-station for some of the fibres of the vestibular nerve branches.¹ This bulbo-spinal system is, at least in the main, uncrossed. It extends into the lumbo-sacral region of the cord; its fibres in their spinal course lie among those of the periphery of the cord near the region of exit of the motor-root. Their collaterals enter the anterior horn.² Some observers³ conclude that this system is derived from cerebellar cells. This can hardly be considered proven. There is some evidence also of a *quadrigemino-spinal* system;⁴ this is mainly crossed, the decussation occurring ventral to the central canal. The fibres pass backward near the raphe of the reticular formation. In their spinal course they lie among fibres of the ventral lip of the ventral column. The system extends to the lumbo-sacral region of the cord. The cells of the red nucleus⁵ also send, according to some authorities, fibres into the spinal cord as far as the lumbar region. This *rubro-spinal* system is a crossed one, its fibres decussating in the roof of the mesencephalon. The fibres in their spinal course lie in the central part of the lateral column somewhat ventral to the main portion of the pyramidal fibres.

Among the fibres passing tailward from the encephalon into the cord, those forming the *cortico-spinal* system or pyramidal tracts are perhaps the best known. Its fibres are branches from certain cells of the Rolandic cortex. They descend through the internal capsule, pes pedunculi, and pedal longitudinal fibres of the pons, and compose the ventral four-fifths and more of each pyramid of the bulb. The decussation of the pyramids is the crossing in bulk of the bundles of this tract at the caudal end of the bulb. The vast majority of its fibres cross at this place and shift into the dorsal part of the lateral column of the cord, lying separated (in man and most examined forms)⁶ from the surface of the cord only by the fibres of the dorsal cerebellar tract. Some of the crossed pyramidal fibres extend the whole length of the cord, reaching the most distal coccygeal region.⁷ In its course along the spinal cord it diminishes, owing to the ending of the constituent fibres at various levels. Its progressive decrease is far from regular, many fibres stopping short at some regions, comparatively few in others. The decussation of the crossed part of the system, especially in man, is not completed at the cephalic end of the cord, but continues back for a variable distance along the cord. The fibres which continue in the homonymous lip of the ventral spinal fissure before crossing form what is called the *ventral pyramidal bundle*, or Türck's bundle, and in man this has been seen extending even into the lowest sacral region.⁸ v.

⁷ Sherrington, *ibid.*, 1889, vol. x.; Boyce, *Phil. Trans.*, London, 1894, p. 186; Dejerine and Thomas, *Arch. de physiol. norm. et path.*, Paris, 1896, tome ii. Previous observers found the tract end at the fourth lumbar level, cf. Tooth, "Spinal Degen.," London, 1890.

⁸ Dejerine and Thomas, *Arch. de physiol. norm. et path.*, Paris, 1896; it had been traced by Tooth, *op. cit.*, 1889, to the second lumbar segment. In the monkey I have not with certainty found it farther back than the eighth cervical level; Redlich, to third cervical in the cat (*Neurol. Centralbl.*, Leipzig, 1897). The actual level of the main decussation seems subject to much individual variation (Flechsig, "Leitungsbahnen, etc.," Leipzig, 1876).

Lenhossék, however, denies that the ventral pyramidal tract crosses; he considers it passes to the homonymous ventral horn.

Though the main bulk of the pyramidal system is crossed, it is in part uncrossed. Hence degeneration in both lateral columns follows unilateral lesions of cortex cerebri.¹ The relative amount of the uncrossed and crossed degenerations varies much according as different regions of the motor cortex are the site of lesion. A minority of the pyramidal fibres, when arrived at the caudal end of the bulb, instead of sloping across the median sagittal plane, deviate² to the homonymous lateral column, and lie there in a position symmetrical with the crossed area occupied by the main crossed division of the system. This *uncrossed pyramidal system* extends also the whole length of the cord.

The fibres of the pyramidal system are the latest in the cord to become myelinated;³ and the slowest, after section in the cord, to show degenerative alteration.⁴ The pyramidal system, so far as is known, exists only in mammals.⁵ There is no other system which shows such increase in relative size as traced from lower to higher mammalian types. Hardly perceptible as a spinal tract in the rabbit, it in the monkey is much larger than in other laboratory forms, and in man is larger still. This relative increase is shown not merely by the tract occupying a larger proportion of the transverse area of the cord, but by its fibres being relatively more densely set within that area. Hence the "scar" left by degeneration of a pyramidal tract is in man not only relatively somewhat larger than in that of the dog, but far fewer sound nerve fibres remain in the sclerosed area.

In its spinal course the pyramidal system lies in the lateral column, nowhere actually abutting on the ventral grey cornu. The existence of a direct synapsis between the pyramidal axon and the ventral cornual root cell has been generally assumed, though rejected by some, and never definitely proven.⁶ After section of the tract, the degeneration of fine medullate fibres in the ventral cornu has been both asserted⁷ and denied.⁸ The collaterals

from this system pass in large numbers toward and into the base of the posterior horn and Clarke's column.¹

THE SPINAL GREY MATTER.

In the grey matter of the spinal cord lie the trophic centres, *i.e.* cell-bodies or *perikarya*, for all the intrinsic spinal and spino-encephalic paths; also all the spinal synapses.²

Schiff³ supposed that "pain"-impulses ascend along the grey matter to the brain. The path for impulses connected with pain does (see "Cutaneous Pain," this vol., p. 965) plunge into the grey matter very soon after entering the cord; it then, probably, after a short course emerges into, in part at least, the opposite lateral column. The short in-and-out traverse of the grey matter by this path is probably typical of all paths in the grey matter; they are probably all quite short.⁴ If all synapses lie in the grey matter, each path where it involves a passage from one link to another in a neural chain must enter the grey matter to establish its linkage; it probably soon emerges thence again. It is unlikely that there are spinal paths built up of any large succession of spinal links. Just as it seems that the spinal grey matter enters into the composition somewhere or another of every efferent path in the cord, including that of the simplest possible reflex, so it enters into the composition of every afferent path with the single exception of the remarkable long direct path of the dorsal column that first breaks into grey matter in the bulb; and therefore, speaking in conformity with the somewhat artificial scheme of delimitation generally employed, above the cord itself.

Very different in its appearance as regards detailed structure from the general spongiosa, is that portion termed gelatinosa which caps the dorsal horn. This *gelatinosa* probably forms an end-nucleus for a cell-system connected with some one particular set of sense organs. The gelatinous formation extends without break throughout the region of each segmental nerve, from the cranial fifth to the lowest coccygeal inclusive. It is extremely developed in the region of ending of the afferent root of the fifth cranial and in the spinal regions corresponding with the limbs. It is therefore probably less concerned with sense organs of viscera and muscles than with those of the skin; it may contain the first synapse for cutaneous pain. The paralysing effect of blood stasis in the lower part of the cord on cutaneous sensation agrees with this view.⁵ Certain chemical reagents, though acting but slightly on the peripheral nervous system with its adjunct motor endings and sense organs, extraordinarily affect the spinal cord. The difference probably rests on the grey matter of the latter with its abundant

¹ Schäfer, *loc. cit.*

² It is possible that some synapses occur outside the grey matter. Further, Clarke's cell-column has a number of cells of aberrant position, especially in man, lying in the afferent root-zone.

³ "Physiologie," Lahr, 1858, Bd. i. S. 251; *Arch. f. d. ges. Physiol.*, Bonn, 1882-1883, Bde. xxviii., xxix., xxx.; also Wundt, "Grundzüge d. physiol. Psychol.," Leipzig, 1893, Bd. i. S. 110-112; and Funke, Hermann's "Handbuch d. Physiol.," 1880, Bd. iii. S. 2.

⁴ Ciaglinski (*Neurol. Centralbl.*, Leipzig, 1896, Bd. xvii.) finds degenerative evidence of a long ascending path in the central part of the spinal grey matter, but his observation stands unconfirmed.

⁵ Münzer and Wiener, *Arch. f. exper. Path. u. Pharmakol.*, Leipzig, 1895, Bd. xxxv. S. 113; Langendorff, *Arch. f. d. ges. Physiol.*, Bonn, 1898, Bd. lxxi. S. 401.

perikarya and synapses. Among the agents are both depressants, as ether and chloroform, and stimulants, as strychnin.

Before it was established by Engelken¹ and others that the intraspinal fibres are, like the peripheral nerves, excitable by various artificial stimuli as well as by natural, the spinal paths of conduction were spoken of as *æsthesodic* and *kinesodic*. These names (Schiff²) implied that the paths would transmit but would not initiate nerve impulses.³

The constant refuge sought at one period for an explanation of the difficulty connected with travel of impulses along the cord in spite of intervening incisions, was a hypothetical long path up the continuum afforded by the grey matter. The grey matter is now no longer thought to offer such a continuum, and it is not at all probable that any conducting path continues long within it.⁴

Many of the fine fibrils contributing to the interlacement in the grey matter are "collaterals" from stem fibres. These appear to myelinate late and to degenerate early. The fine fibrils in the grey matter of the vesicular column of Clarke are usually much reduced in number, and may almost all disappear as a result of degeneration of the afferent spinal roots.⁵ After removal of the Rolandic area of the cortex in the monkey,⁶ I noted degeneration in some of the small fibrils of the grey matter of the ventral and lateral cornua of the cord. Mingazzini⁷ has studied the disposition of the decrease of the grey-matter fibrils in the human cord in lateral sclerosis. He concludes that the interlacement of all but the mesial part of the ventral horn is made almost entirely of pyramidal collaterals. To the postero-lateral group of the ventral horn pass, in addition to collaterals from the lateral tract, numbers of afferent root collaterals. Schäfer⁸ proves that the collaterals from the pyramidal tract pass toward Clarke's column and the base of the posterior horn; he denies that they go directly to the anterior horn. v. Lenhossék⁹ brings forward some evidence that even the "direct reflex collaterals" from the afferent roots do not reach actually to the efferent root cells, but act on them only through mediation of intervening cells or cell branches.

REFLEX CAPACITY OF FRAGMENTS OF THE SPINAL CORD.

Whytt¹⁰ was first to show that integrity of even a fraction of the length of the spinal cord suffices to enable reflex reactions to occur in response to skin stimuli, and therefore that reflex function does not depend on the integrity of the cord as a whole. Legallois¹¹ extended similar observations to the mammalian cord. Striking examples of reflexes from a quite short isolated length of spinal cord are the sexual clasp by the fore-limbs of the male frog after section in front and

¹ *Arch. f. d. ges. Physiol.*, Bonn, 1870, Bd. iii. S. 403; Biedermann, *Sitzungsb. d. k. Akad. d. Wissensch.*, Wien, 1883, Bd. lxxxvii. S. 3.

behind the two nerve pairs of the brachial region,¹ and the wagging of the monkey's tail after spinal transection in the anterior sacral region.² These are comparable with the sting reflex of the bee for which the hindmost abdominal ganglion pair is competent after severance of the longitudinal nerve-cords just in front of it.³ Mayo's⁴ celebrated experiment on what Grainger⁵ calls "a segment of the cranial portion of the spinal cord," went far to draw attention to the fractional powers of the cerebro-spinal organ. Having isolated in the pigeon the "segment" composed of the optic tubercles and the crura cerebri (the optic and third nerves being attached) by section from the medulla oblongata and the brain, Mayo demonstrated that, on pricking the stump of the optic nerve adhering to the optic tubercle, the iris contracted.

Description of spinal function is best introduced by a glance at the organic reactions still possible in regions of the body whence the cord has been *in toto* removed. The destruction of the cord removes the corresponding region from all influence which the sense organs of its own or other parts can bring to bear on it; and also from the possibility of influencing, by means of its own sense organs, other parts. The rupture of these connections between it and the rest of the individual falls with very unequal severity on the various organs composing the part; it falls with especial severity on the skeletal musculature. It also much affects the circulation, at least for a time. If two frogs be placed under curari, so as to eliminate movements, and the brain and spinal cord of one be destroyed and of the other left intact, absorption of sodium chloride (0.75 per cent.) solution takes place much more copiously⁶ from the dorsal lymph sac of the frog with intact spinal cord than from that of the other. The destruction of the cord causes dilatation of the splanchnic vascular area, so that the major part of the blood remains almost stagnant in the portal blood vessels, and with the enfeebled circulation the absorption from the lymph sac is but slight. When in a mammal the lumbo-sacral region of the cord has been excised,⁷ the recovery of innervation by the tissues of the corresponding region appears, when tested by traumata, perfectly good. Ulcers occasioned by pressure, etc., heal readily when treated. The surface temperature is, after shock has passed by, maintained; so is the rectal. In the bitch the inguinal mammæ still yield milk in the puerperium. On application of cold to the skin, the blood vessels respond by constriction and later flushing. The hair is shed and renewed in due season. The rectum empties itself when distended; so also the urinary bladder, though not regularly. Pregnancy and labour occur, and in due course are brought to successful issue. The *constrictor cunnæ* is not toneless, but fairly normally controls the vaginal orifice. The sphincter of the anus in time recovers tone, remains tight, and reacts vigorously to faradic stimulation. It also from time to time, especially immediately after defæcation, exhibits the rhythmic relaxations and constrictions first

noted by Gluge¹ in the spinal rabbit, later by Goltz² in the dog. The skeletal musculature atrophies utterly, and comes to resemble connective tissue. The bones get brittle. Visible perspiration cannot—as far as noted in the dog—be induced.

These details serve to indicate the *status* obtaining in dogs preserved for even year-long periods after spinal exsection. The *status* is not, however, established forthwith. For a variable but not very prolonged period the ablation depresses the vascular function and tonus of the sphincters. These gradually recover. Congestion and œdema of the feet, diarrhoeic stools, *retentio urinæ*, patulous gaping of anal and vaginal ostia, are symptoms which in the course of some weeks subside. But the wasting of the striate musculature, save in these sphincters, is progressive and complete. If the spinal ablation involve the thoracic region, the tissue normally thick with muscle in the intercostal spaces becomes transparent and “as thin as paper.” In the eel, when a length of the cord midway between head and tail has been destroyed, the musculature is permanently slack, although there is good co-ordination between the movements of the front and hind end of the animal in swimming.³ So in *Lumbricus* the ablation of a single abdominal ganglion leaves the local musculature permanently slack.⁴

These changes can be averted in any particular region by retention in that region of even a short fraction of the length of the spinal cord. And in addition, as discovered by Whytt, the solidarity of the whole cord is not necessary for the exhibition of local reflex reactions. When *Amphioxus*⁵ is separated by a couple of transections, each of the three pieces balances itself in water, and executes swimming movements that appear co-ordinate and result in an apparently—so far as the fragment represents the whole—normal locomotion, always with the head-end of the fragment foremost. Of the three pieces, that possessing “the head” exhibits movement spontaneously; but the two other pieces, although progressing co-ordinately under stimuli and maintaining normal posture, exhibit little spontaneity. The severed tail-fragment of *Triton* moves in response to contact. Reflex movements persist in the hind-limb of *Rana* when the piece between the sixth and eighth nerves is the only portion of cord undestroyed. Alternating side-to-side movements have been evoked from the tail of the monkey after spinal transection at the level of the penultimate sacral nerve root. These phenomena are comparable with the reflex attachment of the suckers provokable from even an amputated arm of *Octopus* on its contact with a solid object.⁶

In the frog, after spinal transection close below the brachial region, the reflex movements of the hind-limbs are distinctly co-ordinate. If a pedal digit be pressed, the limb is drawn up. The following is a usual sequence of events. First the dorsal flexors of the toes and tarsus act, then follows somewhat slow flexion at knee, then fairly synchronous contraction of the flexors of the hip and tarsus, so that the calf is deliberately placed against the thigh, the thigh in contact with the abdomen. Frequently the intact frog, in response to a similar stimulus, executes a movement to all appearance similar. Some groups

of muscles are more readily accessible to reflex stimuli than are others. The flexors of the knee and hip and ankle are more accessible than the extensors, and especially than the abductors of the digits. In the fore-limb the adductors and the retractors of the upper-limb are the more accessible. The readiness with which reflexes can be elicited varies also with the region of the skin. As judged by pathic stimuli, *e.g.* by bits of paper soaked in acidulated water, the order of efficiency in descending scale runs in the frog somewhat as follows: anal region, first and second digits, plantar and dorsum pedis, outer side of knee, mesial half of dorsal aspect of lower half of leg, rest of leg except calf, outer side of thigh, upper half of calf, mesial side of ventral aspect of thigh, popliteal region.

The reflex of extension of the frog's hind-limbs is said to lie farther tailward than that of flexion. Gad¹ found that after transection behind the eighth pair of spinal roots, *i.e.* behind the second of the three constituting the hind-limb plexus, all the conditions for the reflex of extension of the limb obtain. Siroinin² found the levels of maximum spinal excitability of the ilio-psoas semitendinosus and gastrocnemius to lie in the frog opposite respectively the fourth, fifth, and sixth vertebræ, both for mechanical and electrical stimuli. It is not clear, however, that the contractions he studied were always reflexly produced.

In the bird (pigeon) the post-thoracic spinal cord after isolation consummates various reflexes employing the musculature of the legs. The muscles are not toneless, but on the contrary tense. Contact with straw in the cage often suffices to excite wild "struggling" of the legs.³ If one of the dependent feet be, when the bird is lifted, pressed, it is drawn up, and the opposite leg is extended. If the extended leg is then gently passively flexed, extension of the contra-lateral, previously flexed, ensues. Not unfrequently, when the animal is lifted by the shoulders, alternate flexion and extension of the hind-limbs is started which may last more than a minute, flexion and extension alternating about twice a second. The tail feathers are immediately spread when the position of the bird, as held comfortably in the hand, is such that its head lies abnormally high, or the plane of the back is at greater inclination⁴ to the horizon than in its ordinary erect posture.⁵ Singer could not obtain inhibition of these reflexes by strong or pathic stimuli, as Goltz found possible in the dog.

In the mammal similar studies have been made. Evacuation of fæces and urine ensue on rectal or vulval stimulation. Even with complete absence of the corresponding region of the spinal cord, these evacuations are more or less regularly maintained, the contents of the viscera exciting efficient contractions of the visceral muscles. The contractions when the cord is present can be reflexly inhibited by strong cutaneous stimuli. Wagging movements of the tail can be elicited by stimuli to its skin. The musculature of the paralytic limbs is far from toneless. When the spinal transection lies in the lower thoracic region, the

¹ *Verhandl. d. phys.-med. Gesellsch. in Würzburg*, 1884, Bd. xviii. S. 8. Masius and Vanlair seem to have found section through the 8th root practically destroy the spinal reflexes for the parts of the limb not innervated from the 7th. But their account is difficult to follow; *Mem. couron. Acad. roy. de med. de Belg.*, Bruxelles, 1869.

"knee-jerks," after the temporary period of "shock" is over, are more brisk than normal. Stimulation of the foot evokes drawing up of the leg and flexion at the hip and knee just as in the frog. The drawing up of the limb stimulated is accompanied usually by the pushing down of the opposite limb (active extension at hip, knee, and ankle), just as is often the case in the frog. To lift the animal by the fore-limbs frequently evokes rapid alternating flexion and extension of the hind-limbs like that observed in birds. The weight of the limbs probably produces tensions that are adequate and sufficient stimuli for apparatus of "muscular sense" within the limbs. The movements thus started can be brought to a standstill by strong "pathic" stimuli to skin, etc. When in the cat or monkey a "limb-region" of the cord has been isolated, reflex movements of the apex of the limb are easily obtained; the reflex movement of hallux and pollex of the monkey is commonly adduction-flexion, often combined with dorsal flexion of the basal-phalangeal joints. Extension of the wrist is not uncommon. In the cat and rabbit spreading of the digits in response to a touch on the foot is common; this is sometimes bilateral. Flexion at knee and adduction at hip are elicitable from almost the whole skin-field of the limb, but are feebler in the monkey than in the cat and dog. Irritation of the perineum elicits protrusion of the anus. Defecation in the paraplegic monkey, as in the dog, soon becomes regular and efficient; it can sometimes be excited by irritation of the anus, but usually more effectually by pressure upon the bladder, and so probably upon the rectum, through the ventral abdominal wall above the pelvis. The act is generally accompanied by elevation of the tail and flexion at hips and knees, and is followed by lateral movement of the tail. Micturition comes, after an interval immediately succeeding the spinal transection, to be fairly easily initiated and performed. On the crossed side to that excited, there occurs in the monkey quite frequently, as in the dog and cat, extension at hip and knee synchronous with the homonymous flexion; adduction of the contra-lateral thigh occurs with perhaps peculiar frequency in the monkey. The cremasteric reflex is well seen in the monkey. In all types it is very usual for a touch on the side of the tail to evoke a lateral movement of the tail, abducting it from the side stimulated, and for the tail to be depressed and drawn to the homonymous side on stimulation of the surface of the hind-limb.

If the isolated length of the spinal cord be thoracic, skin stimuli can in the dog evoke contraction of the lateral muscles, causing incurvation of the trunk with concavity toward the side of the excitation.¹ Skin stimuli to the front of the thorax and back evoke "shaking" of the trunk, much like the movement made by a dog on coming out of water, twitching of the panniculus carnosus, and, by application of cold, a shivering confined to the musculature innervated by the isolated length of the cord. After high thoracic transection, rubbing the skin, especially on the side of the chest or scapula, evokes a "scratch" reflex, namely, rapid alternating flexions and extensions at ankle with protraction of the limb; this is a homonymous unilateral reflex, but reflexes obtained from the skin on the ventral surface of abdomen and thorax usually affect the limbs bilaterally.

Stimulation of a single afferent thoracic root evokes contraction in muscles, limited, roughly speaking, to the area of the corresponding

¹ Sherrington, *Phil. Trans.*, London, 1892.

intercostal space; if the excitation be increased in intensity, muscles in the next space below and in the next space above likewise enter into contraction. The relation of skin (centripetal) innervation to muscle (centrifugal) innervation in this region is that the overlying skin is innervated from segmental nerves of a segmental level rather farther forward than the underlying muscle.¹

If the isolated length of cord be brachial, the reflex movements readily obtainable by stimuli applied to the limb itself are, in the monkey, flexion-adduction of pollex, retraction at shoulder, extension at wrist, flexion at elbow, flexion of fingers, and protraction at shoulder. The hand, especially the palm, is a most efficient reflexigenous area.

From an isolated length of the cervical cord of the cat comprised between transections close above first cervical root and close below third cervical, retraction of the pinna can frequently be obtained with striking regularity and briskness, on excitation of its skin.

The most striking difference between the condition of a body-region with and without its spinal cord lies in the state of its skeletal musculature; in the former the muscles are not toneless² nor altogether flaccid, nor do they atrophy beyond the effect of mere disuse. As regards the visceral and vascular musculature, there is far less difference between the two conditions. The visceral and vascular reflexes are, on the whole, most easily evoked by stimuli applied to reflexigenous regions that are themselves visceral or vascular, *e.g.* the greater reflex effect on blood pressure on exciting a thoracic root than on exciting merely its intercostal nerve.³ Spinal reflexes playing upon skeletal musculature are on the other hand less easily excited from the viscera than from the skin and sense organs of joints and muscles. The cutaneous stimuli which most potently evoke spinal reactions employing skeletal muscles, seem without doubt "pathic." Probably it is their "pathic" quality rather than their mere intensity as "pressure," etc., which renders them peculiarly efficient.

The functional powers exhibited by fragments of the length of the cord furnish the basis of a theory which regards the spinal organ as a linked chain of segmental centres. The morphological evidence of the segmentation of the body into metameræ, each with its segmental nerve, collaterally supports this theory of its physiological segmentation. In lower forms the evidence of such is clearer than in higher; the theory is a good working hypothesis in light of which to study the functions of even such complex spinal organs as that of man. The spinal organ is certainly segmented in the sense that fractions of its length possess considerable functional solidarity. It is also in the same sense functionally divisible into lateral halves. The lumbo-sacral region of the cord can be split longitudinally with retention of the so-called "deep reflexes," *e.g.* "knee-jerks," unimpaired on either side.⁴ This recalls the relatively high degree of independence of function attaching to each of the pair of nerve cords in, for instance, the Arthropoda.⁵ It is the ill-understood phenomenon known as "shock" that especially tends to obscure the segmental analysis of the spinal functions in higher animals. The fact that the referred pains and areas of tenderness⁶ accompanying certain visceral affections are distributed over the skin surface in accordance with the scheme of distribution

of the cutaneous afferents of spinal roots rather than of the peripheral nerve trunks, furnishes evidence that there is still even in the most complex spinal organ some segmental partition in the framework of its function. The cutaneous and, where examined, muscular distribution of the afferent roots¹ and the muscular distribution of the efferent roots is shown to be, even in the limb regions, as certainly and obviously segmental as is their fascicular connection with the spinal organ itself. The physiological architecture of even the mammalian limb exhibits therefore a segmental plan. On the other hand, the solidarity and homogeneity of the plurisegmental motor innervation of the individual limb muscles and of the plurisegmental centripetal bond between each practical unit of limb surface and spinal organ, warns against too lightly inferring that an ancestral segmentation is still upheld in the existing mechanisms of all the spinal regions of the vertebrate.

THE SPINAL ANIMAL.

When, instead of being tested in parts, the spinal cord is experimentally examined as a whole, the reactions obtained are decidedly more complex.²

Amphioxus, after removal of its "head," on application of a stimulus, still swims forward and right side up, though not with normal precision.³ The decapitated eel swims well, turning, mounting, or diving, to normal appearance. Its equilibrium is, however, impaired,⁴ though when laid on its back it rights itself.⁵ The shark and ray still swim co-ordinately forward after decapitation or bulbar transection, but equilibrium is impaired.⁶

The "spinal" frog still retains tonus in the skeletal musculature, and can, it is said, spring.⁷ It is doubtful whether "spontaneous" movements, including respiratory, ever occur, even in animals kept for months under observation. When undisturbed, the creature sits with head abnormally low. The tonus of the muscles seems to have suffered some diminution, though in many cases it is practically impossible to obtain absolute assurance of this. During the period of shock immediately succeeding transection, it is obvious enough, but it is evanescent. The tonus of the extensors of the limbs seems to be more depressed than that of the flexors, at least at hip and knee. On an attempt to passively draw the limb into extension, the whole animal may be pulled back without the limb being straightened. Similarly with the limbs of *Astacus* after transection behind the supra-oesophageal ganglion; the paralytic appendages are more flexed than normal at their "hip" joints,⁸ and the tail-fan is less spread. In the monkey, with thoracic transection I found that the hips and knees become strongly and permanently flexed after the lapse of six months.⁹ In a dog, six months after cervical transection, I found the ankles keep distinctly over-extended, but such rigidity is not the rule.

¹ Sherrington, *Proc. Roy. Soc. London*, 1892, vol. lii.; *Phil. Trans.*, London, 1893.

² Space unfortunately does not allow here of even the briefest sketch of the study of the reactions obtainable from the nerve-cord of Invertebrata. As contributory to a general conception of the "spinal" animal, these are of utmost importance. For recent work reference can be made to papers by Bethe, Loeb, and others, chiefly in *Arch. f. d. ges. Physiol.*, Bonn, 1891, Bd. xlix. and onwards, and to Loeb's "Einleitung in die vergleichende Gehirnphysiologie," Leipzig, 1899.

In the spinal frog placed in water warm enough to form a skin stimulus, e.g. 36° C., I have seen co-ordinate swimming, for a short time vigorous and executed with the normal bilateral stroke of the hind-limbs, and with movements of the fore-limbs. But the total co-ordination is distinctly less good than when metencephalon and myelencephalon remain. There is a tendency for the animal to dive deeper and deeper in the water; this seems due to the sunken position of the head: the loss of the semicircular canals cannot be without importance for this condition. Transection at the calamus almost immediately reduces the latent period for reflex movements of the foot as compared with the period when the section lies close in front of mesencephalon. If the reflex for a particular stimulus have been abolished by post-thalamic section, it is in a few minutes restored by post-calamic. But, on the other hand, the latency and liminal stimulus for the crossed reflex from one foot to the contralateral are less when transection is just above the calamus than when it is post-brachial,¹ indicating some solidarity of the spinal organ as a whole in regard to limb movements. The spinal frog, when placed on its back, does not, as a rule, right itself, though it is said that the lizard and the salamander do; in some spinal frogs, inversion excites very active general movements much more than does any general stimulation of the dorsal skin when the animal is not inverted; but the inversion is not corrected. It is true that spontaneous movements are not observable with anything approaching the number and variety shown by the frog possessed of the lower part of the encephalon. At the same time one does see in the spinal frog from time to time changes of position that are not very clearly related to any detectible stimulus. Volkmann's² experiment, namely, the placing of the hind-limb in a posture of extension during the period of spinal shock, with the result that, as the shock is recovered from, the limb is drawn up to the sitting posture, can hardly be cited, as he cited it, in instance of a movement without external stimulus. An external stimulus to the muscular sense organs of the limb is legitimately postulable. More "spontaneous" in character are occasional short fits of crawling, for which an external stimulus is less easy to assign.³ But the whole question is one of degree rather than of kind, if the definition above offered for spontaneity be accepted in the matter. It is to low forms, and especially to invertebrate, that resort has to be made for salient examples of spontaneity persistent after removal of the cephalic portion of the nervous system.

That the whole spinal cord presents no markedly greater competence in spontaneity than do mere regions of it, may be because its complete length includes no additional kind of sense organ above those distributed fairly equally throughout the body segments belonging to each of its component lengths.

In all the various examples in which co-ordinate progression has been observed as a function of spinal animals, the progression is always, in a sense, of one type only, namely, in the direction habitual to the species. The normal insect and *Astacus*⁴ can go backwards as well as

¹ Rosenthal (in frog), *Biol. Centralbl.*, Erlangen, 1881; Hallstén, *Arch. f. Physiol.*, Leipzig, 1886; Bickel (in *Lacerta*), *Arch. f. d. ges. Physiol.*, Bonn, 1898, Bd. lxxi. S. 44.

⁴ Foster, Huxley, Ward, Bethé.

forwards; both when "spinal" go forwards only and not backwards. So also with *Amphioxus* and the eel,¹ frog and tortoise.

The young puppy, after severance of the upper part of the medulla oblongata, has been found,² on application of a moistened finger to the mouth, to suck the finger, wrapping the tongue round it, and at the same time pushing out the legs, as young animals do when sucking. The anencephalous fœtus sucks when put to the breast.

The condition of the cat and dog after transection at the calamus scriptorius is not very dissimilar from that of the spinal frog, respiration being artificially maintained, and the animal's temperature kept from getting low. The arterial blood pressure is low at first, but that seems to have little immediate effect upon the reflex functions of the spinal cord. As the first "shock" passes off, a number of reflexes become patent, including combined movement of all four limbs, of such a character as to suggest that it represents a portion of the mechanism of progression.

SPECIAL REFLEXES.

The cord may, in its relation to the sensifacient surface and the skeletal musculature, be considered divisible into right and left lateral halves, each subdivisible into regions of neck (cervical, including pinna), fore-limb (brachial), trunk (thoracic), hind-limb (crural), and tail (caudal). A reflex action in which the stimulus applied to a reflexigenous area in one of the above regions evokes a reaction in the musculature of another of the regions, is conveniently called a *long spinal* reflex. A reflex reaction in which the muscular reply occurs in the same region as the application of the stimulus, is conveniently called a *short spinal* reflex. Short spinal reflexes are, as a rule, more easily and regularly elicitable than are long spinal reflexes. It might further be convenient to allocate hard-and-fast boundaries to these regions, but such limits would of necessity be artificial and arbitrary. The scope of the delimitation is indicated and its purpose better served by comparing with one retina, say of the bird, the one lateral half of the skin; and with the corresponding optic nerve, the corresponding lateral half of the spinal cord and bulb. Between these comparable surfaces a difference exists, in that the reflexigenous field of the skin, unlike the retinal, has instead of the one focal region of concentrated sensitivity, a couple at least of such foci, namely, the relatively highly sentient skin at the apex of each limb. But as the retina has muscles at call, so also the skin. The closeness of nexus between a retinal point and the visual musculature is graduate in degree, *e.g.* most close for the muscles of its own bulbus, next for those of the contralateral, then for the neck muscles, etc. Similarly there are degrees of nexal closeness between a point of skin and the related musculature; its connection is most close with muscles of its own limb, next with those of another limb or other region. The sole interest for physiology of the direction of nervous irradiation *per se*—apart from light it may incidentally cast upon the general physiology of nerve—lies in its elucidation of the machinery for working sentient surfaces. That the skin is a region which morphologically considered is composed of a segmental series, seems to have been allowed greater weight in the estimation of its reflexigenous functions than is altogether justified, at least in the higher vertebrata. That its segmental innervation demonstrably limits existing reflex spinal functions in the mammal, is not shown.

The direction of spread of impulses in spinal reflex actions.—Regarding short spinal reflexes, and the directions taken by the ex-

¹ Bickel, *Arch. f. d. ges. Physiol.*, Bonn, 1897, Bd. lxxviii.

² Grainger, "Functions of the Spinal Cord," London, 1837.

amples of intraspinal irradiation which they furnish, it is possible to make certain general statements.¹

i. Broadly speaking, *the degree of reflex spinal intimacy between afferent and efferent spinal roots varies directly as their segmental proximity.* Thus excitation of the central side of a severed thoracic root, e.g. seventh, evokes with especial ease contraction of muscles or parts of muscles innervated by the corresponding motor roots, and next easily muscles innervated by the next adjacent motor roots. The spread of short spinal reflexes in many instances seems to be rather easier tailward than headward. This may be related with the oblique correlation that so largely holds between the distribution of the afferent root in the skin, and the distribution of the efferent root in the underlying muscles.²

ii. Taken generally, *for each afferent root there exists in immediate proximity to its own place of entrance in the cord (e.g. in its own segment) a reflex motor path of as low resistance as any open to it anywhere.* Further, in response to excitation of even approximately minimal intensity, a single afferent root, or a single filament of a single root, evokes a spinal discharge of centrifugal impulses, which tends to occur not only through its own efferent root but through more than one efferent root, *i.e.* is plurisegmental. And this holds especially true in the limb regions. In the limb region the nerve root is therefore a morphological aggregate of nerve fibres, rather than a functionally determined assortment of impulse paths. The formation of functional collections of nerve paths (peripheral nerve trunks) out of morphological collections (nerve roots) seems to be the meaning of the limb plexuses.

iii. *Motor mechanisms for the skeletal musculature lying in the same region of the cord, and in the self-same spinal segment, exhibit markedly unequal accessibility to the local afferent channels as judged by pressor effects.*³ For example, if the primary phase only of the reflex movement be considered, the flexors of the homonymous knee and the extensors of the contralateral are, in most animals, much more accessible than the extensors of the homonymous and the flexors of the contralateral. Inasmuch as at many joints the flexors and extensors are both innervated by motor fibres contained in one and the same efferent root, it follows that the reflex movement obtained from excitation of an afferent root in many cases is quite dissimilar from the movement obtained by excitation of the corresponding efferent root,⁴ in spite of the rule of segmental proximity.

iv. *Where a spinal reflex discharge is prolonged, it usually involves antagonistic sets of motor cells alternately;* it is in each of these several phases that statement iii. holds good, not in the whole discharge taken collectively as a single discharge. It then only applies when, as in very many instances, the reflex movement is not prolonged, and there is no secondary reversal.

v. *The groups of motor nerve cells contemporaneously discharged by spinal reflex action innervate synergic and not antagonic muscles.* This

¹ Sherrington, *Phil. Trans.*, London, 1897.

² Sherrington, *ibid.*; W. Page May, *ibid.*, 1896.

³ It seems necessary to insert the qualification "pressor" before "effects" in the above statement, because there is some evidence ("reciprocal innervation") that inhibitory effects accompany the pressor effects, and it may be only in regard to pressor effect that in any particular case the above statement holds.

⁴ Sherrington, *Phil. Trans.*, London, 1892; W. Page May, *loc. cit.*, 1896.

is the reverse of the view that since Winslow and Duchenne has been a common doctrine concerning muscular co-ordination. It controverts an argument adduced for the view that the limb movement evoked by excitation of an efferent root represents a highly co-ordinate functional synergism.¹ The spinal reflex in its intraspinal irradiation develops a combined movement and synthesises a muscular harmony.

vi. It follows almost as a corollary from this, and from the rule of spatial proximity, that *the spinal reflex movement elicitable in and from any one spinal region, will exhibit much uniformity despite considerable variety of the locus of incidence of the exciting stimulus.* Approximately the same movement, e.g. in the hind-limb flexion of the three great joints, will result, whatever piece of the limb surface be irritated. The seat of incidence of the stimulus will only influence the character of the general movement executed by the limb musculature, in so far that the flexion will tend to predominantly occur at that joint the flexor muscles of which are innervated by motor cells segmentally near to the entrance of the afferent fibres from the particular piece of skin the seat of application of the stimulus.

Regarding the course of irradiation in *long intraspinal reflexes*, namely, those spinal reflexes that initiated from one of the above-mentioned spinal regions spread over into others, Pflüger, in 1853, formulated four "laws."² He argued chiefly from a careful collation of the reports of a number of clinical cases. These "laws" have for many years been widely accepted. They are stated as follows:—

1. The law of homonymous conduction for unilateral reflexes. If a stimulus applied to a sensory nerve provokes muscular movements solely on one side of the body, that movement occurs under all circumstances and without exception on the same side of the body as the seat of application of the stimulus.

If, as is clear from the context in the original paper, by movement on the same side be meant contraction of muscles on the same side, this statement does not in reality very completely express the facts. It is in part an outcome of the rule of spatial proximity, but certain cases which conform to the latter yet offer striking exception to the former; for instance, when the tail is touched on one side, it very frequently is moved towards the opposite, and this in a great number of classes, from the fish to the mammal inclusive.

2. The law of bilateral symmetry of the reflex action. When the change produced in the central organ by excitation of a sensory nerve has already evoked unilateral reflex, it, if it spreads farther, excites in the contralateral half of the cord only those motor mechanisms which are symmetrical with those already excited in the homonymous half of the cord. This statement, although true of a number of instances, fails to conform with fact in many, even perhaps the majority.

The important crossed reflex from the hind-limb of the bird and mammal does not conform to it; so similarly with the fore-limb. The asymmetry of the crossed reflexes of the limbs is important, because probably connected with the fundamental co-ordination of muscles for progression. Again, the wag reflex of the tail, and a reflex I have called the "torticollis reflex" (cervical region), afford important exceptions to the "law." And many other exceptions can be

¹ Ferrier and Yeo, *Proc. Roy. Soc. London*, 1881, vol. xxx.; P. Bert and Marcacci, *Sperimentale*, Firenze, October 1881; J. R. Russell, *Proc. Roy. Soc. London*, 1892, vol. li. Ferrier has more recently (*Brain*, London, 1893) much modified his conclusions on this point.

² "Die sensorische Funktionen d. Rückenmarkes," Berlin, 1853.

found. In the spinal rabbit, on the other hand, the crossed reflex from one hind-limb to the other is often not an asymmetrical movement, but a symmetrical flexion; this seems to stand in obvious relation to the hopping mode of progression of the animal.

3. The law of unequal intensity of bilateral reflexes. When the excitation of a sensory nerve elicits reflex action involving both halves of the body, and the action is unequal on the two sides, the side of stronger contractions is always that homonymous with the seat of application of the stimulus.

This statement is in conformity with a number of instances. The following are examples. When bilateral retraction of the abdomen is excited from the skin of the chest, the contralateral retraction is much the less marked; in the bilateral protraction of the "whiskers" (cat, rabbit, dog) on excitation of the

FIG. 356.—Diagram of the different movements of the head and fore-limb (spinal cat) caused by stimuli applied to the fore-paw and to the pinna respectively; the former evokes a movement of the head toward the stimulus with protraction and lifting of the fore-foot, the latter a retraction of the fore-limb and a twisting of the head toward the opposite side ("torticollis reflex"). 1, The pose of the spinal animal before the excitation; 2, pose after stimulation of left fore-paw; 3, pose after stimulation of left pinna.

skin of the face, the crossed movement is the less ample. An interesting illustration, because it involves inhibitory as well as pressor influence, can be demonstrated in the spinal cat or dog thus¹:—The animal resting comfortably on its back, if one hind-paw be pressed, that leg will be flexed at hip, knee, and ankle, and if the stimulus be strong, or the reflex excitability good, the fellow hind-limb will be extended. If instead of one hind-paw both hind-paws be pressed, both hind-limbs are simultaneously flexed, and there is no trace of extension. The homonymous reflex is prepotent, therefore, and inhibits the crossed reflex.

But there are also a number of exceptions to this "law," among others, the abduction of the tail from the side stimulated, already referred to.

4. The fourth of Pflüger's classical "laws" of spinal reflex action states that with associated spinal reflex centres the irradiation spreads more easily in the direction toward than in the direction away from the head.

¹ Sherrington, *Phil. Trans.*, London, 1897.

My own experience in the mammal is far from completely accordant with this statement; in, I think, the majority of instances, irradiation has spread more easily down than up the cord. It is easy to obtain reflex movements of the limbs and tail by excitation of the skin of the pinna, whereas the reverse is rare. To elicit by excitation of the hind-limb a movement of the fore-limb, is more difficult than by excitation of the fore-limb to elicit movement of the hind-limb. To elicit movement of the tail by excitation of the fore-limb, is easier than to move the fore-limb by excitation of the tail. The irradiation has in my experience been easier across the cord from hind-limb to hind-limb, than from hind-limb to fore-limb; but it is often easier down the cord from fore-limb to hind-limb, than across from fore-limb to fore-limb. In such reflexes also as the "shake" reflex (see p. 815), which implicate the trunk more than the limbs, the radiation is away from the head, for it is well obtained as a rump reflex when the skin of the shoulder is the part rubbed. In the "scratching" reflex, too, the skin stimulus is applied far headward of the region of the muscular contraction evoked.

These so-called "laws" of reflex irradiation have been so generally accepted as to have obtained a doctrinal importance which they really hardly merit. It seems here less profitable to attempt adapting Pfüger's "laws" so as to make them better fit the observed facts, than to briefly describe the salient features of the long intraspinal reflexes as exhibited in an ordinary experiment on the spinal mammal.

When the animal is supported freely from above with its spinal axis horizontal, and the attitude of the limbs determined by gravitation, a point that early strikes the observer is that there are eight areas of skin whence spinal reflexes employing skeletal musculature can be provoked with pre-eminent facility. These areas are the soles, the palms, the pinnæ, and the tail and cloacal region. It is significant that seven of these areas are those which possess the greatest range of motility if the axis of the animal be considered fixed. From the pinna may be excited movements of all the limbs, the neck, the tail, and trunk. The irradiation from this reflexigenous area usually presents the following order—(1) Neck and homonymous fore-limb, (2) homonymous hind-limb, (3) tail and trunk on both sides, (4) contralateral hind-limb, (5) contralateral fore-limb. From the fore-foot can be excited, besides movements in the fore-limb itself, movements in the other limbs and tail. The facility of irradiation is usually in the following descending series—(1) homonymous hind-limb and the tail, (2) crossed hind-limb, (3) crossed fore-limb. The relative facility of spread of the reaction to the crossed fore-limb seems subject to much variation. In the frog the path between the two fore-limbs is, especially in the breeding season, very open and facile. In the cat and monkey, it seems to be much more open in the bulbo-spinal than in the spinal animal. From the hind-foot the frequency and ease of irradiation into other spinal regions usually appears to exist in the following order—(1) crossed hind-limb and tail, (2) homonymous fore-limb, (3) crossed fore-limb. The facility of "spread" from one lateral half of the cord to the other is very dissimilar at different levels of the cord. It is particularly easy in certain parts of the tail region, and these motor mechanisms which are yoked together are for the most part, as with the flexion and extension of the hip and knee, of an asymmetrical kind. In the hind-limb region the crossed irradiation is also fairly free, and largely connects asymmetrical muscle-groups; but one of the most facile and persistent of all bilateral reflexes resulting from unilateral stimulation is the adduction of both thighs, a bilaterally symmetrical movement.

In the trunk the spread across the median plane is not so free in some animals as might have been expected: the yoking is of bilaterally symmetrical muscles.

To excite movement of one fore-limb from the other is less easy than to excite one hind-limb from the other, at least in many animals. In the neck region irradiation across the median sagittal plane is fairly easy, and the yoking connects in large part asymmetrical muscles.

On the whole the long spinal reflexes are more variable and less certain and validly predictable than the short. They vary in a series of experiments, not only as to order of relative facility of direction of irradiation, but especially as to the sense of the movement elicited at the joint, whatever it may be, to which irradiation extends. Not unfrequently a region to which the reflex action usually demonstrably irradiates is altogether omitted, and omitted consistently throughout the whole of a lengthy experiment, although the spinal region in question has as far as known suffered no damage, nor indeed been

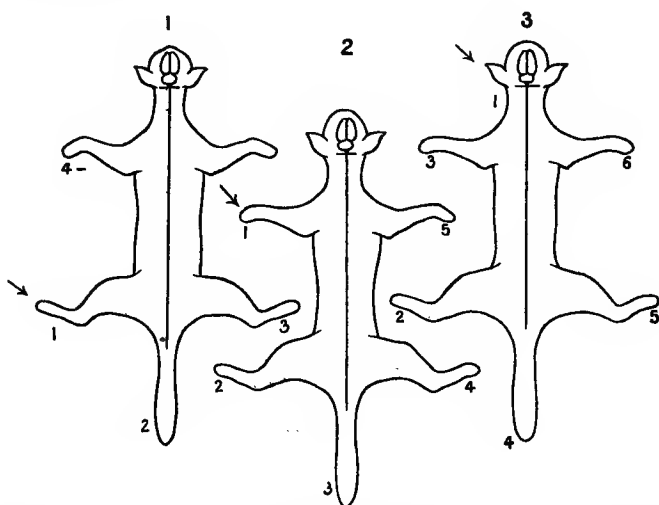

FIG. 357.—Diagram of irradiation of reflex movement in spinal cat in response to stimuli applied—1, to left hind-foot; 2, to left fore-foot; 3, to left pinna. The movements of the head are included in 1 and 2. The numbers attached to the limbs, etc., indicate the order usually taken by the parts in the "march" of the reaction.

directly implicated in any of the procedure. Thus excitation of the skin of the neck or pinna will sometimes spread back along the cord and produce movement in the tail or in the hind-limbs, and in doing so pass by the fore-limbs without evoking a twitch in either of them. The motor mechanisms of the fore-limb thus skipped over may show no sign, when examined by the local reflexes, of being less amenable than usual. Besides the limb movements, some other reflexes involve considerable co-ordination of trunk muscles, thus the "shaking" of the body on stimulating the skin of the back and shoulder. This seems analogous to the shaking of the head and ears on stimulating the ears, well seen in the bulbo-spinal dog. Related to it appears the "scratching" movement called from the hind-limb by rubbing the flank or shoulder.

There seems in the spinal mammal a disproportionate restriction of the range of spread of the reaction below the normal range. It is true that in response to a stimulus, *e.g.* of the skin of the normal animal, no

obvious response may be forthcoming. Yet, in many cases, that does not make us for a moment disbelieve that there has been spread of nervous reaction to the excitation. We say "it was felt, but caused no movement." When movement occurs, it is interesting to note the diversity of range it habitually exhibits, the slightest movement of one part being associated with adjusted movements of others. The widest irradiation of a spinal reflex is poverty-stricken compared with such habitual normal reactions. Further, the incidence of the paralysis falls, as shown by the course of the spinal irradiation, unequally upon different regions of the musculature. The extensor muscles of the limbs, just as they suffer most depression of tonus, seem also, at least in regard to the primary phase of reaction, to be reflexly more paralytic than are the antagonistic flexors. But observations on this point are still scanty under circumstances where the initial spinal shock has passed off. There is some evidence that after a time the extensors of the hip recover much briskness of reaction even in the spinal mammal.¹

In spinal reflexes, the course of irradiation, as compared with that of normal reactions elicited by a similar external stimulus, can be foretold with relative success. The limb on being touched will be flexed at certain joints; this can be said of the spinal animal with far greater likelihood of its proving correct, than the normal animal; but even under the most rigorous conditions the fatality of the reaction in the spinal animal is far from absolute. The field of musculature provoked to action can be predicted with greater certainty than can the direction the movement will take. It cannot be definitely predicted that the normal cat when touched on the planta will move the limb touched; a movement of the eye or head may follow, and none of the limb. In the spinal cat, it can, however, be predicted with much certainty that such a stimulus will cause a movement of flexion of that limb the skin of which is stimulated.

Influence of the quality of the stimulus.—The external stimuli which are excitant of naked nerves, namely, those known as "general" nerve stimuli, *e.g.* mechanical, thermal, chemical, and electrical, are all efficient to evoke spinal reflexes. The adequate stimuli for the cutaneous end-organs are also efficient. Inasmuch as the end-organs have been adapted and specialised for certain external stimuli, the threshold value of the adequate stimuli is low as compared with that of the general stimuli, and this is especially evidenced in their reflexigenous power. This probably explains the fact first noted by Marshall Hall,² that the stimulation of a nerve trunk is *ceteris paribus* less qualified to generate a reflex action than is the stimulation of the skin, although the stimulation of a nerve trunk represents the stimulation of a relatively large sensifacient surface.

At the same time it must be remembered that the "general" nerve stimuli stand in peculiar relation to pain, at least to cutaneous pain; and further, that pathic stimuli seem peculiarly efficient for producing spinal reflexes. The movement provoked may differ with the quality of stimulus: thus, the tail of the eel is made to approach by a tactile

¹ The greater activity of flexors than extensors after spinal transection has been noted by Sanders-Ezn, Wundt, Lombard, and many others. But primary extension at hip is not uncommon when time has been allowed for subsidence of shock. At the ankle-joints (dog) the paraplegic posture often comes in the course of weeks to be rather over-extension than over-flexion.

² "Memoirs on the Nervous System," London, 1837.

stimulus, to withdraw by a pathic (Pflüger). It is curious that the sense organs of both skin and muscle seem to evoke reflexly the same movements one as other. Irritation of the skin of the foot evokes flexion at knee and hip; so also does stretching the muscular sense apparatus in the pedal muscles and ligaments. Certain reflexes are, however, peculiar to skin stimuli; such are the "scratch" reflex and the "shake" reflex in the spinal dog. These are elicitable by rubbing the skin of the trunk, especially of shoulder, back, and flank. They are rhythmic alternating movements.

Mechanical stimuli applied to the skin were those earliest employed in the study of reflex actions. Not only the application of the mechanical stimulus but the cessation of its application is reflexigenous.¹ Of chemical stimuli the application of acidulated water to the skin of the frog was methodised by Türk,² and his plan has been used in many subsequent researches. The fluid is used by bringing it up to the foot or by bits of soaked paper of measured area allowed to rest on the skin a definite time, the skin being then washed with fresh water. The threshold value for chemical and for thermal stimuli applied to the skin of the spinal frog varies greatly in different experiments. The constant current both at opening and closure can excite reflexes under appropriate conditions.³ Pflüger's law regarding the production of the muscular twitch through the motor nerve by galvanism, is found to apply when examined in reflex preparations (frog).⁴ The reflex movement evoked by the break of the current is apt to be peculiarly prolonged. Single induction shocks can also excite reflexes,⁵ but to do so must be relatively very strong. Faradisation easily excites reflexes. Both with faradic and with mechanical stimuli, and both when the stimulation is of cutaneous and of muscular sense structures, it is very usually found that the discontinuance of a prolonged stimulation, especially when that stimulation is itself becoming or has become inefficient, provokes a fresh outburst⁶ of discharge from the spinal centres. After stretching a muscle by its tendon steadily and then suddenly relaxing its strain, a fresh reflex movement results; this is a phenomenon closely similar to that noted by Head⁷ in studying the effects of the vagus nerve on the activity of the respiratory centre for the diaphragm.

The spinal animal owes much of its interest as a field for study of reflex action to the combination it offers of a relatively homogeneous sensifacient surface connected with a large and varied machinery of expression, its musculature. The spinal transection above cuts off all influences of light, sound, taste, smell, from that machinery, and in large measure the very visceral organs. The projectile senses are gone. Tactile and thermal stimuli are well-nigh the only phenomena of the purely external world remaining to it, and of the "material me" the chief remaining phenomena are those adequate for the so-called muscular sense, and in some part the visceral. The quality of the stimulus, as determined by the particular avenue of sense through which it impinges on the central organ, would influence, one might think, the character of the reaction. The spinal frog, when its skin is

removed, still shows reflexes in response to displacements of its limbs. The spinal bird exhibits "struggling" movements in its dependent limbs; so similarly the spinal mammal. Though stimulation of the skin is not thoroughly excluded in such observations, the exciting stimulus is probably in chief part of the nature of muscular tensions and positions.¹ When judged by effects on the rhythm of respiratory movement (the traussection being in the bulb), and on arterial blood pressure, the faradisation of the central end of a purely muscular nerve in my experience, differs in its resultant reaction from that of a purely cutaneous, chiefly in exciting a less intense reaction, *i.e.* quantitatively rather than qualitatively. The mechanical stimulation of the muscles of the rabbit is however said to invariably cause a slight fall in arterial pressure, whereas the mechanical stimulation of the skin causes a rise.² Bradford³ found that, as regards effect on blood pressure, the faradisation of the central end of an intercostal nerve was far less efficient than excitation of the parent trunk including the contribution from the sympathetic, that is, including visceral afferent fibres. The visceral afferent appears, therefore, to be peculiarly efficient for vasomotor reflexes.

When artificially applied "general" stimuli are employed, reflex movement is usually⁴ more easily evoked by excitation of the central end of the afferent spinal nerve root than by excitation on the central side of a severed peripheral nerve; this difference is often very marked indeed. But though it is easy to evoke spinal reflex movements through the afferent roots and their filaments, it must be remembered that the reflex so obtained is obtained under conditions unfitted to exemplify reflex spinal movements of normal occurrence. The mammalian spinal root is less a functional combination than a morphological one. To excite the whole of a single afferent root is to produce a condition probably never under normal circumstances existent. The root reflexes—of which a list is appended to this article—must, in order to be of use for the understanding of the working of the cord, be considered in relation with peripheral nerve reflexes, skin-spot reflexes, muscular sense reflexes, etc.

Among adequate stimuli, a class that are efficient for production of reflexes but of nature as yet insufficiently determined by analysis, are those which institute and determine many *reflexes of posture*. The resumption of the right-side-up posture by the spinal eel, and by the headless *Amphioxus* or *Mantis* or *Grillotalpa*, and even by the amputated ray of *Asterias*, are reactions to contact (stereotropic) or to gravitation (geotropic); in the last-mentioned instance Loeb's⁵ experiments indicate stereotropism. Singer's reflex⁶ spreading of the tail feathers of the spinal bird is on a par with the above. In these and many other

¹ Reflex contraction of the *gracilis* can be regularly obtained by pinching the *tibialis anticus* tendon (cat). Fairly quick passive extension of the hind-limb of the spinal dog often causes activity (contraction) of the extensors of the same knee, sometimes of both knees. This occurs when the skin has been desensitized.

instances the assigning of the excitation to its particular group or groups of adequate stimuli has still to be done. Meanwhile it is well to keep in mind analogy with plant reactions, for instance, the reaction of vertical climbing shown by many insects (*Coccinella*) and by echinoderms (*Cucumaria*) with the "negative geotropism" of plasmodia of *Myxomycetes*. The extent to which, even in absence of connection with the highest parts of the nervous system, the lower reactions are recognisants of differences between different adequate stimuli, is illustrated by the rejection of bits of paper soaked in sea-water by the regenerated tentacles of *Cerianthus*, while bits of crab-flesh are accepted and carried toward the artificial mouth.¹ The chelate limbs of *Limulus* and *Astacus*,² after ablation of the supra-oesophageal ganglion, and in the former when the limb is isolated from the sub-oesophageal ganglion as well, react differently according as a piece of wood or of food is given to them; in the latter case, the reflex movement carries the morsel to the mouth, in the former the object is let fall. Again, the water-beetle (*Dytiscus*), after removal of the cephalic ganglia, remains motionless so long as it rests on a dry surface, but when placed in water executes the usual swimming motions with even excess of energy and rapidity.³

Summation of stimuli.—A single induction shock, the discharge of a Leyden jar, a single prick, etc., can excite a reflex action. Such brief "single" stimuli must, however, in order to produce reaction, be violent, indeed, so violent as to injure the sensifacient tissue too much for repetition. Even when thus strong, they are less efficient than less severe stimuli applied not singly but repeatedly. Stimuli far too weak to singly evoke reflex reaction, are easily able to do so if repeated. With separate electrical or mechanical stimuli, the reflex tends to occur after a given number of stimuli have been applied, although the time-intervals between the individual stimuli may be varied within wide limits,—*e.g.* ranging between .05 sec. and .4 sec.⁴ There seems to result an addition of the effects of the separately inefficient stimuli up to a point at which they ultimately produce the effect,—*e.g.* the reflex discharge. This phenomenon is akin to the "latent addition" of subminimal stimuli by muscle and peripheral nerve. It has been suggested⁵ that perhaps no single stimulus whatever is in reality efficient to excite a reflex reaction, those instances in which a single stimulus appears to do so being explicable by the prolonged and repetitive stimuli set up by the accompanying injury done the sensifacient tissue. When applied to the spinal cord severed from the bulbar vasomotor centre, single induction shocks have no effect upon arterial pressure, or have only a minimal effect, even when the shocks are of extreme intensity.⁶ On the other hand, shocks of moderate intensity produce marked vasomotor effects when applied to the cord at a frequency of twenty per second. A repetition at the rate of twice or thrice a second makes them effective.

Intensity of the stimulus.—The threshold stimulus for exciting contraction of a muscle from the afferent spinal root is higher than

that for obtaining contraction by excitation from the corresponding efferent root; especially is the difference marked for very brief stimuli. The application of 2 grms. to an area of 1 sq. mm. of the plantar skin of the spinal frog usually evokes a reflex response; this represents for the mechanical stimulus the threshold value efficient to evoke from that region a reflex reaction. This high threshold is probably determined by the "neuron-threshold" (Goldscheider¹) at synapsis between afferent and efferent root cells; though it has been found actually lower for the reflex movement than for galvanometric effect led off from afferent nerve.² But the efficiency of the stimulus, of course, much depends on its suddenness of application. A very gradually increased pressure will require values far above what is otherwise liminal.³ It is said that the spinal frog may be crushed without evincing a movement, if the crushing force be applied to it very gradually. Similarly, the application of warmth or cold to the frog's skin, if very gradual,⁴ excites no reflex reaction. If the temperature of water in which one limb of the spinal frog is immersed, be raised not more quickly than $\frac{1}{2} \frac{1}{100}^{\circ}$ C. per second, no reflex ensues, even though the warming be carried up to the production of *rigor caloris*. Foster⁵ has, however, shown that a fallacy in this observation consists in neglecting the warming of the circulating blood which passes through the limb and so into the general circulation. The warmed blood much depresses the spinal reflex activity of the frog. When one toe only is immersed in the gradually warmed water, reflex movement ensues at a temperature of 35° C.

The strength of stimulus exerts some influence on the extent and duration of the reflex movement excited; these tend to increase with increase of the stimulus. But there is no such regular relation between intensity of stimulus and intensity of reply as obtains in indirect excitation of skeletal muscle through its motor nerve. "The reflex arc, as judged by the contraction of its muscles, behaves somewhat like cardiac muscle in responding its approximate best or not at all."⁶ In other words, internal conditions affect the amount of response much more than does mere intensity of external stimulus. This is no doubt the secret of the effectiveness of repetition of slight stimuli and of summation. If in the spinal mammal an external stimulus of an intensity that is usually efficient fails to excite a reflex, to increase its intensity is usually not of much avail.

Rosenthal⁷ has established the fact that there is a distinct relation between the intensity of the external stimulus and the latent time of spinal reaction, the latter becoming much shorter as the former is increased. Wundt⁸ has pointed out that strychnin still further limits the degree to which intensity of the external stimulus influences the intensity of the contraction in response; the evoked contraction tends to be always maximal, provided a certain period has elapsed since the preceding contraction.⁹ During this period the contrac-

tion is dependent on the strength of the stimulus, being proportional to it at the beginning of the period and becoming gradually less so as the period advances. But the reflex responses referred to in these observations under strychnin are of the nature of general convulsions, and the liminal intensity of stimulus under strychnin is high.

The direction of the reflex movement is sometimes with intense stimuli the reverse of that evoked by weak stimuli. In the spinal eel a light touch on the side of the body causes that side to be approached toward the stimulus; an intense stimulus, *e.g.* hot iron, causes it to be withdrawn from the stimulus (Pflüger). The eel's touch reflexes exhibit "positive stereotropism" (Loeb), the pain reflexes "negative stereotropism."

The character of the muscular response.—The reflex contraction of a skeletal muscle may be almost as brief as the simple twitch due to momentary stimulation of the motor nerve,¹ or it may be as prolonged as a long tetanic contraction. It has been suggested that every reflex contraction is tetanic in nature²; but this remains unproven, and is by some denied.³ Only in rare instances is a single muscle alone thrown into contraction if the contraction be vigorous. On the other hand, if the reflex be very weak, it often consists in a slight flickering in a single part of a single muscle; one can note this well in the *gracilis* muscle of the spinal mammal. The duration of the reflex contraction, unlike that of the contraction evoked by stimulation of the motor nerve, tends to continue after cessation of a brief stimulus and to fail before cessation of a prolonged stimulus.⁴ The reflex spinal movement, if prolonged, tends always, in my experience, to be of *alternating* character, offering in this respect a striking difference from a movement of similar duration evoked from the cortex. A movement from the initial posture of rest to another posture is obtained; this is the *primary* movement, and with it the reflex reaction, if of short duration, may come to an end. But with prolongation of the reflex action, the posture first attained is not maintained. A second movement, opposed in sense to the former, sets in. And this alternation of postures may be repeated a number of times. Examples are the wagging movement of the tail, and the repeated "kicks" of the spinal cat when one hind-paw is held. The rhythmic alternation is still more frequent in the "scratching" reflex, where a scrabbling movement of the ankle and foot occurs with alternations of 3 to 5 per second. Also in the "shaking" reflexes, where the animal shakes its ears or its body, as does a dog on coming out of water. In their phasic alternation of condition the motor cells pass through periods of discharge and quiescence; the contraction and the relaxation contemporaneously affect antagonistic muscles, and successively affect synergic muscles. Throughout the phases of this sequence, in which inhibition as well as excitation seems to play a part, it is only harmoniously acting regions of musculature that are at one and the same time in contraction. Thus in the *rectus femoris* muscle the part that flexes the hip contracts alternately with the part that extends the knee, and, on the other hand, synchronously with the other hip flexors

¹ Wundt, *op. cit.* W.'s observations were made under weak strychninisation; Stirling and Kronecker employed unpoisoned preparations.

and flexors of the knee. Each successive phase of the reflex movement is therefore co-ordinate in this sense.

The completion of the main movement executed in a spinal reflex is, in the mammal, very frequently succeeded by a brief "twitch" of contraction. This *after contraction* is sometimes of considerable amplitude, although "twitch"-like in brevity of duration; it is seen well at the ankle-joint of the spinal rabbit after reflexes induced by skin stimuli to the foot. This remaining after effect of a reflex tetanus excited from the cord is often quite prolonged,¹ persisting even more than a minute.

It has been often noticed that a reflex excited in the spinal animal rapidly dwindles and ceases to be elicited if the stimuli applied at a *locus* be repeated rather frequently. This kind of after effect has been spoken of as fatigue, and in studying reflex actions by Türk's method it is necessary to allow pauses of many minutes between the reapplications of the stimulus. Owing to the rule of spatial uniformity, it is easy to bring the same motor apparatus into play from each of several afferent channels. When, after the stimulus applied to one of these channels has had its efficiency for producing the motor reaction greatly depressed or set aside altogether by frequent repetition, if the incidence of the stimulus be shifted to one of the other afferent channels playing on the same motor apparatus, the latter may still perfectly respond.² This indicates that in the so-called "fatigue" of the reflex the block occurs in the afferent channel. It occurs probably at the intraspinal end of that channel, for the effect is seen when afferent nerve trunks are stimulated, as well as when sensory surfaces are used; and that nerve fibres themselves are practically unfatigable has been established (Bernstein, Bowditch, Waller, Wedenskii, and others).

But when more natural stimuli are applied, the reflex movement may persist much longer without becoming exhausted; for instance, the chelate appendage of an *Astacus* reduced to the spinal condition has been observed to prosecute continuously for many hours its reflex attempts to give the morsel it holds into the grasp of the maxillipedes.³

The contraction of the muscles in spinal reflexes is never, in my experience, very forcible. No very great opposition is required to restrain the movements, and the postures assumed by the limbs never attain the full extremes of flexion possible under vigorous willed action, or under excitation of the peripheral nerves. The average character of the contraction reflexly elicited from different muscles is obviously different for different muscles, e.g. that for the gastrocnemius and extensors of the hip is short and sharp as compared with that for the flexors of the ankle and hip, both in the frog and dog.

When a motor nerve is excited by induction shocks of not too high frequency (e.g. 42 per sec.), the contracting muscle vibrates at a similar rate of frequency.⁴ If the transection of the cord be excited instead of the motor nerve, the muscle vibrates, but with a frequency independent of that of the serial stimulus and far slower, e.g. about 10 per sec.⁵ A similar rate of vibration had been seen in spinal movements under strychnin.⁶

Influence of the location of the stimulus.—To the reactions elaborated by each sense probably in some measure there pertains, among other sensual qualities, a quality of sensual space. Of the four senses which pre-eminently furnish space-perception, one has its end-organs in the skin, another in the musculo-articular structures, and these are therefore in great measure spinal senses. It is not surprising, then, that *per se* the *locus* of the stimulus is for a spinal reflex an important determinant of the character of the resulting movement.

The rule of spatial proximity given above (under short spinal reflexes) partly expresses the influence of this factor in the reaction. Much that was mentioned regarding longer irradiation illustrates it further. But the importance of the *locus*, although high when broadly taken, does not appear obvious as attaching to small differences of location in a more or less homogeneous sensory field. Within a single large but functionally related sensifacient area, such as, for instance, the skin of any one limb, considerable areal variation of the incidence of the stimulus fails to at all markedly alter the resultant reflex movement.¹ Thus, under appropriate conditions, a similar flexion of the hind-limb at hip, knee, and ankle is elicited from any small area taken in the skin surface of the limb. The flexions, though similar, are, however, demonstrably not identical.² In the spinal monkey, excitation of the outer edge of the *planta*, while causing dorso-flexion at ankle, in doing so generally brings the *peronei* into play more than is the case when the flexion is excited from the inner edge of the *planta*; then the *tibialis anticus* predominates, causing some inversion. In the frog, excitation of the skin of the knee on the dorsal and on the ventral aspect respectively, alike evoke flexion at hip, knee, and ankle, but in the former case the foot is somewhat everted, in the latter somewhat inverted.³

This influence of the location of the stimulus upon the character of the movement is well seen in the reflex reactions of the spinal frog. It furnishes a large part of the direct evidence of the so-called "purposive" character of spinal reflexes. The physiological study of reflexes must be objective, and from this point of view it is preferable perhaps to adopt the expression "local sign," although borrowing it from the psychologist, to denote a quality in virtue of which the character of the resulting movement is partly determined by the spatial position of the reflexigenous area whence initiated. In the spinal dog (cervical transection) the hind-foot is with fair accuracy brought to scratch the spot of the shoulder under irritation, although that spot lie behind the spinal lesion. The centripetal impulses from the spot—although they can yield no sensation—possess therefore in the above sense "local sign."

"Local sign" is in this sense a quality attaching to spinal and low-level reactions throughout an enormous range of different nervous systems. It is exemplified in the reflex actions obtaining between the manubrium and the nectocalyx of *Sarsia*, and even more strikingly in a naked-eye medusa, called on account of its localising reflexes *Tiaropsis indicans*.⁴ The manubrium deflects itself towards the stimulated part of the nectocalyx; its extremity

¹ This is expressed by that rule of epinal reflex action which states that there is uniformity of response despite spatial variety of provocation (*vide supra*, p. 821).

² If the rule of spatial proximity be considered, moreover, to interact with the previous rule, an explanation is offered for many of those minor differences obtaining in the broadly similar movements, there being a tendency for the muscles belonging to the immediate spinal vicinity of the skin stimulated to respond in preponderant degree.

³ Schloesser, *Arch. f. Physiol.*, Leipzig, 1880, S. 303.

⁴ Romanes, *Phil. Trans.*, London, 1879.

is eventually brought with unerring precision to meet the concurrently contracted inbent portion of the nectocalyx. If one point of the nectocalyx be irritated, and while the manubrium is applied to that point, then another, the manubrium will leave the first point and move over to the second. In this way it may be made to indicate successively a number of points of irritation. "After a series of such irritations, the manubrium subsequently continues for some time to visit first one and then another of the points which have been irritated." A cut between the base of the manubrium and the point of irritation in the bell destroys the localisation, though movement occurs toward some part of the quadrant of the bell containing the site of stimulus; but the accuracy of the localisation is reduced. The reaction recalls the bending of the tentacles of *Drosera*¹ in the direction needful to reach the seat of stimulation on the leaf. The headless bee stings in response to stimulation of the under-surface pretty accurately at the site of irritation.² In the "spinal" crayfish, if one leg is caught it is flexed and drawn up, and soon all the others, if the leg is not released, are brought round it and push at the hand holding the limb. The yellow clover-fly has been observed, twelve hours after decapitation, to stand cleaning its wings with its hind-legs, and to clean its "three pairs of legs, rubbing them together in a determined manner, and raising its fore-legs vainly in air as if searching for its head to brush up."³ But in *Astacus* the accuracy of localisation is much impaired on the crossed side by cutting the cross commissures combining the ganglia most closely concerned with the reaction.⁴ This recalls the effect of the tangential cut in the nectocalyx of *Tiaropsis*.

With the movement executed in a reflex reaction significant of "local sign" in the above sense, the afferent impulses involved seem naturally divisible into several groups according to their place of origin. There must be (1) a group originated at the seat of stimulus, (2) a group initiated in the motor and mobile organs reflexly set in action, and (3) in some cases a group originating at a distant spot to which the movement is directed. Regarding this last group, experiment illustrates its extinction, without extinction of the "local sign." Thus, in *Astacus*,⁵ after section of the nerve cords behind the mouth, when, therefore, the hind creature without mouth has lost all nervous connection with the front creature possessing the mouth, food given to the claws of the hind creature is still at once and accurately carried by them to the mouth, and this often refuses to take the morsel brought. In the grasshopper, after extirpation of the supra- and subcesophageal ganglia (entire brain), the front leg is protracted,⁶ and in the normal way catches the antenna, and the usual movements of cleaning the antennæ go on, though the antenna has entirely lost its innervation owing to the destruction of the brain. Regarding the second mentioned group of afferent impulses, H. E. Hering has made an interesting observation on the frog, and I have several times repeated it. The "cleansing" reflex of the spinal frog which brings the foot to a seat of irritation on the dorsal or perineal skin, is accurately executed after severance of the afferent spinal roots of the limb itself. In the same way, the bulbo-spinal frog brings the fore-limb to the snout when the snout is stimulated after section of the afferent roots of the fore-limb. Guiding sensations for directing the execution of these spinal cleansing reflexes are not essential; the sole important afferent factor as regards the local sign is restricted to the afferent nerves of the place of initiation of the whole reflex.

"Local sign," in the above sense, no doubt attaches to the motile

apparatus, e.g. joints and muscles considered as sources of centripetal impulses, as well as to the skin. The evidence is, however, scanty. The assumption of posture by the spinal frog goes far, I think, toward establishing it. The spinal frog, if gently left under a bell-jar with one hind-limb extended, is found in the course of a variable time to have drawn the limb into flexion; and this it does when the skin of the limbs has been removed. Bethe's observations on insects show that reflex correction of the inverted position after decapitation is a contact reflex. The muscular unrest of a spinal frog (transection behind the eighth cranial nerve), when first inverted, is suggestively greater than when a piece of wood of weight equal to the frog rests upon the dorsal skin.

In connection with localising power and local sign and spinal reflexes, there is the widespread occurrence of stereotropic reactions in spinal animals, as already referred to; such reactions imply localisation. Thus the headless eel and *Amphioxus* swim "upright," the amputated ray of the starfish rapidly rights itself when inverted on a solid surface,¹ and is restless when its ambulacral feet are not in contact with something firm. After removal of the cephalic ganglia, *Grillotalpa* and many insects, also *Astacus*, resist inversion and maintain the body's equilibrium. The balancing compensating movements of the tail of the bird² after spinal transection, and the series of movements by which *Cerianthus* when inverted in a test-tube re-erects itself, are other instances.³

Fatality of spinal reflexes.—The movement resulting from each one of a series of slowly repeated stimuli applied under as far as practicable similar conditions to an afferent channel in a spinal animal, remains often approximately similar through a long series. It can be fairly predicted that the second response will be very like the first. The uniformity of response is, as might be expected, best marked in the simplest reflexes, e.g. such as may be obtained from quite limited isolated fractions of the cord. In them the possible paths are most reduced, and the numbers of links (nerve cells) composing the nervous chains are smallest,—in other words, the synapses are fewest; in some, perhaps, there intervenes but one synapsis. These reflexes are the most "fatal," but their "fatality" is widely removed from absolute. It does not approach that with which similar movements follow repeated similar excitations of a motor nerve. In the frog the successive similar stimulation of a spot of skin, say on the second pedal digit, may regularly evoke flexion of the knee and ankle; but with that flexion may or may not be combined flexion of hip, and the degree of dorsal flexion of the digits will vary.

The fatality of reflexes might be logically inferred from what Grainger⁴ described as their "resemblance to the motion which the function of the organ requires." In the intact complete individual the reaction of one part is as a rule subordinated to the advantage of the individual as a whole. The isolated local nervous system of spinal rank executes, so to say blindly, its special reaction uninfluenced by the condition of other parts of the nervous system. Michael Foster⁵ has pointed out that when the normal *Astacus* laid over on its back is trying to correct its posture, an object, even food, placed

between the chelæ, is either rejected forthwith, or is made use of for leverage in the attempt to return to position. The "spinal" crayfish similarly placed also "struggles," and will recover normal posture; but the placing of food in its chelæ renders idle the struggling movement of recovery, for there is thus evoked a "feeding" reflex which drafts off some or all of the limbs to carry the morsel to the mouth and tuck it between the jaws, leaving the remaining tilting movements of the limbs quite ineffective.

In the living severed halves of *Hirudo*, the reaction of the halves as regards the terminal sucker of each is different. Pressing the sucker of the front half against an appropriate surface usually does not cause it to attach itself, but simply causes the head to be raised and moved vigorously with movements suggesting defence. Pressing the sucker of the "spinal" hind half causes the sucker to be reflexly attached to any appropriate surface (Loeb),¹ in accordance with the spinal reflex nature of sucker reactions in general (Grainger).² A touch on the abdomen or thorax of the decapitated bee causes it to sting itself at the spot touched,³ the creature dying from its own sting. The decapitated snake winds round a hot bar,⁴ just as it winds round a rabbit.⁵ The blind fatality of these reflexes justifies the expression that the animal reduced to the "spinal" condition is no longer an individual, but is a mere series of living segments.

Influence of condition of the central organ.—(1) **Vascular condition.**—A spinal frog in which the circulation has been arrested by ligation of the base of the heart, or in which the blood has been replaced by normal saline solution, will, by limb movements, continue to respond to skin stimuli for some thirty minutes if its temperature be low; for a shorter time only if at summer temperature. In the spinal rabbit the reflexes are abolished by arrest of the circulation in less than one minute.⁶ The reflex reactions of the mammal persist, however, much longer after arrest of the blood supply of the cord if the animal has previously been cooled.⁷ The vascular reflexes appear to persist longer than do those employing the skeletal musculature. After an interruption of the circulation in the rabbit by compression of the root of the aorta for forty seconds, the re-establishment of the circulation fails to restore the reflex function of the cord. After low thoracic ligation of the aorta when the hind-limbs are paralysed, stimulation of their skin can still evoke reflex movements from the fore-limbs. This may be due to the long upward nerve fibre path in Goll's column, which is not dependent on synapses in the spinal region.

When the abdominal aorta of the rabbit is clamped just behind the renal arteries for from thirty to sixty minutes, there ensues permanent sensory and motor paralysis of the hind-limbs, bladder, and rectum, which has its cause in the necrosis of the grey matter of the lumbar cord.⁸ When the animal is killed, five to six hours after the sixty minutes' compression, many of the

spinal nerve cells, examined by Nissl's and other histological methods, are found scalloped in contour, shrunken, and with diffusely staining nucleus. Fixed twelve hours after the compression, all the cells are found altered; and fixed twenty-four hours after the compression, the outlines of all the cells are hardly discernible, and only their diffusely stained nuclei indicate their position. Not in every experiment is the whole grey matter of the region subjected to the stasis destroyed. The ventral horn of the grey matter suffers especially severely. The dorsal horn may remain comparatively unharmed. Clarke's column of cells seems, like the spinal ganglion cells, little harmed. When the cord is fixed seven to nine days after the compression, secondary degeneration is found to have occurred in a large region of distribution. Close round the ventral horns in the lumbar region is a dense ring of degenerated fibres, which are traceable headwards, and come to lie at the periphery of the whole ventrolateral column, except in its dorsal fifth and in the depth of the ventral fissure. Some of these ascending fibres have a contralateral origin, and pass through the ventral commissure. Fibres in the dorsal columns also degenerate. These are the "endogenous fibres" of the dorsal columns.¹ As studied in the rabbit, they seem to be axons from cells of the dorsal grey horn, which enter the dorsal white column all along the limiting layer against the grey matter, and gradually pass into the dorsal mesial column, lying along the lip of the dorsal median fissure (septum). They can be traced forward to enter Goll's nucleus. The dorsal division of the cerebellar tract is little injured, but that is in part due to the fact that the cells (Clarke's column) of that tract for the most part lie headward of the region of stasis. The afferent roots are hardly at all degenerated.

Compression of the aorta of the dog close below the renal arteries does not usually produce spinal symptoms,² although it does so in some cases.³ Fredericq⁴ and Colson⁵ produced paraplegia in the dog by blocking the thoracic aorta through one carotid. That motor paralysis should result from the stasis is only in accord with anticipation, seeing that degeneration of the motor root cells ensues; but the total anæsthesia that has been observed might not have been expected, in view of the intact condition of the afferent root cells. Only a very few fibres in the afferent roots⁶ degenerate after the compression, the spinal ganglion cells seeming more resistant than the intraspinal; and the dorsal columns seem, except for the endogenous fibres, intact. Cutaneous sensation seems therefore to employ a path which early in its intraspinal course involves the grey matter. Münzer and Wiener⁷ observed that in three of their twenty-one experiments one of the dorsal horns of grey matter was not necrotic. In each of these experiments the hind-limb of the same side as the sound dorsal grey horn was noted not to be anæsthetic; from its skin could still be provoked cutaneous pain.

Anæmia and asphyxia cause transient exaltation of the reflex reactions of the spinal cord. The spinal effect of excitation of the peripheral end of the vagus is explicable in this way. The same causes can produce spinal convulsions. When the spinal cord of the cat has been severed in the thoracic region, if the circulation be arrested in the isolated portion of the cord, contractions of the muscles of the hind-limbs and tail ensue.⁸ The actual sequence of the excitation of the musculature is not constant, but one posture is so frequently assumed as to be characteristic, namely, strong flexion of hip, combined with strong extension at knee and ankle; toward the end of the seizure, lifting of the tail and swaying of it laterally often occurs. These convulsions occur

even although all the afferent roots of the isolated length of cord have been cut, and they are much less diminished by the root section than are the somewhat similar convulsions of strychnin poisoning. Contraction of the bladder and erection of the hairs are among the spinal effects of asphyxia in the mammal; in strychnin convulsions, on the contrary, erection of the hairs in my experience does not ensue; the spinal origination of the asphyxial erection is not, however, definitely proved.

During the condition of apnoea the reflex convulsions characteristic of strychnin and similar poisons do not, it is said, occur (Rosenthal and Leube, Uspensky).

(2) **Drugs.**—Some drugs affect the activity of the spinal centres, certain of them greatly. Detailed account of their action lies beyond the scope of this article. Besides depressants of protoplasmic activity in general, *e.g.* chloroform, are certain alkaloids and salts, which selectively depress, *e.g.* morphia, or exalt, *e.g.* strychnia, the spinal centres. Material so unlike the normal constituents of nervous tissue can hardly be supposed to yield fresh nervous force. The influence must consist in facilitation of the discharge of force already latently present, and the rendering of the liberating forces more effective, tending to thwart inhibition. The action of strychnin on spinal nerve cells is comparable with that of atropin on cardiac muscle cells.

Influence of associated parts of the central organ—Inhibition and facilitation (“Bahnung”) of spinal reflexes.—The response made by a reflex arc to an external stimulus is, as mentioned above, dependent as much on the internal condition of the arc as on the external conditions attaching to the stimulus. Reflex arcs, both lower and higher, are inter-connected. The condition of any one is partly dependent on the condition of many others. The nervous system is a unity; in other words, each even local reflex action is in truth a reaction to all sensifacient stimuli incident on the individual at the moment in *sum* both as to space and as to past time. And those activities of the central nervous system which are customarily considered autochthonous, have also, on account of the inter-connection of the arcs, influence upon the reactions of other arcs. The influence arising either way may take expression in depression of the local reaction, *e.g.* the rendering a supraliminal stimulus liminal or subliminal, or, in promotion of the local reaction, rendering a previously subliminal stimulus liminal or supraliminal. The former kind of effect has, since the Weber experiment on the cardiac vagus, been known as “inhibition” (*Hemmung, action modérateur*), the latter has, by Sigmund Exner, who has particularly studied it, been termed “*Bahnung*,” a felicitous expression not easily rendered into English.¹

Inhibition of the heart's beat by excitation of the vagus nerve was discovered by the Webers, and is described in Wagner's Dictionary of the following year (1846). E. H. Weber forthwith extended the notion to the case of the increased spinal activity witnessed after ablation of the brain.² He suggested that removal of the brain removes a nervous mechanism which inhibits the reflex spinal machinery. This notion of the inhibition of the activity of one part of the central nervous system by the

¹ Foster has rendered it by “augmentation,” A. D. Waller by “canalisation,” and the word “reinforcement” has been a good deal used for some of the examples covered by Exner's term. These three English terms are, however, not synonymous. “Facilitation” perhaps most nearly expresses what is intended.

² Wagner's “*Handwörterb. d. Physiol.*,” Braunschweig, 1846, Bd. iii. S. 47. Cf. Volkmann, *Arch. f. Anat., Physiol. u. wissenschaft. Med.*, 1838, S. 87.

activity of another part had, from its psychological aspect, long been expressed; for instance, in the "duobus doloribus simul abortis non in eodem loco vehementior obscurat alterum" of Hippocrates.¹ As a working physiological thesis it only became accepted doctrine after Setschenow² in 1863. He found that stimulation of the mid-brain and bulb, especially of the corpora quadrigemina, prolongs the reflex time. A frog, its cerebral hemispheres having been removed, withdraws its foot from a bath of acidulated water, if the above-mentioned parts are at the same time excited, much later than it does otherwise. The postulation of an inhibitory centre in the mesencephalon (and myelencephalon) was the first interpretation put upon Setschenow's observations. Then it was shown that similar inhibitions of spinal reactions could be obtained from foci in various other parts of the brain,³ and of the cord itself.⁴ The inhibitions are obtained either mediately from sensorial surfaces, or by immediate excitation of the foci themselves. Goltz⁵ introduced the view that a reflex centre, engaged in a particular reflex function, suffers impairment of activity for that particular reflex when it receives incitation from any other afferent channel. Schiff and Herzen teach that each spinal segment exerts an inhibitory influence on all segments lying further backward. Certain it is, a nerve cell thrown into activity may throw others not only into action but also out of action.

Where, as in the higher mammals, the cord possesses an immediate path from a region of the cerebral cortex, it is considerably influenced in its reflex functions by the activity of that cortex. Reflexes purely spinal are facilitated by the removal of this cortex or by the rupture of its descending path. The scratching reflex, which is easy to evoke from puppies and from the adult dog after high spinal transection, can, after ablation of the cortex cerebri, be abnormally easily and even uncontrollably elicited on the side of the body contralateral to the cerebral lesion.⁶ A monkey, in which a brachiolegia has been caused by ablation of the cortical arm area, when one month subsequent to the cerebral ablation the mesencephalon is transected, shows in the decerebrate condition an extraordinary degree of reflex responsiveness in the monoplegic limb to stimuli of the fellow fore-limb, and of the hind-limbs, ears, and other reflexigenous zones.

Various explanations have been offered for the facilitation of spinal reflexes which ensues on removal of the cortex. It has been argued (1) that the energy reflexly set free in the central nervous system is separable into that which is liberated in the brain and that liberated in the reflex spinal machinery, and that when the former liberation is no longer possible, the latter absorbs vicariously the excess.⁷ The view has nothing in its favour. It has been further argued (2) that the Wallerian degeneration of the pyramidal tract acts

⁷ Brown-Séquard, "Sur la physiologie de la moelle epinière," 1855.

irritatively upon the spinal centres "like a mild strychnisation" (Charcot).¹ But the spinal exaltation has been shown by experiment to set in before Wallerian degeneration has time to occur, and this fact also excludes as a cause the local spinal hyperæmia² which undoubtedly accompanies the process of Wallerian degeneration and the subsequent healing in the spinal tissue. The remaining hypothesis (3) is that the ablation removes a nervous centre which under normal conditions constantly restrains these spinal reflexes. But the reflexes become abnormally responsive not only after the loss of the cortex; early arrest of the development of the brain has the same effect,³ producing abnormal facility of the spinal reflexes, e.g. in agenic porencephaly. And there is direct experimental evidence demonstrating that the excitation of the cortex can restrain spinal reflex action.⁴ The lowering of cerebral restraint is often well marked, even when the effect of the cerebral lesion on motility is slight or undemonstrable. It may be recalled that some (Marie, Mann (Breslau), Marinesco) regard the pyramidal tract as entirely an inhibito-motor path.

Even where the nervous system, as in lower vertebrata, possesses no immediate cortico-spinal tract, removal of the hemispheres nevertheless augments spinal reactions (Marshall Hall⁵). Other parts of the brain than the cerebral hemispheres also appear to exert restraint upon spinal reflexes: thus the mesencephalon and metencephalon, as shown by Setschenow's⁶ and Albertoni's⁷ experiments on the frog and toad. The stimulus whence springs the spinal inhibition by the optic lobes of the frog has been shown to act through the retina.⁸ In the dog I have seen a semisection of the posterior part of the bulb enormously increase the spinal reflexes on the same side as the section, e.g. the scratching reflex from the trunk and limbs.

Removal of the "cerebral" ganglia in invertebrata gives to the spinal arcs striking release from restraint. Of the halves of the transected *Hirudo* or *Planarian* the hinder crawls the more restlessly.⁹ After "decerebration," the cephalopod *Eledone* enters into ceaseless motor activity,¹⁰ *Dytiscus* "executes swimming with great energy and rapidity, striking all its comrades to one side by its violence."¹¹ *Limulus*¹² and *Astacus*¹³ constantly execute movements of preening and swinging with their limbs. The removal of restraint occurs on the homonymous side after unilateral lesion in these forms; the effect is in so far like the extensor spasm supervening when one half of the mesencephalon is transected in the mammal.¹⁴

The condition of one part of the cord influences the reactions of the other parts. In this respect its homogeneity may be likened to that of the retina (simultaneous induction). Vulpian, on a *priori* grounds, argued, in his

"Leçons sur la physiologie du système nerveux," that each part of the cord exerts a restraint upon the other parts.

In the spinal crayfish the movement of the leg is at once stopped by touching the tail.¹ Goltz's reflex inhibition of the heart beat by striking the abdomen of the frog does not occur if at the same time the foot is pinched. The "spinal" snake, suspended by its head, makes rhythmical pendulous movements; these cease when the body is lightly touched. In the spinal dog a severe squeeze of the tail or hind-foot will interrupt micturition already in progress. Such a stimulus must be regarded as "pathic"; it often fails to inhibit, but it often succeeds. It is not observable in the bird, nor have I obtained it in the monkey. A more regularly obtainable example, which, moreover, does not require the use of strong stimuli, is the following. In the spinal cat (or frog) excitation of the skin of the foot, when the limbs hang down, causes drawing up of the homonymous and

FIG. 358.—Diagram of the predominant uncrossed flexor reflex of the hind-limb inhibiting the crossed extensor reflex otherwise obtainable by stimulation of the opposite limb. 1, The initial pose of the spinal animal; 2, the pose assumed after stimulation of the left hind-foot, the flexors of the left hip, knee, and ankle, and the extensors of the right hip, knee, and ankle are in active contraction; 3, the pose assumed after simultaneous stimulation of both hind-feet. The extensor action of the hip, knee, and ankle that would appear from either side as a crossed reflex is bilaterally inhibited, and the antagonistic flexor reflexes bilaterally prevail.

extension of the contralateral limb. If both feet be stimulated simultaneously, the contralateral extension does not occur, the extensors are inhibited and the flexors of both sides are thrown into contraction. This experiment seems to be in some sort a converse to that in which one leg of a spinal frog is stimulated by a ligature or acid, while the other is lightly pinched. The latent time for the reaction of the pinched leg is then lengthened, or, with a particular strength of stimulus, the reaction does not occur.

After spinal transection, inhibition of skin reflexes by peripheral excitation of other surfaces is after a time unobtainable, so great becomes the reflex excitability. On stimulation of the pinna or fore-limb after semisection in the thoracic region, the movement of the hind-limb, which previous to semisection is less elicitable contralaterally than homonymously, I found became easier contralaterally.

It is probable that inhibition of one spinal "centre" by another plays a great part in the elementary co-ordination of actions executed under spinal

¹ J. Ward, *Journ. Physiol.*, Cambridge and London, 1879, vol. ii.

mechanisms. The augmentor innervation of one muscle group seems regularly to be accompanied by inhibition of the innervation of another muscle group; this mode of innervation I have termed "reciprocal." It seems a phenomenon common in spinal reactions (see above, p. 820).

In the spinal animal, inhibition due to excitation of a nerve path or centre is usually quite transient, and passes over into exaltation even during the continuance of the stimulation if that be fairly prolonged. This harmonises with the alternating and phasic character general in muscular reactions from the spinal animal.

Rosenthal¹ insists on the longer latency of spinal reflexes evoked from the skin of one hind-limb in the muscles of the other when the transection is low than when high up. He found the reaction time for the above reflex in the spinal frog not altered by sagittal median longitudinal section of the crural region, but greatly lengthened by similar longitudinal section in the brachial. Bickel,² using a crossed hind-limb reflex, finds the reflex time in the frog, salamander, and tortoise much greater when the cord has been transected (days previously) just behind the brachial plexus than when at the bulbo-spinal junction; after transection close anterior to the bulb, the reflex time is slightly shorter than when at the bulbo-spinal junction. de Boeck³ found in the rabbit that stronger stimuli were necessary to excite movement by application to the cord if the transection were below than if above the bulb.

Exner⁴ applied in the rabbit an electric stimulus to the cerebral cortex at a point whose excitation caused contraction of a certain muscle of the foot. The same muscle could also be caused to contract in response to electric stimulation of a given strength applied to the skin of the foot. When both cortex and skin were stimulated simultaneously, the extent of the contraction was greater than when either was stimulated alone. If the stimulus to the skin was so reduced that, alone, it was subliminal for the reaction of the muscle, the cortical stimulus rendered the skin stimulus efficient if applied at any interval less than about three seconds after the cortical stimulus. The efficient skin stimulus similarly rendered subliminal cortical stimuli efficient for a short period. When both stimuli were, taken singly, subliminal, each rendered the other subsequent one efficient throughout an interval of about an eighth of a second. It is true that there is nothing to prove in this experiment that the stimulus to the skin did not act *via* the cortex, in which case the interaction was between two cortical reactions, but the example even in that case serves by analogy to illustrate also spinal reinforcement.

Phenomena analogous to the "staircase" of contractions in cardiac and skeletal muscle are met in spinal reactions. When examining reflexes obtained from the afferent roots of the spinal animal, one often finds that, after beginning the experiment by excitation of a given spinal root in a limb region, the stimuli necessary being of a given strength, on returning to the same root after having excited reflexes by a neighbouring root, the strength of stimulus required has fallen to considerably lower than it had been originally, and this happens under circumstances which seem to preclude

⁴ *Arch. f. d. ges. Physiol.*, Bonn, 1882, Bd. xxvii.

any other change in the conditions than the intercurrent stimulation of an adjacent root. Again, when a bilateral reflex is started by excitation of an area of skin or a nerve trunk, and, as often happens, the contralateral reflex is the lesser, the reflex at first obtained is unilateral and homonymous, but on then proceeding to excite the corresponding skin or nerve trunk of the opposite side, the reflex movement evoked is at once bilateral and stronger contralaterally. The stimulation of the first side has by its homonymous action "canalised" the contralateral part of the mechanism replying to the second side.

An instructive instance is yielded by the following. Excitation of the afferent root of either the eighth or seventh cervical nerve evokes in the spinal mammal sometimes flexion at elbow,—sometimes, on the contrary, extension. Excitation of the afferent root of the first thoracic nerve evokes almost invariably extension at elbow; excitation of the afferent root of the sixth cervical evokes almost invariably flexion at elbow. If excitation of the afferent root of the eighth be preceded by excitation of the root of the first thoracic, the movement at elbow evoked by the eighth is almost always extension, and similarly though not so regularly by the seventh. If, on the contrary, the excitation of the seventh be preceded by excitation, not of the first thoracic, but of the sixth cervical, the movement it evokes at the elbow is almost sure to be flexion; and similarly though not so regularly with excitation of the eighth.

There are many sequences met in experimenting on the cord that the example just quoted typifies. Noteworthy is that the flexors and extensors were never seen to be simultaneously thrown into contraction. I would express the general result by saying that sensory stimuli and reflex reactions which tend, when separate in time, to excite the same group of motor cells, canalise for and tend, when contemporary, to reinforce one another; those which tend, when separate, to excite different but inter-related groups of motor cells, tend, when contemporary, to inhibit one another.¹

The incitement to activity of functional group A of motor units seems colligate with inhibition of the functional group B, whose muscles are antagonistic to those innervated by A. By what mechanism this is ensured is not clear. Group A may have a path not only to the muscles but to the nerve cells of group B, by which it can depress the activity of the latter. Or each spinal path that embouches into A may also embouch mediate or immediately into B, and while exciting A inhibit B. This latter does not necessarily imply two different kinds of disturbance in the paths opening upon A and B respectively; a difference between the condition obtaining at the moment in A and B motor units may determine a different reaction in them under an external influence which falls similarly on both. Whatever the detailed explanation, it is certain that co-ordination is a character common to all reflex actions from the unpoisoned spinal cord, and that reciprocal innervation largely expresses that co-ordination.

The movements that are in the spinal animal at various times elicited from one and the same area, and even same spot, of skin, vary considerably, and even at brief intervals. No phenomenon more often

¹ I am aware this differs from views expressed by Eckhard, Goltz, Schiff, Herzen, Wundt, and others; but see the suggestions of Descartes, "De homine," Amsterdam, 1678, p. 34; of C. Bell, in a footnote, "Physiology of the Human Body," London, 1826, vol. iii.; also "Remarks on Respiratory Co-ordination," by S. J. Meltzer, *Arch. f. Physiol.*, Leipzig, 1883; and *New York Med. Journ.*, 1899; and my notes on "Reciprocal Innervation," in *Proc. Roy. Soc. London*, vol. lii. *et seq.*, 1893-1898, and elsewhere. The suggestions of Descartes and Bell proposed, however, *peripheral* inhibition, not *central*.

meets the observer than this, nor more often disturbs his observations on other points. It brings home to the imagination the constant manifold factors that must be playing upon the spinal cord, even under apparently the most uniform conditions. The play of the external environment upon organ is more or less under control of the experimenter. It is the varying condition of the central organ and of its bodily environments which creates his difficulties.

Under strychnin poisoning the whole skeletal musculature may be thrown into action from any one point of skin, and even when all the afferent roots have been severed, except that particular one conducting from the sole point excited.¹ Each local afferent path must evidently lead to not merely one but many, and ultimately to the whole motor mechanism. The afferent path from a digit is thus, potentially at least, connected with the whole motor organ of the individual. Yet harmonious co-ordination of the contraction of the individual muscles in any functional group, and the harmonious mutual co-operation of functionally related muscle groups, characterises the natural movements of a normal animal. This mechanism has been symbolised by supposing in the cerebro-spinal organ between the various central connections open to the afferent path, resistances so graded and adjusted that only harmonious motor units and unit-groups become excited, and these each only in that degree due for execution of appropriate movement. It might have been supposed that with the cerebro-spinal organ maimed by subtraction from it of the entire brain, any afferent path entering the central nervous system, and there connected with not one but many—potentially all—the motor spinal units, would, the guidance of the brain and its great sense organs gone, act on the motor units both synergic and antergic so indiscriminately as to induce, if strongly stimulated, complete discharge of all of them, or, if weakly stimulated, feeble or incomplete discharge of all of them. Such discharges would of course produce unnatural movements, in which the action of one muscle or set of muscles would impair or defeat the action of another muscle or set of muscles. As a fact, the reactions of the skeletal musculature of the spinal animal display no inco-ordination of this kind. The afferent path evokes discharge only of harmoniously related motor groups. If it be stimulated strongly, the number of motor groups excited may be extensive and their situation involve the whole length of the spinal axis; but the groups excited contemporaneously are always harmoniously acting groups, *e.g.* flexors of hip with flexors of knee, and not groups mutually subversive of each other's action. Each individual muscle of each group, so far as analysed, seems in its action balanced and subordinated as in a "natural" movement. Nor does progressive weakening of the stimulation of the afferent path lead to the appearance of inco-ordination, as might have been expected by the excitation of the various groups becoming irregular and partial. As a fact, it leads only to the non-appearance of the reaction in a progressively increasing number of the harmoniously acting regions of the musculature. No more striking contrast can be cited than that holding between this and the effect of excitation of a motor spinal root or of a filament of a motor root. The latter throws into contraction simultaneously muscles whose action is opposed; what movement results will be determined merely by which muscle of those in action pulls the hardest or has the better leverage.

¹ See Vulpian, "Leçons sur la physiologie du système nerveux," Paris, 1866.

Even when the stimulus, instead of being restricted to a narrow sensory area or path, affects simultaneously large surfaces or wide channels, finally the whole skin, the motor discharge evoked is still confined wholly to harmoniously acting spinal units. Thus the spinal frog placed in water warm enough to stimulate the general skin, swims forward with balanced and symmetrical and synchronously bilateral strokes. The co-ordination of the action of the musculature of each limb, and that of the hind-limbs together, and even of fore-limbs with hind-limbs, is good; the aquatic locomotion is surprisingly efficient in view of such total loss of all the cranial senses.

These considerations clearly indicate that some set of spinal sense organs forms the chief basis of the mechanism which ensures such elemental muscular co-ordination as that under discussion. The fact that it is fairly preserved even in the skinned spinal preparation, indicates that the spinal sense in question does not depend on cutaneous sense organs. Its sense organs are probably those in the musculo-articular apparatus, since it seems hardly possible that the co-ordination is to so large an extent an innate quality of the motor unit groups themselves.

The integrity of the *whole* cord is not required to ensure co-ordination. Short isolated portions are enough. In *Limulus* four pairs of the abdominal ganglia isolated in a group can regulate the respiratory movements of the eight appendages co-ordinately, in total absence of the whole remainder of the nervous system.¹ In spring the three upper spinal segments, isolated from the rest of the head and brain with their connected skin and muscles, execute the frog's sexual "clasp." In the cat and monkey, with spinal transection low in the sacral region, wagging of the tail from side to side by alternate co-ordinate contraction of its lateral musculature, is evoked from the local skin. In short, to employ the metaphor of resistances, in the reflex spinal organ the resistances are so disposed as to ensure synthesis not of a discord but always of a harmony of movement.

The influence which the condition of one part of the cord exerts upon others is seen in the effect which the *initial posture* of a limb can be demonstrated to exert upon the character of the reflex movement elicited from the limb. From the skin of the back of the proximal part of the thigh in the frog and dog, the reflex response in the limb is flexion at the hip, if the resting posture of the limb at the time of application of the skin stimulus be one of extension, *e.g.* if the limb be hanging down. If, however, the resting posture of the limb be one of flexion at the time of application of the skin stimulus, the reflex movement of response is often an extension of the thigh at hip. The difference of the response may be due to the different condition of the musculo-articular sense organs in the two different initial postures, their difference reacting upon the excitability of the antagonistic motor mechanisms of the cord. The experiment is significant of the important part assignable to subconscious muscular sense reactions in regulating the activity of the skeletal musculature. It suggests an explanation for the alternating character of the movements executed by spinal reflexes.

Phasic variation in the reflex activity of the cord.—Although the relative invariability of the movement elicited by repetitions of a particular stimulus is a striking character of spinal reflexes in the mammal, and lends to them a machine-like quality of regularity, curious variety of result occurs, when they are examined in the same individual

¹ Ida Hyde (Loeb's laboratory), *Journ. Morphol.*, Boston, 1894, vol. ix.

from day to day. The very spot of skin that one day evokes nothing but flexion of all the toes, may the next evoke nothing but flexion of the hallux and extension of the other toes; and the next nothing, or again, only the movement obtained three days before. A stimulus usually eliciting dorso-flexion at ankle may on some days elicit in the same individual plantar flexion of the ankle. As a broad rule, spinal reflexes are more easily elicited when a well-nourished animal is hungry and expecting food, and less easily when it has just heavily fed. There is, so to say, a spinal hunger. The knee-jerk in the dog varies in the same way as the true reflexes in relation to time of feeding. But altogether apart from feeding time, on some days hardly a reflex can be elicited from the very animals that on other days yield a variety of reflexes with readiness. Conditions of individual age, and especially of body temperature and general nutrition, influence, as Freusberg points out for the lumbo-sacral reflexes of the dog, the facility of reflexes very greatly indeed.

Autotomy.—Among reflex reactions exciting contraction of muscles, an interesting group discovered by Fredericq, execute what he has called *autotomy*.¹ In many animals, e.g. *Asterias*, *Cometula*, *Ophiurus*, *Arachne*, insects, and crustaceans, if a limb be pulled upon sufficiently forcibly or long, it is suddenly ruptured across and shed. In the same way some vertebrates (e.g. *Anguis fragilis*) shed the tail. The reaction is a reflex one, employing muscular contraction. It can be elicited not only by a blow or a crush, but by an induction shock or a chemical irritant. It requires in *Asterias* the mediation of the ganglion at the base of the ray; the circumbuccal nerve-commissures connecting ray with ray may all be severed without impairing the autotomy, although the reaction is then less easy to obtain. Fredericq's experiments show that the actual mechanism consists, at least in many cases, of a violent contraction of a muscle, so powerful as to break a proximal joint and rupture the tissue. In the crab the muscle employed is the great extensor of the forceps. This contraction does not seem at the disposal of the "will" of the animal. If the limb be gently though effectively fixed, the animal in all its endeavours to escape never performs autotomy. A sudden strong stimulus to the limb itself can provoke reflexly a more powerful contraction of the limb muscle than can be evoked by impulses emitted from the higher centres.

SPINAL SHOCK.

"Shock," like "collapse," a term more used by the clinician than the physiologist, is, like it, a term somewhat ill-defined in scope. In some forms of the clinical condition, circulatory disturbance and inspissation of the blood play part, but, as understood by the physiologist, "shock" is primarily a nervous condition. "If in a frog the spinal marrow be divided just behind the occiput, there are for a very short time no diastaltic actions in the extremities. The diastaltic actions speedily return. This phenomenon is 'shock.'"² Whytt had, a century previous to Hall, drawn attention to the same phenomenon, although assigning to it no descriptive term. The whole of that depression or suppression of nervous function which ensues forthwith upon a

² Marshall Hall, "Synopsis of the Diastaltic Nervous System," London, 1850.

mechanical injury of some part of the nervous system, and is of temporary nature, may be conveniently included under "shock." By Goltz it is considered as entirely a collection of inhibition phenomena. But it has its analogue, no doubt, in the "block" (Romanes, Gaskell) in a conducting tissue (medusa subumbrella, heart) ensuing on mechanical interference. Whether such phenomena are best included under the head of inhibitions is very questionable.

Among laboratory animals it is in the monkey that on the whole "spinal shock" appears at maximum. As studied in that animal, whether the site of spinal transection lies near the front or hind end of the thoracic region, appears to make slight difference to the general result, apart from determining the mere number of spinal segments displaying the phenomenon. The "shock" appears to take effect in the aboral direction only.¹

Section below the brachial enlargement little if at all disturbs the reactions of the upper limb, although the number of headward running channels of conduction ruptured by such a section is enormous. Striking instances of the absence of headward spread of the depression due to "shock" are afforded by transections abutting on the lower edge of the fifth cervical segment; these depress the respiratory activity of the phrenic motor cells hardly at all, even momentarily. On the aboral side of the transection, depression is profound. Analogously, the sudden cutting off of all that stream of centripetal impulses continually pouring for conscious and subconscious elaboration into the encephalon from the cutaneous, articular, and muscular sense organs of the tail, limbs, trunk, and neck, and from the viscera, does not seem at all to disturb the reactions of the head and brain. The animal immediately after the section will contentedly direct its gaze to sights seen through the window, or, if the section have been below the brachial region, may amuse itself by catching flies on the pane. Similarly, the head half of the worm *Thysanozoon*² or *Allolophobus*³ is said to continue the movements of progression almost undisturbed by quick transection across its middle. The bee, if while it is sucking honey the abdomen is suddenly cut off, will rear itself for a moment and then quietly continue sucking.⁴ The exclusively aboral direction taken by shock seems universal in the nervous system. In the monkey, when the transection has been quite far forwards, e.g. at the first cervical level, there seems a tendency to drop off rapidly to sleep; but it is very doubtful whether that is due to any depression of the nervous organs in front of the section, other than that depression of function one might expect from the coincident fall of the arterial blood pressure and body temperature. In the cat a high transection, e.g. brachial or cervical, seems to frequently induce in front of the lesion not a depression but an exaltation of function, the region of the trigeminal distribution appearing hyperæsthetic.⁵ The reactions from the head organs in *Astacus*⁶ seem exalted by section of the nerve cord in front of the thoracic ganglia.

After high cervical transection, "shock" appears more severe in the fore-limbs than in the hind. For an hour or so it may be difficult to elicit any reflex movement from skin innervated behind the transection, whether by mechanical, thermal, or electrical stimuli. An apparently crossed reflex is, at least in my experience, among the earliest obtainable, namely, the crossed adductor reflex and the

"crossed knee-jerk." An early reaction to emerge from the spinal shock is adduction-flexion of the hallux, in response to stimuli applied to the third, fourth, or fifth digits (plantar surface or sides), or to the skin of the sole, especially on its fibular side. The movement of the hallux is then slight and often tremulous. A similar reflex is obtainable in the hand. In the cat and dog and rabbit an equivalent reaction seems to be the arching of the digits, and this is not unfrequently bilateral. Anal protrusion, in response to stimulation of the skin of the perineum, feeble abduction of the tail on pricking it, are also reactions which early emerge from the depression. The limbs at this time feel limp and the muscles more flaccid than they do later. Gradually these reflex movements become more vigorous, and others are added, *e.g.* the cremasteric, and the drawing up of the limb on stimulation of the foot. Extension of the limb is late to be obtained, and very rarely is obtained as a primary homonymous reaction. Crossed reflexes appear, and the march and duration of the individual reflexes gets more extensive. The disappearance of "shock" is very variously rapid in different individuals. In the same individual the progress is usually not steady; on some days reflexes are absent which had been gained, and reappear only later. The extensors of the hips and knees recover later than the flexors. In the spinal dog, after a brachial transection, it can perhaps be said that in five weeks the depression of shock has usually worn off. It is not renewed by a second transection practised behind the first one.

The cause of the "shock" cannot entirely be the fall of arterial pressure which a transection anywhere in front of the second thoracic level must entail, for the head does not participate in the shock, although participating in the lowered blood pressure; and when the transection is in the lower thoracic region, the shock distal to the lesion is about as severe as after cervical transection. Besides, section of both splanchnics does not cause shock. Neither is the "shock" explicable by fall of deep temperature, for it occurs where that is absent and has been almost avoided. It is noteworthy that, although in the monkey among laboratory animals it appears most severe, and is certainly particularly long lasting, it does not in that animal appear more severe as regards depression of function of urinary bladder, rectum, etc., than in other laboratory animals. It is especially well seen in the monkey that the motor root cell, though in spinal shock profoundly inaccessible to stimuli applied *viâ* skin or afferent nerve trunks, lies perfectly open to any applied *viâ* the pyramidal paths; excitation of the pyramidal tract at the top of the cord readily evokes movements in the otherwise reactionless limbs. Also, excitation—mechanical, or by weak electric currents—of the central ends of the spinal afferent roots themselves readily evokes reflex movements, though far stronger stimuli fail absolutely when applied to the skin and afferent nerve trunks.

How long the phenomena of shock may persist, is a question on which very different views are held. Goltz is the founder of a school which works in the belief that the phenomena of shock may persist for months or even years. My own experience inclines me to think that the condition of a spinal cord, isolated by spinal transection, is often more normal a short time after the transection than it is when long periods of weeks and months have been allowed to elapse. The "shock" passes off, to be succeeded, it seems to me, by permanent alterations that in many ways resemble in their effects a recrudescence of shock. The decreasing depression merges in the onset of an increasing "isolation-

dystrophy,"¹ due to the permanent withdrawal from the spinal cells of influences they are normally accustomed to receive from other portions of the central nervous system. The most favourable time for the examination of the independent capabilities of the spinal cord is that when the sum of "shock" and "isolation-dystrophy" together is of smallest amount. That time, compounded as it is of two such variable factors, is itself extraordinary variable. In the monkey, "shock" lasts longer and the "isolation dystrophy" comes on earlier than in other animals commonly observed in the laboratory. It is the conjunction of the periods of these two phenomena which I imagine renders so difficult and so largely defeats attempts at observations of the proper spinal reactions of the monkey. If the overlap of the two is great, then no spinal reflexes or only the merest traces of them may be elicitable. In man it is natural to suppose that even more than in the monkey will spinal "shock" be severe and "isolation dystrophy" arrive speedily. Clinical observation supports and confirms this supposition.² After total transverse lesions of the cord in man, the depression of function of the skeletal musculature is profound and practically permanent. On the other hand, the depression of visceral function seems hardly greater in man and the ape than in the rabbit and frog.

By his sense organs and their nerves the individual is put *en rapport* with the material universe. His sense organs constitute between his mind and that universe the only go-between. That universe for each individual is made up of two portions, one a part beyond his body, termed his environment, the other a part consisting of his own body, or more strictly of all that part of it that can affect his afferent end-organs. This latter part constitutes his "material me." It is divisible. Taking its sensibility as basis for its subdivision, it is a compound of skin, of motor apparatus, and of viscera. With the first of these are concerned perceptions obtained through the projecting as well as through the non-projecting senses. The senses concerned with the motor and visceral apparatus are solely non-projecting. The higher nervous centres are built, especially where most perfected, on the projecting senses far more than on the non-projecting. Of the non-projecting, the muscular much more closely than the visceral is linked with the powers of the great motor organ, the skeletal musculature, itself arisen chiefly as a machine for reacting to the projicient senses. Hence comes it that after destruction of the higher nervous centres, *e.g.* brain, the competence remaining to the spinal centres is found greatest for visceral reactions. From this point of view the visceral reflexes present the most perfect nervous reactions of the spinal animal. The bulbo-spinal animal, receiving as it does the afferent impulses of the vagus as well as of the thoracic and sacral nerves, may indeed be considered, as regards visceral function, a fairly perfect animal. The purely spinal animal does, however, exhibit some amount of damage to the nervous regulation of its viscera; this is chiefly of the nature of "shock," and temporary. The visceral shock appears to be little if at all greater in the ape and man than in the rabbit and frog, whereas in the two former the shock to the spinal mechanisms of the skeletal musculature is enormously greater than in the two latter types. The significance of the deeper depression of reaction into which the higher animal, as contrasted with the lower, sinks when made "spinal," appears this, that in the higher types more than in the lower the great projecting senses actuate the motor organ, and impel the motions of the individual. The deeper depression shows that as the individual ascends the scale of being, the more cognisant does it become of a circumambient universe that is "not me," and that that latter acquires a

¹ Sherrington, *Phil. Trans.*, London, 1897.

² Bastian, *Med.-Chir. Trans.*, London, 1891; Bruns, *Neurol. Centralbl.*, Leipzig, 1893.

more and more preponderant directive influence over those "reflexions," those expressions of the creature's neural states, its "doings." The relative slightness of the "visceral" part of spinal shock in higher animals indicates the extent to which the reactions of the visceral musculature and some of the reactions of the skeletal musculature accessory thereto are normally unconnected with higher conscient nervous organs.

SPINAL VISCERAL REFLEXES.

To the viscera belong three sets of peripheral afferent channels—(1) the vagus; (2) the spinal roots from first thoracic to second lumbar inclusive; (3) the second, third, and fourth sacral roots. The trophism of these channels depends on the vagal ganglia and the spinal ganglia mentioned. The efferent channels to the viscera lie in three corresponding sets.

The viscera are insentient under numerous traumatic and other injuries; in disease they nevertheless may cause pain. Much of this pain is "referred" to areas of the body surface, where the skin is then often found to be "tender," *i.e.* hyperalgesic. James Ross¹ suggested that the pain is in such cases referred to parts supplied by sensory cutaneous nerve fibres ending in the same segments of the cord as do the afferent fibres of the viscus diseased. Head has examined the data for this hypothesis, and has established and elaborated it.² The following conspectus of Head's results states the probable distribution of visceral afferent fibres of the spinal ganglia in man:—

Heart, . . .	First, second, and third thoracic.	Prostate, . . .	Tenth, eleventh (and twelfth) thoracic, and first, second, and third sacral.
Lungs, . . .	First, second, third, fourth, and fifth thoracic.	Testis and epididymis, . . .	Tenth, eleventh, twelfth thoracic and first lumbar.
Stomach, . . .	Sixth, seventh, eighth, and ninth thoracic.	Ovary, . . .	Tenth thoracic, ovarian appendages, eleventh and twelfth thoracic and first lumbar.
Intestines, . . .	Ninth, tenth, eleventh, and twelfth thoracic.	Uterus, . . .	Tenth, eleventh, twelfth thoracic, first lumbar, second, third, and fourth sacral.
Liver and gall bladder, . . .	Seventh, eighth, ninth, and tenth thoracic.	Rectum, . . .	Second, third, and fourth sacral.
Kidney and ureter, . . .	Tenth, eleventh, twelfth thoracic and first lumbar.		
Bladder, . . .	Second, third, and fourth sacral, and eleventh and twelfth thoracic and first lumbar.		

Urinary bladder.—The region of the cord from which efferent and to which afferent channels belonging to the urinary bladder pass is twofold, a sacral with which the second, third, and fourth sacral roots (man), and a lumbar with which the first, second, and third lumbar roots are connected. From this region, when isolated, reflex contractions and relaxations of the detrusor and sphincter can be elicited. The intravesical pressure which the sphincter withstands is lowered³ by spinal transection between the fifth and sixth lumbar segments of the cat (between sixth and seventh in rabbit).

These can therefore be said to form a spinal vesical centre. The upper limit of the region lies near the hindmost level of the origin of the second

lumbar root (cat).¹ The lower limit cannot be so distinctly determined. Transection below the sixth lumbar vertebra in the rabbit causes immediate escape of urine from the bladder.² After spinal transection in the frog, rabbit, cat, dog, and monkey, as after tantamount injuries in man, micturition is interfered with. The exact share played in the suppression of function of the organ by the interference with the innervation of its intrinsic musculature and with that of other muscles, abdominal and perineal, accessory to the emptying of the organ, is hardly known. In the first days after the transection, the bladder can only be competently evacuated by artificial means. This is easily effected, especially in the female, by pressure on the distended viscus through the abdominal wall. The pressure should be light, and quickly applied, and not maintained for long; it appears to act by exciting a brief reflex micturition, no doubt of an imperfect character. The tail is raised, the anus somewhat protruded, the knees are in the bitch flexed, and a brief gush of urine is allowed to escape under the pressure of the hand on the abdominal wall. The pressure alone is quite inefficient to expel the urine, for it can be greater when first applied and ineffective, than later when effective; until the reflex ensues, the pressure cannot void the bladder of its contents; and although the pressure is maintained, the urine after the brief gush is not voided. It is then best to desist from the abdominal compression for a minute or so, and reapply it somewhat suddenly. Sometimes, instead of a brief gush, the whole contents are allowed to be discharged. It has been shown³ by comparing rate of escape with intravesical pressure, that when the bladder is reflexly voided, in response to stimulation of a sciatic nerve central to section, the reflex reaction involves two acts, contraction of the detrusor and relaxation of the sphincter (in addition to concomitant movements due to skeletal muscles). The impression given to the hand when the bladder is emptied by pressure over the hypogastrium is less than of contraction of the viscus than of a resistance low down on the pelvic floor suddenly yielding. I have noted that, in the monkey, variation of the level of the spinal transection anywhere between sixth cervical and fourth lumbar appears to make no noticeable difference in the degree of depression of the act of micturition, although in the latter case the hypogastric afferent and efferent paths are intact, in the former not. This depression seems as severe in the rabbit and cat as in the monkey. For many days the urine may have to be evacuated either by inducing the reflex in the above-mentioned way, or by the catheter. Later, the urine in the monkey as well as in other laboratory animals comes to be voided "spontaneously" from time to time. In some cases in the dog the urine even soon after transection is voided in small quantities, very frequently and apparently without obvious external stimulation having occurred, and without the bladder being even moderately filled. Defæcation frequently accompanies the micturition; the spinal micturition is followed by spinal wagging of the tail.

Goltz and Ewald,⁴ in their observations on dogs in which the lower region of the spinal cord had been removed *in toto*, found the bladder empty itself spontaneously from time to time months after removal of the cord; but the bladder had usually to be emptied by artificial means, and cystitis frequently occurred. Though some degree of retention of urine is a common symptom after total transverse lesion of the cord in man, and usually a permanent one, I have never seen cystitis ensue after spinal transection in laboratory animals, although the animals have been kept under observation many months.

Defæcation.—In the tortoise, after spinal transection behind the second of the three roots of the sciatic plexus, defæcation occurs in the sense that fæces

are expelled.¹ Tampons of cotton-wool introduced into the rectum excite their own expulsion, if they be relatively large. The expulsion is accompanied by movements of both hind-limbs and tail. When the level of transection lies above the sciatic plexus, excitation with smaller tampons, or by electrodes applied just within the anus, evokes a complete act of defæcation. The posterior end of the body is raised on the extended hind-limbs, the tail is raised, and after expulsion of the material from the rectum follow movements of *nettoyage* by the hind-limbs. Defæcation, in the sense of regular expulsion of fæcal matter, occurs without difficulty in mammals after transection in the upper lumbar region, or higher. The external sphincter is patulous in some cases for a few hours or days after the spinal transection, but more usually recovers tone a few minutes after the operation, or never loses it. Goltz and Ewald found the tonus return even after exsection of the lumbo-sacral region of the cord. The rhythmic contractions of the sphincter noted² to set in after high lumbar spinal transection in the dog, can be inhibited by strong sensory stimuli of adjacent parts.³ Gowers,⁴ in describing the condition of the rectal sphincter in disease of the spinal cord, says two states can be distinguished by introduction of the finger. If the lumbar centre is inactive, there is a momentary contraction, due to local stimulation of the sphincter, and then a permanent relaxation. If, however, the reflex centre and motor nerves from it are intact, the introduction of the finger is followed "first by relaxation and then by gentle, firm, tonic contraction. I have verified this by introducing an india-rubber cylinder instead of the finger, and registering the pressure on the cylinder by connecting it with a recording apparatus. The relaxation is then found to be preceded by a very slight brief contraction, and to be followed by unbroken tonic contraction." The relaxation may also be readily produced by stimuli to the mucous membrane above the sphincter. *Incontinentia alvi* is described as usual in man after total transverse lesion of the cord; it is not at all usual in the monkey.

Sexual reflexes.—*The uterus.*—As is well known, uterine contractions may be induced by applying heat or cold to the abdomen, by passing a catheter, by hot or cold rectal injections, by drawing back the perineum, or by putting the child to the breast. In animals, such contractions are strongly excited by faradisation of the central end of the first sacral nerve.⁵ As the irritation in these instances is not applied to the uterine tissue or to efferent nerve channels, the resultant uterine reactions must be induced reflexly. Röhrig⁶ states that asphyxia does not produce uterine contractions or abortion if the lumbar region of the spinal cord is destroyed, although it does produce those events if the cord is cut across in the thoracic region. Cases have been from time to time reported in which parturition has occurred and run its course in normal fashion in paraplegic women, the interruption of the cord being complete, and as low as the tenth thoracic level. Marshall Hall argued from such instances that uterine action is a reflex spinal one connected with a lumbar "centre." In these cases parturition is, of course, unattended with pain, although the labour "pains" are strong and efficacious. In one case, during the second stage, the "pains" recurred about every two minutes, each lasting about forty-five seconds. The patient perspired after each pain, as if she had been exerting herself. There was an indistinct tight feeling referred to the epigastrium at the height of each pain;

by the recurrence of this indistinct sensation of "tightness" she became able to say when a "pain" was present.¹ Goltz² made observations on a bitch; spinal transection was practised at the lower thoracic region; six months later "heat" came on, attended by the usual phenomena, psychical as well as physical. Impregnation was effected, the animal became gravid. The pregnancy was normal; the mammary glands enlarged as usual. Parturition followed in due course. Goltz and Ewald³ have more recently observed in a bitch, whose spinal cord from the lower thoracic region backward they had excised eight months previously, pregnancy follow coitus and terminate with successful parturition. The animal suckled the puppies normally. The mammary glands thus share in the pregnant and lying-in states when there can be no spinal communication between the pelvic organs and the breast. In the case of the patient reported by Routh,⁴ it was so, although the destruction of the cord in the region of the seventh thoracic nerve was, as confirmed by autopsy, complete. The breasts enlarged during the pregnancy, and during the puerperium the mammary function was performed with normal punctuality and persistence. The quality of the milk was good. The relation of parturition to the spinal cord is probably more intimate in the second stage than the first. The communication is with the lumbar region through the three most anterior lumbar sympathetic ganglia. Connection of the lumbar region of the cord with the brain is evidently not essential for the co-ordination of uterine reactions, and even the lumbar "centre" can be altogether dispensed with. More than one observer has, however, noted that section of the lower part of the cord, made late in pregnancy or during labour, arrests labour.

Eckhard⁵ found the secretion of milk from the udder of the goat un-influenced in quantity or quality by section of all the nerves of the organ. The influence of the spinal reactions on the mammary secretion remains unknown; but that the secretion can be influenced through the cord, is indicated by clinical observations which connect disturbance of the mammary secretion with strong emotions, perhaps mediately through vasomotor action. A prolonged contraction of the muscular and erectile tissue of the nipple and areola, elicitable by firm compression of the nipple and areola, has been described as "nipple reflex,"⁶ but it has yet to be shown that the mechanical stimulus does not act by direct excitation of the contractile tissues involved. In the rhesus monkey I have seen menstruation come on and recur regularly after spinal transection at the twelfth thoracic level.

Erection and seminal ejaculation.—Among the very few reflexes which, after total transverse lesion of the cord, are in man preserved even from immediately after incidence of the injury onward, are the sexual reflexes of erection and seminal ejaculation. They occur especially in young adults. Erection is evoked, not only by touching the genital surfaces, but also by pressure on the bladder, or scrotum, or the perineal and anal skin, and from the front of the thigh.⁷ Ejaculation is much less usual than erection. Priapism is of usual occurrence, and probably explicable simply by the vasomotor paralysis.

In the spinal mammal erection can be reflexly elicited. In the dog, after spinal transection above the lumbar region, movements due to the skeletal musculature are easily excited from certain genital regions. Touching the preputial skin evokes bilateral extension at the knees and ankles, and to a less extent at the hip-joints; accompanying this there is depression of the tail.

If through the skin more posteriorly the glans penis be pressed, the posterior end of the body is curved downwards, pushing the penal bone forward. These reflex movements suggest themselves as belonging to the act of copulation, and this suggestion is strengthened by failure to obtain similar movement on touching the analogous parts of the spinal bitch.

At breeding-time the male frog covering the female clasps her with his fore-limbs during four to ten days so vigorously, that much force is required to separate him from her. Decapitation of the male does not, as a rule, suffice to do so. The sexual posture is maintained as a spinal reflex.¹ The cord may be divided both in front and behind the brachial region without interrupting the reflex. Experiment shows that from the spinal male frog at the breeding-season, and also at other times, the reflex is elicited by any object that stimulates the skin of the sternal and adjacent region. In the intact animal, on the contrary, other objects than the female are, when applied to that region, at once rejected,² even although they be wrapped in the fresh skin of the female frog, and in other ways made to resemble the female. The development of the reflex is not prevented by removal of the testes, but removal of the seminal reservoirs is said to depress it, and their distension, even by indifferent fluids, to exalt it. If the skin of the sternal region and arms is removed, the reflex does not occur. Severe mutilations of the limbs and internal organs does not inhibit the reflex, neither does stimulation of the sciatic nerve central to its section. The reflex is, however, depressed or extinguished by strong chemical and pathic stimuli to the sternal skin, at least in many cases. The tortoise exhibits a similar sexual reflex of great spinal potency, and Tarchanoff³ and Albertoni⁴ discovered simultaneously that even weak excitation of the optic lobes (mesencephalon) immediately inhibits the reflex in both frog and tortoise; without exciting contraction in other muscles, those exciting the sexual clasp are at once relaxed, and the male drops from the female. Stimuli applied to the optic thalami occasionally produce the same effect, but other parts of the brain and cord fail to give the reaction.

Other visceral reflexes. — As regards other viscera than the above, little concerning their relations with the spinal cord remains to be said, further than that already stated actually or by implication in the chapters on digestion, renal action, vasomotor distribution, and on the sympathetic nervous system. A frequent and troublesome sequel to high spinal transection, *e.g.* in the brachial region, in the dog, is an alteration in the character of the fæces, these becoming fluid, frequent, copious, and laden with mucus. The explanation lies, perhaps, in vasomotor disturbance having caused congestion of the intestines. The same result follows exsection of pieces of the thoracic region of the cord. Brachial transection (*i.e.* above brachial roots and below phrenic) in the rabbit immediately gives rise to obvious increase of peristaltic activity in the intestines.⁵ This does not follow a bulbar transection in front of the vagus root. Whether the cord gives secretory nerves to the intestines, has been discussed in another part of this work.⁶ In frogs the secretion of urine is said to continue normally after the whole spinal cord has been destroyed.⁷ In the dog, inasmuch as the flow of urine is abolished when the aortic pressure falls to 40 mm. Hg, and as it has been frequently noted to fall

to below that after cervical transection, it might have been supposed that suppression of urine would, for some hours at least, succeed the transection. This, however, does not, in my experience, happen; the secretion of urine, if ever stopped, soon recommences, and the regular emptying of the bladder is one of the earliest and constantly recurring cares required from the attendant.

The vagus appears to be the afferent and efferent nerve to the pancreas, but the common bile duct, though opening together with the pancreatic, possesses afferent fibres from the spinal ganglia. If a small quantity of saline be injected into the common bile duct so as to distend the duct, a reflex alteration of arterial pressure results, of very marked and regular character; the afferent channels for this reflex pass through a large number of the thoracic spinal roots, especially perhaps those from the sixth to the twelfth, and I find the reflex not obviously lessened by section of both vagi. The liver and bile ducts have frequently, from Haller's experiments onwards, been found insensitive to artificial stimuli; this and the insensitivity of the liver under incision or puncture by the surgeon, both stand in contradiction to the pains caused by biliary calculi. The ease and certainty with which mechanical stimulation of the duct by a little fluid excites a strong vascular reflex, is of interest in this connection. The reflex still ensues when the fluid is prevented from entering the gall bladder. In the tench the musculature of the intestine is of the striped variety, but no spinal reflexes involving it can be found.¹

Spinal reflexes affecting the musculature of the blood vessels.
—On severance of cord from bulb, arterial pressure falls, owing to damage done not to the innervation of the heart,² but to that of the blood vessels,³ especially of the smaller arteries. Goltz earliest drew attention to the partial character of the atonia of the blood vessels of the spinal frog, and its conversion into completeness by destruction of the spinal cord. In the dog he transected the spinal cord at the hind-end of the thoracic region, and waited until vascular tonus of the hind-limbs was restored; destruction of the lumbo-sacral region of the cord he found then renew the vascular dilatation in the hind-limb regions. Schlesinger⁴ obtained in the spinal rabbit, after doses of strychnin, slight reflex alterations in general arterial pressure; and similar have been sometimes obtained without the use of strychnin. In the rabbit the reflex has given heightening of pressure, in the dog depression. Nussbaum⁵ obtained in the curarised spinal frog reflex contraction of the blood vessels of the plantar web; Vulpian⁶ obtained a similar result in the crossed hind-limb, after transection of the spinal cord of the dog in the mid-thoracic region, on stimulating the sciatic nerve central to section of it; fall of temperature, as evidenced by a thermopile and galvanometer, was taken as index of the vaso-constriction. The same result has been noted in the rabbit. In order to obtain these reflexes, the lower part of the thoracic region of the cord must lie below the transection; the lumbo-sacral region of the cord does not of itself suffice. After spinal transection at the hindmost thoracic segment, Goltz⁷ found mechanical stimulation of the glans penis cause erection; this result was not obtained after subsequent destruction of the lumbo-sacral region of the cord. Similarly, excitation of the sciatic nerve, proximal to its section, causes flushing of the skin of the contralateral hind-foot. After spinal transection at the third cervical level, excitation of the brachial plexus cords, proximal to their

section, produces a fall of general arterial pressure. This depressor action is probably a reaction upon the abdominal viscera.

The fact that no obvious difference to the degree of fall of blood pressure is made by varying the position of a transection in the cervical region, led Stricker¹ to exclude that region from the distribution of his spinal vaso-constrictor centres. The further fall of arterial pressure, caused by cutting the splanchnics after cervical transection, indicates that the upper thoracic region also contains vaso-constrictor centres. Bradford and Dean² demonstrated outflow of vaso-constrictor nerves to the lungs in the upper thoracic roots, and Bayliss and Bradford³ demonstrated vaso-constrictor fibres to the brachial limb, leaving by the fourth to the ninth thoracic roots. This, together with the well-known upper thoracic origin of the cervical sympathetic,⁴ proves, in conjunction with the fact that the spinal cells of the sympathetic lie at the same segmental level as the exit of their fibres from the cord,⁵ the existence of various spinal vasomotor mechanisms throughout the upper thoracic region of the cord. Vulpien's and Kabierski's⁶ above-mentioned results placed similar centres in the lower thoracic region, a location confirmed by Bradford's identification of the roots containing vaso-constrictors to the kidney, and Bayliss and Bradford's determination of those supplying the vessels of the hind-limb. The outflow of vaso-constrictors agrees, as pointed out by Gaskell,⁷ with the region of white rami communicantes and of preponderance of small myelinate fibres in the ventral root cells. The details concerning this vascular nerve supply do not belong to this portion of the book; excerpts are given here only as indicating the location of spinal centres that control the calibre of blood vessels and are capable of being influenced reflexly. The spinal vasomotor centres not only control smaller areas than does the bulbar centre, but are probably less accessible or excitable than it. The rise in arterial pressure which accompanies asphyxia fails altogether or occurs later after cervical transection than when the bulbar centre remains in connection with the cord.⁸ In the latter case the rise begins in 5 to 20 seconds, and reaches its maximum 15 to 40 seconds later. After spinal transection, the rise does not set in until 80 to 130 seconds after respiratory movement has ceased, and does not reach its full height until 100 to 120 seconds later. The reaction of the isolated spinal centres seems therefore an altogether slower process than the bulbar. Probably the ordinary reflex reactions, in response to excitations of different nerves, etc., play chiefly through the bulbar centre. The most remarkable afferent nerve, in regard to effect on arterial pressure, is the depressor, and this, a branch of the vagus, passes probably direct to the bulbar centre. The afferent path for spinal nerves must suffer interruption in the shape of synapses somewhere in the cord *en route* to the bulbar centre, for certainly the long dorsal-column direct path does not subserve vasomotor reflex action. Excitation of the whole sciatic trunk central to its section does not, with the dorsal columns of the cord alone intact, evoke any change in blood pressure. The path seems to ascend in the lateral part of the ventro-lateral column.⁹ The path descending from the bulbar centre to

subsidiary spinal lies also in that region of the transverse area of the cord, and, though mainly uncrossed, is partly crossed. Lateral semisection of the cord in the cervical region has been found to depress the arterial pressure very little; the temperature of the skin of the head, forearm, hand, leg, and foot becomes for the time higher on the side of the semisection¹ than on the opposite; contrarily, that of the trunk, shoulder, upper arm, and thigh is lower on the side of the lesion; this latter is probably due to the depression of tonus in the skeletal musculature. But the subject is still not clear. A wound of the dorsal column, for instance, produces a rise of temperature in the foot of the homonymous side, although there then can be no question of breaking of vaso-constrictor paths. After transverse lesions of the human spinal cord, the surface veins of the lower limbs are swollen, and the temperature of the feet is often higher than that of the hands.² Priapism is also a common symptom, and probably indicates vasomotor paralysis rather than heightened reflex excitability.

The heart and blood vessels can be regarded not only in virtue of their musculature as organs of expression for reflexes, but also to some extent as constituting a region whence reflexes can be initiated. Heger³ injected into the crural artery, the crural vein being tied, a minute quantity of nitrate of silver solution, a salt to which it is believed the capillary wall is impermeable. The quantity injected was believed sufficient to extend into the capillaries. The injection caused an immediate alteration of the general blood pressure, even when the sciatic nerve was the only structure undivided at the root of the limb. The heart itself is a reflexigenous region of potency. Harvey's observations on Viscount Montgomery showed, as have all similar opportunities, that mechanical contact, even with some pressure applied from without, is an inadequate stimulus to the sense organs of the normal heart as regards the production of sensation. The afferent channels of the heart, however, are not, so far as yet known, any of them spinal; all, as far as investigated, run in the vagus nerve. From the endocardium and the pericardium, both visceral and parietal, under mechanical and chemical excitation, muscular, respiratory, and vascular reflexes have been provoked.⁴ From the cardiac branches of the vagus have been excited, under certain circumstances, not only their well-known effects on blood pressure (through bulbar vasomotor centre) and on rhythm of cardiac beat, but general reflexes affecting the skeletal musculature.⁵ The efferent channels connected with the cardiac afferent are therefore far from confined to vascular nerves. But further statement of vascular and heart reflexes belongs to the chapters on the circulation.⁶ Increased frequency of heart beat can, it seems, be evoked as a spinal reflex.

Significance of spinal reflexes.—The reactions of the skeletal musculature obtainable from the "spinal" animal in response to stimuli applied to its sense organs, exhibit often such obvious propriety as replies to those stimuli that they are termed "purposive." Some have regarded them as evidence of "conscious choice."⁷

⁶ The spinal "sweat" centres and their connections are also treated elsewhere in this work (see Waymouth Reid, vol. i. p. 676).

⁷ E. Pfüger, "Untersuch. ueber d. sensor. funct. d. Rückenm.," Berlin, 1854.

A drop of acidulated water applied to the skin over the inner femoral condyle of the frog, elicits the drawing up of the limb; at all joints except the digital, flexion occurs. The foot and digits thus sweep over the irritated point of skin as though to remove the source of irritation. The opposite leg is at the same time extended. If the foot of the irritated limb be amputated, the stimulus evokes a movement similar to the previous, but, on account of the absence of the foot, inefficient to remove the irritant. There then often ensues a drawing up of the opposite limb, extension of that limb being converted into flexion, and the foot of this second limb is swept over the irritated area of skin; to do this thoroughly requires some adduction. When the seat of irritation is on the skin of the back, a corresponding result is not infrequently obtained. The tail of a spinal animal is often abducted in response to "painful" stimuli applied to its lateral surface, but it is said the strychnin convulsion evoked by a similar stimulus always causes the tail to move toward the side stimulated; that is to say, if the stimulus be a painful one, it is in the former case taken out of harm's way; in the latter case plunged further into injury.

It is, of course, as impossible to disprove as to prove that psychical events accompany or that they do not accompany the nervous reactions of the spinal animal. To argue, as has been done, that conscious choice directs reactions solely spinal, is merely to raise a question perhaps interesting, but at present, and seemingly for ever, insoluble. The Darwinian theory of evolution and adaptation to the environment suggests how "purposive" neural mechanisms might arise.

A well-known controversy (Pflüger, Lotze) as to the psychical powers of the cord, occurred prior to the advent of the Darwinian theory. Long previously, Prochaska had written: "The general condition which dominates the reflexion from sensorial impressions (*i.e.* those affecting his *sensorium commune*) to motor nerves is the instinct of the preservation of the individual." For "the individual" Grainger substituted "the organ." Lotze's position may be illustrated by the following quotation:—"The using of the limbs, in so far as the local direction of them goes, is no independent and self-completed labour of the will, but only the employment of an already present mechanism, the action of which the mind merely wills to go or not to go, but by no manner of means can regulate in all its details. We find arranged and interconnected in groups combined movements serving to protect the organism from harm, and in these the tendency to action in response to stimuli is so strong, that in many cases the mind cannot suppress the tendency even by the willing of antagonistic movement, *e.g.* coughing, sneezing. In fact, how ill were it for our bodily welfare, in many circumstances, did its defence depend on intellectual decision instead of on a mere machine."

As to the interpretation of the "purpose" of spinal reflex movements, it is more difficult than with higher reflexes, because the movements are often of more limited extent. The wider the field of a combined movement—if not convulsive but co-ordinate—the less dubiously does it indicate its object. But there is at best much room for fancy, and great caution is required. The spinal reflex "drawing up" of the limb that forms the usual response to a moderate stimulus to the foot, is generally and can be with plausibility construed as an effort to lift the irritated foot out of the way of harm. The stimulus is indeed usually of an intensity sufficient, were the cerebro-spinal system intact, to cause sensation of unpleasant quality. But it is possible to interpret this reflex as the local part of a larger reflex of progression. That alternative obtains support from the usually concomitant reflex extension of the fellow-limb of the opposite side. Further, the drawing up and protraction of the stimulated leg is usually succeeded by its extension, namely, by the phase of movement that

would normally succeed flexion in the performance of progression. Again, in examining the instances adduced to illustrate the supposed purposive protective movement, resulting in removal of an irritant from the skin, it must be remembered that the flexion of hip, knee, and ankle in the frog is the regular primary response to stimulation almost anywhere in the skin of the limb or loin. And the same movement is seen when the spinal preparation is altogether deprived of skin; also when the afferent roots to the limb are severed, the stimulus being applied to the skin of the loin. The alternative movement (flexion of the contralateral leg) ensuing when the primary movement of reaction has been performed—that it has been performed uselessly may be only of influence in so far as it means prolongation of the stimulus—may be simply the second phase of the spinal reflex, which always tends to be of alternating character, especially when a stimulus is prolonged. Besides, it must be granted that the ablation of the foot, or the pressure necessary to restrain it if not ablated, is in itself an additional stimulus. A suggestive context to the experiments of so-called “spinal choice” is furnished by the revival to action of a phrenic nucleus, after being thrown out of action by severance from its own half of the bulbar centre. Severance of the contralateral phrenic nerve then brings it into action again.¹

Considered in the light of the Darwinian theory, the normal connections between any afferent path (*e.g.* from a piece of skin), and the motor apparatus conjoined with it, *can* only be such as to lead to a purposive movement. The whole ground of “purpose” is speculative. The physiologist can only state that the “spinal” animal exhibits visceral digestive reflexes, performs excretory and sexual functions, executes a number of movements preservative of the cutaneous sensorial surface, and in simpler animal types shows maintenance of habitual posture and movements preparatory for and partly executive of progression. The inclusion of the bulb with the spinal cord does not in this respect essentially alter the statement. More actions in which the skeletal musculature is co-ordinated immediately with and for the service of visceral organs are added, such as the taking of food, including oxygen, the out-putting of the pulmonary excretion, and the regulation of the activity of heart and blood vessels. But of any further reaction toward defence or self-preservation than is already included by implication in the above essentially visceral reactions, there is scanty evidence. Perhaps hunger and thirst, so far as certain subconscious nervous conditions pertain to them, may be present, but, as far as is observable, they initiate no movement; that is, in the spinal and in the bulbo-spinal animal the skeletal musculature as a motile mechanism lies still beyond their reach. Grainger’s conclusion² was that spinal cutaneous reflex movements “are either of a preservative character, or resembling the motions which the function of the organ requires.” From the skin of the spinal creature, reflex movements resembling those executed by the normal individual in “preening” or cleansing itself, are of widespread occurrence. Together with the “preening” actions of the “spinal” fly, grasshopper, astacus, etc., there fall into this category the movements by which the “spinal” frog wipes irritants from its back and face; the “nettoyage” by the tortoise, the posturing of the hind-limbs and tail of the “spinal” dog concurrently with reflex evacuation of the fæces, tending to keep the body from being soiled, and the “scratching” and “shaking” reflexes of the spinal dog. All these are

¹ W. T. Porter, *Journ. Physiol.*, Cambridge and London, 1895, vol. xvii. p. 455.

² “Functions of the Spinal Cord,” London, 1837.

preservative of the part whence they are initiated. The conjunctival reflex closing the palpebral fissure, essentially a cutaneous and from the broad point of view a spinal reflex, is similarly preservative of the organ whence initiated.

In some instances, however, preservation of the individual, rather than of the organ, seems the key to the reflex spinal reaction. In many cases, such an interpretation has been given to signs, that when examined without prejudice, are of themselves quite equivocal. But in reflex *autotomy*, where the organ is sacrificed and the individual is freed from capture, there seems no other valid meaning. The preservative reflex here seems to offer one of the strongest guarantees that there is some solidarity in the spinal reflex creature,—that it is still an individual, that it has still some personality.

The spinal reflexes significant of locomotion seem never to give indication of any other locomotion than that of the most usual kind. Thus they yield always a going forwards, not a going backwards. They share markedly that character of purely spinal reactions of the skeletal musculature, namely, feebleness as compared with the prototype. It suggests itself that they may contribute chiefly toward preparatory posture in readiness for onset of action executed by the musculature under the driving of the higher centres. Thus the well-known reflex spinal posture of the frog is flexion of the hind-limbs, with the extensors of the joints taut and ready for spring. Again with the primary reflexes from the pedal ends of the limbs of the mammal. These apparently relate to progression—walking. But they do not take the form of the propelling stroke, the extensor push, that thrusts the body forwards. On the contrary, they flex the limb and lift it from the ground. This is no doubt the phase of the limb's movement in progression which requires least of force; it resembles in so far the expiratory phase preceding the inspiratory of respiratory movement; it may almost be likened to the diastole of the heart; and like both these it is preparatory for a succeeding phase of greater muscular effort. That phase succeeds also in the spinal animal, but it is less easy to obtain, and recovers from shock less soon. The subject is speculative, but certainly in the assumption and maintenance of posture pure reflex spinal reaction upon the skeletal musculature plays an important part.

In opining whether spinal reactions are conscious or not, the following considerations arise. After total rupture across the spinal cord in man, the reactions of the isolated portion are never conscious. Where nervous reactions have to be studied entirely objectively, as in the lower animals and in young children, a criterion that may be well taken as test of their conscious character seems associative memory.¹ Associative memory would seem to be a postulate for the very existence of perception. Consciousness can be regarded as a sequence of processes, namely, of ideas, and of states of passage between such. Where even simplest ideas, *i.e.* raw perceptions are not, there cannot be consciousness. Animal movements that are appropriate not only for an immediate but also for a remote end indicate associative memory. The approach of a dog in answer to the calling of its name, the return of an animal when hungry to the place where it has been wont to receive food, such movements may be taken as indicative of consciousness, since they indicate the working of associative memory. Examined by

¹ Cf. J. Loeb, *Arch. f. d. ges. Physiol.*, Bonn, 1894, Bd. lvi.

this criterion, all purely spinal reactions fail to evince features of consciousness. If two frogs, the one spinal, the other intact, be placed together in water which is then gradually warmed, the intact animal, as the water approaches 35° C., exhibits movements significant of effort to escape. But the spinal frog will not move, though the temperature rise to even fatal height, so long as the ascent be gradual. A spinal frog placed direct from cold water into water at 35° C. exhibits at once lively movements, but these, in view of their above-mentioned absence under the other condition, are no sign of associative memory. They may therefore be unconsciously reflex. Not so the reactions of the intact frog.¹

Such a view of the relation of spinal reflexes to consciousness corrects a tendency to see in such reflexes the germs of volitional acts. The mainsprings in the evolution of volition are feeling and perception. From reactions unconscious, and therefore devoid both of feeling and of perception, volitions cannot have sprung. On the other hand, our individual experience shows how readily volitional acts by repetition and practice ultimately become actions involving neither attention nor even consciousness,—create, in fact, habitual reflexes. The spinal reflexes may be regarded as descended from volitional acts, inherited and therefore instinctive habits of simplest order, testifying to a so-to-say primitive process akin to memory in the spinal cord.² It might be thought that, arisen thus, they would be most in evidence in the spinal organ of the most elaborated nervous systems. As a fact, they are there less obtainable and seem there less active than in simpler systems. This may be due to the greater solidarity of the whole nervous system in its higher than in its lower forms. The greater solidarity renders the more severe the injury wrought by mere isolation of any part from the whole. And this the more so that in higher animals the great projecting senses of the cranial region dominate the spinal cord and actuate the motor organ, the skeletal musculature of the whole body, more than in lower forms.

SPINO-CEREBRAL AND CEREBRO-SPINAL REACTIONS.

The spinal cell systems are not concerned only with reactions confined in their extension to the cord. They also transmit, on the one hand, impulses to nerve cells in the brain, and, on the other, receive impulses from nerve cells in the brain. The cell systems in the brain seem able to discharge all efferent root cells, especially those of the skeletal musculature. This is implied in the old remark that "to move things is all mankind can do." On account of its connections with the brain, the spinal cord has therefore to be studied in respect of (1) the elaboration of cutaneous, muscular, and visceral sensations; and (2) contractions of the skeletal, vascular, and visceral musculature in response to stimulation of the cranial sense organs; and (3) as the instrument of emotional and intended movements. Many of the reflex arcs commencing in the spinal afferent root cells lead *via* encephalon back to the spinal cord again, involving cerebral links. These reflex arcs, in their course, react on and are reacted on by arcs based upon

¹ F. Goltz, "Beitr. z. Lehre v. d. Nerv. d. Frosches," Berlin, 1868.

² Hering, "Ueber d. Gedächtniss als allg. Funct. d. organisirt. Materie," *Sitzungsber. d. k. Akad. d. Wissensch.*, Wien, 1870.

cephalic sense organs. Cerebral confluence of long-conduction arcs seems of high importance in neural evolution. Complete transection of the cord ruptures, of course, all these long-conducting paths for all regions on the caudal side of the transection. After *partial* transections, the motor and sentient state of the distal region gives information as to the course that impulses must take.

Lateral semisection of the cord.—The results of semisection have been studied at various levels of the cord. As regards the paths interrupted, it is found that nerve fibres degenerate on the cephalic side of the lesion in both the dorsal and ventro-lateral columns. The degeneration in the former is completely homonymous, and extends up to the bulb, reaching the *dorsal column nuclei*,—Goll's only, if the semisection be not anterior to the thoracic levels; both Goll's and Burdach's, if the semisection be in the cervical region.¹ The number of degenerating fibres gradually diminishes with increase of distance from the level of transection, and as it is traced headwards concentrates toward the median line. In the ventro-lateral column the degeneration implicates fibres ascending to the superior vermis of the cerebellum by the restiform and retroflexed conjunctival cerebellar tracts, and to the mesencephalic roof and to the optic thalamus in lesser quantity.² The degeneration in the ventro-lateral column is heavier on the homonymous side, but is not confined to it. From lesions low in the thoracic region, ascending fibres degenerate in the ventral lip of the column, which seem to end in the cervical region of the cord and lower part of the bulb.³

Gotch and Horsley have examined the action currents⁴ arising on stimulation of the sciatic nerve, after semisection at the lower thoracic region, and these are found to agree fairly with the data ascertained by degeneration. Seventy-seven per cent. of the angular measure of the galvanometric deflection appeared to belong to the dorsal column. Of the remaining 23 per cent. rather less than four-fifths was referable to the rest of the homonymous half of the cord. A discrepancy between the observations by the galvanometric and by the Wallerian method lies in the existence of action currents in the contralateral dorsal column, to the extent of one-fourth of that observed in the uncrossed, whereas no Wallerian degeneration occurs in the contralateral dorsal column. The degeneration and the action current in the homonymous dorsal column both conform with the course of the ascending stems of the dorsal root fibres. After spinal semisection at the lower thoracic region, stimuli applied to the skin of the foot are more effective for producing movement of the fore-limb when applied to the foot homonymous with the lesion, than when contralateral. There is no crossed path in the dorsal column at the level of semisection to account for this, and it still occurs when much of the grey matter and ventro-lateral column have been excluded. In the action-current observations it was noticed that semisection at the bottom of the thoracic region reduced the galvanometric deflection obtained from the cord a few segments higher when the homonymous sciatic was faradised. Three observations were made; the reduction varied from 56 to 85 per cent. of the angular deflection. When the crossed sciatic was faradised, the deflection in one of the observations was somewhat greater than before the semisection, in the other two it fell to 63 and 90 per cent. of the previous angle. Most of this was probably referable

simply to the section of the roots in the dorsal column. After low thoracic semisection, the angle of galvanometric deflection obtained from the cord a few segments higher was, under sciatic faradisation, less when the nerve was homonymous than when contra-lateral. In the eight observations the defect of deflection on the uncrossed side varied between 26 and 78 per cent., and was presumably for the most part referable to the severance of the root-fibres in the dorsal column. A semisection some segments behind the faradised cut end of the cord in the thoracic region abolished the action current, however, in the homonymous sciatic nerve. What relation the degree of galvanometric deflection bears to the aggregate size or number of a spinal fibre system is not ascertained. One would think it more influenced by number of fibres than by size of fibres. For one and the same fibre system it presumably varies in a direct sense with the physiological intensity of the reaction, but in what ratio is difficult to estimate. One difficulty in interpreting in terms of normal spinal conduction the spread of action-current, is the fact of double conduction. Thus, when the cord is excited in the lower thoracic region, the chief channel of spread of action currents both up and down seems to be the dorsal column.

Observations, taking note of not only the relative amount but also the physiological quality of the reactions for which the cord is blocked or still patent after semisection, find special difficulty in regard to the quality of the long dorsal column path. Its severance has in various hands,¹ and practised at various levels, made no striking alteration at all either in movement or in signs interpretable of sensation. There is clear evidence that the path belongs to an afferent chain of which the next neural link begins in the dorsal column nuclei of the bulb, and leads in the main by the crossed mesial fillet to the thalamus and, less directly, to cerebral cortex (especially its post-central and fornicate gyri). The clinical evidence collected about the physiological quality of the dorsal column is of negative character. Lesions in it, either unilateral or bilateral, have occurred without any obvious disturbance of sensation; at utmost a slight clumsiness in the movements of hand or foot. After arrest of the circulation in the lower region of the spinal cord, Münzer and Wiener² found that "pathic" stimuli applied to the skin of the hind-limbs were not effective to provoke signs of sensation, and Langendorff³ that excitation of the afferent roots as well as light tactile stimuli to the skin, even under slight strychnisation, remained ineffective. The argument from these stasis experiments rests on the supposed earlier paralysis of grey than of white matter by the stasis, and infers that, therefore, tactual and painful sensorial impulses must embouch into grey matter near the entrance of the root conveying them into the cord; the further inference is that the long dorsal column path is not the path used in the reactions of touch and pain. But I have seen strong pathic stimuli evoke reactions when applied to the skin of the hind-limbs at a time when, by arrest of the circulation in the cord, those limbs themselves were flaccid and paralytic; here the reaction probably occurred *via* the long dorsal-column path. After transection of all the columns, except the dorsal, signs of sensation can still be evoked from the parts innervated by segments posterior to the section, as also from the cerebral face of a

section of the column.¹ Schiff concluded that the stimuli, even when such as calculated to evoke painful sensations, no longer evoke signs indicative that any painful quality attaches to the reactions manifested. Herzen² and others confirm this. Chiefly for this reason the long dorsal-column path is often considered "tactual." Anatomists³ have written of it as "reserved for conscious sensation." Some authorities treat it as acknowledgedly connected with muscular sense. Its nerve fibres seem in the monkey to give reflex collaterals to the motor root cells of the hand and foot muscles especially, for electrical excitation of the path at the top of the cord excites those movements. The function of the long path must be considered still unproven; my own opinion inclines to relate it to muscular rather than to tactual sense. There is much in favour of H. E. Hering's view that it serves to conduct centripetal impulses which, arising in the apparatus of movement, regulate by unconscious reactions the movements of the skeletal musculature.⁴

Concerning the ventro-lateral columns, there is good evidence that in their lateral portion runs down the path concerned with the direct regulation of muscular contraction, while in the same region headward, runs the path from all sensory apparatus in its first relay after the first synapse. Woroschiloff's experiments⁵ showed that, at the level of the last thoracic vertebra, this lateral region is patent to downward impulses that move the hind-limb for progression, and upward that connect its skin with encephalic nervous centres, so as to allow reactions indicative of unimpaired sensitivity of the limb's surface. When at the lowest thoracic level the only part of the cord remaining unsevered is the lateral region of each ventro-lateral column, the rabbit, as judged by its movements and its reactions to sensible stimuli, is to all appearance still in a normal state. In the lateral region also, and apparently exclusively in it, ascend paths for vasomotor reflexes from the sciatic nerve. Direct faradisation of the ventro-lateral column⁶ in areas as circumscribed as practicable produces, according to the locality of application to the face of the section, movement of the wrist, fingers, trunk, hip, knee, and digits, all on the homonymous side. To evoke movements is far easier from certain spots of the cross-section than from others. The easiest foci lie in the ventral root-zone, and the next easiest in the dorsal half of the lateral column. The path descendent from each half of the bulbar respiratory centre lies in the homonymous lateral column,⁷ and in the phrenic region either descendent path gives branch paths across to the contralateral motor cells.⁸ The descending path connecting the brain with the lumbo-sacral "centre" for the motor nerves of the urinary bladder lies similarly in the dorsal part of the

lateral column,¹ and on arriving at the spinal vesical centre gives branch paths across the median sagittal plane of the cord, forming therefore bilateral connection with the local centre, which is itself bilateral. The ascending path linking the sense organs of the hind-limbs with the bulbar vasomotor centre and the descending path from the latter to the thoracic efferent root cells of the vascular musculature, lie both of them in the lateral column,² the descending in that of the side homonymous with their main ending, the ascending perhaps mainly in the side crossed from the peripheral sense organs possessing access to them (see below, p. 867).

Observations with the method of Wallerian degeneration yield clearly one negative point in regard to the ventro-lateral column, namely, that none of its fibres are afferent root cell fibres. They furnish also positive evidence that of its fibres many of the ascending pass to the cerebellum, entering it on the same side as the column in which they lie; and that probably a certain smaller number pass to the mesencephalon and diencephalon, as also to the upper part of the spinal cord itself. Of the ventral portion of the ventro-lateral column, especially its part between the ventral fissure and the exit of the ventral root bundles, little is known relative to function. Bilateral section of this region produces, so far as observed, no detectable impairment in the animals examined.³ Kürschner,⁴ Longet,⁵ Volkmann⁶ found mechanical and weak faradic excitation of this region, or above it, when it alone of the whole thickness of the cord remained, produce movements of the muscles far behind the level of section. Brown-Séguard concluded, after a similar transection, that some signs of sensation were still elicitable from regions behind the lesion. In agreement with these observations, the Wallerian degeneration method demonstrates fibres descending in this column from both roof and floor of mesencephalon,⁷ from metencephalon,⁸ and in mammals from the mantle of the hemisphere itself. The degeneration method also shows fibres ascending in this column in large numbers from spinal cells even many segments posterior;⁹ these fibres are for the most part small, the descending for the most part large.

It was long ago¹⁰ known that an effect of lateral semisection of the cord is to impair the motor and sentient functions of the parts of the body innervated by the spinal nerves behind and on the same side as the section. It was more recently¹¹ noted that the impaired motility becomes in course of time partly restored. Further study of the motor and sensory defects led to the belief that, while the path subserving intentional movement descends the same side of the cord as the muscles which contract, the sensitivity of each half the body involves a double

path employing the two halves of the cord,¹ though the major division descends on the side homonymous with the peripheral sense organs.² Bilaterality of the path was next accredited³ as well to the descending spinal conduction for intentional movement of the skeletal musculature of each side-half of the body; the homonymous path was stated as in sensation to be the chief one, that is, the side homonymous with the musculature innervated. It was noted,⁴ especially in the frog, that the impairment of the volitional motility and of the sentient function of the limb is, when the semisection lies though headward yet near to the nerves to the limb, greater than when placed further forward. After semisection in the cervical region, a certain power of volitional movement is retained for the hind-limb homonymous with the semisection. Attention was drawn, especially by the long series of experiments by Chauveau,⁵ to a great contrast existing in the homonymous side, between heightened reflex activity and defect in true sensifacient power. This increase of reflex excitability was noted to gradually increase rather than to subside with time. It was also observed that the temperature of the homonymous hand and foot (skin) rises after cervical semisection, but that the temperature of the axilla and groin falls (muscle).⁶

In a series of experiments by Weiss⁷ the difference between early and late symptoms was carefully recorded, the semisection lying at the hindmost thoracic segment in the dog. The exact extent of the lesions was verified by subsequent microscopical examination. (1) On the homonymous side the condition for the first day or so was: *Motor power*; "volitional" gone, reflex greatly impaired; the hind-limb hangs extended at knee and ankle, adducted at hip: *Sentient power*; very defective. Later, in the course of some weeks, there ensued restoration of function: *motor power*, for standing, walking, running, became almost perfect, and the movements of the affected limb were well associated with the movements of the other limbs. As regards the *sentient functions*, mechanical and electric stimulation of the skin and of the nerve trunks of the limb showed deficiency; movements evoked reflexly in the limb by skin stimuli, though often vigorous, were never accompanied by whining. (2) In the contralateral limb the motility was at first somewhat impaired, but was soon restored to normal. The sentient functions, at first markedly depressed, as compared with the fore-limb, in course of time returned in part, though permanently subnormal. The sensory defect exists, according to Weiss⁸ and Botazzi,⁹ for all kinds of cutaneous sensation and for "muscular." A second semisection practised after recovery from the first, and on the opposite side one spinal segment further headward, abolished permanently motility under "volition" and all sentient power in both hind-limbs, and in as

⁷ *Sitzungsb. d. k. Akad. d. Wissensch.*, Wien, 1879, Bd. lxxx. Abth. 3. Homén's experiments (Helsingfors, 1885) yielded results on the dog identical with those of Weiss. The secondary degenerations were carefully studied as well as the functional condition.

⁸ *Loc. cit.*

⁹ *Centralbl. f. Physiol.*, Leipzig u. Wien, 1894, S. 530.

far as could be judged all parts postjacent to the section. Further experiments of this kind¹ on the dog show that when in the hindmost thoracic region an interval of some six or seven spinal segments is allowed between the semisections, recovery of motility of the hind-limbs in walking and progression may ultimately, although long delayed, be almost as complete as after single semisection. Restoration of sensitivity is longer delayed and less perfect. The incipient effect of the second semisection is to destroy locomotor and volitional motility and sentient power altogether in *both* hind-limbs. In one experiment three semisections were successfully accomplished,—the foremost at the highest lumbar segment; the second, three spinal segments lower and on the opposite side; the third, the final, on the same side as the first and six spinal segments behind it. The power to stand was in time recovered. The strongest stimuli to the hind-limbs failed to evoke any sign of pain, as also did faradisation of the sciatic nerve. Faradisation of the spinal cord in the cervical region excited no movement in the hind-limbs. On more than one occasion irritation of the skin of the neck evoked scratching movements of the hind-paw. But I have myself seen this remarkable phenomenon after *total* transection at the eighth cervical level; the movement in front of the spinal severance is clearly mechanically conveyed to parts behind the lesion, and there in turn excites the spinal "scratch" reflex.

The conditions produced by spinal semisection have been studied recently in the ape (Mott,² W. A. Turner,³ Schäfer⁴). The seat of the lesion has been cervical, thoracic, or lumbar. Mott found impairment of "volitional" movement in the homonymous limb or limbs, but with time some restoration, just as noted in the dog,⁵ especially of associated movements. The defect of sentient power appeared at first considerable when tested by the application of a spring clip to the homonymous side; but there was much less impairment for tactual, pricking, and thermal stimuli. With the recovery of movement there gradually ensued considerable recovery of response to the pressure of a clip.⁶ Muscular sense was *thought* to be impaired on the homonymous side. Mott also noted *allochiria*;⁷ a spring clip applied on the homonymous side occasionally directed attention not to the place stimulated, but to one symmetrically situated on the opposite side of the body. As to the effects of semisection, there obtained, for some years after publication of observations by Brown-Séguard,⁸ a view fraught with practical importance from the support it seemed to obtain from clinical observations. It was held by Brown-Séguard that the path subserving cutaneous sensation ascends the spinal cord entirely contralateral to the initiating sense organs, the decussation of the afferent channels occurring soon after their entrance in the cord. Paralysis of intended movement without cutaneous anæsthesia on the one side, and on the opposite cutaneous anæsthesia without volitional paralysis, is

a clinical condition of acknowledged occurrence ensuing upon spinal injuries. That in man such symptoms have been satisfactorily demonstrated to be associated with uncomplicated and accurately limited local destruction of one lateral half of the cord, cannot, however, be affirmed. Experiments on animals have led some observers¹ to uphold the view that Brown-Séquard first put forward and for some time held. The general consensus of opinion and the greater weight of evidence have been, however, both before and since Brown-Séquard's original report, against it. That important ascending paths do cross in the cord is beyond question. That they are ascending does not prove that they are "sensory;" the necessity of interpolating the remark emphasises the drawback attending the time-honoured misuse of the term "sensory"—as of "volitional"—in such connection. The increase of arterial pressure, caused by faradising the central end of one sciatic nerve, the cord having been at the hindmost thoracic level severed except for one lateral column, is greater² if the nerve be contralateral to the undivided column than if homonymous. This does not, I think, prove that the path, even for impulses ascending to the bulbar vasomotor centre, is *mainly* contralateral; it is as well explained by supposing lumbar relay centres below the semisection more irritable on the side of the semisection than on the comparatively normal side. Similarly, in experiments³ in which movements of the fore-limb were used as index of ascendent conduction, the results in this connection merely indicate that a spinal path up from the hind-limb has become contralateral at the level of the lower thoracic region; the experiments do not necessarily show that the crossed path is the main one. There is the Van Deen⁴ experiment in the frog: a lateral semisection of the cord close in front of the crural plexus (say right), then a semisection of the opposite side close behind the brachial plexus. On stimulating the skin of the left fore-limb, movement of each of all the limbs is evoked; on stimulating the skin of the right hind-limb, movement of each of all the limbs is also evoked. Vulpian⁵ affirmed that this is true even when only one column of white matter connects the front and posterior halves of the animal. He extended similar observations to the dog. A semisection on the right side in the lumbar region produced what he considered hyperæsthesia in the right hind-limb, and slight depression of sensory function in the left. A second semisection on the left side at the fourth cervical level, practised a few hours after the former semisection, caused the hyperæsthesia of the right hind-limb to disappear, but produced marked hyperæsthesia of the left fore-limb.

These results naturally lead to consideration of the well-known zonal hyperæsthesia occurring as the result of various kinds of spinal lesion. It was noted, originally by Fodéra,⁶ that after partial transection of the cord, stimuli applied to a zone of skin just posterior to the lesion evoked signs of sensations more readily than normally. Fodéra concluded also that the muscles behind the section are more excitable by local reflex channels than they normally are. The hyperæsthesia of Fodéra is now a phenomenon universally acknowledged. It includes hyperalgesia. It seems to ensue when the spinal lesion involves the extreme dorsal part of the lateral column.⁷

Türk first showed, in the frog, that it is demonstrable behind a total transection as well as after a partial lesion. I have seen it extremely marked in the dog after high spinal complete transection, *e.g.* in the brachial region. The lightest touch on the skin of the shoulders or arms appeared to cause acute sensation, though there was no redness or sign of vascular disturbance in the skin. It has been suggested that the hyperæsthesia is due to vasomotor disturbance; but Foster¹ points out that irritation or paralysis of the cervical sympathetic is not shown to cause any disturbance of sensation in the skin of the ear, and a one-sided hyperæmia of the cord itself is difficult to postulate. It has been noted immediately after the establishment of the lesion, which is against its being of inflammatory origin; it does certainly usually become more marked a few days after the establishment of the lesion. Its persistence for many weeks excludes its explanation by "injury currents" set up in the spinal nerve fibres. Woroschiloff's seems the best explanation, namely, the removal of tonic inhibitory influences; although to state this is, in our present knowledge, to say little definite. In the cat, immediately after high spinal transection, *e.g.* from the first cervical level as far back as the sixth, a peculiar condition is often observable in front of the section, *e.g.* in the sensorial field of the trigeminus. A single touch on the snout elicits vigorous licking of the spot touched; the mere approach of the warm can used to protect the animal from cold evokes screwing-up of the eyes and mouth; salivation is often profuse; a touch on the vibrissæ produces exaggerated facial movement; there often seems to be some photophobia. But in the dog and monkey, although there are indications of a somewhat similar condition, they are but slight. Perhaps related to the Fodéra hyperæsthesia is that heightened sensitivity, which a field of skin, supplied by a portion of an afferent spinal root, exhibits after severance of the rest of the root and of adjoining roots in front of and behind it. Similarly the knee-jerk (cat) is extremely brisk when the two segments to which its reflex arc belongs are isolated from all the rest of the cord, by spinal transections just in front and behind. This reaction recalls the observation by Brown-Séquard, that after section of the dorsal columns it is the posterior face of the section that is the more sensitive, and that of the two next adjacent dorsal spinal roots it is the one on the posterior side of the lesion that is the more excitable. Here injury currents were perhaps playing a part, for the observations were all made soon after the establishment of the lesion. But it has been shown that a semisection carried out on the same side a few segments further back reduces the hyperæsthetic symptoms, Vulpian² says actually to inexcitability, excito-motility as well as sentience suffering extinction.

TONIC FUNCTIONS OF THE CORD.

Among the reflex functions of the spinal cord are some that, on account of the comparatively prolonged and steady character of their centrifugal effect upon the extrinsic tissues, are described under the term "neural tonus." It is in certain parts of the musculature that this tonus lies best open to examination. The sphincters of the anus, urinary bladder, and larynx, by a continued degree of steady unwilld contraction, guard their respective orifices. Destruction of the spinal cord abolishes their action for a time, but in the instances of the anal and vesical sphincters an efficient amount of tonic contraction is eventually regained. The sphincter muscles can, like other muscles, be excited reflexly through the cord to that *status* of decreased extension and increased tension which constitutes tetanic or voluntary contraction. But in addition to these intercurrent relatively brief contractions, they exhibit under

¹ "Text-Book of Physiology," 1891, pt. 3.

² *Compt. rend. Soc. de biol.*, Paris, 1855.

the so to say resting condition of their spinal centres a certain tension and contraction sufficient to offer resistance to the opening of the orifices they surround. Depression of function of the spinal cord, e.g. in spinal shock, diminishes greatly, at least for a time, the tonic contraction of the sphincter muscles. Destruction of the cord renders the orifices for a time patulous.¹ Similarly, the tonic contraction of the vascular musculature is for a time² decreased by section of spinal nerves or destruction of the spinal cord; lateral semisection of the cord in the neck is followed by more or less permanent narrowing of the homonymous pupil. Section of the vagus produces in the dog an increased frequency of heart-beat. These phenomena, like the rhythmic discharges of the respiratory centre, point to a continued activity of the bulbo-spinal centres, probably in result of some extrinsic, constant, or frequently repeated stimulus. The tonic action of some of the spinal efferent root cells that embouch into the sympathetic, although marked, is not apparently so dependent on the afferent root cells of their own locality as is that of the motor root cells innervating skeletal musculature. I have repeatedly found no perceptible difference in size between the pupils, after complete section of all the afferent roots of one side in the cilio-spinal region; nor when the cervical sympathetic has been cut weeks subsequent to complete spinal transection at the seventh cervical level. I have seen careful section of all the afferent roots of both sides, from the second thoracic to the thirteenth inclusive (cat), leave the arterial pressure practically unaltered. In accord with such observations is the greater difficulty of obtaining, from the second and third thoracic afferent roots in the spinal mammal, a pupillar dilatation than a contraction of the skeletal musculature.

As with other centrifugal nerve discharges, especially with rhythmically recurrent, there arises the question here whether the initiation is peripheral and reflex, or whether autocthonous and outcome of the independent individual metabolism of the nerve cells that themselves discharge. The rhythmic explosion in the muscle cells of the heart and their tonicity, expression of a more continuous discharge, seems shown autocthonous in origin. So also, among nerve cells, the explosive discharges of the bulbar respiratory seem to offer counterpart to that of cardiac cells among the muscular. In some instances the tonus of spinal nerve cells may be autocthonous in origin, evolved by "inner stimulation" of the "centre" itself. In other instances, spinal neural tonus is distinctly of peripheral initiation and demonstrably reflex.

The resting length of an innervated muscle varies.³ The bladder accommodates itself to various volumes of contents.⁴ If urination be deferred, when need is felt, the feeling of need will pass by, and Mosso found the intravesical tension then fall to that which previously obtained under a much smaller content of urine. The need for micturition felt at waking is perhaps chiefly due to increase of tension resulting from increase of neural tonus, as the activities of the cord return with the general awakening of the nervous system.

The lengthening which some muscles have been proved to exhibit after separation from the motor root cells, may be taken as evidence that, in the state which is called "rest," their fibres are not perfectly at rest in the sense of devoid of contraction. Their state is then, moreover, due to indirect excitation through the nervous system. The sensible changes in the environment are so numerous and frequent, that an unceasing reflex activity of the nervous system is not surprising. It is, however, surprising, on the view generally taken, to find that in regard to the skeletal musculature the reflex effect takes the form of an equable, minute, continuous contraction. The fundamental observation on this subject is Brondgeest's¹ experiment.

In addition to its *neural* tonus, the muscle has of course, in common with all living cell tissue, its *vegetative* tonus, on which Virchow has laid stress. The doctrine of a spinal tonus expressed by muscles is older than Brondgeest's experiment. J. Müller wrote in his text-book (1837), "The muscles, even in the condition of rest, are continually being acted on by their nerves." Marshall Hall, two years later, pointed to the difference between the tension of muscles, in the decapitated rabbit when the cord is destroyed, and when undestroyed. In the "spinal" animal the tonus of the muscles, especially of some muscles, is less than in the normal condition; but tonus does still exist. As a rule, it may be said that the "spinal" tonus of the flexors is greater than those of the extensors; in other words, a spinal transection depresses the tonus of the extensors more than that of the flexors, at least at first. This is seen not only in the spinal mammal, but in the crustacean and the insect.² It is typically illustrated by Brondgeest's fundamental experiment.

Chloroform and ether abolish this neural influence; so also does severance of the afferent roots. The neural influence is exerted chiefly on the muscles from which reflex contraction can in the spinal animal be evoked first and with most facility. Great depression of the tonus of the flexors is produced by section of afferent spinal roots alone, as well as by section of the efferent.³ When the afferent spinal roots of a limb have been severed, the muscles of the limb feel flaccid, more flaccid than the muscles of the spinal animal. Some influence acts on the cord through the afferent roots causing portions of the limb musculature to be to a certain degree steadily braced and more tightly strung than when completely denervated. The influence does not, however, originate in the cutaneous sense organs,⁴ or at least there only in minor degree. Its maintenance appears to be one of the functions—a subconscious function—of the organs of "muscular sense." The severance of the afferent roots of a limb, besides causing ataxy of its "intended movements," renders certain of them impossible;⁵ besides these obviously sensual impairments of the local skeletal musculature, are others bearing more on subconscious reflex influence on the muscles. The section of the afferent roots delays the onset of rigor mortis⁶ much as does section of their motor nerves. It also acts upon the extensor muscles of the limbs, for, after transection in front of the mesencephalon, decerebrate rigidity⁷ does not occur in the limb the afferent roots of which have been divided.

The knee-jerk and allied phenomena.—The reflex neural tonus of the skeletal musculature influences not only the resting length and tension of the muscles, but also their direct excitability to a particular form of mechanical stimulation. When the leg is held supported in a

posture of slight flexion at hip and knee, and all its muscles lie at rest, a tap on the patellar ligament evokes a short contraction of the quadriceps cruris,¹ so that extension at the knee ensues. This is the phenomenon known as the "knee-jerk." Others similar exist in other pieces of musculature, e.g. at the tendo Achillis for the triceps suræ, and at the extensor tendons of the wrist, and the masseter. The knee-jerk may serve as their type. Muskens² finds deficiency of jerk a usual, though not invariable, accompaniment of subnormal tension of the Achilles tendon; conversely he finds hypertonus of the *triceps suræ* to co-exist with exaggerated jerk. He estimates degree of tonus by measurement of the pressure required for displacement of the tendon, the ankle resting in semi-flexion. The study of the time-phases of the muscular contraction has shown it to have all the characters of a simple twitch (Brissaud,³ Eulenberg,⁴ MacWilliam⁵). The interval elapsing between the application of the tap and the appearance of the contraction is too short to permit of the reaction being considered a reflex⁶ *via* the afferent root, the cord, and the motor root cells. The time is about the same as that of the contraction response on direct electrical excitation of the muscle, *i.e.* less than a quarter of that of the briefest reflex time. In accord with Sternberg's supposition that the mechanical excitability of the muscle varies directly as the jerk, Muskens⁷ observes the tap elicit in the hypotonic calf muscle a slow and merely local contraction instead of the normal quick response of the whole muscle.

A sine quâ non for the elicitation of the "jerk" is slight tension of the muscle which is to respond; and the stimulus to the reaction is a sudden slight passive increase of the tension. Gowers has suggested,⁸ therefore, that the "jerks" be termed "myotatic" contractions (*ράττικός*, extended). They are sometimes termed "tendon-phenomena," but tendons are not essential. The terms "tendon reflexes" and "deep reflexes" have obvious objections as applied to the "jerk phenomena," for they are not proved to be reflex, although there do exist, in addition, undoubted reflexes from tendons and other deep structures.

On analysing⁹ the spatial distribution of the phenomenon in the muscles of the thigh, it is found to involve chiefly the *vastus medialis* and adjacent *crureus*, and when not strong to be entirely limited to them. When isolated in those muscles, it is at once abolished by severance of the afferent nerve fibres belonging to those particular muscles, whereas combined severance of all the other afferent nerve paths of the limb does not abolish it. The phenomenon, though not a reflex act, is therefore dependent on a reflex spinal arc,¹⁰ the afferent part of which is based on sense organs in the muscle itself and its appurtenances.

A great interest attaches to the knee-jerk and similar reactions as indices of the condition of the nervous system. Extinguished when the neural tonus of the muscle is extinguished (e.g. by complete rupture of the reflex arc) or is replaced by the active innervation of intentional movement, these "jerk" phenomena are indicators delicate enough to show many shades of spinal state.

Under apparently like circumstances, there are, in any large collection of

FIG. 359.—Scheme of the arrangement of the nerves and muscles of chief importance in the knee-jerk, as determined in the Macaque monkey. The numbers 4L-8L indicate the post-thoracic spinal roots of *Macacus*, and the numbers in brackets the corresponding lumbar and sacral roots of man. The arrows pointing to the right indicate efferent paths, those pointing to the left afferent paths.

healthy individuals, not inconsiderable differences of knee-jerk. In a very few persons, apparently healthy, the knee-jerk is at times inelicitable¹ even under most favourable conditions. Of alterations in the jerk, some are referable to conditions directly affecting the local reflex arc itself. Thus, a second tap given soon after a first will generally evoke a more ample jerk.² A series of taps too feeble to singly evoke the jerk, will, when repeated at intervals from a fifth to a tenth of a second, become efficient. Conversely, after the jerk has been elicited for a number of times, it tends to fail for a short period, despite the taps being continued as before. Local fatigue of the extensor muscles diminishes the jerk;³ general fatigue of the nervous system⁴ at first increases, but if severe, later diminishes the jerk. The rendering of the limb bloodless by the Esmarch bandage causes the knee-jerk in about fifteen minutes to disappear.⁵ "Pathic" stimuli⁶ applied to the skin increase the jerk, and friction of the skin of the leg,⁷ and the cold bath⁸, are means of increasing the jerk in patients in whom it is defective.

Westphal¹ noted that in patients in whom, after epileptic seizure, the knee-jerk was inelicitable, it became elicitable after a reflex had been evoked from the leg by pricking the plantar skin. The duration of the reinforcement of the jerk by a local stimulus is variable, but may be long persistent if the stimulus have been strong.

Faradisation of the central end of the contralateral sciatic nerve reinforces the knee-jerk.² Excitation of the central end of the nerves of the flexor muscles of the knee³ (which in the cat are collected into a trunk free from cutaneous nerve fibres) strongly inhibits the jerk, causing at the same time a relaxation of the extensor muscles of the knee if they are then—*e.g.* under decerebrate rigidity—in tonic contraction. Mechanically stretching the knee flexors—isolated in such a way as to prevent the pull upon them affecting the freedom of the knee-joint—similarly inhibits the jerk. On discontinuance of the stimulus, the jerk is much reinforced, and soon is so even during the stimulus, if that be prolonged beyond a certain time. Section of the nerves of the knee flexors is followed by a long lasting, slight augmentation of the jerk,⁴ so also is section of the whole sciatic nerve. Faradisation of the cutaneous nerves⁵ of the limb also generally depresses the jerk, but not so regularly or potently as the excitation of the nerves from the muscles antagonistic to the knee extensors. Bowditch and Warren⁶ found sensible stimuli to skin and mucosæ, *e.g.* sudden application of cooled air to conjunctiva, skin of neck, and nasal passages, reinforce the jerk if applied simultaneously with or not more than 0·2 second to 0·4 second before the tap on the patellar tendon. If applied earlier than that, they exerted an inhibitory or depressor influence, which reached its maximum about 1 second after application of the sensible stimulus. Stimulation of the skin of the knee, either of the side whence the jerk was elicited or of the contralateral side, caused little reinforcement, but when applied at appropriate intervals, a distinct inhibition was noticeable even when the stimulus preceded the tap for the jerk by fully three seconds. With other stimuli tried, no effect on the jerk was traceable, if the sensible stimulus preceded the knee tap by two seconds. A sudden sound reinforced the jerk, and never depressed it; it reinforced most when it preceded the tap by 0·2 second to 0·3 second. A flash of light also reinforced; the best interval being 0·1 second to 0·3 second; even at appropriate intervals it caused little inhibition.

Arrest of the circulation in the lumbar region of the cord was shown by Prevost⁷ to first exalt, and later depress and abolish the knee-jerk. Stimulation of the peripheral end of the cardiac vagus in the dog and monkey similarly exalts the jerk,⁸ no doubt by impeding the circulation. Chloroform and ether inhalation depress the jerk, and finally extinguish it, the speed of extinction being about the same in the spinal as in the intact animal, but in the latter, after cessation of the administration of the anæsthetic, recovering the more quickly.⁹

In the monkey, spinal transection usually depresses the jerk for a longer time than in the cat and dog.¹⁰ Occasionally in the monkey, after transection at the lower thoracic region, the jerk is not elicitable for a week or so after transection. In the cat and dog it is elicitable in a quarter of an hour or less. After transection in the thoracic region, the jerk does not disappear immediately, but only in the course of a minute or so;¹¹ similarly, the knee-jerk has been elicited immediately after decapitation in man.¹² In man, complete transverse destruction of the cord, even well above the lumbar region, seems usually to permanently abolish the knee-jerks; but a certain number of well-authenticated cases show that it is not always so.

¹² Barbé, *Compt. rend. Soc. de biol.*, Paris, 1885, p. 533.

The spinal reflex mechanism connected with the knee-jerk of each side is unilateral, and lies in its own half of the cord. In the cat and dog it lies in the fifth and sixth lumbar segments; in the monkey (*Macacus*), in the fourth and fifth, chiefly the latter; and in man in the third and fourth, chiefly the latter. It has been experimentally shown that the lumbar cord can be split lengthwise along the median sagittal plane without impairment of the jerk of either side.¹ Spinal transection above the lumbar region renders the jerk, after the short period of depression, more brisk than normal. After transection at the junction of diencephalon and mesencephalon, the briskness of the knee-jerks is enormously increased. A single tap on the *tendo patellæ* will excite a series of jerks, and often the relaxation of the muscle between the jerks is only imperfect.² Such a condition of jerk is sometimes called "tremospasm." Raising the intracranial pressure has been noted to have a like effect on the "jerk."³ Cortical excitation has also been found to exalt the jerk. After ablation of the Rolandic cortex, the contralateral knee-jerk becomes usually the more brisk.⁴

Jendrassik⁵ noted that a willed movement of the arm, if carried out by the subject at the time of the elicitation of the knee-jerk, augments it. It was later remarked⁶ that to get the full effect of the reinforcement, the patellar tap must be delivered at just the right moment after the reinforcing act. Bowditch and Warren,⁷ in their research, found the reinforcing influence to last only from 0.22 second to 0.6 second, and to be followed, in most persons, by a more persistent period of inhibitory influence, the normal degree of jerk being recovered in 1.7 seconds to 2.5 seconds. The willed movement of another part, no doubt, removes the attention from the limb whence the jerk is to be obtained; in directing attention to any part of the body, there is a strong, in some persons an irrepressible, tendency to innervate the skeletal musculature of the part. How it is that even feeble excitation (*viâ* cerebral paths) of the motor root cells prevents the muscle from giving the twitch, in response to the patellar tap, is not clear. The fluctuation in the condition of the motor root cell, from minute to minute, as wakeful life proceeds, is well illustrated by the fluctuation of the knee-jerk, as for instance observed by Lombard⁸ under ordinary daily events. Swallowing, talking, the hearing of a child crying in a near room, the declamation of a poem, an itching of the ear,—events such as these seem to be mirrored as regards their influence on the motor root cells for the skeletal musculature by reinforcements of the knee-jerk. In sleep the knee-jerk is, when sleep is deep, usually unobtainable,⁹ but sensory stimuli, too feeble to wake the sleeper, make the jerk elicitable for a short interval. The perturbations of the condition of the extensor muscle of the knee and its local reflex arc brought about by sensory stimuli, customarily regarded as without consequence to, or almost indifferent as regards that region, show to what extent the whole nervous system is consolidated, and how continually its state of tension is braced or slackened by stimuli whose influence we do not recognise, or recognise only in one partial aspect. Fatigue, hunger, and enervating weather decrease the average knee-jerk, while rest, nourishment, and invigorating weather increase the average knee-jerk. In the winter frog the knee-jerk is difficult to elicit,

but during the breeding season it is easily evoked.¹ There is a diurnal variation of the jerk ; it is at its maximum, as a rule, soon after breakfast.

A crossed effect is of common occurrence. It is often an adduction at hip rather than an extension at knee.² Its time has been found much longer³ than the ordinary knee-jerk time, and sufficient to allow of its being a true reflex movement ; but there are also reasons against accepting it as such.⁴

TROPHIC FUNCTIONS OF THE SPINAL CORD.

Magendie⁵ showed that intracranial section of the trigeminus is followed in many instances by keratitis, ulceration of lip, palate, etc. Similarly, broncho-pneumonia ensues and proves fatal after bilateral vagotomy.⁶ Severance of the nerves of a limb produces wasting not only of its muscles but of its bones and ligaments.⁷ Section of the spermatic nerve produces atrophic changes in the testis.⁸ Ablation of the superior cervical ganglion leads, in the turkey-cock, to atrophy of the corresponding half of the comb.⁹ Section of the cervical sympathetic trunk has led in young rabbits to hypertrophy of the corresponding pinna,¹⁰ although in many no definite difference results.¹¹ Schiff¹² and S. Mayer¹³ found the hair on the side of the nerve-section grow the more quickly. Section of nerves of the salivary glands leads to the results described in Langley's article.¹⁴ The most striking of all the changes in the nutritive condition induced by separation from the nerve centres is, however, that which ensues in the skeletal muscles. In two or three weeks the muscle fibres begin to become smaller, and after some months or years they have dwindled out of recognition, leaving a tissue to all appearance like mere connective tissue.

The rate of this change is very different in different muscles,¹⁵ and in different fibres of the same muscle. In the "red" muscles and "red" fibres of muscles the change is slower than in the "pale." In none of the fibres of the extrinsic eye muscles of the monkey did I find, sixty days after section of their nerves, more than a slight increase of the interfibrillar granules that osmic acid blackens ; the difference from normal was hardly discoverable.¹⁶ The intrafusal muscle fibres of the sensory organs (muscle spindles) of the skeletal muscles belong to the "red" variety of fibres, and are extreme examples of that variety. I am not convinced that there is any change in these muscle fibres, even where the nerve to the muscle has been severed three years previously,¹⁷

and its regeneration prevented. Accompanying this histological change, and in a sense heralding it, are the well-known alterations in the electrical reaction of the muscle, which characterise the "reaction of degeneration." The muscle comes to respond to electrical stimuli in a manner apparently qualitatively different from normal. The excitability of the muscle to induced currents is abolished, that to the constant current is exaggerated. In regard to the response to the latter, the normal order of appearance of contraction, as the strength of the current is gradually increased from subliminal, begins with the kathode to the muscle and at the making of the circuit. To obtain a contraction when the anode is applied to the muscle and the current is made, requires a stronger current. In a well-marked reaction of degeneration, the anodal contraction, at make, appears with a weaker stimulating current than that required for the kathodal contraction at make. The contraction is greatly prolonged. Galvanotonus is easily produced.

Disease of sensory as well as of motor nerves is accompanied by change in the condition of nutrition of peripheral tissues. Alterations, both of atrophic and inflammatory kind, occur in the skin in relation to primary changes in nerve trunks. Of the latter alterations the course of herpes zoster is one example. The primary lesion seems an inflammatory condition of the spinal ganglion;¹ on this ensues an eruption more or less occupying the field of skin for which the ganglion cells provide sensory channels. There is severe pain referred to the area of skin. Head's recent researches² have placed beyond doubt the connection between this cutaneous eruption and focal inflammation of corresponding spinal ganglia. Occasionally a similar herpes ensues on irritation of the ganglia in spinal caries.

When the afferent spinal roots belonging to a limb are severed—proximal to the ganglia—there is distinct wasting in much of the musculature of the limb; and, especially in the lower limb, ulceration is prone to occur on the outside of the ankle-joints. In man, where injury of the spinal cord upsets the condition of the skeletal musculature more than in animals, and where, therefore, the disturbance to the skin is probably also proportionately greater, there is especial tendency for ulceration (bed-sores) of the skin and tissues to occur; but these are met with as the result of similar lesions in laboratory animals.

When all these cases are examined, so far as by present methods they can be, they seem to yield evidence that every nerve and nerve centre that can influence the proper and specific activity of a tissue—and that is the sole function of nerves—possesses, in so far, a trophic influence on that tissue. If by trophic nerve be understood no more than this, all nerves are trophic nerves. That, on the other hand, any nerve directly modifies the nutrition of a tissue independently of inducing vascular changes in it, or influencing those particular metamorphoses of material for which the tissue is the machine specifically adapted, there is no proof. The function and the nutrition of these physiological machines form an inseparable unity. Such a doctrine is a just corollary to the cell theory. Under the notion of normal nutrition is understood maintenance of a certain average form and certain average chemical composition. When the maintenance of the nutrition of one cell is directly and greatly dependent on the maintenance of another, the inference amounts to certainty that the latter governs the function of the former. This consideration shows clearly how, far more than any

¹ v. Bärensprung, 1861.

² Allbutt's "System of Medicine," London, 1899, vol. viii. p. 635.

other peripheral tissue, the skeletal muscles are governed by the efferent root cell system of nerve cells. No other tissue, except skeletal muscle, practically dies down, in consequence of injury of the root cell system.

The inflammation so prone to occur in exposed sensifacient surfaces, when their nerve channels are broken, does not stand in such direct relation to the nerve injury. The anæsthesia and analgesia of the surface lead to the unperceived accumulation of irritant effects. The most exposed part of the apæsthetic limb is the seat of ulceration, as the result of long-continued and undue—because unperceived—pressure. The keratitis often ensuing on section of the trigeminus can be avoided by careful protection of the eye from dirt. The ulceration about the lips after a similar unilateral lesion, has been noted to extend quite freely across the median line, so that there seems no difference between the essential resistance of the anæsthetic and of the normal tissue. The broncho-pneumonia, after vagotomy, seems entirely explicable by irritation of the respiratory tract from particles inhaled or entering from the digestive tract, the former tract being no longer securely guarded from this accidental leakage of material from the latter.

Not only are the nerve cells in the above cases trophic for peripheral tissues, but some nerve cells are trophic for other nerve cells, some nerve cell systems trophic for other nerve cell systems. It will have been remarked, from the foregoing paragraph, that the direction of the trophic influence is the same as that of the normal nerve conduction, that is, for instance, from motor root cell to muscle fibre, and not from muscle fibre to motor root cell. So in the cell systems of the cord and brain. Section of an optic nerve leads to trophic changes in the cells of the pulvinar, internal geniculate body, anterior corpus quadrigeminum, etc. If the section be made before the growth of the dependent cells is complete, their further growth is hindered. Thence results Gudden's or *agenesic* atrophy. A series of many links of a nerve cell chain may be affected by it, indeed the whole chain from end to end. But the damage must, in order to effect that result, be at the end which is the seat of excitation of its normal function. The sensory root cell is the alpha of each and every neural series, whatever the function and whatever the complexity. On the afferent root cell is therefore based the trophism of the whole nerve system, so far as there is a nervous system possessing solidarity as a whole, above and beyond the individual entity of the component cells. After severance of the afferent roots, the motor root cells of their spinal region soon present recognisable structural change.¹ The nucleus of the motor root cell becomes markedly excentric in position, the Nissl bodies become very small or disappear, or lose their normal colour reaction; the cell becomes large, and the nucleus may even disappear. These changes do not occur with all the ventral horn cells, but only with certain of them; the larger number of cells reveal no distinct alteration, and in the cells of the lateral horn no change is detected. The nutritive condition of the afferent root cells themselves is to some extent governed by the sensifacient organs that regularly play upon their distal extremities. Hence probably the atrophy of the

¹ W. B. Warrington, *Journ. Physiol.*, Cambridge and London, 1897, vol. xx. A full bibliography is given in Warrington's paper. For further aspects of the question of the relation between the visible structure of the nerve cell and its functional condition, reference must be made to the article "Nerve-Cell," in this volume.

dorsal column, and of the grey mater consecutive to amputation of a limb. Of the spinal cell groups in the limb region, one belonging to the motor root cell system appears to suffer more than the rest. This is the dorsal-lateral group in the ventral horn,—which there is reason to think innervates in the crural region the muscles of the foot, in the brachial region the muscles of the hand. Whether the amputation of the limb has been at wrist or shoulder, at ankle or hip, this is the group that exhibits the chief atrophy. It is probably only after functional influence of one nerve cell on another, or on a peripheral tissue, has become established, that the nutrition of the latter is affected by the action of the former. In an amyelous fœtus, possessing of course no efferent spinal roots at all, the skeletal musculature may appear as well developed as in a normal fœtus of similar term.¹

Trophic influence in a direction contrary in sense to the ordinary functional relationship and connection, is very obscure. The herpes zoster due to an inflamed spinal root ganglion, unless, as is possible, of reflex production, seems to be an example of this exercise of influence, so to say, "against stream." The cutting of the facial nerve is said to cause recognisable alteration of the structure of the root cells of that purely motor nerve. The section of a ventral spinal root seems also to affect its cells of origin.² Transection of the spinal cord in young animals entails even in course of a few weeks atrophy of the cell-group of Clarke's column. These injuries are, it is true, applied actually to a portion of the cell itself which they are found to alter; but the phenomenon, which is one now under active investigation, admits at present of little that is satisfactory in way of explanation. The tearing out of the motor roots is said to be more productive of the central changes than is their simple section.

REGENERATION OF THE SPINAL CORD.

It has been asserted that the spinal cord of the frog³ and pigeon,⁴ after complete transection, may, in the course of a few weeks, show reunion, nerve cells and nerve fibres existing in the tissue bridging the lesion. Figures⁵ given of the cells believed to be nervous suggest connective tissue fibroblasts or neuroglia cells rather than nerve cells. The supposed regeneration is in accord with a number of observations of a not altogether convincing kind, none of them recent, in which restitution of "volitional movement" and of "conscious reaction" in relation with the regions behind the transection, appeared to occur.⁶ It must be remembered that some recovery of function is possible without regeneration of the tissue,⁷ and reflex movements can be only with difficulty discriminated from intentional.

The whole question bases itself on the discovery by Spallanzani, in 1768,⁸

that the spinal cord is reproduced in the lizard in the regeneration of the tail. His description has been many times confirmed, and its fact thoroughly established.¹ The regeneration takes place even when the spinal cord has been transected above the tail, in the thoracic region.² But although the new formation of both ependyma cells and nerve cells in the caudal cord is clear and abundant, there is much less restitution of both these elements in the cicatrix in the thoracic region.³ Regeneration of the cord in the tail-region of *Lacerta viridis* is less complete⁴ than in that of *Triton*, and some are doubtful whether the nerve cells reappear in the former,⁵ though several observers regard this as unquestionable.⁶ In the tadpole the regeneration only includes the ependyma cells.⁷ In the adult frog, in spite of the observations of Masius and Van Lair, Sgobbo finds no karyomitosis or other signs of nervous regeneration at the transection of the cord. Similarly, the results of Brown-Séquard in the pigeon are contradicted by the careful observations by Piccolo and Santa Silena,⁸ and by Sgobbo.⁹ After semisections and total transections, these latter observers find in the pigeon no neoformation of nervous elements, but degeneration of nerve fibres extending for various distances, although the ependyma cells of the central canal remain almost unaltered, quite close up to the seat of trauma. It seems an established fact, that in the higher vertebrata, no karyomitosis goes on in the spinal nerve cells after that early stage of development at which the dorsal white columns are sufficiently formed to cause a distinct dorsal median fissure to the cord.¹⁰ But as to spinal regeneration, numerous observations upon dogs have led to somewhat discordant conclusions. Regeneration of cells has been described;¹¹ also the extension of nerve fibres across the scar without any regeneration of nerve cells;¹² whilst by others neither regeneration of nerve cells nor extension of nerve fibres into the scar could be found.¹³ Karyomitosis has been found in the ependyma cells of the central canal at the exit of lesion, but none in the nerve cells proper. The neuroglia cells of adult animals normally show some karyomitosis.¹⁴ The origin of the new nerve fibres that in some cases traverse the scar has not been ascertained.

APPENDIX.

*Table of Effects of Excitation of the Dorsal (Afferent) and Ventral (Efferent) Roots of some of the Spinal Nerves in Macacus rhesus.*¹

DORSAL ROOTS.	VENTRAL ROOTS.
<p><i>Fourteenth post-thoracic.</i>—Tail lifted and generally moved laterally, very often toward the opposite side; no movement of arms or of limb.</p> <p><i>Thirteenth post-thoracic.</i>—Tail lifted and generally moved laterally, very often toward opposite side; no movement of arms or of limb.</p> <p><i>Twelfth post-thoracic.</i>—Tail moved, very often toward opposite side; no movement of arms or of limb.</p> <p><i>Eleventh post-thoracic.</i>—Tail moved, very often toward opposite side; no movement of arms or of limb.</p> <p><i>Tenth post-thoracic.</i>—Tail moved, often to opposite side; protrusion of anus; no movement in the limb proper.</p> <p><i>Ninth post-thoracic.</i>—Tail moved, less commonly to the opposite side; protrusion of anus; flexion of hallux, less frequently of other digits as well. It makes no difference to this movement whether the plexus be post-fixed or not.</p> <p><i>Eighth post-thoracic.</i>—Tail moved to same side; protrusion of anus. The anal movement obtained from this and the two preceding roots is almost always protrusion, and rarely shows more than a trace of unilaterality, so that here again must occur a cross-path of low resistance athwart the median plane of the cord.</p> <p>Flexion and adduction of hallux and flexion of other digits; slight flexion of knee (contraction of hamstring); slight plantar flexion of ankle (in one experiment this was bilateral, but more vigorous on the same side than on the crossed). When all the reflexes have been abolished by pushing the chloroform, the hallux reflex is usually the earliest to return.</p> <p><i>Seventh post-thoracic.</i>—Tail moved to same side; flexion of knee; flexion of hallux and digits, especially of hallux and second toe; dorso-flexion of ankle (very rarely plantar flexion). When</p>	<p><i>Tenth post-thoracic.</i>—Tail moved laterally toward the side of excitation.</p> <p><i>Ninth post-thoracic.</i>—Tail moved laterally. In some individuals slight external rotation of thigh, and adduction-flexion of hallux and toes; contraction of bladder.</p> <p><i>Eighth post-thoracic.</i>—Tail moved laterally; slight external rotation at hip and flexion at knee, with extension at hip and ankle; strong flexion of digits, with flexion-adduction of hallux; movement of arms; contraction of bladder.</p> <p><i>Seventh post-thoracic.</i>—Extension of hip; flexion at knee; extension at ankle; inversion of sole; strong flexion-adduction of hallux; depression of tail; movement of arms.</p>

¹ Sherrington, *Journ. Physiol.*, Cambridge and London, 1892, vol. xiii.; *Phil. Trans.*, London, 1896.

DORSAL ROOTS.	VENTRAL ROOTS.
<p>the filaments of this large root are separated into three sets, made up respectively of the anterior, middle, and posterior groups, no distinct difference between the replies obtained from each of the three is observable; crossed plantar flexion of ankle.</p> <p><i>Sixth post-thoracic.</i>—Tail moved to same side; flexion of knee, flexion of hip, with some internal rotation; flexion of hallux and of other digits; less easily, dorsoflexion of ankle with tilting up of the outer edge of the foot; adduction of thigh, easily obtainable as a crossed reflex.</p> <p><i>Fifth post-thoracic.</i>—Flexion at hip; flexion at knee (inner hamstring and gracilis seem particularly active); flexion of hallux, less of toes; slight dorsoflexion at ankle at times; adduction at hip as a crossed effect; movement of tail, not constant. <i>Knee-jerk.</i></p> <p><i>Fourth post-thoracic.</i>—Curving of body so that the hind-limbs point toward side stimulated; flexion at hip; flexion at knee; flexion of hallux occasionally, and still less frequently flexion of digits; quite rarely slight dorsoflexion at ankle; adduction at hip, occasionally with crossed adduction. <i>Knee-jerk.</i></p> <p><i>Third post-thoracic.</i>—Curving of body as with fourth root, but more so; flexion at hip, rarely flexion at knee; occasionally flexion of hallux, and occasionally of other digits as well; drawing up of testis (<i>cremaster</i>).</p> <p><i>Second post-thoracic.</i>—Curving of body as above; flexion at hip; drawing up of testis (<i>cremaster</i>); very occasionally flexion of hallux.</p> <p><i>First post-thoracic.</i>—Muscles of flank contract; retraction of abdominal wall low down; flexion at hip.</p> <p><i>Twelfth thoracic.</i>—Muscles of flank and abdomen contract; flexion at hip, but not regularly or in all individuals.</p> <p><i>Eleventh thoracic.</i>—Muscles of flank and abdomen and intercostal space; with moderate strength of stimulation never any movement in limb.</p> <p><i>Seventh thoracic.</i>—Muscles of back and side of chest; some of the more superficial respond more readily than do the intercostals. The intercostals that most readily respond are those of the seventh and eighth spaces, and next to them of the sixth space. It is difficult to evoke contraction in the crossed intercostals.</p> <p><i>Fifth thoracic.</i>—Muscles of back and side of chest; intercostal spaces involved are chiefly fifth and sixth; occasionally some retraction of shoulder.</p> <p><i>Fourth thoracic.</i>—Retraction of shoulder; slight dilatation of homonymous pupil; occasionally contraction of triceps.</p>	<p><i>Sixth post-thoracic.</i>—Extension of hip; adduction of thigh; weak flexion at knee; dorsoflexion at ankle; extension of toes; adduction of hallux.</p> <p><i>Fifth post-thoracic.</i>—Adduction at hip; extension at knee; slight flexion at ankle; slight extension of hallux.</p> <p><i>Fourth post-thoracic.</i>—Retraction of lower part of abdominal wall; flexion and adduction at hip; extension at knee.</p> <p><i>Third post-thoracic.</i>—Retraction of lower part of abdominal wall; flexion at hip; contraction of round ligament of uterus and of cremaster.</p> <p><i>Second post-thoracic.</i>—Retraction of abdominal wall; slight flexion at hip.</p> <p><i>First post-thoracic.</i>—Retraction of abdominal wall; no movement in the limb itself.</p>

DORSAL ROOTS.	VENTRAL ROOTS.
<p><i>Third thoracic.</i>—Retraction of shoulders ; contraction in part of triceps occasionally well marked ; dilatation of homonymous pupil.</p> <p><i>Second thoracic.</i>—Movement at shoulder, slight flexion of thumb and digit ; sometimes contraction in triceps ; sometimes dilatation of homonymous pupil.</p> <p><i>First thoracic.</i>—Movement at shoulder, certainly sometimes retraction ; contraction in part of triceps ; adduction and flexion of thumb and other digits ; extension of elbow, sometimes flexion at elbow ; with stronger stimulation slight flexion and some pronation at wrist.</p> <p><i>Eighth cervical.</i>—Adduction and flexion of thumb, flexion of other digits, flexion more often extension at wrist ; drawing inward and downwards of shoulder, retraction of upper arm. At elbow rarely extension, sometimes flexion ; during the latter movement the supinator longus acts, but the biceps acts very little. When the examination of the root is conducted by splitting it in three fore-and-aft divisions, extension at elbow and triceps contraction are less common from the foremost than from the hindmost division ; and flexion and supinator longus action more common from the foremost than from hindmost division.</p> <p><i>Seventh cervical.</i>—Adduction and flexion of thumb and flexion of other digits ; flexion of elbow ; retraction of shoulder.</p> <p><i>Sixth cervical.</i>—Flexion of elbow ; adduction and flexion of thumb ; flexion of other digits, and retraction of shoulder less marked than with Root 7.</p> <p><i>Fifth cervical.</i>—Flexion at elbow ; movement at shoulder, sometimes retraction, sometimes drawing up ; adduction and flexion of thumb. Sometimes the movement at shoulder is simply adduction.</p>	<p><i>Second thoracic.</i>—Retraction of shoulder ; slight flexion of wrist ; flexion of fingers and thumb with opposition of the latter ; sometimes slight pronation at wrist ; lateral curving of the spinal column. Dilatation of pupil ; eye opens.</p> <p><i>First thoracic.</i>—Retraction of shoulder ; slight lateral flexion and retraction of neck ; slight extension at elbow, flexion at wrist with pronation ; flexion of fingers and thumb with opposition of the latter ; there is usually a slight abduction of wrist toward ulnar side.</p> <p><i>Eighth cervical.</i>—The shoulder drawn downwards (latissimus dorsi). The adduction is not so extreme as in case of Root 7. Rotation inwards of arm ; flexion and pronation of wrist ; flexion of fingers, and of thumb with opposition.</p> <p><i>Seventh cervical.</i>—Retraction and strong adduction at shoulder with some inward rotation of arm ; the arm is carried across the body. Extension of elbow ; slight flexion at wrist and some pronation ; slight flexion of the fingers. The shoulder is drawn downwards. Slight retraction and lateral flexion of neck.</p> <p><i>Sixth cervical.</i>—Moderate adduction at shoulder ; strong flexion of elbow ; slight extension of digits and hand (not in every individual). Some supination of wrist ; slight extension of wrist in most individuals, but in a few flexion and not extension of wrist. In one individual flexion of fingers was obtained from this root, but that may have been due to mechanical effect of extension of wrist, which if extreme in <i>Macacus</i> partially flexes the fingers. Very slight lateral flexion of neck toward side stimulated and slight retraction of neck and head.</p> <p><i>Fifth cervical.</i>—Elevation, abduction, and some outward rotation of the shoulder ; flexion of elbow, the wrist becoming slightly supine ; slight radial abduction of wrist ; very slight lateral flexion of neck toward side stimulated,</p>

DORSAL ROOTS.	VENTRAL ROOTS.
<p><i>Fourth cervical.</i>—Retraction of shoulder or sometimes protraction and lifting of shoulder; flexion at elbow, but not invariably; occasionally flexion - adduction of thumb; lateral flexion of neck.</p> <p><i>Third cervical.</i>—Elevation of shoulder; drawing down of head to same side; flexion of elbow feeble and occasional. The flexion of elbow is in great measure supinator longus action: twisting of head and neck to opposite side.</p> <p><i>Second cervical.</i>—Drawing up of shoulder, down of head to same side; turning of chin toward opposite shoulder with neck. Neither in this root nor in preceding did moderate stimuli evoke contraction in the muscles of the hyoid region.</p> <p><i>No dorsal root.</i></p> <p><i>Fifth cranial nerve.</i>—Opening of mouth; turning of chin toward opposite shoulder; wrinkling of muzzle; conjunctival reflex.</p>	<p>with some (slight) retraction of neck and head.</p> <p><i>Fourth cervical.</i>—Elevation of shoulder, dragging it headward and toward the spinal column. Slight lateral flexion toward side stimulated with marked retraction. When the shoulder is fixed, slight turning of the head toward the opposite side previously obtainable becomes more pronounced.</p> <p><i>Third cervical.</i>—No movement of the limb proper. Lateral flexion of the neck toward the side stimulated, with marked retraction and a little turning of the neck, so that chin is thrust upward toward opposite side.</p> <p><i>Second cervical.</i>—No movement of the limb proper. Lateral flexion of the neck toward the side stimulated, with some retraction. Little or no rotation of the head, but the chin may be turned slightly toward opposite axilla.</p> <p><i>First cervical.</i>—No movement of limb proper. Lateral flexion of the neck toward the side stimulated without rotation of the head.</p>

THE PARTS OF THE BRAIN BELOW CEREBRAL CORTEX, VIZ. MEDULLA OBLONGATA, PONS, CEREBELLUM, CORPORA QUADRIGEMINA, AND REGION OF THALAMUS.

BY C. S. SHERRINGTON.

THE MYELENCEPHALON OR REGION OF THE MEDULLA OBLONGATA.

THE roof of this portion of the encephalon contains neither nerve cells nor nerve fibres. From the present point of view, therefore, it is functionless. The floor, on the other hand, forms the bulb, and exercises manifold neural functions.

Belonging to the afferent root cell system of this part are the ganglion cells of the nervus intermedius (geniculate ganglion), receiving impulses, perhaps gustatory, from the tongue region; the ganglion cells of the cochlear and vestibular nerves, conducting impulses from the organs for hearing, geotropism and space-relations of the head; the ganglion cells of glosso-pharyngeal and vagus nerves, conducting impulses from alimentary and respiratory mucous membranes and from heart; and occasionally ganglion cells belonging to the hypoglossal nerve, their distribution being unknown. The afferent root cell system of this region brings no impulses from skin, except from a tiny patch at the

meatus of the ear. In addition, the region contains the end-nuclei which receive the fibres of the above afferent root cells (the descending stems of the

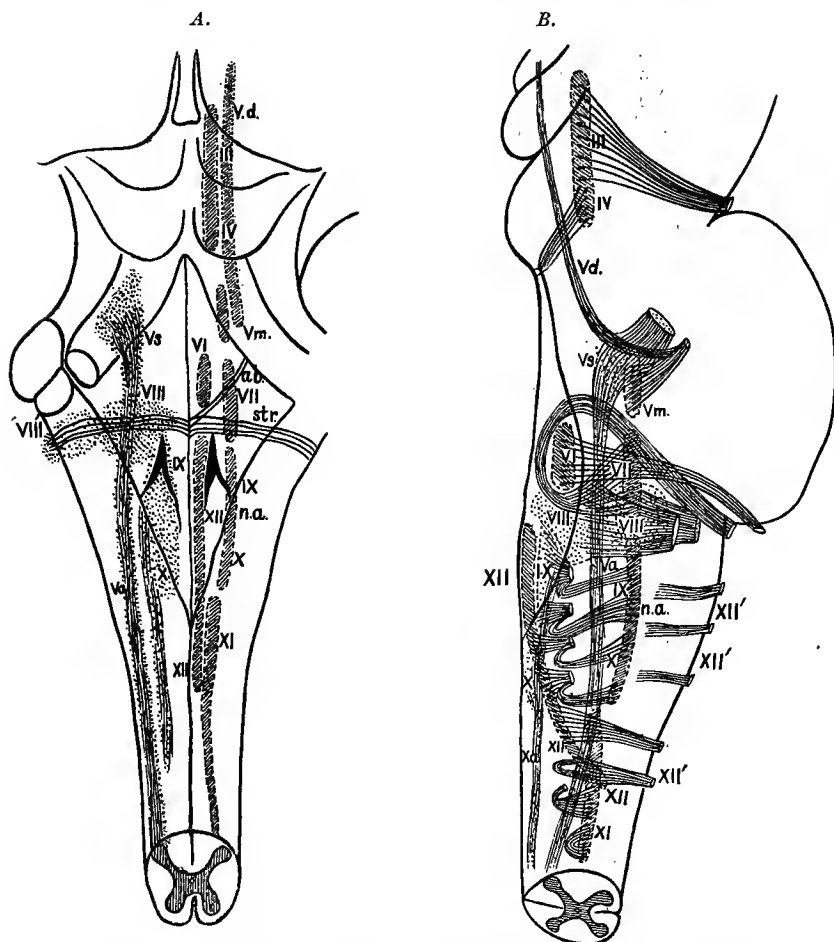

FIG. 360.—Diagrams to show the situation of the chief nerve nuclei in the medulla oblongata and pons near the floor of the fourth ventricle. *A*, from behind; *B*, profile view of the right half, the medulla and pons being supposed to be transparent. The efferent or motor nuclei are shaded with oblique lines, the afferent or sensory nuclei with dots. In *A* the efferent or motor nuclei are represented on the right side only, the afferent or sensory on the left. III, IV, oculomotor and trochlear nucleus; Vd, descending root of the fifth nerve; Vs, so-called sensory nucleus of the fifth; Va, ascending root of the fifth; Vm, motor nucleus of fifth nerve; VI, nucleus of abducens; VII, nucleus of facial; n.VII, root of facial curving round abducens nucleus; VIII, inner or dorsal nucleus of auditory; VIII', outer or ventral nucleus of auditory; IX, X, vago-glosso-pharyngeal nucleus; n.a., *nucleus ambiguus*, accessory or efferent vago-glosso-pharyngeal nucleus; XI, nucleus of spinal accessory; XII, nucleus of hypoglossal; XII', issuing roots of hypoglossal.—Schäfer (twice the natural size).

afferent fibres of the vagus, *tract. solitarius*, partly pass to crossed nuclei, *nuc. commissurales*, and the end-nuclei also for three other afferent roots. First, for the afferent root cells (in trigeminus), leading from the frontal, ocular, nasal, facial, buccal, and lingual skin; second (Goll's nucleus), for afferent

root cells, leading from the segmental nerves of the whole body below the brachial region; third (Burdach's nucleus), for afferent root cells, leading from all the brachial and cervical nerves.

The efferent root cell system discharges impulses to various regions of the alimentary secretory epithelium, from mouth to pancreas inclusive (chorda tympani, Jacobson's nerve, and branches of vagus), and the musculature of the alimentary canal from the soft palate along the pharynx and œsophagus to and inclusive of the stomach,¹ including the respiratory diverticulum (larynx, trachea, and lungs), and the tongue. The *nucleus ambiguus* is the cell group whence arise most, if not all, of the efferent fibres of the glosso-pharyngeal, vagus, and accessory nerves; the rootlets of the last named are entirely efferent. Cajal² has found that some of the axis cylinders from the nucleus ambiguus pass to the rootlets of the crossed glosso-pharyngeal nerve, though the great majority enter the homonymous nerve: the same condition he found in lesser degree to hold in relation to the vagus rootlets.

In the frog, removal of the encephalon down to the level of the octavus nerve leaves the animal with regular and apparently normal respiratory movement and circulation, but with considerable impairment of its locomotor powers. It rests sprawling with head sunk. It crawls only under obvious external stimulation.³ Locomotion is easier to provoke than when the transection lies at the caudal end of the fourth ventricle.⁴ It will usually, when laid on its back, try to right itself, and usually succeeds. This evidences the existence of geotropic sense and of considerable muscular co-ordination. The co-ordinating action of the frog's myelencephalon on the skeletal musculature, may be likened to that of the ring commissure of *Asterias*. When placed in the tank upside down, a united action of the five rays soon rights the animal. But if without injury to the individual nerve systems of the several rays, the circum-buccal nerve ring be severed between the adjacent rays, ability to correct the inverted posture is destroyed.⁵ The individual action of the rays is vigorous, but they largely neutralise each other's mechanical effect. The inco-ordinate activity fails to arrive at the result attained when due correlation is ensured by the nerve-ring. The actions of the individual rays must therefore, when the nerve-ring is intact, influence each other. The convergence of afferent spinal paths from the skeletal musculature and of paths from the vestibular nerve towards the region which possesses this co-ordinating influence, is suggestive of their co-operation toward the result.

The mammal, after similar removal of all encephalon in front of the bulb, still breathes with regularity, and possesses good circulatory adjustments. There is still some degree of co-ordinate movement of progression, but such movement is difficult to provoke. When the transection lies below the junction of the middle and lowest thirds of the fourth ventricle, it becomes in some mammals⁶ extremely difficult to evoke by any sensory stimulus a movement in which all four limbs come into play. I would remark that, by this transection, the vestibular

apparatus is cut off from the cord. The fall of arterial blood pressure, consequent on the interference with the bulbar vasomotor centre, is not responsible for the difference in the reflexes.

Ablation of the rest of the bulb annuls the respiratory movements, depresses the arterial blood pressure, and destroys a number of vasomotor reflexes that were previously possible. The cardio-inhibitory centre connected with the vagus and its accessory nerve is also destroyed, and the reactions through it of sensory nerves upon the heart are of course lost with it.

In the bulb lie also, in major part, the nervous mechanisms guarding and working the apparatus of the great anterior opening of the body, by which material from the environment is seized, tested, and admitted as pabulum for digestion. The respiratory apparatus belongs to this same system, although with additional excretory functions, and in higher groups partly subservient to emotional and mental expression. Nothing perhaps shows more clearly the want of functional solidarity of the individual "segments," as morphologically defined, than the profound degree to which the nervous "centre" for the ingestion of food extends across the boundary between metencephalon and myelencephalon in the floor of the fourth ventricle. This "centre" pervades both, and in its spatial distribution, as in that of the bulbar mechanism of speech, little can be traced of any boundary between them, although its fractions can be located more or less independently. These are often referred to as "centres" of deglutition, phonation, vomiting, coughing, hiccough, etc. With all its complexity, the mechanism is essentially that of a great oral sphincter. Special details are given concerning them in various appropriate sections of this work. The visceral sensory surfaces and alimentary epithelium connected with the myelencephalon extend far backward. The reflex centres for movement of the œsophagus, and for secretion by the gastric¹ and pancreatic glands,² lie in the caudal part of the bulb, in connection with the vagus and its accessory nerve. After removal of the entire encephalon in the frog, the intestines enter into a condition of long-continued peristaltic activity. If, however, the bulb be left, a status of apparently abnormal quietude obtains in the intestine.³ A point of general interest in the physiology of the great "alimentary" nerve centre in the bulb is the high degree to which it employs inhibition. Each subdivision of it is depressible by "inhibitory" fibres from some afferent nerve trunk or another; thus, the respiratory portion by fibres in the superior laryngeal nerve, the deglutition portion of it by fibres in the superior laryngeal, and partly in the inferior laryngeal, the secretory portion by fibres in the afferent branches of the gastric and thoracic vagus, and so on.⁴

The term centre has been used with perhaps especial laxity in speaking of the bulb. A "convulsion" centre has been, among other centres, postulated for the bulb. Widespread convulsions of the skeletal musculature can be produced by chemical stimulation there.⁵ A drop of 10 per cent. sodium-

chloride solution, or a crystal of kreatin placed on the floor of the fourth ventricle of the frog, produces, after a minute or so, a cry which ushers in a seizure, during which the fore-limbs are crossed under the sternum, the hind-limbs at first flexed at hip and extended at knee and ankle, until the animal rolls backward. Then extension at hip follows. The muscular contraction, at first clonic, later becomes tonic. The whole seizure lasts about one minute. The seizure is less intense, if the cerebral hemispheres have previously been removed. Convulsions cannot be similarly excited from the spinal cord itself.

It is in the bulb that nerve cells are met that more than any others in the neural axis seem to have automatic in contradistinction to reflex activity. The bulbar respiratory cells, like the muscle cells of the heart, seem to be able to rhythmically convert stores of their potential into kinetic energy apart from any spur by external stimuli, although profoundly responsive to these latter.

The bulb is indicated by various data as the part of the nervous system in which has been earliest developed, on a grand scale, that kind of communion between constituent neural units, which concentrates function and combines in co-ordination a number of various working factors. There seem to have been early centred in it regulating nervous mechanisms for certain reactions of fundamental import to the very existence of the individual. It thus gave, so to say, opportunity and guarantee for the response of the neural axis in front of it to the call for building up, in the course of ages, under the direction of the sense organs, especially those of sight and smell, the organs of perception, memory, and intellect, with culmination in the mammalian cerebrum and mind. On the other hand, behind it, somewhat similarly, proceeded a development of neural mechanisms for a great senso-motile organ, the skeletal musculature with its bony levers and its overlying skin, each lateral half of which may be considered as equivalent to the senso-motor mechanism of one eye or of one ear. As vertebrate evolution has gone on, the great motile organ has come more and more to lie at the disposal of the upper hierarchies of nerve powers composing the supreme senses, especially the visual with all its spatial quality. Hence the bulb stationed between these two developments is threaded by strands for their conjunction, pathways for travel up and down between them.

Concerning the bulb as a conductor, the following résumé must suffice. There descends into the cord, from the opposite half of the mesencephalon,¹ a path that probably co-ordinates movements of the body with stimuli impinging on the retina. From the end stations of the vestibular nerve² there descends into the cord an uncrossed path, that probably relates the body movements with the sensations originated in the semicircular canals. Paths also, both uncrossed and crossed, descend into the cord from the red nucleus³ and the large diffuse nuclei of the reticular³ formation of both middle and hind-brain; the functions of these are even more conjectural. In mammals a path descends from the cerebral hemisphere into and through the bulb to reach the motor root cell system. This makes the pyramids, and is largest in the highest forms of nervous system. It appears wanting in vertebrata below mammals (Singer, 1881).⁴

In the guinea-pig the pyramid path crosses into the dorsal column of the cord. The excitation of each pyramid evokes movements chiefly in the contralateral skeletal muscles, especially of the limbs, but to some extent also in the homonymous.¹ Complete severance of both the pyramids does not, however, produce even in so high a type as the dog any obvious permanent paralysis of movement,² nor does it prevent in the dog excitation of the Rolandic cortex, producing movement both on the crossed or uncrossed limbs.³ The pyramidal paths decussate in major part at the caudal end of the bulb. The decussation, when examined by excitation, extends over a longer⁴ area than anatomical

path is also believed to exist. The mesial longitudinal bundle is in part a descending path from visual and auditory centres to spinal, especially cervical, motor mechanisms (Cajal, van Gehuchten).

Of the paths *ascending* through the bulb from the spinal cord, the chief are—(1) The continuation from the dorsal columns of root fibres, that by a second link pass from the dorsal column nuclei to the fillet of the crossed side; (2) the two spino-cerebellar; one (the *restiformis*) chiefly uncrossed from the cord and entering the inferior peduncle of the cerebellum, the other (the *conjunctival*) entering with the superior peduncle of the cerebellum. With this latter pass probably spino-bulbar, spino-mesencephalic, and spino-thalamic paths toward end-stations in and in front of the bulb itself. (3) The mesial longitudinal bundle contains fibres ascending (Held, Tschermak) from v. Lenhossék's commissural cell-group of the ventral horn of the cervical cord to reach motor cerebral nuclei, especially of the eye-muscles. The path from the dorsal column nuclei by the crossed fillet extends to the diencephalon (optic thalamus) and in part to the cerebral cortex, especially its parietal region. Of the function of the inferior olive little is known: its connection with paths from the vestibular nerve is suggestive.

THE METENCEPHALON OR REGION OF THE PONS, VAROLII AND CEREBELLUM.

If in the frog all the brain anterior to the metencephalon be removed, the animal can still walk, spring, and swim. The croak reflex is elicitable, but not readily; it is annulled when the metencephalon is destroyed. The animal reacts on the turn-table perfectly, but this reaction is destroyed when the ablation is extended to the root of the trigeminus. Goltz's reaction to the tilted board is perfect as regards head movement, imperfect as regards correction of the posture of the body by crawling up the board. The animal, if undisturbed, remains inert; if the ablation include the cerebellum and fore-part of the metencephalic floor, the creature becomes active, crawling about until it reaches some corner that blocks further progress. The condition resembles that of the annelid *Nereis* after removal of the supra-oesophageal ganglion.¹ It jumps very rarely. That its locomotor co-ordination is good, is shown by its climbing over obstacles successfully; in swimming it rarely uses the bilateral stroke, but swims "like a dog."² In the condition of which continual crawling is characteristic, there is extraordinary activity of the swallowing reflex. Anything touching the muzzle is snapped at, taken into the mouth, and swallowed. The "embrace" reflex is in the male similarly active, more so than in the normal animal, even at the height of the breeding season. The respiratory movements appear normal. Even when the front part of the metencephalon has been removed, the frog at once rights itself when placed on its back.

In the rabbit similar ablation apparently destroys the power of progression. A condition likened to strychnisation³ sets in, and the skin of the head and trunk seem "hyperæsthetic." When the muzzle is touched the homonymous fore-limb is lifted toward it, and when that is restrained the contralateral fore-limb is brought up as though as an alternative manœuvre.

For further description of the functions of the region, it is convenient to follow the morphological subdivision of it into a floor and roof, the former the pons of higher vertebrates, the latter the cerebellum.

THE PONS.

All the root cell system of the metencephalon belongs to its floor. The afferent root cells include the collection of the trigeminal root conducting impulses from the cutaneous sense organs of the forehead and face and from the mucous membranes of the nose, eye, and mouth. It is not clear whether the afferent root cell system in the metencephalon includes any units from sense organs of muscle. If the eighth nerve be reckoned to this region, the system includes the sense organs for the spatial sense of the head, and in air-breathers the sense organ for hearing, which in mammals comes to rival in importance that of vision itself.

The efferent root cell system of the region discharges into muscles that execute prehension of food and mastication, facial expression (emotion), and that oral modification of throat sounds that contributes so largely to vocal expression and to speech. It is probable that the frontalis and orbicularis palpebrarum muscles get their motor innervation only *through* and not *originally* in this region. Lateral movement is also in part furnished to the retina from this region. Some of the fibres in the facialis root come from cells of the crossed facialis nucleus.¹

For the details of the special physiology of these nerves, reference can be made to the appropriate sections of this work. Out of those details features which rise as salient characteristics of the function of the region may be briefly stated thus. Into it extends the cephalic end of the great neural system for the reception of impulses generated in sense organs of the skin and its appendages, and since much of this region lies inaccessible to the visual field, their importance is in so far unique. The cephalic end of the skin connotes "most headward pain." Tactual space perception of the head directs prehension of food, though least in man. Among its sense organs are those contributory to the testing of objects in regard to their suitability for food, and alongside these lies a main part of the system for discharge into the muscular organs for the prehension and buccal examination and preparation of food. In this region enter the impulses from the organ that, comparably with the visual, forms the basis of an enormous superstructure of highest nervous reaction, and a medium for communication of feelings and ideas. Thirdly, into it pour the vestibular impulses informing as to position of the head, and so in great measure as to position of the body as a whole, and thus regulating the activity of great fields of skeletal musculature.

A number of "centres" are described in this metencephalic floor, many of which can be inferred directly from its efferent root cell groups. Among the reflexes localised within it may be mentioned the following:—Closure of the eyelids on touching the conjunctiva, in man

¹ Lngaro, *Untersuch. z. Naturl. d. Mensch. u. d. Thiere*, Bd. xv.; Cajal, "Apuntes para el estudio del bulbo, etc.," Madrid, 1895; van Gehuchten, "Le système nerveux," 2nd edition, Gand, 1896; v. of either eye (conjunctival reflex). Various stimuli, especially to the region of the first and second divisions of the fifth nerve, provoke this. Its period has been found to be particularly short, even as low as .035 sec. (Mayhew),¹ more frequently, .04 sec. A flash of light produces the same movement less quickly .08 sec. (Garten).² Excitation of the pinna or dura mater also elicits the closure. Excitation of the buccal mucous membrane near the canine tooth has been noted to very constantly evoke retraction of the lip (*reflexus ultimus*, Dastre). Twitching of the pinna on stimulating its skin is also obtained in part from this region, and is a very constant reflex in the cat.³ All these are reflex actions not early

annulled by narcotics. The conjunctival seems to involve the myelencephalon as well as the metencephalon.⁴ In the rabbit the tonus of the muscles of the pinna falls after severance of the sensory root of the trigeminus.⁵ Binswanger⁶ has called attention to the existence of

mechanisms in the tegmental region of the pons that can, on excitation, evoke convulsive movements of the trunk, neck, and limbs, and can be easily brought into action reflexly by stimulation of the trigeminal nerve.

As a conductor the floor of the metencephalon contains the mesial fillet, with its constituents from the dorsal column nuclei, etc., as elsewhere described. Near it the lateral fillet contains ascending paths from the end nuclei of the auditory nerves, chiefly contralateral. The superior olive is probably of auditory function, to judge from its close connection with this path. In the more lateral region, ascend paths from the ventrolateral column of the spinal cord, chiefly from mediate cells in the opposite half of the grey matter. Some of this path is probably connected with "pain." They are on their way to the roof of the metencephalon (cerebellum) and the mesencephalon. Transection of the dorsal portion of the metencephalic floor to one side only of the median sagittal plane produces (monkey) complete anæsthesia (including analgesia) of the contralateral half of the body, without any paralysis.¹ Of the paths connected with the cerebellum a most notable is, the ascending of the inferior peduncle coming from the lateral column of the cord and Clarke's column of cells (uncrossed mediate cells of the cord). There is also a path conducting upwards from this region into the crossed corpus striatum.² There descend into the pons three main paths from the cerebral cortex, one from the frontal cortex which ends in the grey matter of the pons, a second from the temporal cortex which ends in the grey matter of the pons, and a third, the pyramidal, which only in small part terminates in the pons, in its motor nuclei. Of these the fronto-pontine is the most lateral, the temporo-pontine the most median. Among the fibres of the pyramidal tract which end in the pons, some have been traced to the crossed nuclei of the motor fifth and seventh, and some also to the homonymous nuclei. From the "reticular formation" of the pons a descending path passes into the ventro-lateral columns of the cord, partly decussating in its descent; the crossed path lies more dorsal in the cord than the uncrossed. Of their function nothing can with certainty be said. There pass through the reticular formation of the pons paths descending from the mesencephalon (red nucleus and anterior corpus quadrigeminum) to the ventro-lateral column of the spinal cord. Both these paths are mainly crossed ones. The posterior longitudinal bundles form two more paths, chiefly descending. They in part mediate between the motor cell groups of the ocular and other muscles. This explains, perhaps, the elicitation of eye-movements, like those obtainable from the anterior corpus quadrigeminum, from the floor of the fourth ventricle behind the *nucleus abducens*.³

THE CEREBELLUM.

Excitation.—Ferrier⁴ discovered (1873) that faradic excitation of the cortex of certain parts of the *superior vermis*, and postero-superior part of the lateral lobe, evokes in the dog and cat conjugate movement of the eyes *toward* the homonymous side; in the rabbit the movement obtained from the lateral lobe was sometimes not conjugate. Similar conjugate movements he obtained later⁵ in the monkey, also in that animal pure conjugate upward and downward movements of the eyes elicitable from the middle line of the *superior vermis*. From the flocculus was elicited

conjugate rotation of the eyeballs around their anterior-posterior axes. With the movement of the eyeballs occurs constriction of the pupils, chiefly of the homonymous eye, and turning of the head in the same direction with the eyes. Movement of the limbs of the same side as the excitation was also elicited. In the pigeon he obtained drawing of the head backward and to the homonymous side, flapping of the homonymous wing, and flexion of the homonymous leg. In the carp he found curving of the tail to the homonymous side, spreading of the homonymous fins, and movement of the homonymous eye. He pointed out that the relation between the cerebellum and the musculature of limbs and trunk is therefore, unlike that between the latter and the cerebrum, an homonymous one; and similarly that cerebellar connection with the eye muscles is, as regards relations of laterality, the reverse of that possessed by the cerebral hemisphere. His experiments appear to have been the earliest to decide these important points. Hitzig,¹ Nothnagel,² and Dupuy³ also have obtained definite muscular reactions by localised excitation of the cerebellum, and believe the excitations originate sensations of a painful character.

It has been found, independently by M. Löwenthal and myself,⁴ that excitation of the cerebellum, as of various other parts of the central nervous system, can not only excite contraction of the muscles, but can inhibit contraction. Certain forms of tonic spasm in various parts of the body relax on excitation of the cerebellar surface. When "decerebrate rigidity" has developed, it can be inhibited by faradisation of the anterior (cerebral) surface of the cerebellum at points (in the monkey) over a large area extending from near the middle line far out toward the lateral border of the cerebellar surface.⁵ Faradisation at these points causes immediate relaxation of the rigid neck and tail muscles, and of the rigidly fixed joints of the limbs, especially of the fore-limb, and especially of the *same* side as the site of excitation in the cerebellum.

Lesions of the cerebellum.—The earliest experiments in which successful recovery was obtained from ablation of the cerebellum (and cerebrum) in higher animals, seem to be those by du Verney in 1697.⁶ He noted that there remained still some "use of sense." Little progress was then accomplished until Rolando⁷ (Sassari, 1809); from that time onward a number of workers followed in this field.⁸ Flourens affirmed that removal of even considerable portions of the

⁷ "Saggio sopra l. vera struttura d. cervello, etc."

⁸ Between du Verney and Rolando the chief experimenters studying destructive lesions of the cerebellum were:—Lorry, *Hist. Acad. roy. d. sc.*, 1749, tome iii. p. 344; Haller and his pupils, especially Zimmermann and Zinn, and Saucerotte later in 1769. After Rolando the more important contributions in the same line have been the following, and chiefly on them the present section of this article is based:—Flourens, "Rech. exp., etc.," *Mem. Acad. d. sc. de l'Inst. de France*, Paris, 1822; Magendie, *Journ. de physiol. expér.*, Paris, 1825, tome iv. p. 399; Desmoulins, "Anat. des systèmes nerv.," Paris, 1825; Hertwig, "Exper. quædam," *Inaug. diss.*, Berlin, 1826, S. 151; Serres, "Anat. compar. d. cerveau appliquée à la physiologie," Paris, 1826; Bouillaud, *Arch. gén. de méd.*, Paris, 1827, tome xv. p. 64;

cortex does not entail clear or obvious symptoms; but that pronounced disturbances ensue on injuring the deep structures. Experiments by Thomas¹ show, however, that purely cortical ablations of cerebellum produce symptoms similar in type, though not so severe, as those entailed by injury of the deep nuclei and tracts. Very extensive removals of cortex induce symptoms of full and long-lasting severity.

Unilateral ablation.—The phenomena observable in a mammal after ablation of a lateral (*e.g. right*) half of its cerebellum may be briefly sketched thus.

No symptom is noticeable until the deep chemical narcosis employed during the operation has diminished. The animal then lies on the right side, with neck and trunk curved concavely to the right, and with some torsion of the unsupported head, so that the occiput tends to the right, but the muzzle rather to the left of the median position, and the left ear rather higher than the right. The limbs, especially the fore-limbs, are stiffly extended, the right more than the left. There is some abduction of the right limbs. There is often conjugate deviation of the eyeballs to the *left*. The animal cannot stand; it falls to the right side, that is, so that its right side is undermost. It may, if it try to move, roll round the long axis of its body, with a movement continued in the same direction as its fall. The movement of rotation may be accompanied by lateral nystagmus, the slower slipping over of the eyeballs being from right to left, the return snatches in the reverse direction. The majority of observers believe that muscular weakness as well as spasm exists, especially in the right limbs. The next three or four days witness considerable recovery from some of these symptoms, and it is found that the tendon phenomena are brisk in the spastic limbs, therefore

¹ *Loc. cit.*

especially in the right. When suspended, the animal now exhibits less pleurosthotonus (concavity, to the right). The right forepaw often lies folded in the supine position, a sign significant of paresis. It can now be seen, if the animal tries to raise itself on its fore-limbs, that tremor, which may be present even when the animal is at rest, prevents the attempt, becoming very severe. The hind-limbs seem weaker than the fore-limbs, but the extensor rigidity is more marked in the fore-limbs (in the dog and cat, etc.; in the monkey (Luciani, Ferrier and Turner) the rigidity assumed is flexor, not extensor (at elbow and knee). Some days later the power to stand is regained, the fore-limbs becoming able to carry the

FIG. 363.—Posture assumed after removal of the right half of the cerebellum.—Thomas (from an instantaneous photograph).

body earlier than the hind-limbs. When first attempting to walk, the hind-quarters drag or crouch, so that in the latter case the rump stands lower than the shoulder. Tremor and lateral oscillation, especially of neck and trunk, disturb every effort. If an obstacle be met in walking, the tumble occurs to the right, although the right limbs are widely abducted. Progression follows not in a straight line, but the main direction is broken by curves, is "festooned" to the right. The paces taken by the widely abducted legs are short. The whole gait is a reeling one. The right paws are lifted and set down again with an abnormal abruptness and with exaggerated muscular action, as compared with the less abnormal side. The knee-jerk is often found to be more

FIG. 364.—Foot-prints of a normal dog. *p*, walking; *g*, galloping.—Luciani.

brisk on the homonymous side. Placed in water, the animal swims better than it can walk; in swimming, the direction of progression is curved toward the *left*; the left side of the body is plunged deeper than the right. In attempting to walk up steps, the left foot is used first. After the eyes are bandaged, any attempt to remove the bandage is made with the left foot.

The head and neck are at every effort so disturbed, by swaying and tremor, that feeding is impossible unless the head be held fixed for it. The muzzle is plunged deeply into the food, or sways about helplessly over it. The inco-ordination is not obviously increased by bandaging

the eyes. The performance of every movement quickly produces great fatigue. Sight, hearing, and cutaneous sensation seem normal. Gradual improvement succeeds in effacing more or less completely the worse degrees of the above disturbances; they persist obviously in running longer than walking; an unwonted movement is apt to produce them again, after they have disappeared from the more ordinary movements; thus the dog in shaking itself after a swim is apt to shake itself off its balance, falling to the right. It is especially long before the dog recovers his habitual bark. Entire disappearance of the symptoms has not been obtained. Some glycosuria is usual in the early stage, and the animal is for a long time thin, voracious, and depressed; perhaps the longest of all symptoms to persist is tremor, when a strongly-willed movement is executed. Cerebellar tremor is one of the most exquisite examples of "intention tremor," *i.e.* of tremor marking movement that is "willed."

Ablation of the whole cerebellum.

—The disturbance ensuing immediately upon ablation of the whole cerebellum appears at first sight less severe than that following removal of a lateral half of it. Opisthotonos, retraction of the neck, throwing up of the chin, tonic extension and abduction of the limbs, especially of the fore-limbs, are

FIG. 365.—Footprints of a dog ten days after ablation of the middle lobe of the cerebellum.—Luciani.

simply the bilateral duplication of the former picture, the asymmetrical distortion of which is reduced to symmetry by doubling the insult. The progress toward recovery is, as might be expected, more slow than after unilateral ablation. Every attempt to move induces tremor and oscillation, and long remains abortive. Swimming is much easier to these animals than is walking (Luciani).¹ "I kept for eight months a water-dog from which I had removed the cerebellum; he made hardly any progressive movement during all that time except when I placed him in water" (Magendie).² The muscular power of the body is weakened in *all* regions (Luciani), most notably in the hind-limbs and

¹ *Loc. cit.*

² "Physiologie," Paris, 1817.

in those which fix the vertebral column. Unsteadiness is most marked in the movements of the neck. A residuum of disturbance of motility is permanent; but in Luciani's dog, which lived for two years after ablation of the whole cerebellum (except for two small pieces adjoining the flocculi), improvement (compensation) progressed for about a year. The hind-quarters remained weak, tremor persisted in the muscles which fix the head, and the movement of the eyes and limbs, especially of the fore-limbs, were not perfectly harmonic. The senses and intellect remained perfect, and the animal could swim, run, jump, and feed itself. On the whole, perhaps the most significant symptom of cerebellar ablation is the tremor which disturbs willed movements—"intention tremor." I have myself seen it in the dog persisting two years after an ablation of almost the whole cerebellum. The animal when resting, *e.g.* lying in his cage, exhibited no tremulance; but on being called to activity, especially when released from his cage, and free and evidently pleasurably excited by his freedom, one saw almost his every motion shaken by tremor.

Destruction of the middle lobe.—The main phenomena following

FIG. 366.—Gait after destruction of the *vermis*; the fore-limbs are abducted, the hind are abducted and protracted.—Thomas (from an instantaneous photograph).

this lesion are opisthotonos, retraction of the neck, vertical nystagmus, abduction and extension of all four limbs (especially of the anterior), some weakness and tremor in all four limbs (especially in the posterior). When trying to walk forward, the animal often, instead of advancing, retreats.¹ These disturbances subside much more rapidly and completely than after ablation of the whole cerebellum.

Bisection of the cerebellum.

—The splitting of the organ into its two lateral halves by a clean incision is followed by disturbances closely like those following ablation of the *vermis*, but of less severe and less persistent character. "The animal seemed alternately impelled to right and to left, without preserving a fixed position; it first rolled a turn or two to one side, and then changed, as for relief, to turn as many times in the opposite direction."² As an early symptom it generally induces a tonic extensor rigidity, comparable with the extensor form of decerebrate rigidity.³

Ablation of the cerebellum in the bird.—In the pigeon,⁴ ablation of the cerebellum similarly produces malposture and a status in which each intentional movement is hampered or thwarted by uncontrollable deviation from the desired direction; abrupt oscillations seem grafted upon the movements executed. It is impossible for the animal to perch, the legs and talons being stiffly extended. In attempting to walk, the limbs become seized with extensor spasm; the animal falls; wild struggling of limbs, body, and head sets in, to terminate only in utter exhaustion. There is obvious difficulty in bending

² Magendie, *loc. cit.*

³ Sherrington, *Journ. Physiol.*, Cambridge and London, vol. xxii. p. 319.

⁴ Flourens' classical observations (1822) were chiefly on the pigeon.

the neck downward, and when the head is at last sufficiently lowered it is liable to be suddenly and uncontrollably drawn back (Schiff,¹ Lange²); hence the animal cannot at first feed itself. The difference between this condition and that resulting from ablation of the cerebral hemispheres is very marked. "Take two pigeons," wrote Longet, "from one remove the cerebrum, from the other only half the cerebellum; next day the former will be firm on his feet, the latter will reel and struggle like a drunken man."³ But the severity of the disturbance soon diminishes.⁴ It is notable that flight very rapidly recovers. Pigeons soon fly adroitly and turn apparently perfectly in the cramped space of a room. Walking is more slowly and less perfectly regained. In the decerebellate pigeon it can be seen that the front digits are over-extended when it walks, and the hind digit does not touch the floor at all.⁵ Perching remains a difficulty for a long time; at the moment of alighting, the legs and talons become suddenly rigid in extension, defeating as it were their own intention. The move-

FIG. 367.—Pigeon after removal of the cerebellum (Dalton).

ments are most distraught when the creature is excited and seems at greatest pains to execute them.

Ablation of the cerebellum in lower vertebrates.—In the lizard and tortoise, little disturbance appears to result from ablation of the cerebellum.⁶ Dickinson says that when in the snake the lateral connections of the cerebellum are severed on one side, the animal's posture becomes twisted to a spiral.

In the frog the cerebellum is small, a simple transverse band jutting over the fourth ventricle. Many observers state that its removal or destruction occasions no obvious departure from normality. But Budge⁷ noted that after ablation of one lateral half, *e.g.* right, the animal sits with the right side lower than the left, with the spine concave to the right, and with the digits of the left hind-foot extended. The animal can be made to lie on its right side, but never on its left. In crawling or springing forwards, there is deviation towards the right. Goltz⁸

⁸ *Loc. cit.*

further found that *after* removal of the cerebrum and optic lobes, ablation of the cerebellum rendered the movements of progression, which previously were quite possible, unsteady and well-nigh impossible.

In fish, all observers¹ seem agreed no obvious disorder of locomotion ensues on destruction of the cerebellum, unless deep and perhaps extraneous connections are injured. Loeb and Steiner have recently confirmed this in *Squalius* and in the shark, in both of which the cerebellum is large.

Phenomena caused by section of the cerebellar peduncles.—**Section of the anterior (superior) peduncle.**—Section of the anterior peduncle, after it has crossed the median line and is in the tegmentum, causes rolling round the long axis from the side of the lesion toward the sound side (Longet, Lafargue, Lussana, Lemoigne,² etc.), as does injury to the posterior part of the optic thalamus (Flourens, Schiff, Lussana, etc.).³ The homonymous limbs are abducted, the crossed adducted (Lussana).⁴ The direction of progression swerves toward the crossed side.

Its section before the decussation, near its exit from the cerebellum, causes disturbances similar to the foregoing, but in the opposite direction (Lussana, etc.).⁵ Ferrier and Turner⁶ noted also tilting of the chin to the crossed side, the occiput being drawn to the homonymous side, and (in monkeys) flexion and adduction of the homonymous limbs, with tremor in them, increased on exertion, and reluctance to use them. Intense perturbation and swaying of the body on the slightest attempt at movement was present at first, but soon passed off. The knee-jerk was brisker on the homonymous side.

Section of the middle peduncle.—Rolling round the long axis of the body⁷ and deviation of the eyeballs⁸ have long been known and studied in connection with this peduncle. Much controversy has taken place as to the direction of the rotation. Magendie described the rotation as occurring from the sound side toward the injured, the deviation as toward the sound side, the homonymous eye turning forward and downward, the crossed backward and upward. The same result was obtained by Schiff, Budge, Lussana,⁹ etc., when following Magendie's mode of operation, also by Ferrier and Turner,¹⁰ following a different and more exact method of section. Magendie's result is similar to that obtained by lateral ablation of the cerebellum itself. Longet's method,¹¹ in other hands as well as in his own (Schiff, Lussana, Lemoigne),¹² causes rotation *from* the side of the lesion. Rotation in a similar sense to Longet's is produced by Bernard's glycosuric piqûre,¹³ by evulsion of the facial nerve,¹⁴ scratching the pons in neurectomy of the trigeminus. It is also seen sometimes as a first and quite transitory effect of Magendie's section,¹⁵ and is then soon replaced by the reverse and comparatively permanent rotation.

¹ Desmoulins, Vulpian, Philipeau (with Vulpian), Ferrier, Bandelot, Steiner, *loc. cit.* But Dickinson reported "loss of balance."

The difference between the effects of Magendie's and of Longet's sections is *not* one of mere description. Magendie's section implicates especially the posterior part of the pons, and Longet's especially the anterior; the explanations offered by Schiff¹ and Longet² do not appear to me satisfactory.

Suppose the right peduncle cut. The animal bends its neck toward the right shoulder, its chin toward the left (as though the left sternocleido-mastoid muscle had been paralysed), the right shoulder is turned toward the breast, the left toward the back, and thus the cephalic half of the animal has turned through an arc of about 90° on the pelvic half. This is so long as the animal rests quiet; when it tries to move, the torsion of the body is converted into actual revolution about the long axis. The rate of rolling has been described to be as high as fifty turns a minute. It may persist for days, but gradually passes off; it leaves a permanent inability to turn the head to the left (Lussana).³

With the rolling and ocular deviation usually coexist incurvation of the trunk to the side of the lesion, some lateral nystagmus, adduction and ataxy and tremor of the homonymous limbs, abduction of the crossed limbs. In the dog and rabbit the limbs are extended, but in the monkey the homonymous limbs are flexed (Ferrier and Turner).⁴

Section of the posterior peduncle.—This experiment has been practised very frequently from the time of Rolando⁵ and Magendie⁶ onwards, and there exists little or no discrepancy in the observations. The phenomena ensuing are incurvation of neck and trunk to the side of the lesion, falling *to* that side, deviation of the eyeballs *from* that side; adduction of the homonymous limbs, with ataxy and tremor in them; abduction of the crossed limbs; tendency to roll toward the side of the lesion, and some twisting of the head, so that occiput points to lesion, chin in the direction of the eyes. Ferrier and Turner,⁷ the only observers who have employed monkeys, noted in that animal tonic flexion in the homonymous limbs, tonic extension in the crossed; but this characteristic position was not so persistent as incurvation of trunk, tendency to roll, and tremor on movement.

Bilateral section of the peduncles.—It has been shown by many observers, *e.g.* Magendie, Lussana, that the rolling movement ensuing on section of *one* peduncle can be cut short by a symmetrical section of the opposite peduncle.

Phenomena of cerebellar origin in human disease.—On turning to the symptomatology of cerebellar disease for help toward the understanding of the functions of the organ, we find that the clinical material must be much sifted, to yield secure data for the purpose. No detailed attempt of that kind can have space here. But the following can be said:—A reeling gait, oscillations of the body which may impart a zigzag direction to the walk, difficulty in standing upright owing to unsteadiness of limb, are common phenomena in cerebellar disease. Occlusion of the eyes does not augment the unsteadiness or "reeling;" hence there is no "Romberg's sign." The arms are less unsteady than the legs, but the handwriting is shaky. Sometimes there is swaying of the head, and very usually a peculiar "scanning" quality of speech, in which the syllables come haltingly evolved. Giddiness may be

¹ "De vi motoria baseos encephali," etc., Francofurtum a/Main, 1845.

⁷ *Loc. cit.*

troublesome; also nystagmus (sometimes lateral, sometimes not). Nystagmus, unsteadiness, and giddiness may be associated, but are often apart, and there seems no necessary cerebellar connection between them.¹ Tetanoid rigidity with retraction of the head has been noticed.² Illusions of rotatory movement, actual imperative movement of head and eyes to one side, or actual imperative rotation of the body about its own long axis,³ have been well recorded symptoms, especially where the lesion has been found localised in a middle peduncle. Where the lateral lobe has been the site of lesion, there have been among the symptoms⁴ paresis of the homonymous arm and of the legs, and in those limbs instability and tremor in volitional effort; conjugate deviation of eyes, and of the head away from the side of the lesion; lateral nystagmus, the jerks being toward the side of the lesion: these signs, co-existing with an intact cutaneous sensibility, and without alteration of psychical condition, compose a series absolutely accordant with Luciani's⁵ descriptions of the symptoms in the dog and monkey. Just as, *e.g.*, in Luciani's dogs, the legs are set widely apart, as if to enlarge the basis of support, and the steps taken are abrupt and short.

Especially valuable from the present standpoint are observations upon cases of atrophy or agenesis of the cerebellum. Occasionally there come to light congenital defects, amounting to absence of one cerebellar hemisphere.⁶ In such instances the huge defect has, in more cases than one, occasioned practically no symptoms whatsoever. Movement has been neither uncertain nor tremulous. In one case, the right being the hemisphere lacking, the person had "a habit" of keeping the head turned somewhat to the left; in childhood, it was stated there had been "restlessness" of the head. Of unsteadiness of attitude or of gait, of weakness of the limbs, nystagmus, peculiarity of speech, vertigo, or defective sensation or intelligence, it is certain there was no trace. The knee-jerks were normal and equal right and left. Further, in other instances there has been arrest of growth or atrophy of almost the whole, indeed of the whole, cerebellum.⁷ Not a hundredth part of the cerebellum has remained, and yet ability existed to stand, to walk, to handle and lift objects; in fact, a very fairly normal condition of volitional motility was preserved. Noteworthy in the records of such cases is absence of detection of any trace of impairment of cutaneous sensibility. The remarkably negative character of even extreme cases of atrophy or agenesis is paralleled by the frequency with which cerebellar lesions of even large size but non-irritative type await unsuspected a post-mortem revelation.

Inferences regarding function of the cerebellum drawn from comparative anatomy.—Unlike that of the cerebral hemispheres, the development of the cerebellum does not consistently and directly increase with progress upward in the grades of animal hierarchy. The cerebellum is found developed in extremely various degree in closely allied forms. Many forms higher, on general grounds, have simpler cerebella than some which are much lower. The crawling reptiles possess less cerebellum than the great swimmers, the Teleosteans and Selachians. In birds the cerebellum is relatively enormous, but even in them it consists entirely of the median vermis. In mammals the lateral lobes appear, small in the Marsupials, larger in the Carnivora, largest in the apes and man. The lateral lobes have

⁶ Lallement's case, *Bull. Soc. anat. de Paris*, 1862; Hitzig's case, *Arch. de neurol.*, Paris, 1884; Neubürger and Edinger's case, *Berl. klin. Wchnschr.*, 1898, S. 69.

⁷ Combettes, *Bull. Soc. anat. de Paris*, 1831; Shuttleworth, *Brit. Med. Journ.*, London, 1885, etc.

been supposed to be developed in connection with the part played by the limbs in locomotion. But their absence in birds and frogs and their remarkably large development in the Cetacea negatives such a view; the experiments above related have moreover shown that the vermis is connected with limb as well as with trunk muscles, and the lateral lobes with the trunk as well as with limb muscles. The deduction has been made, that size of cerebellum is related to degree of locomotivity. But the smallness of the frog's cerebellum is against that. Its size does, however, seem connected with range and variety of movement in some way; the cerebellum of the albatross is very large among birds. On the whole the suggestions given by mere gross anatomy have been in the case of the cerebellum more than usually unfortunate.

In the development of the organ it is interesting that even the azygoid median lobe makes its appearance as a pair of lateral structures. Further, that the organ is by its ontogeny a portion of the sensory region of the neural tube. Histological completion of its tissue, to judge by date of myelinisation, occurs first in the vermis and in the flocculi,¹ and is in the lateral lobes very much later; this agrees with the late appearance of the lateral lobes in the phylogenetic history of the organ.

Functions of the cerebellum.—It remains to attempt to form a conception of the functions of the cerebellum. For such an attempt two steps are to be taken: the tracking down the fundamental mischief at the root of the raw "symptoms" catalogued above; the drawing from this mischief inferences regarding the share taken by the cerebellum in the work of the nervous system.

The former problem may best be attempted by discussing an able analysis offered by Luciani. As first pointed out by Flourens, injury of the cerebellum causes inco-ordination of movement—ataxia. Much of the clumsiness of movement of the first (ten) days after cerebellar injury, Luciani ascribes to the tonic spasm existent in certain muscles, or, if not actually existent, liable to appear at the moment of active innervation. This tonic spasm and overaction renders certain groups of musculature unmanageable. This spastic rigidity affects especially the lateral and extensor muscles of the trunk and neck, and the extensor and abductor muscles of the fore-limbs (dog; in monkey the flexors and adductors).² The more permanent inco-ordination evident after the period of rigidities has passed is considered by Luciani to be associated with, and probably due to, three defects of neuro-muscular action, namely, to *parasthenia*³ or defective force, *paratonia* or defective tone, and to *astasia* or unsteadiness of contraction. The three defects accompany each other, and affect, after total ablation of the cerebellum, the muscles of the body everywhere (Luciani), but predominantly the muscles of the loins and hind-limbs, and the muscles fixing the head.

Concerning the parasthenia, Luciani points to his direct dynamometrical observations; he found, *e.g.*, the movements of the homonymous limbs weaker than those of the crossed side; his dogs in swimming circled *toward* the crossed side, although in walking they deviated toward the homonymous side.

Concerning the paratonia, Luciani points to the slackness of the

¹ Alexander Bruce, *Brain*, London, 1895, vol. xviii.

² Luciani, Ferrier, and Turner, *loc. cit.*

³ Luciani has applied the full negative in his nomenclature, but as he does not use the terms in the sense of complete deprivation, I venture here to modify his "asthenia" and "atonia" to "parasthenia" and "paratonia."

muscles, their flaccid feel, the semiflexed droop of the limbs, which, as the animal stands, sometimes appear to give way under it, especially if the animal's attention be suddenly diverted. An illustration of the paratonia is afforded by the slow slipping over of the eyeballs to the crossed side, after the return jerk of nystagmus has replaced them in the normal "forward" pose. The tonus of the lateral muscles pulling toward the lesion seems insufficient to balance the tonus in the muscles which swing the eyeballs in the opposite direction.

The astasia of muscles, a tremor heightened or only appearing when the musculature is set into action, Luciani attributes to imperfect fusion of the simple contractions, which on the "tetanus" theory compose willed contractions. It affects especially the muscles fixing the head, and occurs in monkeys more markedly than in dogs. This is his explanation of the "intention tremor." Some features of the peculiarity of movement in both the early and later periods are no doubt due to actions intended to correct the defects and disabilities. The animal more or less rapidly learns by the experience of many failures, *e.g.* falls, deviations in a particular direction, etc., to correct its mistakes as they arise. Among such compensatory acts may be probably the spreading of the limbs to right and left to give to the body a wider basis of support; also, perhaps, the incurvation of the trunk toward the side which is the weaker. The dog that as a result of removal of the right cerebellar hemisphere forges to the left in swimming, learns to swim straight by keeping the lumbo-sacral part of the vertebral column curved appropriately to the right. By such compensatory innervation as this the ataxia is gradually more or less successfully hidden. Luciani found that ablation of the Rolandic area of the cortex of the cerebral hemisphere largely hinders the development of this compensation for cerebellar defect. He urges on various grounds that the cerebellum has an important influence upon the activity of the Rolandic region of the cerebral cortex, the left half of the cerebellum acting on and with the right hemisphere of the cerebrum. The influence he describes to be of a tonic and trophic nature, modifying the excitability of the Rolandic cortex in a way comparable with that in which the afferent spinal root modifies the excitability of the motor nerve cell. Bianchi, as a test of the excitability, is reported to have faradised the sensori-motor cortex some days after ablation of the crossed half of the cerebellum, without obtaining results which to his mind establish clearly a departure from the normal excitability of the cortex. Similar experiments have been made by R. Russell and Luciani, the former concluding that the excitability may be raised, the latter concluding that the excitability is in some points of the Rolandic area exalted, and in others depressed. Luciani finds his "cerebellar influence on the cortex," trophic as it is and thereby affecting excitability, chiefly effective on the Rolandic region.

Regarding the field of distribution of the motor effects, both of spastic and of asthenic type, it is clear that each lateral half of the cerebellum mainly affects its own homonymous half of the body; it is in the eyeballs and hind-limbs that the more marked instances of any bilaterality of its action are seen. It may be, however, that almost the whole musculature is represented in each half of the cerebellum, and Luciani points out that after total ablation of the cerebellum the defect is *everywhere* greater than after lateral ablation.

There is no evidence that purely cerebellar lesions impair instinct or intelligence.

Regarding sensory defects, Luciani, one of the earliest to hold that sensory disturbances are caused by destruction of the Rolandic cortex, finds none after ablation of the cerebellum, confirming in this respect the original observations of Rolando and Flourens. Clinical observations, in this respect especially valuable, are accordant with their views. There is, however, clearly one sensory disturbance, namely, vertigo; animals often indicate it by their actions, patients describe it. It may be asked whether the vertigo is not secondary to abnormal movements of the eyes, etc. It is not so, for it occurs in absence of the eyeballs, and is said clinically to occur sometimes apart from any obvious inco-ordination. To interpret this vertigo, disturbances other than cerebellar occasioning vertigo may be recalled. These include, besides ocular squint, many spatial positions and movements unwonted to the body: the looking from a height, the gliding over ice, sea travel, to some even travel by train or the covering of one eye. Common to all these conditions is the synchronous rise of perceptions of spatial relations between the self and the environment which have not, or have rarely before, arisen in synchronous combination. The tactual organs of the soles and the muscular sense organs of limbs and trunk are originating perceptions that indicate that the self is standing on the solid earth, yet the eyes are at the same time originating perceptions that indicate that solid earth is far away below the standing self. The combination is hard to harmonise at first; it is at least not given as *innately* harmonised. The conflicting senses occasion the feeling of giddiness. The cerebellum has paths to it from most, if not from all, afferent nerve roots. But to one of these it stands associated especially closely, so closely that, as its place in the neural axis implies, it may be regarded as having been evolved above that root, namely, the vestibular, the nerve of the semicircular canals, the sense organs furnishing data for the appreciation of positions and movements of the head. Traumatic like other abnormal irritations of this nerve or of the cerebellum originate sensations at variance with those derived from other sources contributing to the space perceptions of the moment. The movement of the body becomes thus imperfectly adjusted to the spatial requirements of the act it would perform. Giddiness also supervenes. Giddiness appears a symptom of only the irritative period of cerebellar lesions; and is less marked in cerebellar than in labyrinthine or eighth nerve lesions. Since with huge cerebellar defect all conscious sensation may remain good, the failure of the sensorial adjustment of the body's movements to outer space-relations in consequence of cerebellar lesion must be ascribed to loss of impulses which regulate body-movements without being on their way into or within the cerebellum elaborated to conscious sensations.

Though some degree of imperfection of the movements persists long or always, the above loss of direct unconscious co-ordination may in large part be compensated, it would seem, by conscious sensations (perceptions). The movements thus compensatorily regulated, although correct, strike the observer as under constant guidance by attention and wanting the natural ease of automatic consummation.

Clinical experience even more than experimental indicates that if

the lesion occur early before the mechanisms of the nervous system have lost in some degree their pristine elasticity, and if sufficient length of time be then allowed them, injury to the cerebellum, even though large, can be to an extraordinary extent compensated, and its evil overcome. Man with one-half of his cerebellum congenitally gone can pass muster among his fellows as normal both in mind and body. Such adaptive compensation is as striking as the instances that occur in animals after removal of portions of the cerebral hemisphere¹ or removal of the otic labyrinth.² Luciani's searching investigations have indicated that it is in the crossed hemisphere of the cerebrum itself that this compensatory mechanism must be looked for, at least in major part.

The second step toward interpretation of the cerebellum is already partly prejudiced in the procedure toward the first. The main fact available from the study of the structure of the organ is its extraordinarily rich connection with afferent nerves. The main phenomena displayed by cerebellar excitation and destruction are, on the other hand, not sensory but motor in kind. The action of the cerebellum must lie, therefore, somewhere within this gap.

A notion tacitly admitted above, in dealing with the disturbances ensuing on cerebellar lesion, supposes that ablation is followed by "irritative" signs at first, and then by signs of pure defect. Luciani has dealt with the discrimination between the two. He finds the former accentuated when the lesion involves the peduncles. It must be remembered that a peduncular lesion is the exact kind of injury which breaks the greatest number of paths with the least mechanical disturbance. If I take his meaning rightly, its argument is as follows. The cerebellum is an organ acting in a tonic and trophic way upon the sensori-motor (Rolandic) sphere of the cortex cerebri and on other parts. An immediate accompaniment of a mechanical lesion of the cerebellum is excitement of the organ in the vicinity of the lesion. This affects organs influenced by cerebellar activity, the effect simulating increased cerebellar action. This "irritative" effect of the lesion lasts, maintained by chemical and mechanical changes at the seat of injury, for a considerable time, some days at least. To it succeeds a period in which the excitation due to irritation having subsided, the results of deficient action of the cerebellum lie unmasked. There appear to me objections to this view. (1) The symptoms ascribed to irritation are hardly sufficiently the converse of those of defect, *e.g.*, the spastic extension and abduction of limb characteristic of the first stage might on this hypothesis be expected to give way to marked flexion and abduction in the second. (2) The immediate though almost momentarily transient effect of severing a peduncle is the production of an attitude truly the converse of that which very quickly later, on completion of the severance, ensues in permanence.³ It would be useful to know what is the movement elicited by electrical excitation of the peduncles. If the attitude be the converse of that produced by ablation, the explanation of the latter cannot well be irritative. Ferrier's excitations of cortex

³ For instance, see Budge, "Lehrbuch d. speziel. Physiol. d. Menschen," 8te Aufl., Leipzig, 1862; Lussana, *loc. cit.*

cerebelli produced in the head and eyes a turning to the homonymous side, the reverse direction to that produced by ablation even in the so-called irritative stage. Through the variety of forced attitudes assumed under cerebellar lesions, there is repeated a group of features, suggesting that the cerebellum reacts upon some focus of innervation in which the motor elements of that group are knit together to an entity. The turning of the head, the lateral deviation of the eyeballs, the pleurosthotonus, the extension of elbow, can all be evoked from the extreme posterior end of the optic thalamus, as if from a focus for a co-ordinate movement in which these components existed. It is perhaps on this that a cerebellar influence is exerted. As to the direction of its influence, it seems probable that the clean removal by a skilled experimenter of a portion of cerebellum leads, though its effect at first be compounded of irritation and deficiency, almost at once to a result in which deficiency is dominant. The interpretation of the irritative symptoms would then be, that in the organ from which Luciani's tonic and trophic cerebellar influence was removed, there ensued for a time an overaction, comparable to the profuse paralytic secretion of a submaxillary gland after section of its nerves—comparable, in fact, to an escape from control; such overaction would of itself entail after a time exhaustion. This phenomenon would come under the class of "isolation dystrophies" already spoken of. Luciani, in describing the influence which the cerebellum exerts upon the cerebral cortex, compares it luminously to that exerted by the afferent spinal root upon the motor nerve cells. It would represent his view hardly fully, perhaps, to say that the cerebellum maintains the tone of certain "muscular" regions of the cerebral cortex. From the construction of the cerebellum it is clear that it may act as an adjuvant to the Rolandic cortex in one or all of several ways as follows:—

1. The afferent impulses gathered up from the cord, the trigeminus, and especially the vestibular nerve, may, acting through the cerebellar cortex, and then the corpus dentatum and crossed rubro-thalamic nuclei, finally react on the cerebral cortex, mainly of the side opposite to that whence they started. Such a path of action is implied in the view of cerebellar action sketched by Gowers. Impulses coming from muscles and ligaments, originated by contractions and tensions, impulses from the semicircular canals and from the muscles of the eyes, impressions not affecting consciousness, reach the cerebellar cortex, and thence react mainly on the Rolandic region of the cerebral cortex. Such a view does not deal with the middle peduncle nor with the afferent portion of the posterior. It brings forward clearly, however, a cerebellar factor in the "tonus" of the cerebral cortex.

2. The afferent impulses gathered up from the cord and cranial nerves, especially from the vestibular, may, acting through the vermis, react upon the cerebello-spinal and vestibulo-spinal efferent systems, and through these last contribute a necessary factor to the normal tonus and excitability of the spinal and cranial motor root cells. If this factor in the normal condition of the motor root cells were wanting, they might be expected to reply in various abnormal ways under excitation from the cortex.

3. Each half of the cerebellum receives a great incoming tract from the pontine nuclei across the median line. There is little doubt that these nuclei are themselves end stations for fibres efferent from centres

further forward, among others from the cerebral cortex. By functional discharge of certain upper and cortical regions, the crossed cerebellar hemisphere may, one can believe, be excited. The cerebellar excitation so evoked can recoil by way of the anterior peduncle on the cerebral hemisphere whence it started. After severing both the anterior (superior) peduncles and the tracts from cerebrium to the pontine nuclei, I found¹ "*decerebrate rigidity*" set in, a condition—opisthotonos, extensor rigidity of limbs, retraction of neck, etc.—closely like that ensuing on ablation of the cerebellum. It would seem that interruption of these peduncles approaches in effect to removal of the cerebellum, a fact which lays stress on the importance of the above cerebro-cerebellar circuit as a factor in cerebellar action. On the other hand, the cerebellar activity excited by action of the crossed cerebral hemisphere can, to judge by the structural connections, react on the cranio-spinal motor root nerve cells of its own side, *i.e.* of the side to which the pyramidal crossing will mainly carry the impulses generated from the cortex cerebri. Thus, one and the same cerebral discharge may perhaps pour upon the motor root nerve cells a combination of cerebral and cerebellar impulses. Destructive lesion of the cerebellum, by rendering the latter impulses impossible, may upset the co-ordination of the movement to be executed.

No fact is clearer in the physiology of the central nervous system than that many movements of great taxic complexity, *e.g.* of progression, etc., can be carried out in a co-ordinated manner in the absence of the Rolandic cortex and of the cerebral cortex altogether. It is also clear that lesions of the cerebellum greatly disturb these movements; the impression that they disturb them preponderantly is perhaps illusory. There is some evidence that these movements are related to the thalamencephalon, much in the same way as higher movements, such as grasp of hand, are related to the cerebral cortex. With the thalamencephalon the cerebellum has the same broad structural linkage as with the cortex, only the linkage seems structurally closer and more abundant. It is to these ties, rather than to those connecting it with the cerebral cortex, that I would relate the disturbance of attitude and locomotion so prominent among the results of cerebellar ablation.

The so to say highly technical movements ordered by the cerebral cortex employ comparatively limited aggregates of musculature, *e.g.*, speech employing the muscles of the oral and laryngeal regions, grasp employing the muscles of a single limb. The muscular mechanisms of progression and pose, the innervation of which may, as above suggested, be centred together, perhaps in the thalamencephalon, are of wider spatial distribution, and employ not one side of the trunk but both sides, not one limb but all four. Often they probably involve the musculature of the entire body. It is because of its intimacy of connection with such movements as these that the cerebellum is an organ which justifies Hesiod's *ὄσφ πλέον ἤμισυ παντός*. The division into hemispheres and middle lobe is founded merely upon gross anatomy. The organ commonly, probably always, "functions" as a whole. Luciani is right to insist on this, and the reason that it "functions" as a whole seems clearly because it is so largely a piece of mechanism that deals with the innervation, not

¹ Sherrington, *Proc. Roy. Soc. London*, 1896, vol. lx.

of this or that piece of musculature, but of the musculature of the body as a whole. The earlier observers, Flourens, Bouilland, etc., stated this when they spoke of the cerebellum as an organ of "equilibration."

In Rolando's "*saggio*" the cerebellum was likened to Volta's then newly invented electric pile, and was argued to augment the power of movements initiated by the cerebrum. Its removal was shown to leave the innervation of certain parts weakened. This view, apart from the crude simile, is to-day accepted in great part; witness Luciani's parasthenia. The rolling about the long axis of the body and other phenomena of similar kind are generally explained by weakened innervation on one side, leading to upset of balance in assumption of attitudes which demand bilaterally symmetrical innervation; the sound side pushes over the weak side. Some¹ have, however, urged that the phenomenon is rather due to abnormal over-action on the part of the stronger side; there is plenty of analogy for this latter view, although specific proof is wanting. Such analogy is found in the fact that severance of afferent spinal roots and that semisection of the spinal cord heighten the spinal reflexes, long and short, in one-half of the cord.² As to the exact nature of the depression of action on the one side, and of the questionable increase of action on the other, there seem as yet insufficient data to discuss these profitably here.

Flourens analysed differently from Rolando. He had, by reason of Legallois's and his own researches on the bulbar *nœud vital*, been faced by the existence of real foci in the nervous system, capable of marshalling a complexus of muscles for orderly accomplishment of a single end. Indeed, Legallois and he had discovered what Bell, having guessed at, had actually groped for by dissection, but, neglecting more delicate and potent means, had failed to reach, namely, the focal centre guiding and co-ordinating the movements of respiration. Flourens translated the disturbances ensuing on destruction of the cerebellum to mean loss of a part possessing ability to co-ordinate the innervations which guide and execute complex movements. By his doing so, the idea of nervous co-ordination was, it seems to me, formally introduced into physiology.

Lussana and Carpenter were the earliest to literally express what Flourens' inco-ordination and the vast afferent connections of the organ conspire to suggest, that we have here in the cerebellum a part of the machinery for, in the widest acceptance of that term, the muscular sense. Impressions originating in the sensifacient organs of muscles, tendons, joints, and ligaments, and those arising in the apparatus of the labyrinth, appear to be transmitted directly or indirectly to the cerebellum. Therein is elaborated reflexly an adjustment of the bodily "me" to the existent and constantly varying spatial relations between that "me" and its environment. The connection of the cerebellum with the vestibular nerve, and so with the labyrinth, is as marked as is the connection between each of these structures and the tonus of the muscles of the homonymous half of the body. Destruction of each lowers the muscular tonus; and I would suggest that reflex muscular tonus bears to these structures the same relation as the reflex movement bringing a luminous image into more central vision bears to the eye and nervous visual centres.

¹ E.g., Brown-Séguard, *loc. cit.*; Vulpian, *loc. cit.*

² See above, p. 865.

"Muscular sense" is a complexus. By its processes, out of a number of contributory impressions collected from various channels, are synthesised specific perceptions. As in the physiological basis of other senses, so here a number of impressions have, apart from and devoid of psychical accompaniment, a reflex influence upon motor (muscular) innervation. It is with this reaction that the cerebellum is, it would seem, employed. That it is apparently devoid of psychical accompaniment need not imply that the impressions concerned in it are crude and inelaborate. The seeming want of reaction of so much of the cerebellar structure under artificial stimulation, and the complex relay system revealed in the histology of the cerebellum, suggest that the impressions are elaborate.

But the results of destruction of the cerebellum show plainly that much co-ordination of muscles is possible in absence of the organ. The ataxies of an apæsthetic limb and of the tabetic patient present instructive differences from cerebellar ataxy. In this latter, there is no ignorance of the malpositions; they are acutely recognised and even anticipated. The dog prepares to lean against the wall to obviate the fall that he expects will happen on that side. In the former ataxia the malposition often remains unnoticed until attention is directed to it by its falling within the central region of vision. The apæsthete and the tabetic are without sensations which the decerebellate possesses, and to the former deprivation of vision, a sense that contributes, not improbably as importantly as the labyrinthine, to the co-ordination of innervation requisite for equilibrium, means a severer loss. Hence Romberg's symptom—staggering on closure of the eyes—occurs with the former but not with the decerebellate condition. The amount of recovery of execution of movement possible to animals deprived of cerebellum is a measure of the potency of the supplementary means for guidance of muscular innervation; many of these may be conscious. In decerebellate animals a phenomenon regarding which observers are unanimous is the profound lassitude which forthwith succeeds execution of movements ordinarily quite unfatiguing. This is probably in large part a mental fatigue, due to strained endeavour to continually obviate, or correct, constantly recurring distortions of movements, keenly perceived at their genesis to be imperfect.

To sum up: the cerebellum is the organ rather of a particular class of reactions than of a particular sense. Its reactions have their sources in the sensifacient organs of various senses, but especially of those pregnant with spatial quality, and in those subserving the "muscular sense," in the widest meaning of that term. It supports the tonus of the majority, perhaps of all, the cranio-spinal motor root cells, of some more than others, *e.g.*, those connected with eye muscles, neck muscles, muscles of the spine. It preponderantly helps to secure co-ordinate innervation of the skeletal musculature, both for maintenance of attitude and for execution of movements. So far as the geotropism and stereotropism of the animal can be "centred" at any one limited field of the central nervous system, that field is cerebellar. It supports habitual posture, and is at least as importantly associated with the movements dependent on the lower cerebral centres (*e.g.* walking, running), as with those elaborated in connection with the highest (*e.g.* technical movements).

MESENCEPHALON OR REGION OF THE CORPORA QUADRIGEMINA.

An afferent root cell system has not been identified in this region, though there are reasons for thinking it exists in connection with sensory organs in the ocular muscles.¹

The efferent root cell system comprises the motor cells innervating all the eye muscles, except the lateral rectus and the dilatator pupillæ. Some of the cells of the oculo-motorius are crossed,² that is, contribute the nerve fibre process to the nerve trunk of the crossed side; but to which of the eye muscles the crossed fibres pass is not yet ascertained. The fibres of the trochlearis decussate in their peripheral course on the roof, the mesencephalon. Whether the decussation is total is not yet ascertained. The smaller root cells of the oculo-motorius send their nerve fibres to the ciliary ganglion, whence, as from a sympathetic ganglion, fresh nerve cells emit fibres (but in this case, unlike the sympathetic elsewhere, myelinated) to the ciliary muscle and constrictor pupillæ. Among the units of the motor root cell system are perhaps to be reckoned those that supply the upper facial muscles, frontalis, corrugator, and orbicularis palpebrarum;³ the nerve fibres from these root cells do not, however, emerge from the central nervous system in the mesencephalon, but pass down to join those which innervate other facial muscles, and leave the metencephalon in the facial nerve.

The distinction between roof and floor in the mesencephalic region, though clear enough, does not so lend itself to experimental opportunity as in the parts of the brain previously dealt with. The nervous masses of the roof form in mammals the corpora quadrigemina, the hinder pair of which are the enlarged equivalents of two comparatively small nuclei, occupying only a small hinder edge of the lobi optici of fish and *Sauropsida*. The relatively huge size of the front pair in reptiles and birds harmonises with the preponderant rôle played by vision in those animals.

Excitation of the mesencephalic roof succeeds under stimuli of all kinds, electrical, mechanical, thermal, and chemical; electrical stimuli are most efficient. In fish,⁴ the tail is drawn toward the side excited, and the dorsal and anal fin are spread and inclined towards that side; the pectoral fin is spread, and there is movement of the eyeball of the same side. In the frog the head is thrown to the opposite side and upward, and croaking may be elicited. The heart is usually inhibited, but not strongly.⁵ If telencephalon and diencephalon have been previously ablated, weak and prolonged excitation of the mesencephalic roof by sodium chloride increases (Setschenow)⁶ greatly the latency of move-

ments evoked by stimuli to the skin. The latency may be increased eight-fold, or the reaction may even be suppressed altogether. This "inhibition" holds good for "pathic" stimuli, but not for pure "tactile."¹ In connection with this inhibition of spinal reflexes and the close ties between the mesencephalic roof and the retinae, it is interesting that in the blinded frog the croak reflex can be elicited with machine-like regularity.²

In birds,³ excitation of the optic lobes evokes contralateral pupillar dilatation, spreading, raising, and flapping of the contralateral wing, and movement of both legs. Faradic stimulation of an anterior corpus quadrigeminum in the rabbit and in carnivora⁴ produces dilatation of the contralateral, and later of the homonymous pupil, conjugate deviation of the eyes upward and to the opposite side, retraction of the ears and angles of the mouth. To these effects are added pricking of the crossed ear, and vocalisation if the electrodes are applied to the posterior instead of the anterior corpus. In the dog,⁵ but not in the rabbit,⁶ it has been possible to elicit different co-ordinated eye movements from different points of the anterior corpora; from the sulcus between them, return of the divergent bulbs to parallelism without any change in the pupils; from a posterior point, elevation of the eyes with dilatation of both pupils; further back still, convergence with contraction of both pupils. After sagittal section in the median plane, the excitation affects only the homonymous eyeball. In all the conjugate reactions, the contraction of one muscle is accompanied by relaxation of the tonus of its antagonist. But the eyeball movements elicited are not always conjugate; and sometimes one only is elicitable from the whole of both the anterior corpora.⁷ In the monkey, Ferrier⁸ discovered reactions similar to those of the dog, with the addition of wide opening of the palpebral fissures, elevation of the eyebrows, and turning of the whole head in the direction of the gaze, *i.e.* away from the side of excitation. Excitation of the posterior corpora in the monkey produces vocalisation, the sounds ranging among many varieties of cries.

Ablation.—The frog, after removal of all parts in front of the mesencephalon, but with the latter intact, continues to exhibit occasional movements that are "spontaneous."⁹ It swims and springs co-ordinately, but it no longer reacts by climbing to the tilted board. The condition of the animal resembles torpor; let down gradually into water, it floats without stirring, although it still can swim. Probably vision and smell are gone. Croaking is easily elicited. On stroking the flanks, not only is croaking elicited, but the animal gradually rises on its four limbs with curved back and muscles in tonic contraction. It remains so for many minutes after the stimulus to the flank skin has been discontinued, even for half an hour.¹⁰ Destruction of the mesencephalon renders the croak reflex difficult to elicit, and altogether abolishes the tonic reflexes, though the latter are still possible in the

fore-limbs after destruction of the front part alone of the mesencephalon. After transection through the posterior part of the region, pressure on the foot often excites a crawling backward; with the lobes intact it always excites a spring forward. Circus movements and forced asymmetrical postures frequently attend partial lesions. After transection behind the mesencephalon, the cutaneous reflex time to Türk's stimulus (acid water) is still abnormally long, though shorter than when the lobes are stimulated, or the transection lies in front of mesencephalon.¹

Removal of the mesencephalic roof in *Testudo palustris* induces extraordinary activity.² The creature does not stumble against objects, and evidently retains some visual power. The retraction of the head on the shell being tapped, a normal reaction, drops out. When put into a tank, instead of diving at once and hiding, the animal swims continually at the surface. The ablation reduces the latent time for movement of leg in response to stimulus of head from .08 sec. to .05 sec., and the liminal stimulus is lowered.

In birds, destruction of one optic lobe impairs,³ but does not completely destroy, the visual power of the contralateral eye.⁴ Destruction of an anterior corpus quadrigeminum abolishes⁵ reflex contraction of the pupil to light, "Whytt's reflex."⁶ It is removal of the surface layer of the lobes that seems to impair visual sensation, while it is the deeper lesions which seem to most easily produce forced movements. Transection, close in front of mesencephalon, leaves vocalisation fairly intact.⁷ I found it still obtainable in the monkey, even after transection close behind the anterior corpora; transection behind the posterior bodies seems to abolish it. The cry is a prolonged one, and in all the reflexes obtained from the monkey (cat, dog, etc.), after transection at the front limit of mesencephalon, there is a peculiar feature in regard to their time character.⁸ The reflex movements produced are executed with a curious deliberate slowness, and the attitudes assumed are long maintained. It has been concluded by Ziehen⁹ that the tonic component of the epileptic discharge into muscles is not cortical but subcortical. The "cataleptoid reflexes," elicitable after transection at the mesencephalon, recall to mind his conclusions. The state of constrained immobility, so-called "hypnotic," into which many animals, e.g. frog, hen, can by skilled handling be brought, has been shown by Verworn¹⁰ to be accentuated in decerebrate individuals.

And it is after complete transection here that the condition called *decerebrate rigidity*¹¹ supervenes. In this state the respiratory

movements proceed regularly, and the pulse remains quiet and full, but certain groups of muscles become rigid. The elbows and knees are stiffly extended, and do not allow of the usually easily made passive flexion. The tail is stiff and straight instead of pliable and drooping; the neck and head retracted. The condition seems more accentuated in the fore-limb than in the hind. Wrist and ankle are much less affected, the digits not at all. Passive movement of the limb hastens the development of this prolonged spasm and re-develops it when it has subsided. The spasm seems dependent on an action—perhaps a tonic action—of the afferent spinal roots of the region implicated by the spasm. Section of the afferent roots of the arm, prior or subsequent to the transection of the mesencephalon, prevents or abolishes the rigidity in it. The influence thus based upon the afferent roots seems to descend from a region above the lowest third of the bulb, for unilateral transection at that level abolishes the rigidity or prevents it, and on the same side as the section. The inhibition influence from the optic lobes of the frog has been noted to be crossed.¹

In this condition of decerebrate rigidity reflexes can be elicited which actuate the neck, trunk, and the four limbs as a whole, and treat them as components of a single motile apparatus. There must, therefore, in the mammal exist behind the diencephalon a nervous mechanism, which can co-ordinate the action of the great regions of skeletal musculature (including the tail), and the character of the combined movements resulting leaves little room for doubt that the combination is subservient of quadrupedal progression. The combined movement treats the pair of fore-limbs in such a manner that the one is flexed and protracted, the other is extended and retracted at the same time, and similarly when the one limb is flexed at hip and knee, its fellow is extended at those joints. Further, there is a diagonal relation between the limbs in the combined movement of such a kind that a fore-limb and the diagonal hind-limb are flexed together or extended together. It results, therefore, that there are two possible postures that the reflex can produce as regards the limbs—(1) Left fore-limb and right hind-limb flexed, with right fore-limb and left hind-limb extended; (2) left fore-limb, left hind-limb extended, with right fore-limb and left hind-limb flexed. Which of these is produced is determined by the seat of stimulus. The stimulus regularly provokes flexion in the limb stimulated as a starting-point, and affects the other three limbs in the way above stated. These reflexes are frequently “alternating” in character, so that successive flexions and extensions of the limbs follow in sequence, extension and retraction succeeding to flexion and protraction; and in this alternation the diagonal symmetry characteristic of the primary movement is maintained through the succession. The rigidity ensues after a semisection of the region, and is most marked on the side of section. It can then be inhibited in various parts of the musculature, by stimulation of appropriate parts of the Rolandic area of the crossed hemisphere.

A point of importance attaching to decerebrate rigidity is the field it offers for examination of the play of inhibition, and this is exemplified in the execution of the combined limb reflexes just mentioned. Thus, to give a single example, if the skin of the left hand be the locus of excitation, there ensues inhibition of the left triceps brachii, with con-

¹ Langendorff, *Arch. f. Physiol.*, Leipzig, 1877.

traction of the flexors of the elbow, and inhibition of the right extensor cruris, with contraction of the hamstring muscles; while, on the contrary, there ensues inhibition of the flexors of the right elbow with contraction of the triceps brachii, together with inhibition of the right hamstring muscles, together with contraction of the right extensor cruris. In this reflex there is also bending of the neck and turning of the head toward the left side, somewhat as if to meet the protracted and raised left arm.

Besides reflexes obviously associated with an "act," as the above are with quadrupedal progression, others can be elicited when the mesencephalon is the highest part of the encephalon remaining, some of them less easy of interpretation. The following may be mentioned as fairly significant. Irritation of the pinna in the dog and cat evokes with the progression reflex a turning of the head and neck away from (not as with fore-foot stimuli toward) the side stimulated. This movement frequently culminates in the shaking of the head from side to side as though to shake the ears.¹ Mechanical stimuli to the nostrils provokes a fit of sneezing, but not, as far as I have seen, of coughing.

Tracts of conduction.—Paths that ascend in the mesencephalon and partly end in it, lie in the fillet, and these come partly from the ventro-lateral column of the spinal cord, partly from the end-nuclei of the auditory nerve. A large path from the cerebellar hemisphere crosses the midsagittal plane to enter and in part end in the red nucleus of the tegmental region. Severance of the tegmental region and fillet on one side of the midline produces complete anæsthesia and analgesia of the skin of the contralateral half of the body, the analgesia, at first total in degree, gradually subsides to partial. The posterior longitudinal bundles running up and down the region seem mainly commissural and associational between the ocular nuclei.

The main descending paths of the region are the mesencephalo-spinal, a crossed path traceable from the anterior and posterior corpora quadrigemina into the ventral part of the opposite ventro-lateral spinal column;² I would interpret this as a projection system belonging to vision. Then there are in the mammal, the cerebral descending paths, fronto-pontine, temporo-pontine, and pyramidal. These in their descent are seen to give fibres to the substantia nigra just dorsal to them, and from the pyramidal pass fibres, probably indirectly, to the motor root cell system, represented here by the oculo-motorius and trochlearis nuclei; some fibres pass to the crossed and some to the homonymous nerves. Cajal³ showed that efferent fibres pass out of this region into the retina by way of the optic tracts and nerves, and these have been traced by the degeneration method from the optic lobe of the bird into the crossed optic nerve.⁴ Conversely from the ganglion cell layer of the retina of the bird passes a path into the "optic nuclei," dorsal and ventral, of the surface layer of the crossed optic lobe.⁵ In some birds (*e.g.* owl) the connection is probably partly uncrossed; in mammals it seems to be always partly uncrossed,⁶ and the ratio of the size of the uncrossed to the crossed portions is particularly large in

animals in which the visual axes are parallel, *e.g.* man. Paths of which the functions are less well indicated than the above run to the homonymous and contralateral corpora striata, to the homonymous half of the cerebellum, to the motor nuclei of the bulb, chiefly of the crossed side.¹ The mesencephalon also receives a path from the corpus striatum,² but in the bird none from the pallium (cortex cerebri).³

THE DIENCEPHALON OR REGION OF THE THALAMUS OPTICUS.

This region includes as its main divisions, studied in regard to function, the optic thalamus, subthalamic body, and lateral geniculate body. The two latter bodies may be considered grey nuclei somewhat more definitely separable than, but otherwise comparable with, the remains of some twenty (Nissl, v. Monakow) grey nuclei composing the thalamus. Of the first and last named only, has more definite knowledge been acquired. The region relatively to its bulk sends but very few fibres in a caudal direction; on the other hand, it is an abundant source of fibres passing into the telencephalon (both corpus striatum and cortex). It is connected with the Rolandic region of the cortex by a system of fibres that, among cortical fibres, become myelinated somewhat early (ninth fetal month), and by later developing systems with—(1) The gyrus hippocampi, cingulum, and gyrus fornicatus (first post-natal month), and (2) with the frontal convolutions (fourth post-natal month). It is also connected with the cortex of the insular region, and sends an especially numerous fibre system to the occipital and temporal cortex, including pre-eminently that of the calcarine and angular gyri. The researches of Dejerine⁴ prove that there is practically no region of the cortex of the hemisphere which does not receive nerve fibres from the optic thalamus, and that, on the other hand, there are no fibres from the thalamus to the pes pedunculi cerebri.

Panizza⁵ and Jos. Swan⁶ almost simultaneously discovered that destruction of an eye is followed by shrinkage of the contralateral optic thalamus. In the lower vertebrata the corpora bigemina are the chief regions of reception of the fibres of the optic "nerve." In the higher mammalia diencephalic nuclei of ending of the optic nerves assume larger and larger proportions as compared with mesencephalic.⁷ In the rabbit the main nucleus is still the anterior corpus quadrigeminum; in man the lateral geniculate body preponderates. Only in primates is the pulvinar large; in other mammalia it is small. All goes to indicate the growing importance of the cortical mechanism concerned with vision in the evolution of the sense. Of the four masses of grey matter into which in mammals the thalamus is broadly and easily divisible, it is the hindmost (pulvinar) that is directly in receipt of fibres from the optic

⁷ Gudden, Ganser, Monakow, Edinger, etc.

"nerve"; and from pulvinar pass fibres to the occipital and to the angular regions of the cortex.¹ The lateral geniculate body also sends fibres to the occipital cortex, including the borders of the calcarine fissure.²

In the lateral grey mass of the thalamus end many of the fibres of the fillet; they enter especially the ventral and posterior part of the lateral mass, and lie around the median centre of Luys. Their region there is known as the "field of the fillet." And it is from the lateral grey mass of the thalamus that corticopetal fibres pass to the parietal and falciform (mesial) regions of the cortex. From the front end of the thalamus pass fibres to the frontal region of the cortex. A large and, both phylogenetically and ontogenetically, early developed system of fibres connects the thalamus with the corpus striatum. This in mammals connects especially with the head of the nucleus caudatus; but the thalamus is also connected with the nucleus lenticularis (*ansa lenticularis*). It also receives fibres from the superior cerebellar peduncle.

Excitation of the thalamus.—Excitation of the thalamus by weak faradisation produces little obvious result.³ Ferrier⁴ says: "I have not observed any outward manifestation on irritation with a current sufficient to excite active contraction when applied to the corpus striatum"; except that, in a monkey, when the electrodes were applied to the mesial surface near the soft commissure, spasmodic extension of the legs resulted, and in a rabbit movements of the eyes⁵ and twitching of the opposite ear. These phenomena might, he adds, "be regarded as indications of irritation of sensory centres."

Destructive lesions and ablations of the thalamus.—Observers, from Rolando,⁶ Panizza,⁷ and Renzi⁸ onwards,⁹ have, after experimental lesion of one thalamus, noted visual defect and dilatation of the contralateral pupil, the latter a merely temporary symptom. The observation by Hughlings Jackson¹⁰ in 1875 of a case in which, post-mortem, a softening of the right optic thalamus was discovered, confined to the posterior part of the thalamus, and uncomplicated by destruction elsewhere, was of fundamental assistance in indicating the functions of the thalamus. The symptoms observed were diminution of tactual sensibility on the left side of the body, impairment of common sensitivity in the left nostril, slight impairment of taste on the left side of the tongue, and of hearing in the left ear, and loss of the left half of the field of vision of each eye, *i.e.* blindness of the right half of each retina. Experimental work on the subject thoroughly substantiates the teaching of this case.¹¹

The defect of vision for the contralateral retina seems, at first at

(See also Fournie, "Recherches expérimentales," Paris, 1873).

any rate, more than a hemianopia,¹ i.e. a hemianopia plus amblyopia of the whole field. The hemianopia does not involve the central region of the visual field of either eye. Severance of corpus callosum leads to no permanent objective impairment;² Ferrier and Turner and Lo Monaco, making use of this fact, have proceeded to open the lateral ventricle subsequent to partial section of corpus callosum, and with the thalamus well exposed have destroyed the posterior part of it. There resulted total blindness of the contralateral eye, impairment of tactual and dolorous sensitivity in the crossed half of the body, and slight defect of force in movements executed by the contralateral limbs. In Hughlings Jackson's case, muscular weakness on the crossed side was noted. Symptoms both in the dog³ and monkey⁴ abate in the course of some weeks; the total crossed blindness becoming amblyopia. The hemianopia and defect of power of skin localisation appears permanent. The older observers⁵ on experimental thalamic lesion obtained very regularly great disturbance of motility, such as forced movements of various kind and degree. It was in experimenting on the thalamus that Magendie discovered the forced movement which he styled *mouvement de manège* (circus movement). Recent⁶ observers have not confirmed "forced movement" as a necessary part of the symptomatology of thalamic lesion. Neither is paralysis; the utmost impairment of the motor power amounting only to a slight hemiparesis. Many observers⁷ have noted signs of disturbance of the muscular sense.

The effects of removing the cerebral hemispheres, either along with or without simultaneous removal of the diencephalon, have already been described (see article, "Cerebral Cortex"). In both cases there is loss of intelligence, in higher mammals imbecility. There is a great difference between the animal without telencephalon but with diencephalon, and the animal deprived of both telencephalon and diencephalon, especially in regard to the facility and completeness of performing complex muscular movements. The most plausible explanation seems that which supposes, that with diencephalon remaining there is still possible a conjoint influence of visual impressions with impressions derived from other senses (tactual, muscular, and labyrinthine), which makes itself felt upon the machinery of the skeletal musculature: when the diencephalon is lost, the contribution from the retina largely disappears.

Experimental lesions of the thalamus cause distinct rise of body temperature, apparently without vasomotor disturbance.⁸

One territory of the thalamus (*corp. genic. lat.*) functions as a station between relay cells from the nerve cells (retinal) of vision and nerve cells conducting through the "optic radiations" to the visual field of the

cortex. Another of its territories (ventral nucleus) similarly mediates between relay cells from nerve cells (spinal) of muscular and cutaneous sense and nerve cells conducting to the somæsthetic field of the cortex. In both these cases the thalamic nucleus projects upon the cortex a sense field in which the body is largely bilaterally represented. The other territories and nuclei of the thalamus are believed similarly to project other sensorial fields upon the cortex. The thalamus is therefore a high intermediary centre between the sense organs and the cortex. There is evidence of a particular dependence of emotional and mimetic expression upon action of the thalamus. In some cases regions of the face are paralysed for emotional but not for willed movements; in other cases the converse occurs. This has been found related to presence or absence of concomitant thalamic lesions.¹

CUTANEOUS SENSATIONS.

By C. S. SHERRINGTON.

CONTENTS:—THE SENSE OF TOUCH, p. 921—Touch-Spots, p. 921—The Adequate Stimulus, p. 924—Weber's Law in respect to Tactual Sensations, p. 928—The Spatial Quality of Touch, p. 934—Theory of "Localising" Power of Touch, p. 938—Projection of Touch, p. 941—Illusions in Tactual Judgments, p. 943—Reaction Time for Touch, p. 945—THE SENSE OF TEMPERATURE, p. 945—"Cold" and "Warmth" as Distinct Species of Sense, p. 945—Distribution of Apparatus for Thermal Sensations in the Skin, etc., p. 946—The Adequate Stimulus, p. 950—Other Stimuli, p. 954—Paradoxical Sensation of Cold, p. 954—Some Characters of "Cold" and "Warmth" Sensations, p. 955—Relation of Thermal Sensation to Pain, p. 955—Influence of Areal Extent of Stimulus upon Intensity, p. 956—The Physiological "Zero-temperature" and "Adaptation," p. 957—The Degree of Projection of Thermal Sensation, p. 958—The Thermal Sense in relation to Thermotaxis, p. 959—The Liminal Difference of Intensity of Stimulus, p. 959—Reaction Time, p. 962—Antagonism of Sensations of "Cold" and "Warmth," p. 965—Paths of Conduction, p. 965—COMMON SENSATION, p. 965—Cutaneous Pains considered in relation to Pain in general, p. 966—Relation of Pain to Intensity of Reaction, p. 966—Quality of Cutaneous Pain, p. 967—Scope of the term "Common Sensation," p. 969—The Viscera and Common Sensation, p. 970—The Musculo-articular Apparatus and Common Sensation, p. 972—Nature of "Physical Pain," p. 973—Action of Painful Stimuli, p. 974—Character of the Motor Reactions provoked, p. 974—The Central Neural Mechanism for Cutaneous Pain, p. 976—Tickling, p. 976—Dolorous Reflexes compared with Tactual, p. 977—The Spinal Path of Pain, p. 977—Associated (Referred) Pains, p. 981—Interference of Pain with other Sensations, p. 984—The Peripheral Path of Pain, p. 984—"Pain-Spots" in the Skin, p. 984—Pain and Nerves of Muscular Sense, p. 989—Pain and Visceral Nerves, p. 990—Hunger as a type of Visceral Sensation, p. 991—Evolution of Visceral Pain, p. 993—Cutaneous Pain and Adequate Stimuli, p. 994—Specific End-organs or Undifferentiated Endings, p. 995—The Forms of "Excess" of Stimulus, p. 997—Summation in Production of Pain, p. 998—"Inertia" of the Neural Apparatus of Pain, p. 998—The Brain and Physical Pain, p. 1000.

Sense spots.—The surface of the skin is found to be a mosaic of tiny sensorial areas. The elements of this mosaic are set not actually edge against edge as in the retina; between each element and its neighbours of like function extends a relatively wide interval, insentient when examined by stimuli of little above liminal intensity (Blix).¹ The more locally limited and the nearer to minimal the stimuli, the smaller appears each individual sensifacient field; ultimately, by carrying the tests to

¹ *Ztschr. f. Biol.*, 1885, Bd. xxi. S. 152. Also Goldscheider, *Monatsh. f. prakt. Dermat.*, Hamburg u. Leipzig, 1884, Nos. 7-10; *Arch. f. Physiol.*, Leipzig, 1885, Suppl.; *Arch. f. Psychiat.*, Berlin, 1887, Bd. xviii. S. 659; and Eulenburg's "Real-Encyclop. d. ges. Heilkunde," 3te Aufl., art. "Empfindung."

further refinement, the individual fields may be reduced to mere "spots." Each of these "spots" is found to subservise a specific sense,—touch, cold, warmth, or cutaneous pain. Each doubtless coincides with the site of some sensorial "end-organ," or with a tiny cluster of such. Rather, indeed, than to a mosaic may the skin be likened to a sheet of water wherein grow water-plants, some sunken and some floating. An object thrown upon the surface moves the foliage commensurately with the violence of its impact, its dimensions, and with their propinquity to its place of incidence. Where the foliage grows densely, not a pebble striking the surface but will meet some leaf; and beyond that or those directly struck, a number will be indirectly disturbed before equilibrium of the surface is re-established.

Throughout almost all regions of the skin "touch spots," "cold spots," "warmth spots," and "pain spots" lie strewn in intercommingled fashion. In some districts one variety predominates, in other districts another. On the whole, "pain spots" seem to be the most numerous, and certainly "warmth spots" are the least so.

TOUCH.

Touch means, in physiology, a sensation evoked, under normal conditions, by mechanical stimulation from the skin; under abnormal conditions it may also be evoked by a variety of other stimuli.

Touch spots.—If in an area of the skin, *e.g.* of the calf, the hairlets be cut short, and the surface minutely tested from point to point by pressing on it perpendicularly a bristle, a certain number of spots are found, at which the slight pressure employed (about 33 grms. on the square millimetre, applied to an area equal to the cross-section of a fine

FIG. 368.—Map showing the relative distribution of the sensitivity to touch, warmth, and cold in the palm of the left hand. In A the whole surface is, when tested by a small cork applied by a spring, found of approximately equal sensitivity except in the areas marked black; these are relatively insensitient for touch. In B the areas of sensitivity to warmth stimuli are represented by degrees of shading, the most sensitive by the black shading, the next by the lined areas, the next by the dotted areas, and those of least sensitiveness by the blank spaces. In C the topography of the distribution of sensitivity to cold stimuli is indicated in the same way as that to warm stimuli in B.—From Goldscheider.

bristle)¹ is perceptible. These spots are called "touch spots." In a square centimetre of such skin the touch spots are about fifteen in number. If into one of these "spots" a fine needle be thrust, there is excited a strong sharply localised sensation of pressure, unaccompanied by smart or sting or any painful quality. Goldscheider² describes the impression as having a "shotty" character, as of a little hard body embedded in the skin, and there pressed upon. The sensation is unaccompanied by "cold" or "warmth," even when a cold or warm needle is employed.

Almost invariably there are one or more "touch spots" close to the place of emergence of each hair; they lie usually on the side from which the hair slopes. It is usual for "touch spots" to be arranged in short lines, radiating from the mouth of a hair follicle. In an area of the forearm (back) containing fifteen hairs, Goldscheider figures seventy-eight "touch spots"; also, on the flexor aspect, 147 "touch spots" to twenty-two hairs; and sixty-six "touch spots" to thirty-eight hairs in a small area of the scalp. In hairless regions—which compose about one-fiftieth of the total body surface of man—the "touch spots" also lie in short chains radiating from certain points.

The "touch spots" are much more numerous in some regions than in others. An area of the dorsum of the ungual phalanx of a finger contains about seven times as many as an equal area from between the shoulders. Regions comparatively poor in "touch spots" are the flexor aspect of the upper arm, the upper third of the thigh, the leg above the inner malleolus, the neck, and in general the skin over subcutaneous surfaces of bone. In some of these regions, roughly oval intervals, measuring a centimetre along the major axis, exist between the individual "touch spots."

Neither are all regions of skin equally freely furnished with "touch spots," nor do some regions contain any purely tactual apparatus at all, if we agree to sunder from pure "touch" the sensations which are elicitable from "pain spots." It is obvious that as there are scattered upon the cutaneous surface sensory end-organs of four different functional groups, *e.g.* touch, cold, warmth, and pain, the organs of these four classes can be in different regions commingled in different proportions. Nowhere are touch organs the only end-organs present, nor are they in any region interspersed with only one other of the three remaining kinds of sense spots. Together with "cold spots" and "warmth spots," they contribute to a ternion combination for the surface of the cavity of the mouth; throughout that cavity pain spots are few, and from certain parts of the inside of the cheek are wanting altogether.³ Elsewhere the touch organs where they occur lie commingled with individual organs of all three of the other kinds. But they do not occur in quite all the mucous and cutaneous regions in which representatives of the other kinds are present. They are absent from the cornea⁴ and conjunctiva of the upper lid,⁵ and from the glans penis.⁶

When the skin of the frog is stimulated by light blows with a tiny blunt-pointed lever, some spots are found, as judged by electrical response of the sensory nerves, to be easily excitable, and others to be inexcitable. Punctiform distribution of the tactual surface seems thus proved in the frog's as well as in the human skin.¹

As to the tactual sensitivity of the cornea, there exists difference of opinion. Some observers² maintain that pure tactual sensations can be elicited from it and from the conjunctiva as well, although all regard the palpebral conjunctiva under the upper eyelid as very poorly tactual. The difference is less a difference between actual observation than of interpretation of observation. The latter turns on the question of the quality of weak sensations evoked by contact stimuli. Some consider even the weakest of these to have unpleasant quality, when elicited from cornea and conjunctiva. If the differentiation between (α) pure tactual sensations and (β) sensations of contact of ineradicably painful quality, be admitted at all, then there can be little hesitation in allowing that the cornea (and parts of the conjunctiva), although richly endowed with "pain spots," are destitute, or almost destitute, of "touch spots."³ The passage of the upper eyelid over the eyeball in blinking is seen but is not felt as touch, except at the moment of meeting of the borders of the two lids. The eyelids being closed, the point of a blunt pencil pressed upon the cornea through the upper eyelid is not felt at the corneal surface, although clear enough on the skin of the eyelid, and although, as the pencil is pressed by one's self, the fingers by secondary touch easily feel the resistance of the hard cornea against the point of the pencil.

As to the identification of the particular end-organ, among those *structurally* recognised in the skin, to which "touch" may be specifically assigned, no doubt the short hairs are most sensitive tactual apparatus. To them are distributed nerve fibrils which end in the hair papilla, and others which encircle the hair follicle, in many instances composing a rich ring-like arrangement near the level of the openings of the sebaceous glands into the hair follicle. Further,⁴ Meissner's corpuscles have for long been regarded as tactual, and with much probability of justice. They seem to take the place of sensory hairs in hairless parts. Hairs are by some⁵ regarded as homologues of certain cutaneous sensory apparatus found in fish and amphibians. Such a relationship conforms well with a certain degree of physiological analogy that can be discovered between hairs and Meissner corpuscles.

The following data are useful for comparison with those above given regarding the distribution of touch spots:—

*Average Number of Meissner's Corpuscles to 1 sq. mm. of Skin Surface.*⁶

Volar surface	{	of end phalanx of index finger	21
		„ second „ „	8
		„ proximal „ „	4
		„ metacarpus of little finger	2
		„ plantar face of end-phalanx of hallux	7
		„ middle of sole	2

One corpuscle occurs on the average in every 35 sq. mm. of skin over the front of the forearm; von Frey and Kiesow located 99 touch-spots in 6 sq. cm. of the

front of distal end of the forearm. In the toes, on the average, one papilla out of every four contains a corpuscle (Meissner). It is not clear that the so-called "tactile cells" (Merkel) are concerned with touch, but in addition to the Meissner corpuscles there occur in the papillæ of the palmar and digital skin the "plume-organs" of Ruffini, so called on account of their shape.¹ These possess a nerve-ending quite different from that of either the simple or the compound Meissner organs; the network of terminal nerve filaments is much more rich and complex in the "plume-organs," and is not enclosed in such a thick or definite capsule as that of the Meissner organs. Beneath the organs of the papillæ there lie at various depths the nerve-endings discovered by Ruffini,² the "elastic tissue spindles." Numerous and of wide distribution, these are very probably tactual. Deeper still occur the Golgi-Mazzoni corpuscles, and in some regions fair numbers of Pacini corpuscles.

The adequate stimulus.—The "touch spots" are found to be the most sensitive points of the skin surface. They are readily excited, not only by pushing the skin surface inward, but also by pulling it outward (v. Frey). When of small amplitude, a push at a touch spot cannot be distinguished from a pull of equal amplitude. Meissner³ years ago pointed out that the hand immersed in a fluid at body temperature fails to feel the contact of the fluid, although the fluid pressure may be far above that of liminal intensity for touch. It seems clear that the adequate stimulus for touch organs consists in *deformation of the skin surface*. Fluid exerting everywhere a pressure normal to the face of the submerged skin does not deform the surface, except at a boundary of submerged and unsubmerged parts. At that boundary it is, as Meissner observed, felt. Elsewhere it bears on the sides as on the summits of the skin ridges equally. On the contrary, a solid surface presses primarily on the ridge summits and not on the ridge sides. The solid, therefore, causes deformation, and its contact stimulates the tactual surface, and is perceived.

A bristle attached to the prong of a vibrating tuning-fork can be used for stimulating a "touch spot" intermittently. The resulting sensations retain a quality of intermittence, even at high frequency of repetition of the stimulus. The vibrations of strings are recognisable as such by the finger, even at a frequency of 1552 vibs. per second.⁴ Induced currents evoke distinctly intermitting sensation, at a repetition of 130 per second.⁵ A wheel with toothed edge gives sensation of smoothness at its edge when the teeth meet the skin in succession at the rate of 480 to 640 per second.⁶ As compared with the sensation obtained from pain spots, "touch" is quicker both of development and subsidence.⁷

⁷ Goldscheider, *loc. cit.*; Nagel, *loc. cit.*; v. Frey, *loc. cit.*

The first instance in which a variation of the resting currents of a sensory nerve was obtained by application of an adequate stimulus to the end-organs was in the case of the eye.¹ Working with cooled (hyper-sensitive) nerves, Steinach has obtained negative variation of the resting sciatic current by dealing a light blow to the skin of the frog's foot with a graduated lever. Within limits the extent of the negative variation varies directly with the force of the blow applied.²

Fontana³ showed in 1780 that by gradually increased compression a nerve can, without exciting it, be paralysed as a conductor. The first application of the pressure is felt, and then the sensation subsides, if the compression be steady and not too rapidly increased. Similar pressure applied to the skin evokes a sensation which does not so subside,—the sensation continues. The inner stimulus must therefore be tetanic in character. This difference between nerve and end-organ does not, however, hold if the stimulus to the latter is but little above liminal,—then the touch is felt for a moment after contact, and speedily subsides.⁴ It may be again felt for a moment at the sudden discontinuance of this stimulus;⁵ in this the reaction resembles many reflexes obtainable from the spinal cord, where discontinuance⁶ of a prolonged stimulation evokes a renewal or an increase of a reflex reply that had ceased or become feeble.⁷ "Touches" evoked by brief stimuli, even of very slight intensity, especially from the region of the nose, may persist for very long, or leave a very protracted after sensation. The prolongation of the sensation is of an itching, tickling quality, and may continue even for minutes. This secondary sensation may be due to a local vascular reflex initiated by the stimuli, for the itching spot can generally be seen to be flushed.⁸

The principle of "adaptation," laid stress upon by Hering and G. E. Müller, in the visual and muscular senses, plays a part also in tactual. After the skin has been tested by a number of light weights, a heavy weight appears disproportionately heavy; and light weights disproportionately light, after a series of much heavier. The large areas over which contact of the skin with clothing is habitual become, even under attention, almost insentient of the contact. A plate carrying artificial teeth is for the first few hours almost unbearable to the mouth, and provokes reflexly for a time excessive salivation, etc. In a comparatively short period the intensity of the reaction to the stimulus dwindles to an extraordinary extent. A similar adaptation is experienced when eye-glasses, spectacles, etc., are first worn.

The method of application of the adequate stimulus for touch has been, in the vast majority of instances, the application of pressure. This has been done with weights in a scale-pan;⁹ with a spring balance (the baræsthesiometer);¹⁰ with a pulsating elastic tube, distended by hydrostatic means;¹¹ by a mercurial balance, enabling rapid variations of pressure to be made

without shock;¹ by a combination of a delicate spring and beam balance;² by applying fine elastic filaments, glass, wool fibres, hairs, etc.³ An adjustable projection from a smooth subspherical surface has been introduced by Graham Brown. v. Frey⁴ has been, as far as I know, the first to employ measured degrees of traction as stimuli.

Liminal intensity of stimulus.—When a solid body of known weight, with one side smooth and of known area, is warmed to the skin temperature, and allowed, in virtue of its own weight, to rest smooth side downward on the supported hand, it causes a sensation of touch of a certain intensity, *i.e.* it “touches” with a certain degree of intensity. The intensity of the physical stimulus is easily written in such instances as values of “pressure.” The resulting sensations are often, especially when the intensity is somewhat high, termed “pressure sensations.” Such pressure sensations are, however, to be regarded merely as degrees of touch sensation.

Kammler⁵ measured the least weights with contact surface of 9 sq. mm. capable of exciting touch sensation at different skin regions. He found .002 grm. liminal for the forehead, temple, and back of hand and forearm; .003 grm. for flexor aspect of forearm; .005 grm. for lips, chin, eyelids, and abdomen; .01 grm. for palmar surface of fingers; 1 grm. for ankle and finger-nail. It must be remembered, however, that for one and the same region it is found, in actual practice, that the liminal stimulus varies considerably, even when tested by contact areas 7 mm. in diameter; thus, in the pulp of the finger, at some areas, the liminal intensity is four times greater than at others.⁶ Where thick and unyielding, the skin will, *cæteris paribus*, require greater pressure to deform its surface than where thin and supple. The pressure required to evoke sensation is therefore, if deformation of surface (*v.s.*) be the immediate stimulus, a mode of expression that has for each surface to be interpreted.

The expression *liminal stimulus* includes three important values of stimulus, namely, the least stimulus that never fails to evoke sensation, the least stimulus that in the whole series of observed cases does evoke sensation, and the least stimulus that in half the number of observed cases evokes sensation. These are respectively the *upper*, *lower*, and *median* limina.

The short hairs of the skin much enhance its tactual sensitivity. On 9 sq. mm. of skin from which the hairs had been shaved, the liminal stimulus was found to be 36 mgrms., whereas, on the same surface, before it was shaved, 2 mgrms. was the liminal stimulus. The liminal stimulus for the touch spots about a short hair is three to twelve times greater than for the hair itself, *i.e.* the hair is three to twelve times more sensitive than the “spots.” The liminal stimulus for the hair progressively increases as it is progressively cut shorter and shorter.⁷ Each short hair is a lever, of which the long arm outside the skin acts at an advantage upon the touch organs at the root. The short hairs are probably the most sensitive tactual organs of the body.

⁶ Kiesow, *loc. cit.*

⁷ v. Frey, *loc. cit.*

More critical than the larger areal methods of touch testing are observations by a method introduced by Hensen (1893).¹ By using the bending of a glass-wool fibre, one end of which rested on the skin (face), Hensen found a pressure of less than .001 grm. easily perceptible. A somewhat artificial but otherwise convenient way of expressing the intensity of stimulus thus used, is to give the weight per sq. mm., which will exert, on an area equal to the cross-section of the fibre or bristle used, the pressure actually exerted by the fibre or bristle employed in the observation. The following results obtained by v. Frey, using Hensen's method, are expressed in that way. The contact surfaces ranged between $\frac{1}{100}$ sq. mm. and $\frac{1}{8}$ sq. mm.

Tongue and nose	2 grms. per sq. mm.
Lips	2.5 " "
Finger-tip and forehead	3 " "
Back of finger	5 " "

Outside of thigh }	28 " "
Shin and sole	
Back of forearm	33 " "
Loins	48 " "

Applying weights to 1-10 sq. mm. area of skin of the frog's foot, Steinach² found 2 grm. the liminal weight.

To excite a naked nerve, the minimal mechanical stimulus is in experiment .2 grm. moving at 140 mm. a second (Tigerstedt). For the touch spot, v. Frey finds .2 grm. at .17 mm. a second minimal. The limen is lowest with a contact area of about .5 mm.³

It is probable that tactile stimuli of subliminal intensity can by repetition become summated to liminal intensity. If a point of skin be faradised with the secondary coil of the inductorium too distant from the primary for any single shock to evoke sensation, a sensation can still be evoked from the skin.⁴ That is, electric shocks individually too feeble as stimuli, repeated in series eventually evoke sensation. The stimuli are in this experiment not, however, of the specific quality for touch organs; but the phenomenon of "latent summation" is clearly shown.⁵

An important determinant of the intensity of the limina stimulus, is the speed of its application. When quickly applied, the pressure required is less.⁶ The energy of the stimulus is the criterion.

When touch spots and pain spots are tested with mechanical stimuli, e.g. pressure with a bristle, the liminal stimulus for touch lies lower than for pain; the quotient $\frac{\text{touch-limen}}{\text{pain-limen}}$ varies from $\frac{1}{3}$ in the forearm to $\frac{1}{100}$ in the finger-tips.⁷ Examined by faradic currents, the quotient of

⁷ v. Frey, *loc. cit.*

excitability is altered to more than unity, the "pain threshold" lying lower than the "touch threshold."

Many other conditions affecting the skin affect the liminal stimulus. Cold blunts the sensibility at "touch spots," but less than at "pain spots." To stretch the skin much lowers its sensitivity at "touch (and pain) spots," deformation of the skin surface is then, of course, less facile. By rubbing and by scratching, it is easy to raise the liminal stimulus for a local region threefold. Hence the rubbing or scratching to "remove irritation." By practice and attention the liminal stimulus for a patch of skin may be soon reduced to half its original value.¹

As to drugs, cocain² locally applied (5 per cent. solution injected subcutaneously), depresses all forms of cutaneous sensitivity, after causing evanescent hyperalgesia. Tactual sensitivity is more depressed than painful, and less than thermal. Applied to the conjunctiva, cocain abolishes pain more speedily than tactual and than cold sensation. Carbolic acid (5 per cent.) acts similarly to, but less strongly than, cocain. In subcutaneous injections of 2.5 per cent. solution, it can locally completely paralyse all cutaneous sensation. Chloroform, applied with a sponge, after a temporary burning sensation, leaves sensibility, especially to temperature, blunted for a longer period.³ Orthoform acts as does cocain, but its action lasts longer; unlike cocain, it is not toxic.⁴ Menthol, after producing a temporary hyperæsthesia, especially of the "cold spots," depresses sensibility, especially for cold. The feeling of local coolness, caused by applying menthol to the skin, is due less to evaporation than to hyperæsthesia of the end-organs for cold.⁵

The liminal difference of intensity.—That smallest increment or decrement of stimulus which occasions a noticeably different degree of sensation can serve as criterion of fineness of gradation of a sense. E. H. Weber,⁶ in measuring such "differences," found it best to apply the comparable stimuli *successively to the same surface of skin*. He used the two distal phalanges of two adjacent fingers, which, with the whole arm, lay fully supported on a rigid surface. The time interval between two successive stimuli must be brief, *e.g.* 5 secs., and regular, in comparing pairs successively. The duration of the stimuli should be equal. No thermal stimulus should accompany the tactile. By measuring the stimuli, giving "just noticeable differences," Weber found the limit of discrimination for tactile stimuli, evoking sensations from the volar skin of unguis phalanx, was reached when the weights used as stimuli were to each other as 29 to 30. But the ratio was not the same for all skin regions, and it differed in different individuals. The ratio for a given region and individual remains approximately constant throughout a considerable range of absolute value of external stimulus. This is the basis of Weber's "law"; it applies best to stimuli of moderate intensity. With tactile stimuli, as the stimulus decreases to near liminal intensity, the ratio of increment or decrement required for perceptible difference has to be much greater than for stimuli of moderate intensity; thus in the palm 1.66 grms. and 1 grm. Similarly, in the case of very intense stimuli, the ratio is departed from. With moderate weights, a difference of pressure is perceptible when the ratio of alteration is smaller than

when either very small or very large weights are used; that is, sensitiveness to pressure difference is keenest under moderate stimulation. With slower rates of change the threshold difference is lower than with quicker.¹ The average threshold difference, the initial pressure being 5 grm. on 20 sq. mm. of the second phalanx of the finger, was found with *instantaneous* addition to be .35 grm.

Methods.—The "liminal difference" for touch has been estimated in various ways—(1) As by Weber, referred to in the above paragraph. Of two stimuli, easily judged to be of different intensity, one is diminished or increased to the extinction of perceptible difference; or, of two indistinguishable stimuli, one is increased or diminished (in the above case by addition to or subtraction of weight from it), so that a difference between the two stimuli can just be noticed. When the test starts *from* equality, the difference remains longer unnoticed than when tests go *towards* equality. The direction of change, *i.e.* whether decrease or increase, may be known to the subject or not known. The former is the "conscious" method, the latter the "half-conscious." The direction being unknown, the changes may be of regular order or utterly irregular, the latter giving the "unconscious" method. The values of liminal difference found are different for these different methods. These are quick methods, but less precise than others to be mentioned. The two modifications of the method can be used together, and the mean liminal differences ascertained by each compared together. This combination constitutes the *method of smallest difference*.³ The method as used by Weber is known as *method of just noticeable difference*. (2) *Method of right and wrong answers*.⁴—Two equal stimuli are, under favourable conditions, judged as a rule to be equal, although in certain proportion of instances to be slightly different. Two unequal stimuli are judged to be unequal with greater

¹ Hall and Motora, *Am. Journ. Psychol.*, 1887, vol. i. p. 72; Stratton, *loc. cit.*; Seashore, *Stud. Yale Psychol. Lab.*, New Haven, 1896, vol. iv.; Heinzmann, *Arch. f. d. ges. Physiol.*, Bonn, 1872, Bd. vi. S. 222; Fratschner, *Jenaische Ztschr. f. Med. u. Naturw.*, Leipzig, Bd. ii. S. 130.

³ G. E. Müller, "Zur Grundlehre d. Psychophysik," S. 11.

⁴ Fechner, "Elem. d. Psychophysik," Bd. i. S. 71. Fechner elaborated this method, but it appears to have originated in Vierordt's laboratory, see Hegelmayer, also Renz and Wolff in *Arch. f. physiol. Heilk.*, Stuttgart, 1856, Bd. xiv.; and *Ann. d. Phys. u. Chem.*, Leipzig, Bd. xxviii. S. 600.

certainty the more they are unequal. When the difference between them is above a certain degree, they are constantly judged to be unequal. As the inequality between the stimuli is reduced more and more, less and less correctly is judgment made as to their inequality. The distinction between the stimuli is in each case either right or wrong. Occasionally no answer can be given, the judgment remains indeterminate. Such instances are dealt with by being added half to right answers, half to the wrong. For each value of the difference between the stimuli the ratio between the number of right answers and the total number of answers is determined $\frac{r}{t}$. The delicacy of perception of difference is inversely proportional to the differences of stimulus which produce equal ratios $\frac{r}{t}$. Thus if in two equal sets of experiments, *e.g.* on two individuals, $\frac{1}{35}$ and $\frac{1}{70}$ of difference of external stimulus elicited the same ratio of right to total answers, *e.g.* 80 per cent., the liminal difference of stimulus is half as great, and the delicacy of judgment of difference is twice as great in the second as in the first. (3) *Method of mean error.*¹—It is sought to make the two stimuli equal, that is indistinguishable, by use of the single sense under examination, in this instance touch. At the end of each attempt the objective stimuli judged equal are physically measured, *e.g.* on the balance. The smaller the difference between the stimuli so measured, the greater the delicacy of judgment of difference, the lower the liminal difference; always supposing the number of observations made is sufficiently great. (4) *Method of apparently equal intervals.*²—Three stimuli are arranged in series by the subject, so that the difference between the first and second appears to him equal to that between the second and third. (5) *Method of apparently doubling the stimulus* (Merkel).—The subject tries to make one stimulus seem just double another. The two stimuli chosen are then physically compared. In regard to the two last methods, it has been objected that considerable intervals are compared one with another by a different law from that applying to barely noticeable intervals.

It was during his study of touch that E. H. Weber discovered and first investigated the law that bears his name. The visual is perhaps the sense best suited for its accurate observation. For that reason its full discussion must be left to "Vision," but a brief sketch of the law and its significance, and of the superstructure of theory built on it, seems demanded here. Our sense is provided with no exact measure of itself. Yet we can compare sensations of the same quality, and express opinions as to their differences. Thus, of two touches, one may feel "heavy," the other "light." The difference may be wide or not, *e.g.* the light touch may be little lighter than the heavy, or much lighter. It is usual to consider this kind of difference between easily comparable sensations to be a difference of quantity. The heavier touch is considered a stronger sensation than the lighter. When the thus assumed quantity of sensation is on the same hypothesis supposed to be increased, and the assumed increase is obtained without increase of the area or duration of application of the stimulus to the sensifacient surface, the increase of sensation is considered an increase of intensity of sensation. The difference between the sensation of a light touch implicating an area of skin and of a heavy touch implicating the same area, is therefore considered to be a difference of intensity. *How much* more intense one sensation is than another cannot be known. Whether a rifle's report be five or twenty times louder than a pistol's we cannot that way know. We can only roughly judge the degrees of difference. All we know is that a different sensation results when the physical stimulus is intense from what results when the physical stimulus, otherwise similar, is less intense. That

¹ Fechner, "Elem. d. Psychophysik," Bd. i. S. 120. For calculation, see Bruns, *Phil. Stud.*, Leipzig, 1893, Bd. ix. S. 1.

² Plateau, *Bull. Acad. roy. d. sc. de Belg.*, Bruxelles, 1873, tome xxxiii. p. 376.

the sensation from the former is the more intense is an inference from knowledge of laws connecting the sensation with the outward cause of sensation. We are only at the beginning of such knowledge. We do know that a more intense light applied to the excised eye causes a greater change in the electrical condition of the optic nerve than does a similar but less intense light; and that a heavier tap on the web of the pithed frog causes a greater swing of the needle of a galvanometer connected with the sensory nerve than does a lighter tap. Once within the penetralia of the central nervous system, we have, however, still no knowledge of the matter. A first step towards the problem would be to obtain an exact measure for sensation itself. The stars invisible by day are brightly perceptible by night. Yet they constitute to the untired morning eye an external stimulus physically at least as potent as to the eye at night. One and the same stimulus, according to the circumstances under which it operates, will be perceptible either more or less or not at all. If to the stimulus of the starlight there be added the overwhelmingly greater stimulus of daylight, the sensations from the retinal points at which the stimulus is sunlight + starlight, cannot be distinguished from the sensation generated by the rest of the retina where the stimulus is daylight alone. As daylight fails, the brightest stars become visible, followed by those less and less brilliant as the twilight deepens. A stimulus to be felt may be so much the weaker, the weaker the coexistent stimulation of the sensory organ, and must be so much the stronger the stronger the coexistent stimulation. Evidently sensation does not alter in identically the same progression as does stimulus. If a stimulus of intensity (1) causes a sensation counted as 1, a stimulus of intensity (2) evidently does not evoke a sensation 2, or stimulus (3) sensation 3, etc. Were it so, a sensible stimulus added to a pre-existent strong stimulus would provoke as great a difference (increase) of sensation as if added to a weak stimulus. Intensity of sensation, therefore, increases less than directly proportionately with increase of the intensity of the external stimulus. By noting for each strength of stimulus the addition required to evoke a just perceptible alteration of sensation, a series of quantities is obtained expressing the law according to which sensation alters when stimulation is increased. This expression is the so-called "law" of Weber. It says that a given stimulus is perceived less when added to a large stimulus than to a small one, or that an addition to a large stimulus is perceived less than an addition to a small one, unless it, relatively to the stimulus, is as great. The "law" may be phrased variously in physiological theory. It is true that it may be interpreted as not physiological at all, but psychological. The disproportion between increment of stimulus and increment of sensation may take place in purely psychological events and processes. Wundt is of that opinion. He points to the wide occurrence of such a ratio in all psychical activity as outcome of the relativity inherent in every conscious process. Waller finds the response in a nerve trunk directly stimulated, as judged by action current, increase much more nearly directly as the increase of external stimulus than does the response from muscle when nerve is stimulated, or from nerve when retina is adequately stimulated.¹ Waller's evidence seems to point to the law being in part a function of nerve cell endings; probably, therefore, applicable to synapses as to motor plates. Delboeuf considers the law an expression of an ever-increasing proportion of loss of effect in the central nervous system, due to "fatigue." The notion of fatigue has been in the physiology of the senses expanded so as to include phenomena to which the term is perhaps little suitable, e.g. Helmholtz's theory of successive contrast. Delboeuf's seems similarly a strained use of the term. A process need not be of the nature of fatigue to make an ever larger part of the work of the stimulus

¹ *Brain*, London, 1895, vol. xviii.; see also Fick, "Untersuch. u. elekt. Reizung," Braunschweig, 1869; Hermann, "Handbuch d. Physiol.," Bd. i. Abth. 1, S. 107; J. J. Müller, *Arch. a. d. "go to overcoming resistances, and an ever smaller part to the production of the feeling-bringing state" (James). When the pans of a balance are already loaded, but in equilibrium, it takes a larger weight added to one of them to incline the beam. As James says, Weber's law may be a sort of law of friction in the neural machine. The molecules of the sensorial and neural cells are complexes of atoms and atom-groups, spinning, oscillating, and colliding. They can be thought of as embracing hundreds rather than tens of atoms, each possessing its motion. The more violent the oscillations of an atom-group, or the further the group's centre of oscillation from the systemic centre of the molecule, the greater risk of its detachment altogether from the system. Each atom or atom-group, with its kinetic and potential energy, when either of these energies, or both together, exceed a certain amount, must leave the region of molecular affinities, and the molecule be in so far decomposed. Constancy of composition exhibited by a substance, and the uniformity with which it reacts in our testings, is no sign of a dead sameness and calm within it, but merely means that the energy of its molecular life is distributed so as to present a constant average. Among the million molecules of living matter subjected to test *en masse* by even our most delicate physiological experiments, there will at any given time be a certain number in the act of decomposing, and a certain number more on the verge of doing so. There will also be a certain number in the act of creation. The majority of the molecules will be in that average phase of the molecular existence in which the atomic movements most perfectly harmonise, somewhere about the mean between the extreme phases of the molecular condition of the particular substance in question. In addition to the molecules in this mean phase exhibited by the majority, there will be numbers in condition approximate to that critical for decomposition, and numbers the condition of which is more than usually stable. If a formula analogous to Maxwell's for the conditions of a gas is with modification, as urged by Ebbinghaus, applied to the conditions of the molecules of protoplasm, the numbers of molecules in degrees of more than average instability and of more than average stability, arrange themselves about the majority possessed of the particular stability which is average for the chemical substance in question, approximately symmetrically. When the adequate stimulus impinges on such a substance, one may suppose the energy of movement of all the particles accessible to it to be increased. But the external result and the result upon the chemical constitution of the substance must be different in the different molecules. Those molecules already at verge of decomposition are doubtless easily and at once broken up, and likely enough also a number less near the critical condition; a number of which the stability is mean for the substance may also be decomposed, and if not decomposed brought nearer toward easy decomposition. If the stimulus is weak, the number of molecules sufficiently liable to be decomposed by it is relatively small. When the stimulus is sufficient to induce decomposition of the molecules of mean stability, they being the most numerous, the condition as regards strength of stimulus will be peculiarly favourable for producing a high ratio of released force to releasing force. Since a great number of the molecules approximate to the mean molecular condition of the substance, relatively small gradations in intensity of moderate stimuli will cause relatively large differences of effect. As the stimulus is progressively increased in strength, the further number of molecules involved in decomposition becomes progressively less. Finally, even the last and most stable that can be decomposed by the stimulus are reached. The "maximal" stimulus is thus arrived at, beyond which further increase of stimulus fails to cause further increase of effect. The reactions at base of Weber's law can probably be pictured somewhat on the lines of such an hypothesis as the above, but the total reaction must be the sum of an as yet unknown number of such simpler ones.

It must never be forgotten that Weber's law deals with judgments.

The comparison of one sensation with a second of similar *qualé*, but of dissimilar *quantum*, involves more than the mere neural process concerned with a simple sensation. From the very outset it works with ideas based on perceptions, these latter themselves elaborated from sensory impressions. The "law" expresses a striking relation found to hold approximately between the quantity of physical action at one end of the complex chain and the psychical action, as examined by introspective comparison, at the other. Moreover, the process of "attention," variable as it is, has to be used to focus the perceptions, which are therefore *apperceptions* of variable intensity. On the other hand, the conditions appear simpler in so far that by the "law of relativity" every sensation is *ab initio* in some sort a judgment and has implicit the terms of a comparison.

If it be assumed that the just noticeable difference of quantity of stimulus always evokes in a given sense the same quantity of sensation, and if it be further assumed that the "quantity" of sensation evoked by the liminal intensity of the stimulus is the same quantity as that evoked by each liminal difference of intensity, it may be said that the intensity of sensation increases in arithmetic progression when the external stimulus increases in geometrical. The intensity of the sensation varies as the logarithm of the stimulus (Fechner). It has been urged that, as a logical consequence of such assumptions, when 100 grms. is laid on the palm, and to it another 100 grms. added, and when, secondly, instead of 100 grms. a weight of 200 grms. is placed there, and to it another of 200 grms. added, the two weights added must in the two cases appear of equal weight;¹ but in fact they are felt to be different.

The so-called "psychophysical law" (Fechner) is an attempt to supply an absolute measure for sensation. It has yet to be shown, however, that it introduces anything more than an arbitrary scale of measurement. Stimulus (x) and sensation (y) are, somewhat remotely, connected as cause and effect. x is a quantity capable of measurement, and of numerical expression. Of y no measure in the ordinary sense can be found, and the statement that one value of y was double of another, would have, apart from special conventions, no definite meaning. Sensation like temperature is no doubt variable in degree, but changes of sensation, unlike changes of temperature, do not, so far as known, produce measurable changes in any object. Anything comparable with a thermometric scale cannot, therefore, be constructed for sensations. So long as there is no independent measure of sensation, the "psycho-physical law" cannot be spoken of as either a right or wrong interpretation of fact, although it may offer a convenient mode of representing, numerically, intensity of sensation.

The strength of an adequate stimulus may—its duration remaining the same—alter in three ways. It can act with more or less intensity on a certain definite number of end-organs; it can act with an unvarying intensity upon a more or a less extensive number of end-organs; or, by combination of both the preceding, its intensiveness and extensiveness may simultaneously and independently vary. It is noteworthy that the physiological results are in the three cases less dissimilar than might have been thought. Paths of conduction in the nervous system communicate in virtue of the branching of nerve cells, and across nerve cell junctions. The endings of nerve channels frequently embouch into common mechanisms,—that is, their areas of end-distribution overlap. Further, the impulses excited in nervous reactions tend to "irradiate" in nerve centres. By "irradiation" or "overflow," variation in pure intensity of stimulus produces some of the same effects as variation of the stimulus in extensiveness. In virtue of "overlap," variation in the mere spatial extension of the stimulus

¹ Hering, *Sitzungsber. d. k. Akad. d. Wissensch.*, Wien, 1875, Bd. lxxii. Abth. 3, S. 310. This communication contains also the experiments testing Weber's law, carried out under Hering's direction by Löwit and Biedermann.

produces by summation some of the effects of variation of stimulus in intensity. In examining Weber's "law," and Fechner's corollary thereto, the variation of the value of the stimulus should be ascertained to refer either purely to its intensiveness or purely to its extensiveness. The examination of Weber's law began as regards tactual sense exclusively as an examination of intensity.¹

The spatial quality of touch.—Simultaneous tangible stimuli, alike except as to site of incidence, have in many cases the property of evoking sensations distinct one from another. With this property is intimately bound up much of that perception of the spatial relations between environment and organism which the latter possesses. By some it has been argued that all the numerous sensations contributory to space perception possess, by associative experience or as a native attribute, a quality of locality, a "local sign."² The degree to which "locality" attaches to different sensations is various. Touch and sight possess it in high degree. In contradistinction to the organs of muscular sense and the semicircular canals, the skin and eye may be considered the *external* organs for space perception. From this point of view the two offer similarities of arrangement—1. The nerve-endings are spread out in a single plane for the reception of stimuli which likewise are of plane extension. 2. (*a*) Excitation of each point of the sensifacient surface is colligate with a sensation different from that ensuing on simultaneous excitation of any other point of the surface, (*β*) provided the second point be more than a minimal distance from the former point. 3. An object impresses the skin over an area the extension of which in the plane of contact is identical with its own; in the retina, the area, although of smaller extension, owing to the ocular dioptric mechanisms, similarly conforms to that offered by the object. 4. The spatial extension of the object generates, therefore, a set of simultaneous sensations; these can be compounded and, thanks to 2β , as a *continuum*. 5. For each position assumed by these two sense organs, the perceptions attaching to each distinct point of their sensifacient surfaces come by experience to correspond with a definite place in the environment.

The localising delicacy of touch has been measured in two ways—(1) The skin of a blindfolded person is touched with a blunt needle,—the person touched has then to indicate the position of the place touched. (2) The blunted points of a pair of compasses³ are laid lightly and simultaneously on the skin, and the smallest distance of the points apart at which they are perceptibly separate is measured (Weber).⁴ If the points are sufficiently close together, a single sensation results. The liminal distance can be determined, either by the method of just noticeable difference, or by the method⁵ of right and wrong answers.⁶ For the latter about thirty pairs of blunt needles are set, each pair in a little holder at a certain fixed distance apart. The distances should range from about 3 mm. to 80 mm. The answers obtained are "single," "double," "uncertain." The last are treated as half "single,"

¹ For fuller discussion of the Weber-Fechner "law" in regard to touch, reference can be made to Wundt's "Gründzuge d. physiol. Psychol.," Leipzig, 1893, Bd. i.; "Vorlesungen ueber die Menschen- u. Thier-seele," Leipzig, 1892, translated by Creighton and Titchener, London, 1894. Also, cf. Helmholtz, "Handbuch d. physiol. Optik," Berlin, 1897.

⁶ Not necessarily as a step toward the examination of the Weber-Fechner psychophysical "law."

half "double." But with certain observers¹ and in certain series² of observations they have not occurred. With increasing separation of the points of contact the proportion of right answers to total answers increases; at a certain separation the answers are all right. Throughout the observations single contacts are intermingled with double contacts.

When "touch spots" are sought out for excitation with the compass points, liminal distances are found much smaller than the average liminal distance of the region.

Some "æsthesiometers" allow of the reading of the pressure applied to each of the points.³

In vividness and delicacy of local sign, touch resembles the muscular and visual senses. It, however, falls far short of the last, being at best more than three thousand times less delicate when skin distances are compared with retinal.

Table of Liminal Distances for the "Sense Spots," in Millimetres.⁴

Skin Region.	Touch Spots.	Cold Spots.	Warmth Spots.
Volar side of finger-tip	·1
Palm	·1	·8	2
Hypothenar eminence	·1
Back of hand	·3	2	3
Foot	·8	3	...
Forearm, flexor side	·5	2	2
" extensor side	1	3	3
Leg below knee	·8	2	3
" above knee	3	2	3
Upper arm	·6	1·5	2
Chin	·3	8	4
Cheek	·4	8	3
Forehead	·5	8	4
Abdomen	1·5	1	4
Chest	·8	2	4
Back	·4	1·5	4

As said above, the "touch spots" tend to be arranged in tiny systems radiating from centres. The compass points are perceived to lie apart with especial distinctness, when applied to "touch spots" of two such separate systems. The above list shows that the liminal distance is least for "touch spots," and greater for "warmth spots" than for "cold spots." The direction of the axis joining any two stimulated "touch spots" is judged with greater nicety than is that of the line joining temperature spots of similar distance apart.⁵

The same has been noted with "average liminal distance."⁶ Weber's method, as applied by himself,⁷ C. Vierordt,⁸ and others,⁹ is, however, of special value for giving an idea of the "average liminal distance" for a cutaneous region. It is this rather than the special details of liminal distance in relation to the distribution of "touch spots" that yields data valuable for dealing with the majority of space perceptions elaborated from tactual sensation. In estimating the

“average liminal distance,” certain precautions must for accuracy be taken. When the stimuli are successive instead of simultaneous, the distance is much reduced, *e.g.* from 20 mm. to 5 mm. on dorsum of hand.¹ The æsthesiometer points must both be at skin temperature. The average liminal distance varies greatly in different skin regions. When children and adults are compared, it is found to be less in the former.

*Table of Average Liminal Distances in Millimetres.*²

Skin Region.	Adult Man.	Boy, æt. 12.
	Mm.	Mm.
Tip of tongue	1·1	1·1
Volar face of unguis phalanx of finger	2·3	1·7
Red surface of lip	4·5	3·9
Volar face of second phalanx	4·5	3·9
Dorsal face of third phalanx	6·8	4·5
Side of tongue	9·0	6·8
Third line of tongue, 27 mm. from tip	9·0	6·8
Plantar face of unguis phalanx of first toe	11·3	6·8
Palm	11·3	9
Back of second phalanx of finger	11·3	9
Forehead	22·6	18
Back of ankle	22·6	20·3
Back of hand	31·6	22·6
Forearm, leg	40·6	36·1
Dorsum of foot	40·6	36·1
Outer sternum	45·1	33·8
Back of neck	54·1	36·1
Middle of back	67·1	31·6-40·6
Upper arm, thigh	67·1	31·6-40·6

In the limbs, the “average liminal distance” for touch is greater parallel with the long axis of the limb than across it. The distance can be reduced by practice. The blind, who partially supply by other senses their deficiency of visual space-perception, recognise small shapes, *e.g.* letters, coins, with enhanced nicety by practised touch.³ Type-setters similarly discriminate between letters, correctly and rapidly by touch. Under repeated examination by Weber’s method, an area of skin will, in even a few hours, reduce its average liminal distance by a half.⁴ The “education” is at first slow, then quicker, and finally slower, dwindling to cessation when a certain decrement of the distance has been effected. The decrement obtained by “education” is completely lost by a few months of want of practice. In those inaccessible and relatively immobile regions of the body surface, where the liminal distance is very

¹ When two pressure stimuli are applied simultaneously near together, the areas of deformation of the skin surface are likely to meet and overlap. This will not occur when the same two stimuli are applied to the same two points successively. This, however, is an explanation insufficient to account entirely for the reduction of the average liminal distance obtained by applying the stimuli successively instead of simultaneously. Cf. Judd, *Phil. Stud.*, Leipzig, Bd. xii. S. 409; v. Frey, *Sitzungsb. d. phys.-med. Gesellsch. zu Würzburg*, 1899, Bd. xii.

² The observations on the adult are condensed from Weber’s list in the “Handwörterbuch,” with a few additions from the “Programmata,” 1834, fasc. 1. The observations on the boy are from Landois, “Lehrbuch,” 1881, 2te Aufl. S. 929. The distances given are the minimal from which double sensation is obtained, when stigmatic excitation of selected touch spots is not undertaken.

⁴ Volkmann. *Ber. d. k. sächs. Gessellsch. d. Wissensch.*, Leipzig, 1858.

great, it cannot be reduced so speedily or largely as in the fingers.¹ Education of an area of skin in one lateral half of the body reduces the average liminal distance, not only in and around the area itself, but in the symmetrically placed area of the other half of the body as well. Similarly, the learning of a movement by the right hand imparts a partial ability to perform it with the left.²

Delicacy of tactual space perception at any point of the surface of the body seems in part a function of its mobility (C. Vierordt).³ It depends both on the variety of direction and on the linear amplitude of the movements of the part. It increases with the distance of the part from the axis of rotation. In the arm the delicacy increases continuously from acromion to finger-tip, but at unequal rate between the different joints. If the localising power for touch at the acromion be valued at 100, it increases to 2582 at the finger-tips. In the upper arm it increases to 151, in the forearm to 272, in the hand exclusive of digits to 659, in the thumb to 2417, and in the middle digit to 2582. These values in each segment (*e.g.* forearm) of the limb can be considered the sum of two quantities. One of the quantities depends on the distance from the main axis of movement of the limb as a whole, *e.g.* from shoulder. The other is determined by the distance from the axis of movement of the segment itself, *e.g.* from elbow. Even in each separate finger the rate of increase of delicacy is different in the different segments and greatest in the terminal. The relation between delicacy of sense and degree of mobility is least easily examined in the head, because of the complexity of movement of that region. The difference is only as 100 to 160 between all mobile (but not motile) parts of the head's surface. Yet Vierordt's theory seems to apply very perfectly there also.⁴ Thus there is a continuous and regular decrease of average liminal distance along the cheek from ear to lip. In the head and in the arm the average liminal distance is not only inversely as the mobility of the part, when passively partaking in movements of the head upon the neck, but is further reduced by the active movements of the part itself, if mobile. Thus the average liminal distance decreases rapidly from base of tongue to tongue-tip. Again, its measure is less for the surface of the lower than the upper lip, for the upper than the lower eyelid; lower eyelid and upper lip are the less mobile.

Among conditions affecting the fineness of localisation by touch, are the following. It is decreased by anæmia of the skin and by venous hyperæmia;⁵ also by too frequent testing, and by mental fatigue,—thus, three hours of school classes will double some threshold distances on the face;⁶ also by cold and by excessive stretching of the skin.⁷ In relation to the last-named point, there is an experiment of some theoretical interest. If the skin of the neck be stretched by throwing back the head as far as possible, the distance of two skin-points can in certain regions of the neck be doubled. The *average* liminal distance in that region is, however, not doubled, but only increased 8 per cent.⁸ The passage of a

subliminal electric current between points only little above liminal distance apart, causes simultaneous touch sensations from those two points to lose their separateness, and fuse.¹ Narcotics markedly increase the average liminal distance.²

The sense of touch locality is disturbed and injured, disproportionately to damage of other tactile qualities, by lesions of the cortex of the cerebral hemisphere. In a hemiplegic patient the sense of touch in the affected limb is sometimes but little impaired, when tested by the liminal intensity or liminal difference of intensity; but when the patient is required to localise, great, often enormous, deficiency is found (Westphal), so that a touch on the hand may be perceived as though located on the upper arm.

Theory of "localising" power of "touch."—A something attaches to or is inherent in a "touch" which gives it *place*, establishing it within ideal space. There is reason to think (see "Muscular Sense" and "Spinal Cord") that something analogous may attach to even very simple reactions not involving consciousness, *i.e.* to what are sometimes called neuroses in distinction from psychoses.

This quality of "place" is by some regarded as native to and intrinsic in touch (Czermak, Vierordt), which thus possesses a simple *spatial quale*. Others (Lotze, Meissner, etc.) have regarded it as the outcome of experience of association, of sensations concomitant with each touch sensation; the associate groups centred on touch sensations generated at sufficiently separated spots of skin are, it is argued, sufficiently different to be perceptibly distinct. Each such little compound system of sensation serves as differentiating and recognisable sign, labelling the "touch" attached to it with "locality," or, in Lotze's language, giving it "local sign." Lotze's scheme of local signs was based mainly on muscular sense; Meissner attributed it in tactual sense to physiological differences in the structure of the skin of different regions.

A difficulty in the way of accepting locality as a native quality of simple touch, is its relativity. At the root of locality lies discrimination of place, and to discriminate in place between even only two touches implies perception not alone of the excited points, but of the extensiveness of an unexcited interval. Thus localisation would commence in duality. Weber insisted from the outset on the perception being not only of two points, but always also of the *interval between*. How is it, then, that a *single* touch comes to be localised? Previous experience has taught the recipient subject that when either point was impressed by an object, the same object usually touched also certain immediately neighbouring points. Each point becomes thus associated with an area of circumjacent points, the associated fading in strength as the distance from the point increases. The point about which the associated area thus centres has its own peculiarity or shade of feeling. Wundt writes: "If we touch first the cheek and then the palms, each time with the same pressure, the sensation is, notwithstanding the similar stimulation, markedly different in the two. So if we compare the feeling of the palm with that of the back of the hand, in short, of any two distant parts of the skin with each other. Moreover, we easily remark, by attentively observing, that spots even near together differ in respect of quality of feeling." Each has its "local sign." But the feeling of each point is, as above said, associated by experience with the feeling of the circumjacent. Its sensation revives consciousness of the whole region round about. The "local sign" of the central point, therefore, suggests the feeling of the entire district, and its locality is given by judgment of the relation between it and other points in the revived regional perception.

¹ Suslowa, *Ztschr. f. rat. Med.*, 1863 (3), Bd. xvii. S. 155.

² Lichtenfels, *Sitzungsb. d. k. Akad. d. Wissensch.*, Wien (2), Bd. xvi. S. 3.

In the limbs and mobile parts, when a spot of less discriminative sensitivity is touched, instinct moves the member, so that it brings to the object the part where its own sensitivity is delicate, *e.g.* the finger-tips. It is apparent to most of us that if, with closed eyes, we attend to the consciousness of the resting arm, the hand, and especially the fingers, are the parts we are most aware of, best outlined, so to say, in consciousness. There arise lines of habitual association between all points of the member and its sensitive tip. James writes: "I think anyone must be aware when he touches a point of his hand or wrist that it is the relation to the finger-tips of which he is usually most conscious."

"Muscular" sensations may be regarded as varying in *intensity* according to extensity of movement. A more intense sensation accompanies a larger movement; a more prolonged sensation a longer lasting movement. Touch sensations may be regarded as varying in *quality* with the place of the skin whence they arise. Touch sensations are yoked with "muscular" in four main modes. (1) The same tactual point is moved successively over various points of an object, *i.e.* the same touch in regard to quality is yoked with a series of "muscular" sensations differing in intensity; "active touch." (2) An object is allowed to move over a series of tactual points, the tactual surface being held stationary, *i.e.* one muscular sensation is combined with a series of tactual; "passive touch." (3) One tactual surface is moved over another, *i.e.* one set of "muscular" sensations is yoked with a double simultaneous series of tactual; "double touch." (4) The movements of the body, apart from contact with objects, are combined with corresponding series of tactual sensations due to stretching and folding of the skin. Disparate sensations, if connected frequently, become "associated," so that genesis of one involves reproduction of the other. In thinking of our arm's *movements* we always in some degree recall its field of touch. "Muscular" sense is more delicate for shoulder than for hand, yet in recalling a movement of the arm we habitually recall the hand more than the shoulder. Conversely, perception of a tactual point is fraught with "muscle" sensations linking to it other tactual points whose perceptions frequently precede or succeed or accompany it. These sensual links lend themselves well to measurement, because differing in many instances in mere intensity rather than in quality. The measure of their differences yields by associative experience a basis of estimation of the spatial distances of the tactual points. Tactual space includes the idea of the skin as a *continuous surface*, although its organs are punctiform. This results from infinitely graded muscle sensations accompanying infinitely graded rectilinear movements possible in various directions in a plane.

It is noteworthy how little vision seems to contribute to tactual localisation; some of the most delicately localising touch surfaces never come within the visual field at all. Tactual localisation differs from auditory and gustatory in that, whereas a single drop of fluid on the tongue may give a mixed sensation, and two sounds may be perceived to come from the same place, two compound touches of different quality, *e.g.* a blunt and a sharp, applied simultaneously in the same sensory circle, do not combine to any simultaneous sensation, but alternate, as in the struggle of different colours presented to identical spots of the two retinae.

Weber¹ described the whole surface of the skin as resolvable by analysis into "sensory circles." If for any part of the skin we measure exactly the distance between compass points the sensations aroused by which appear single, and make this measure in many directions about a single point, we obtain for this part of skin a figure of rounded form within which simultaneous touches appear single. Such an area is a Weber's

¹ E. H. Weber, *loc. cit.*; also "Tastsinn u. Gemeingefühl," Leipzig, 1852, S. 106.

"sensory circle." It is in most regions oval, since discrimination is most delicate usually in some direction at right angles to the direction of least delicacy, *e.g.* across the limb. It might be supposed that in each "sensory circle" the two stimuli generate an indivisible sensation, because they both excite the terminal field of a single sensory nerve fibre,—that in fact each "sensory circle" is the area of ending of a single nerve fibre. But a sensory circle where large, *e.g.* in the back, with a diameter of more than six 6 cms., contains more than 200 touch spots; and histological examination shows that no cutaneous nerve fibre breaks up into anything like that number of end-fibres. Besides, if the sensory circles be represented by brackets $(a+b+c)$ $(d+e+f)$ $(g+h+i)$ containing cutaneous points *a*, *b*, and *c*, and if $a+b+c$ represent the ending of one sensory nerve fibre, and $d+e+f$ the ending of another, and if the explanation of the sensory circle be that two simultaneous touches cannot be felt as separate, if affecting only one and the same nerve fibre, the "average liminal distance" (that is, the size of the "sensory circle") will vary greatly in one and the same skin region, according as the simultaneous stimuli fall on points *c* and *d* or *f* and *g*, or on *a* and *c*, or *d* and *f*. The sensory circles must be larger than the anatomical units of the sensory surface. Moreover, a few hours' use and practice can reduce the size of the sensory circles in the finger to one quarter their previous area. No morphological alteration could be effected in that time. Weber urged that for two simultaneous touches to be distinguishable, a certain number of unstimulated nerve-endings must intervene between the stimulated ones. The now recognised existence of "touch spots," each coinciding with a tiny cluster of or a single tactile end-organ, bears out Weber's view. When the compass points are felt as double, a striking part of the sensation is the feeling of an interval between the two points. The smaller "average liminal distance" for the fingers than for the back, is not explicable entirely by greater number of "touch spots" per unit surface in the former than in the latter. A sensory circle in the back may contain many more than 200 touch spots, while a digital sensory circle may contain many less than 200. "Local sign" seems possessed in higher degree, therefore, by sensations generated through digital "touch spots" than through "touch spots" in the back.

The division of the skin into a mosaic of tiny sensifacient areas, each of diameter less than the radius of a "sensory circle," explains perception of contact along an unbroken line, even when the object in contact with the skin has spatial gaps, *e.g.* edge of comb or saw, so long as the gaps are less wide than are the "sensory circles."

That two stimuli, identical in quality and quantity, evoke when applied to two different sensory circles tactual sensations correspondingly different, is certainly referable to occurrences situated in the higher nervous "centres." A cutaneous nerve trunk stimulated in its course evokes tactual sensations referred to the skin area of the peripheral distribution of the nerve. The sensation evoked, although one towards which the end-organs have not collaborated, possesses in considerable degree its "local sign." It is noteworthy that at the distal ends of the limbs, where local sign is better developed than in the proximal parts of the limb, the nerve roots in their distribution to the skin overlap especially widely.¹ This means that the area of embouchment into the central

¹ Türk, *Denkschr. d. k. Akad. d. Wissensch. Wien*, 1855; Sherrington, *Phil. Trans.*, London, 1892.

nervous system of the sensory channels for a patch of the palm is greater than for an equal patch from the shoulder. It has been pointed out that in the limb the amount of sensory root overlap of distribution corresponds broadly with the degree of "local sign." But in other parts there are striking exceptions to this, *e.g.* the tongue; though there again the area of embouchment of the sensory channels into the grey matter is very large (descending root of fifth cranial). The paths of the spinal columns, including the tactual, embouch into and diffuse in the spinal grey matter. It is the wide spatial extent of the deep (central) connections of tactual paths, after their entrance into the cord and brain, that probably form an essential character of the physiological mechanism, correlated with the development of "local sign."

That the determination of the average liminal distance is by central as well as by peripheral factors, is shown not only by the rapid effect of

FIG. 369.—Map of the skin distributions of the seventh, eighth, ninth, and tenth afferent nerve roots of the frog. The test used in determining the distributions was occurrence or absence of response (movement) of the "spinal" animal to mechanical stimuli applied to the skin when all but one of the roots in question had been severed.—Method of remaining *æsthesia*.

local "education," and by the local reference of tactual nerve fibres stimulated in their course, but also by the small increase of the distance when the skin is stretched even to twice its unstretched length (see above, p. 937), and by its general increase under mental fatigue.

Of two lines seen under like conditions, a longer may be regarded as a greater stimulus than a shorter. A surface of 2 cms. in contact with the skin may be considered, *cæteris paribus*, a greater stimulus than a surface of but 1 cm. That Weber's law holds for comparison of pressures applied to skin, does not imply that it will hold for comparison of areas applied to the skin. The examination of the scope of the "law" in the latter direction has been less followed than in the former in its application to "touch." Fechner concluded that the law is inapplicable for areas of contact.¹

Projection of "touch."—Sense perceptions inform at first hand of alterations in the condition of sensifacient organs. Since these alterations are, under normal circumstances, habitually occasioned by external objects, we habitually consider many of them as qualities of

¹ "Elem. d. Psychophysik."

environmental objects, that is, we project them. The force with which the quality inheres is different in different senses. Visual perceptions seem almost unconquerably the properties of objects in space round about. Among the cutaneous senses, touch is that one most possessed of objectivity. When an external object is touched by or touches the finger, there arises, as an immediate rather than as really a mediate result, a presentation of a something not "I," endowed with quality, "hard," soft," "smooth," etc. Complete emancipation from the involuntary "projection" is not possible for us. In some cases the degree of projection of touch is very marked. Thus the perceptions of touch evoked by contact of objects with hairs are referred to the insentient free portions of the hairs themselves, even to their very tips. Similarly with the teeth. Again, the surgeon, as far as touch is concerned, actually lengthens his fingers by using a probe; a rod pressed by the fingers by one end upon a yielding or hard object gives two sensations, —one to the fingers where it meets them, and a second referred to the point of contact of the rod with it. In this we have a germ of the projicience so marked in visual sense of space.¹

That identical muscular sensations may be accompanied by non-identical cutaneous, is probably a main factor in giving the latter "objectivity." In all movements that involve the cutaneous surface, that surface being a sensifacient one, if those movements occasion adequate stimulation of the surface, cutaneous sensations will be generated in addition to the muscular sensation inherent in the movement. The two senses together will react to an object in greater range of quality than will either alone; the two will obtain more criteria for judging the object than will either one; the two are alike endowed pre-eminently with "local sign," and "projection" is an adjunct of the intuition or perception of space. When different objects or one object under different circumstances, evoke sensations, tactual and muscular, which vary (as to extension, intensity, and especially "local sign") not harmoniously, but in almost infinite combination, the compound perceptions resulting form a store of data especially favourable for the judging of space. The very variety of the variously congruent combinations of muscular sense and touch, the irregular flux of correspondence and of non-correspondence between the two, comes to imbue the perceptions of the latter with projection.

In the retina the extension of the sensifacient surface in space is such as to preclude in the same individual any one retinal point ever supplying the adequate stimulus to any other, *i.e.* no part of the two retinae can be seen by any other part. With the skin it is different. One part of its surface may supply adequate stimuli to other parts, and often does. A very small fraction only of the human surface is inaccessible to touch by the individual's own hand. It results thence that we regard the cutaneous sensifacient surface—although it, like the retina, belongs to the sentient "self"—as, relatively to that, an external thing, and come to endow it, as we endow other objects of the environment, with the qualities of our sensations. Thus on this, the so-called "double touch," is built, so to say, a bridge from "outside of me" to "me" and "self." Hence tactual and the thermal cutaneous sensations, although "projected," are less so than are visual.

Illusions in tactual judgments of space.—Two "touches" a certain

¹ E. H. Weber, *loc. cit.*

distance apart appear further apart if tested where the "local sign" is strong than where it is weak. The points of a pair of compasses, when moved with a sufficient speed over a length of skin, appear to get wider apart as they pass from skin less endowed with local sign to skin more endowed, *e.g.* from ear to lip.¹ Moved in the opposite direction, they seem conversely to close together. Moreover, if moved with uniform speed, they appear to travel faster as they pass over the more perceptive region, *e.g.* towards lip.²

When two skin-points (*a* and *b*) are simultaneously touched with the compass-tips, the distance between them appears greater than if one compass point travels—not too slowly—from *a* to *b*. The quicker the travel the shorter appears the distance; the slower the travel the longer the distance; so that it may, if quite slow, appear longer than if *a* and *b* be simultaneously touched.³ It is easier to read letters as they are traced on the skin than letters already fully shaped and pressed upon the skin. It must be remembered here that for the reason given above (p. 936, note 1), the deformation of the skin will be greater in the former case than in the latter.

If a body, *e.g.* a ball, be touched with a rod, the eyes being blindfolded, and its periphery followed by touching it with the rod, the dimensions appear smaller the longer the rod used.⁴

Owing to the inequality of the "average liminal distance" when measured along various axes in a single region of skin, it is easy to be deceived about the form of surface in contact with the skin. The cross-section of a circular tube pressed on the skin appears transversely oval; whereas contact with a true oval, and its longer axis lengthwise, along the limb, appears circular. Again, experiment shows that if a metallic tube, with triangular, circular, or rectangular cross-section, is pressed on the skin, it is not easy, unless the tube be much larger than the "sensory circles" of the skin in question, to distinguish its shape. A circle can be "felt as circular" by the tongue-tip, if the diameter be not less than 3.3 mm.; but to be felt to be circular by the skin of the abdomen it must measure 55 mm. across.⁵

An experiment, which as long ago as the days of Aristotle was of recognised psychological interest, is the following. If one crosses the first and middle fingers, and then places between them a small round body, *e.g.* a pea, the pea is "felt double," as though it were two peas. The illusion is strengthened by moving the surfaces of contact. The two sides of the fingers in use are in their ordinary position invariably turned away from each other. Experience has taught that they usually touch two different objects, and this association may be, in the unpractised person, sufficient to override the correcting perception furnished by the muscular sense.

If a penholder be held between the lips, it can be felt to be straight. If one of the lips be displaced sidewise, the holder seems broken. This illusion vanishes in front of a mirror. So also with transplanted portions of skin: in the nose made from a flap of frontal skin, touches continue for months to be referred to the forehead.

Tactual judgments of form.—For judgment of the shape of objects and their dimensions by touch, we possess four methods of acquiring data,—

¹ Weber, *loc. cit.*

² Vierordt, *loc. cit.*

³ Fechner, Vierordt, *loc. cit.*

⁴ Tourtual, cited by Vierordt, "Gründriss d. Physiol.," Tübingen, 1877.

⁵ Vierordt, *loc. cit.*

1. The object in contact excites a certain number of tactual sensations of definite intensities and imbued with "local signs." These component sensations are combined, either (1) simultaneously, or (2) successively as well as simultaneously. 2. The successive component sensations can be acquired by *actively moving the tactual surface*, to increase or renew the simultaneously-given groups of sensations, and in so doing the muscular sense is combined with the tactual in obtaining criteria for judging the shape and size of the object by the distances moved. 3. The tactual perceptions can be accompanied by visual. 4. The tactual perceptions can be accompanied by both muscular and visual.

The man blind from birth, on whom Cheselden performed his historic operation, on first obtaining his sight described the visual field as flat and its contents as "seeming to touch his eyes." Children cured of congenital cataract at the age of 6 and 7, when, in spite of blindness, well acquainted through their other senses with the form and number of objects, and able to remember, recognise, and describe them, have still, on first obtaining vision, to touch objects in order to know what and how many they are. When shown a box, a coin, two fingers, etc., they do not recognise what they are, nor their squareness, roundness, or that the fingers are two (not one or three); after touching them over (tactual and muscular sensations), they recognise the species, form, and number at once.¹ Judgment of direction and distance has similarly to be translated into visual signs from tactual and muscular.² The child for many days after recovering sight, if in a strange room, feels its way between the furniture as though in a dark place. Faulty naming of objects seen, that are perfectly correctly named when touched, is said to be traceable in such children for some years.

The degree of importance of tactual sensation for guidance and execution of movement is very various. To enervate the foot induces no obvious defect in the stepping of the horse. A bird, in which the cutaneous nerves of the foot have been paralysed by section, will still grasp the perch, and sleep balanced on the enervated foot.³ On the other hand, Bell found the prehensile movements of the lips of the horse were abolished by section of the sensory nerves to the face. A monkey, in which the fifth cranial nerve of one side has been cut, and sensation lost there, keeps, in drinking from a bowl, moving round it toward the side away from the side of section.⁴ The guiding sensations for drinking with the lips are therefore almost exclusively supplied by touch.

Hering has devised a cylinder æsthesiometer for testing delicacy of judgment of surface form by touch. A set of reels (usually twelve), each about 8 cm. long and 15 mm. in diameter, are closely wound with silvered wire, each reel with a differently-sized wire, the coarsest wire being 1 mm. thick. One reel has an absolutely smooth polished turned surface. The test is carried out by finding with which of the reels the sensation of roughness or smoothness begins or ends. To the finger-tips of many persons, whose hands are not much employed for rough labour, the coils of wire of .11 mm. thickness give a distinctly "uneven feel."

³ A. Chauveau, *Brain*, London, 1891, vol. xiv.

⁴ Sherrington, *Phil. Trans.*, London, 1892.

Touches may be perceived as of separate *locus*, though their mutual direction be imperceptible; a line 9 mm. long is perceived by touch as linear, but for the direction to be perceived must exceed 12 mm. Alphabets for the blind have linear or punctate letters. The threshold of space for recognition of line direction is more than twice as high as for successive points. The dimensional distances being the same, the point alphabet is therefore the easier, especially if the points be taken in succession as in the New York horizontal point-letters; the Braille point-letters are vertical.

The central paths and centres concerned with the conduction and elaboration of the nervous reactions of "touch" are dealt with in the sections dealing with the "spinal cord" and the "cerebral cortex."

Reaction-Time.—The reaction-time for touch is longer on the average than that for audition, shorter than that for vision. The average time observed by Exner was .1337 seconds, by Hankel .1546 seconds, by Baldwin .125 seconds, by Hirsch .182 seconds, by Wundt .213 seconds. The reaction-time for electric skin stimuli is shorter than for tactile, thus Wundt .201 seconds;¹ for tactile shorter than for cold and warm. But the experiments have too many psychological factors to warrant discussion here.

CUTANEOUS SENSES OF COLD AND WARMTH.

Recent evidence has led to the cutaneous sensations of cold and warmth being regarded as specific and distinct from tactual sensations, and from each other.

"Cold" and "warmth" as distinct species of sense.—This view implies that even a "localised" cold (or warmth) sensation possesses no tactual element, and that a cold (or warm) stimulus, *e.g.* the point of a cooled (or heated) metal pencil applied to a "cold spot" (or to a "warmth spot" respectively), acts there not at all as a tactile stimulus. Much has been brought forward in support of such a view. It is in some ways more in accord with what we should expect from introspective examination, to regard the sensations we derive from the skin as all of them sensations of greater or less tactual intensity, some of them, however, inseparably accompanied, as it were coloured, by qualities of sensation which we call "cold" and "warmth," others not so accompanied or coloured. There is much to show that while we possess sensations of brightness quite uncoloured, the sensations of colour we possess are all of them inseparable from sensation of brightness. If each sensation of "cold" or "warmth" is a concomitant inseparable from a tactual sensation, it is simpler to treat it not as a separate species of sensation, but as a quality of tactual sensation. The weight of evidence seems at present, however, to be against this. It can be urged against it that thermal stimuli unaccompanied by any tactile element (*e.g.* radiant heat), or accompanied by only such as lie far below the threshold value of tactile stimuli, can yet excite strong "cold" and "warmth" sensations. On the other hand, to some² even warm vapour moving over the skin gives a sensation that they describe as having some tactual character as well as the character of "warmth."

¹ "Physiolog. Psychol.," Leipzig, 1893, Bd. ii. S. 223.

² See Eugenio Tanzi, "Sulle sensazioni del freddo e del caldo," Milano-Torino, 1886.

Observations by Blix¹ and Goldscheider² first led to any general adoption of an analysis of the sense of temperature into distinct specific senses of "cold" and "warmth" respectively. These observers discovered that pre-eminently at certain points of the skin a cool object evokes sensation of "cold," and at certain others a warm object with special facility evokes sensation of "warmth." This discovery was reached by application to the skin of minutely localised stimuli, *e.g.* use of the points of cooled or warmed metal pencils, or minute drops of ether or oil. "Spots" of skin exist at which an object, very lightly applied, fails to evoke the sensation of touch, but, if cold, evokes the sensation of cold; and at these points any stimulus, if sufficiently intense, evokes the sensation of cold.³ Also other spots are similarly sensifacient for "warmth." These "cold spots" and "warmth spots" are therefore considered, in accordance with the theory of specific energies, to be the seat of specific end-organs of nerves for two senses, namely, of cold and warmth.

Weber wrote:⁴ "When the hand is benumbed, there oftentimes may arise from it a subjective sensation of warmth, but never, I believe, of cold." Herzen⁵ noted that his arm, when numbed by compression of its nerve trunks, could feel warmth, *e.g.* the warmth of his other hand, but not cold, *e.g.* the cold of a marble table. Faradisation of a nerve trunk evokes sensations of cold and of warmth referred to the area of distribution of the nerve.

Herzen⁶ has reported the following condition of a patient (in whom post mortem examination showed destruction of the dorsal columns of the spinal cord and the periphery of the dorsal part of the lateral columns in the cervical region); in the skin of the lower limbs there existed loss of tactual impressions, but not of painful; contact with objects at temperatures between 27° C. and 60° C. was felt, and the degree of warmth of them could be well estimated; objects at temperatures below 27° C. evoked no sensation whatever.

Distribution of apparatus for thermal sensations in the skin, etc. 1. Distribution of "cold spots" and "warmth spots."—Over all the cutaneous surface of the body, when examined in areas not too minute, "cold spots" much outnumber "warmth spots." Observers are unanimous in finding the latter more difficult to mark and delimit. The "spots" are arranged in short, slightly curved, lines, which radiate from centres. These centres coincide with hairs, or, strictly speaking, with the points of the surface which lie immediately over the papillæ of hairs. Thus it comes about that each set of lines radiates from a point near the exit of a hair on the side opposite from that to which it slants. The "cold spots" and "warmth spots" are usually but slightly interspersed with each other along any individual ray, but "cold" rays and

¹ *Ztschr. f. Biol.*, 1884, Bd. xxi. S. 152.

² *Arch. f. Physiol.*, Leipzig, 1885, Suppl. S. 1. Goldscheider's discovery was made before, but published after, the appearance of Blix's paper. The analysis achieved by Blix and Goldscheider was clearly suspected by Czermak ("Physiol. Stud.," Wien), in 1855, as the result of experiments of his own. This is the more noteworthy because at that date leading physiologists, including E. H. Weber, taught that even tactual and thermal sensations were evoked in common from one and the same set of nerve organs and fibres. E. H. Weber drew this interpretation from the fact that cold bodies feel heavier than warm bodies.

³ Goldscheider, *loc. cit.*, v. Frey, *Ber. d. k. sächs. Gesellsch. d. Wissensch. zu Leipzig, math.-phys. Classe, loc. cit.*; admitted in a qualified manner only by Kiesow, *Phil. ⁵ *Arch. f. d. ges. Physiol.*, Bonn, 1886, Bd. xxxvii.

⁶ *Ibid.*, *loc. cit.*

"warmth" rays diverge from common centres. In some places, besides the centres coinciding with hairs, there are others apart from them.

The number of "spots" varies greatly, from minute field to field, even in the same local district of skin. Tested by surfaces of 3 to 4 mm. diameter, the same small area will contain patches where sense of cold is more acute than sense of heat, side by side with patches where sense of warmth is more acute than of cold; and interspersed with these, lie other patches paræsthetic or anæsthetic to either or both. These last are possibly places where nerve trunks pass up into the skin,¹ and may be likened to multiple blind spots in a retinal field.

Neither cold nor warmth sensations can be evoked from the cornea (except at its margin),² nor can they from the dentine or tooth pulp.³ In the conjunctiva, "cold spots" are everywhere much more numerous than "warmth spots." A reflex closure of the eyelid is much easier obtained by a cool object as stimulus to the conjunctiva than by a hot one, and the reflex in the former case is much more difficult to inhibit.⁴ Very cold air easily causes lachrymation; very hot air, e.g. in a Turkish bath, has, on the contrary, little effect. The glans penis, although devoid of true "touch spots," is richly beset with "cold spots"; on the other hand, "warmth spots" are very sparse there.⁵

As to identification of the structural characters of the specific end-organs for "cold" and "warmth," it is suggestive that in those regions (conjunctiva, glans penis) whence "cold" sensations can be readily and almost exclusively evoked, the structures known as "end-bulbs" are numerous. These, as found in the conjunctiva, seem to be the simplest examples, as regards histological structure, of the type of end-organ, of which the Pacini corpuscle is the most complex. Though particularly numerous in the above-mentioned regions,⁶ they occur also in the skin elsewhere,⁷ and in the mucosa of the mouth. In the glans penis and clitoris they are larger than in the conjunctiva, and are often of compound construction. It must be added, however, that end-organs somewhat similar in general appearance are found near joint-surfaces ("articular end-bulbs"), whence, so far as we know, neither "cold" nor "warmth" sensations can be evoked. There is reason to think that the end-organs for cold in the glans penis lie particularly near the surface; on the other hand, that in the finger-tips they lie particularly deeply embedded in the skin.⁸ Ruffini's,⁹ end-organs in the finger-pulp, in which he finds nerve terminations resembling those of a Golgi tendon organ, may, it is suggested,¹⁰ be organs for "cold." Tomsa's¹¹ "nerve knots," sometimes called "genital corpuscles,"¹² may without difficulty be related to the end-bulbs, of which they in some respects appear the most developed form. In that case it might be said that in all likelihood in "end-bulbs" we have the terminal organs for "cold sensations."

The long reaction time and the difficulty and want of sharpness of delimitation of "warmth spots" point to a deeper situation in the skin for the end-

¹ Goldscheider, *loc. cit.*

² v. Frey, *loc. cit.* Nagel says that in some individuals there are "cold spots" over the corneal surface, *Arch. f. d. ges. Physiol.*, Bonn, 1895, Bd. lix. S. 570. He never found corneal "warmth spots," or obtained from the cornea a warmth sensation.

³ v. Frey, *loc. cit.*

⁴ Nagel, *loc. cit.*

⁵ Max Dessoir's statement (*Arch. f. Physiol.*, Leipzig, 1892), that the glans penis does not possess temperature sense, is certainly wrong.

¹² This name, given by W. Krause to the organs discovered by Tomsa, is misleading, as a specific "genital" sense seems implied, a proposition which is quite untenable.

organs of "warmth" than of "cold." Ruffini¹ describes, in the deeper layers of the skin of the hand, end-organs of larger size, and cylindrical form, placed more deeply than any other end-organs there. These organs of Ruffini have been found also in the skin of the eyelid and of the upper arm, and therefore appear of pretty general distribution. v. Frey suggests that they are the organs of "warmth spots."

Instruments employed for applying thermal stimuli to the skin are usually called thermo-æsthesiometers. Many forms of them have been employed. Drops of warm or cold fluid,² heated or cooled metal pencils,³ wires,⁴ tiny plates of known surface and thickness, and made of silver,⁵ or other metal of known thermal capacity and conductivity, or offering electrical resistance, have been employed. Kronecker introduced a modification of his perfusion cannula for this purpose, and Miescher-Ruysch further elaborated the same instrument. For many observations the Kronecker-Miescher thermo-æsthesiometer is the most handy and the best.

It consists of a conical tube (German silver) 45 mm. long, divided longitudinally by a partition, which is incomplete below at the apex of the cone. The end of the cone is a circular platinum plate 1 mm. in diameter. One compartment of the instrument is connected with an inlet, to which an indiarubber tube can be attached. The other compartment is connected in similar fashion with an outlet. Warmed or cooled water that is made to flow through the instrument, can only pass from the inlet compartment into the outlet compartment by the hole at the apex of the cone. The bulb of a fine thermometer is placed in the compartment that leads to the outlet; it is so mounted that it is not affected by the warmth of the hand holding the instrument. The whole instrument weighs 50 grms., and is held like a drawing pencil. The water supplied to it should be filtered clear, and not hard. Control experiments with the instrument have shown that the temperature of the apex is, when water more than 26° C. above the temperature of the room flows through at 15 c.c. per minute, estimable within .1° C. if .1° be subtracted from the reading of the thermometer at any moment. When used at temperatures less different from that of the room, the correctness is greater.

Some observers⁶ have used radiant heat for excitation.

2. The degree of thermal sensitivity of different regions of skin.—This is determined partly by the thickness of regional distribution of the "cold spots" and "warmth spots," as described in the preceding paragraphs, partly also by the sensifacient efficiency of the individual thermal "spots," also in some respects by the relative thermal conductivity of the skin, which is chiefly conditioned by the thickness of its epidermis and its moisture. Only by testing with surfaces of not much less than 100 mm. sq. can the grade of general sensibility of a skin region be ascertained.⁷

Weber's estimations⁸ were carried out by testing the degree to which, at various regions of the body surface, *distinction*⁹ can be made

⁸ Weber, *loc. cit.*

⁹ Nothnagel's estimations of regional thermal sensitivity were made in the same way; so also Eulenburg's, *Monatsh. f. prakt. Dermat.*, Hamburg u. Leipzig, 1885, Bd. iv., and *Ztschr. f. klin. Med.*, Berlin, Bd. ix.

between glass phials filled with oil and warmed, or cooled in water, but of course applied dry. But the regional degree of development of thermal sensitivity in the skin may be more truly estimated in another way. If media with a contact surface of about 100 sq. mm., and at temperatures more than 15° C. to 17° C. below or above that of the area of skin to be tested, be employed for an appropriate time, they excite from the skin maximal sensations¹ respectively of cold or warmth, which cannot be increased by further increase of the physical intensity of the stimulus. The maximal sensation thus evoked varies much in intensity in different regions.

Twelve grades can be readily distinguished in "cold" sensation, and eight grades in "warmth" sensation.² The following scale was obtained by using brass cylinders of 1 cm. diameter.³ The scale commences with the places yielding lowest maximal intensity of sensation:—

Cold Sensations.

1. Tips of fingers and toes, malleoli, ankle.
2. Other parts of digits, tip of nose, olecranon.
3. Glabella, chin, palm, gums.
4. Occiput, patella, wrist.
5. Clavicle, neck, forehead, tongue.
6. Buttock, upper eyelid.
7. Lower eyelid, popliteal space, sole, cheek.
8. Inner aspect of thigh, arm above elbow.
9. The intercostal spaces along the region of the axillary line.
10. Mammary areola.
11. Nipple, flank.
12. Certain areas of the loins and abdomen.

The period of application of the brass surface for obtaining "warmth maxima" has to be more prolonged than that required for testing "cold maxima," 1·5 seconds instead of ·5 second.

Warmth Sensations.

0. Lower gum, mucosa of cheek at lower second molar, cornea.
1. Tips of fingers and toes, cavity of mouth, conjunctiva, patella.
2. Remaining surface of digits, middle of forehead, olecranon.
3. Glabella, chin, clavicle.
4. Palm, buttock, popliteal space.
5. Neck.
6. Back.
7. Lower eyelid, cheek.
8. Nipple, loin.

The observations, to a certain extent, bear out what might have been supposed, namely, that those portions of the body surface habitually protected by clothes would possess higher sensitivity to cold than parts habitually naked. The clothed parts of the body are, however, as will be seen later from other observations, less imbued with power to discriminate between small degrees of difference of cold than are many other and unclothed parts.

When fluids quite cold, *e.g.* at 2° C., or quite hot, *e.g.* at 50° C., are swallowed, sensations of cold or of warmth are felt in the mouth and at the

¹ Goldscheider, *Arch. f. Psychiat.*, Berlin, 1887, Bd. xviii. S. 659.

² Goldscheider, *ibid.*

³ The method is called by Goldscheider a method for testing the "absolute sensitivity."

fauces and part of the pharynx, but not from the alimentary canal farther down. When hot fluids are drunk, a sensation is obtained which is referred to the pit of the stomach. E. H. Weber taught that this sensation has no quality of "warmth," but is obscurely painful; but Schlesinger gives distinct evidence to the contrary.¹ A clyster introduced per anum evokes no sensation of cold until it is discharged, when, if at 15° C., it elicits a strong sensation of cold from the anal skin.² I once had opportunity to test the mucous membrane of the cæcum for sensibility to cold and warmth. I used small test-tubes containing water warmed (up to 50° C. at highest), and cooled (at lowest, to temperature of melting ice). The patient experienced no sensation whatever from any of them.³ I also have had opportunity to examine the small intestine by its peritoneal surface, also the surface of the liver in the same way; in neither case did the patient experience any sensation whatsoever. When very cold air is inspired through the nose, the sensation of cold evoked is confined to the nostril, the floor of the nasal chamber, and the upper surface of the soft palate.⁴ In the hotter rooms of a Turkish bath, the feeling of heat which is so marked at the nostrils is very slight inside the nasal chamber; similarly, the very hot air does not cause lachrymation, although very cold air easily does so. From the granulating surfaces of wounds and cutaneous cicatrices thermal stimuli evoke no sensations of either cold or warmth, although, if strong, they may produce sensations of pain.⁵

The adequate stimulus.—In the cutaneous sensations of cold and of warmth is exemplified with especial distinctness the physiological law, that in the nervous system and its immediate agents, change of condition, rather than absolute condition, acts as stimulus. The warmth of the skin excites specific sensations chiefly when it undergoes alteration. When a point of skin becomes cooler, then does it provoke a thermal sensation. So long as its temperature remains unaltered, it does not, except under extreme conditions, generate any thermal sensations.

Under ordinary circumstances, a continuous stream of heat of fairly steady intensity passes from the interior of the body outward through the skin. So long as the conditions for this flow remain constant, the temperature of end-organs in the skin also remains constant, and different though the temperature of the different thermal end-organs in different skin regions may be, no difference between them is felt. The stream of heat flowing outward through the skin may be altered by alteration of conditions either within or without. To take the latter case first: the heat-stream may be checked by covering the free surface of the skin with clothes; the temperature of the thermal organs in the clothed skin will then rise, and the skin there will "feel warm," although the clothes are no warmer than the skin was. On the other hand, the loss of the heat streaming from the skin may be increased by simply cooling, without otherwise altering, the surrounding medium. The temperature of the thermal end-organs will then fall, and they will produce sensation of cold. The heat-stream flowing through the skin will be influenced not

¹ Weber described the sensation evoked from the stomach by very cold fluid as possessing slightly the quality of "cold," Wagner's "Handwörterbuch," Bd. iii., Schlesinger, "Die Syringomyelie," Wien, 1895, S. 23.

² Weber found that if the clyster were quite cold and retained for a time, a sensation of coolness is felt in the anterior abdominal wall; he supposed this due to actual cooling of the skin of the abdomen, *ibid.*

³ Weber touched the mucosa of the sigmoid flexure with a hot iron through an artificial anus; no sensation was perceived, *ibid.*

⁴ Weber, *loc. cit.*

⁵ Cf. Weber, *loc. cit.*, and others; see Goldscheider, "Ueber den Schmerz," Berlin, 1894.

only by the *temperature* of the medium, *e.g.* air, in contact with its surface, but also by other conditions of the medium, in so far as they affect its power of abstracting (or of supplementing) the skin's heat. This power will in any substance depend not only on (1) its temperature, but also on (2) its thermal conductivity, (3) its specific heat, and, in the case of any particular object, (4) on the nature of its contact with the skin, and (5) its interference with, or addition to, radiation. The degree to which an object acts as a "cold" stimulus increases *cæteris paribus* with the degree to which it is cooler than the skin it acts on. Thus water at 20° is a stronger "cold" stimulus than water at 25°, but it does not follow that it is a stronger "cold" stimulus than mercury at 25°, although certainly a stronger "cold" stimulus than oil at 25°. That is, the activity of the object as a "cold" stimulus depends on its thermal conductivity as well as on its temperature. Hence, of water and oil at the same temperature (below the skin temperature), the latter is *cæteris paribus* the weaker stimulus, because it conducts less; of water and mercury at the same temperature (below the skin temperature), the former is *cæteris paribus* the weaker stimulus, the latter conducts better, and more than sufficiently to counteract its lower specific heat. Capacity for heat is also a factor.¹ The nature of the contact is also a determinant of the intensity of the stimulus; continuous surfaces of contact are more effectual than are broken.² Also, of course, renewal of contact is very important. The very air around us in a room, the temperature of which, the skin having become thermally adapted to it, is giving us no sensation, does, if it move more quickly over a skin-surface, very readily produce sensation of cold, *i.e.* we "feel a cold draught." Sensation of cold can also occur without contact with cold substances, namely, by increased radiation. Thus we may feel bitterly cold in a room the temperature of which is high, if the walls are nevertheless very cold, *e.g.* in a mountain hut. In harmony with these facts are others regarding the "adequate temperature." Given an area of skin fully adapted "for the conditions of heat-supply and heat-loss under which it is living, it then, *ex definitione*, produces no sensation either of "cold" or "warmth." An object which, when in contact with that skin, evokes no sensation either of "cold" or "warmth," is of the "adequate temperature" (Hering). But the "adequate temperature" is not one definite temperature; it is a short range of temperatures above and below a mean. This range is far greater for oil than for mercury. The better heat-conductivity of the latter makes it difficult to so adjust it to the temperature of an area of skin, *e.g.* finger, that it shall not in unit time abstract from or add to the heat of skin sufficiently to cause a perceptible lowering or raising of the temperature of the end-organs. The experimental difficulty is increased by variation of the adequate temperature of different areas of skin, and also of one and the same area of skin.³ These facts all point to the intensity of a "cold" stimulus of given contact area being dependent on the amount of heat which it can withdraw from the skin in unit time; in other words, on the degree to which

¹ Hering, Hermann's "Handbuch," Leipzig, 1880, Bd. iii. Abth. 2.

² Hering gives numerous examples of this, *ibid.*

³ Thus Hering found the adequate temperature of the little finger regularly somewhat higher, and that of the index-finger regularly somewhat lower, than that of the middle finger, *ibid.*

it can cool the cutaneous end-organs. It is assumed, in consequence of the results of the spatial analysis of the sensifacient surface, that lowering the skin temperature does not stimulate "warmth" organs, and that conversely the "cold" organs are not excited by a heightening (unless very excessive)¹ of the skin temperature.

The complexus of attributes (temperature, thermal conductivity, specific heat, nature of surface, etc.) which combine to constitute the value of an object as a "cold" stimulus when the object is of temperature below the "adequate," combine to constitute its value, conversely, as a "warmth" stimulus when the object is above the "adequate" temperature. The thermal senses are often termed "the sense of temperature," and rightly, in so far that it is "temperature" which, ranging on either side of the "adequate temperature" as zero, determines the *species* of the sensation; the other thermal qualities, such as conductivity, etc., only affect the quantity or intensity of the sensation. Alteration in skin temperature sufficient in speed and degree to evoke sensation, may be brought about by internal as well as by external changes. Thus, a flushed cheek "feels hot."

Weber urged that the actual process of falling or rising of the temperature of the cutaneous end-organ constitutes the adequate stimulus for the temperature sense. Hering has, on the contrary, put forward the view that the difference existing between the temperature of the end-organ and a physiological zero of temperature, to which it in its skin region is for the time being "adapted," constitutes the stimulus for temperature sense. Vierordt suggested that the transmission of a certain quantity of heat through the skin is the objective cause of all temperature sensations. The direction, according to him, as well as the intensity, of the transmission determines the sensation, the sensation, in his view, being altogether independent of the alterations of the objective temperature of the skin. The fact that a "warmth" sensation can be produced by a sudden hyperæmia of the skin, as well as by a warm object applied from without, controverts Vierordt's view that direction of transmission of heat determines the sensation.

If a metal disc, a little above 0° C., be applied to the skin, *e.g.* of the forehead, for 30 seconds, the resulting "cold sensation" persists fully 20 seconds after removal of the disc. The "cold sensation," therefore, endures while the locally depressed temperature of the skin is rising; and, conversely, after strong stimulation by warmth. This offers a difficulty to Weber's view. Facile evocation of positive after sensations is characteristic of the temperature senses; in this respect both resemble the cutaneous pain sense. Further, the physical stimulus, the change in temperature, not only stimulates the nerve-endings, but actually alters their temperature; and if their temperature be much reduced or heightened, their excitability for a fresh stimulus is lessened. The nipples are exquisitely sensitive to warmth; if one be cooled, and then to both the same warm stimulus be consecutively applied, of the resultant warm sensations, that evoked from the cooled nipple is not the greater but the less.² The finger held in water at 40° C. for 10 seconds, and then, together with the dry finger of the other hand, placed in water at 15° C., "feels the cold" less than does the unwarmed finger. Further, if the finger of one hand (A) be held in water at 32° C., and the corresponding finger of the other hand (B) be at

¹ v. Frey, *loc. cit.*, states that from "cold-spots," by excitation with hot objects, "cold sensations" can be evoked. So also S. Alrütz, *Skandin. Arch. f. Physiol.*, Leipzig, 1897, Bd. vii. S. 321; F. Kiesow, *Phil. Stud.*, Leipzig, 1898, Bd. xiv. S. 585.

² Goldscheider, *loc. cit.*

the same time held in water at 15° C., and if then both are placed in water at 40° C., the finger of A feels the warmth better than that of B. These and similar observations show that each temperature stimulus of above a certain intensity involves, besides its action as a stimulus, other consequences for the temperature end-organs. First, it excites end-organs (and their nervous apparatus) for which it is adequate, and therefore involves, especially in view of the long-drawn character of the after sensation, a temporary reduction of the excitability of the apparatus for a second stimulus: the sense organs of temperature are peculiarly easily tired. Secondly, it alters the temperature of the skin in a direction which tends to lessen the difference of temperature between the physical stimulus and the recipient organs, and therefore to reduce the intensity as a stimulus of any repetition of the original or a similar kind of stimulus. Thirdly, by altering the temperature of the skin, if the alteration be carried beyond a small range close above and below the normal skin temperature, the excitability of both the cold and warmth organs is markedly lessened by the alteration.

An experiment laid stress upon as instancing "adaptation" and "contrast" is the following:—A mercury bath is warmed to such a temperature as to feel to the finger neither warm nor cold. From it the finger is transferred to mercury at the temperature of the room. After half a minute or so, the finger, on being transferred to the bath at skin temperature, then "feels it warm." Similarly, if the finger of one hand be held in water at 15° C., and the corresponding finger of the other in water at 35° C., and then both are transferred to water at 25° C., the same water is felt warm by one finger, cold by the other. It must be remembered that Hering wrote prior to recognition of the separateness of the physiological apparatus for cold and for warmth sensations. I do not see that the above presents difficulty for Weber's view if the mechanism be postulated to be double, as may now be done. Weber's view, equally with Hering's, accounts for bodies cooler than the skin giving rise to "warmth" sensation. But there are experiments of Weber's own which seem to me to argue strongly against his view. If, for instance, at the ordinary temperature of the room, one presses a cold piece of metal (2° to 8° C.) for 20 seconds against the palm, the temperature of the skin there falls 5° to 8° C. The sensation is painful. After removal of the metal, the cooled patch of skin gets warmer again, rapidly at first, later more slowly. Even in eight minutes' time it does not fully reach its previous temperature, although its temperature is rising all the time. Throughout the whole of that period, although the objective temperature of the skin is rising, a cold sensation is clearly felt. A converse experiment can be performed with warm metal. These results offer difficulty to Weber's view, but can be explained by Hering's. In these cases the periods seem altogether too long to be explicable by positive after sensations, even combined with concomitant lowering of excitability.

Again, as we sit before a fire, we can for hours continue to enjoy sensations of warmth from a surface of skin exposed to it. But we cannot suppose that under such circumstances a continual rising of the temperature of the skin and its thermal organs is lastingly going on. And, conversely, long-continued sensations of cold, produced under conditions that do not vary, are facts of experience which Weber's theory of the adequate stimulus for the thermal sense fails to meet successfully.

Hering's appears the most probable theory. It seems to me altered by the recent dual analysis of the thermal sense only in so far that we must suppose that the difference between the temperature of the end-organ and its physiological zero temperature (settled by adaptation)—which difference is, in his view, the cause of sensation—acts, when the existing temperature is *higher*, only on the one set of end-organs (apart from paradoxical sensation); when the existing temperature is *lower*, only

on the other set of end-organs. It is important to note, however, that, as thus modified, the physiological sensory reaction and the psychological sensory reaction experienced when a skin-surface is changing from a condition, as regards sensation, "warm" to "less warm," are both totally distinct from the physiological and psychological reactions concomitant with the transition from "cold" to "more cold," although the physical process initiating both reactions is the same, and although to both, in ordinary parlance, the term "cooling" can be equally correctly applied. And similarly with the comparison between the transitions from "cold" to "less cold," and from "warm" to "more warm."

Weber¹ suggested, as the internal stimulus of temperature sensations, hypothetical conditions resulting from the fact that bodies undergoing changes in temperature undergo changes in volume. Most substances with rise of temperature expand, and, conversely, as their temperature falls, contract; and the change in volume is greater in the case of fluids than of solids. The sensorial end-organs of the skin are composed of fluid parts and of more solid parts. It may therefore be "that as tension acting on the parts of the skin in one definite direction generates sensations of touch from certain cutaneous organs, so also distension or collapse, with diminution or increase of tension coincidentally in several directions, in certain skin organs generates sensations of cold and warmth." It is in such a manner as this that, Weber² suggested, cold stimuli can summate with tactile stimuli for the production of pressure sensations.

The wall of the aorta was found by Roy³ to contract in length when warmed. The pressure exerted between a fibrous capsule and fluid contents within it, as the temperature of the whole rose and fell, might alter considerably; or heat may affect the end-organs mediately through pressures generated in the tissues round about them.

Other stimuli.—Other nervous excitants than thermal are able to excite the apparatus for "cold" and "warmth" sensations in the skin. It is a question how far they excite the end-organs or the nerves. The liminal value for electric stimuli (faradic) applied to the conjunctiva is higher for "cold" sensations than for "pain."⁴ Pressure on the ulnar nerve trunk at the elbow evokes, obscurely, however, sensations of cold or tingling warmth, referred to the ulnar side of the hand more especially. Cold applied to the nerve trunk at the elbow, apart from the sensation of cold produced locally at the place of application, occasions, according to some observers, no sensation of cold⁵ in the hand; in the experience of many, however, although tactual tingling referred to the ulnar side of the hand is the main result, a certain amount of cold sensation referred to the same region is felt also. Such observations are among the most easily demonstrable in illustration of the importance of the end-organ or the efficiency of the adequate stimulus, and for its connection with "specific nerve energy."

Paradoxical sensation of cold.—A warm surface of a certain temperature applied to a "cold spot" produces a sensation of cold—paradoxical cold sensation.⁶ The temperature of the metal applied to elicit the cold sensation has to be about 45° to 50° C. For the skin at large, 45° C. is usually

¹ *Loc. cit.* ² *Loc. cit.*, but see also Klug, *Arb. a. d. physiol. Anst. zu Leipzig*, 1876.

⁶ Alf. Lehmann, "Die Hauptgesetze d. Gefühlsleben," Leipzig, 1892, S. 35; v. Frey, *loc. cit.*

efficient; for the nipple, 40° C. suffices. Alrütz¹ found 48° C. for the elbow, and 52° C. for the forehead, sufficient. According to Alrütz, the paradoxical cold sensation can also be evoked in the following ways:—(1) By applying to the inner side of the elbow, or to the front of the thigh, a silver plate (Thunberg's)² of 4 c.c. surface and 25 μ thick, heated to 100° C. A short cold sensation is immediately felt, succeeded by a “hot” sensation, and sometimes by a painful one. With thicker plates the final sensation of pain is of regular occurrence. (2) By fatiguing the warmth spots. A piece of metal at 52° to 54° C. is laid on the front of the forearm. It evokes a hot sensation, then this declines, and a cold sensation is felt pricking through. (3) After a bath of water at 37° to 39° of some duration, the foot is passed quickly through very hot water. The first feeling that then ensues is of “cold so distinct and so pure as to be indistinguishable from cold water”;³ this subsides, and after it is felt a smarting painful sensation. Cold stimuli, even severe, are not found by Alrütz to give “warmth” or “heat” sensations.

Some characters of “cold” and “warmth” sensations.—Contact under feeble pressure with an object of the “adequate temperature” elicits from neither a “cold spot” nor a “warmth spot” any tactual sensation. But if the contact, although feeble, be with an object sufficiently cool or hot, it will elicit a corresponding thermal sensation (Goldscheider), which may be combined with sensations which are in part at least tactual. At many, though not at all, thermal “spots,” it can also be shown that analgesia exists, at least so far as to tests by pricking with a needle. When tested by a highly-heated metal point, able to elicit almost unbearable smarting, a thermal spot evinces little, or much less, pain, although if the “spot” be a “warmth spot,” a hot feeling arises. Goldscheider considers the sensation ordinarily evoked by contact with an object hot enough to be “painful,” to be compound of (1) warm sensations of high intensity, due to strong adequate stimulation of “warmth spots”; (2) tactual sensations evoked by contact in accordance with conditions laid down in the previous chapter; (3) pain sensations evoked by the physical heat exciting pain-nerves and their endings, in virtue of its property as a general nerve stimulus.⁴ The “burning,” painful sensation of a hot body, on this view, owes its painful quality, not to over-excitation of “warmth spots,” but to concomitant excitation of pain-nerves by the heat.

When the temperature of the cuticle rises to 48°–49° C., or falls to 12°–11° C., pain, in addition to thermal sensation, results.⁵ The above are average figures. The extreme temperatures at which stimuli, when applied to the skin, still evoke purely, *i.e.* not painful, thermal sensations (if one may for brevity use thermal in that meaning), varies under various conditions—(1) It is different in different skin regions;⁶ (2) it depends greatly on the duration of application of the stimulus. The hand dipped into water at 50° C. feels for the first moment a pure “warmth” sensation, without any painful character. The sensation then decreases somewhat, and then increases, rapidly becoming painful. A silver plate of about 4 c.c. surface can be laid on the skin at a temperature of above 110° C., and allowed to cool there, without causing pain, if it be only .01 mm. thick: if it be .5 mm. thick, it will evoke pain and

³ *Mind*, London and Edinb., 1898, vol. vii. p. 141.

⁴ Goldscheider, *loc. cit.*

⁵ Weber, *loc. cit.*

⁶ For details, see Donath, “Ueber d. Grenze, etc.,” *Arch. f. Physiol.*, Leipzig, 1884, S. 694.

"burn." For a similar reason, a hot glass or a live coal can be touched with impunity to pain if the contact last but a very short time. (3) It depends to a remarkable degree on the size of the area of application of the stimulus. This last point entails separate description.

As stated above (under Touch), a stimulus applied to a sensifacient surface, like retina or skin, has an influence on sense not only in virtue of its intensity, but also in virtue of its extension in space as well as in time. So that, *cæteris paribus*, a stimulus affecting a larger area evokes more sensory reaction than one affecting a smaller area. In accordance with the overlapping arrangement of the mechanisms of the nervous system, a stimulus simply in virtue of greater extent of application to the sensifacient surface evokes, at least in some cases, greater intensity of sensation. This is markedly exemplified in the cutaneous senses of "cold" and "warmth."

If one finger of one hand and the whole other hand are dipped simultaneously into the same cold or warm fluid, the sensation of cold or warmth is not equally intense in the two places; it is stronger in the larger surface. Weber wrote:¹ "This greater strength of impression, which results from the same impression acting upon a greater number of sensory points, is easily confused with that strength of impression which, under other circumstances, results from the fluid having a higher or lower temperature. Cold water, therefore, feels colder to the whole hand, warm water warmer, than to a single finger, in spite of the subject nevertheless knowing that the temperature of the water is the same. If one dips a finger of one hand and the whole other hand into water the temperature of which one is ignorant about, one is deceived. Water at 29°·5 R. is, if the whole hand is dipped in it, thought to be warmer than water at 32° R.² into which one dips a single finger. Similarly, one is deceived in case of water at 17° R. and 19° R.

It is an important observation of Weber's, that the reinforcing influence which one thermal stimulus, *e.g.* of cold, has upon the *intensity* of another (of the same species) simultaneously applied, is greater when the places of application of the two stimuli lie near than when they are far apart. For instance, the difference between the temperatures of two equal surfaces can be distinguished with greater nicety when the surfaces are large than when small, but when the two smaller surfaces are applied not far apart from one another, the discrimination is more exact than between the larger surfaces if the latter be applied a considerable distance from each other.

So is it with the pain concomitant of cold and warmth sensations occasioned by thermal stimuli of excessive temperature. The bath comfortably hot to the finger of the nurse, may be very uncomfortably hot to the immersed child or patient. The finger can be kept for any length of time in water at 48° C., but the whole hand held in, soon feels prolonged immersion painful. On the view taken by Goldscheider, therefore, in pain sense, as in thermal sense, mere areal increase of stimulation induces higher intensity of sensory reaction.

Besides the above factors determining the temperatures at which stimuli cause pain, as well as act on thermal sense, are of course others such as specific heat and the thermal conductivity of the object.

The objective temperature of the sensifacient thermal organs of an area of skin, in which we are conscious of neither cold nor warmth, is called the physiological zero temperature. It is not a constant objective temperature; it differs in different areas of skin,

¹ *Loc. cit.*

² Gad says water at 27° C. to the whole hand feels warmer than water at 40° C. to the finger. This overstates the effect in my own experience, but my sensation gives figures nearer to Gad than to Weber.

and in the same area of skin, at different times. Its value is determined by "adaptation." When an area of normal skin is resting at such a thermal equilibrium, *i.e.* is generating in its own sense organs of cold and warmth no trace of sensation detectable by us, that skin has its thermal sense organs in a state of "complete adaptation" to the thermal conditions of the moment. In a comfortable room we feel at no part of the body either hot or cold, although different parts of the surface are at different temperatures, with almost 10° C. between them, *e.g.* lobe of ear $28^{\circ}8$ C., tongue $37^{\circ}6$ C. When we pass from such a room to another which is colder, we experience at first a feeling of cold. But this feeling after a time, if the room be not too cold, passes off. Hering says that under such conditions the temperature of the skin, physically measured, is somewhat lower in the second room. But the thermal sense organs within a certain range adjust themselves to the altered conditions, and a fresh physical temperature is taken for the physiological zero. On then returning to the former room, we experience a sensation of warmth; and this persists in decreasing degree until the physiological zero temperature has been re-established at the original skin temperature—as measured by the thermometer—once more. This adaptation there is no doubt is much greater in range and speed in some individuals than in others.

The range of physical temperature through which the subjective zero temperature may oscillate in virtue of "adaptation," can also be illustrated by experiments such as those given above on p. 953, in which a portion of body surface is brought into contact with objects of various temperature and thermal quality. But it plays a more important part in the formation of certain perceptions than of others. The sensations of cold and warmth evoked from the cutaneous organs are in respect to projection like those of touch, intermediate in kind between visual and muscular. In respect to projection, it is easy to distinguish two groups of thermal sensations, the one group much more projected than the other. Many of our thermal sensations are habitually concomitant with tactual, *e.g.*, we touch a warm object to feel if it is hot, etc.

It has been shown that a cold spot does not evoke a sensation of "touch," if contact of a test-object with it be sufficiently feeble. It does not, however, appear to have yet been shown that by contact more intense no sensation akin to touch is producible at a thermal spot. The glans penis and the cornea, endowed practically only with pain spots and cold spots, yet yield sensations in response to contact which possess some, though perhaps remote, likeness to touch; and these sensations, evoked from these parts by thermal stimuli acting in contact with them, are different from those evoked by thermal stimuli applied without contact, and the difference appears to me one of quality. These sensations in which the tactual and the thermal senses combine are to some extent projected; and to such an extent, even where the pure tactual component must be slight, *e.g.* in examining fluids (see above, p. 924), as to suggest that the thermal end-organs themselves display some reaction to tactile objects. The warmth perception resulting from contact with a hot body is referred to the hotness of the hot body; the expressions "burning hot" "scalding hot," "comfortably warm," etc., are applied not to any part of "me," but partly to the skin and partly to the heated object. It is noteworthy that in the great majority of instances the thermal sensations accompanied by sensible contact are obtained actively, that is to say, by muscular movements which bring the sensifacient surface into contact with the

objects that furnish the stimuli. Thus it is, probably, that Funke¹ comes to place thermal sensations among those that do not belong to the passive experience of the organism, but to the active and the most precise. He was thinking of those thermal perceptions in which the quality of the sensation appears to consciousness incorrigibly and forthwith as a property of the object.

But another, and perhaps purer, group of thermal sensations emphasises the attributes that Volkmar,² unlike Funke, ascribes to thermal sense, namely, its origin in passive experience, and its lack of projection into the environment. This group takes origin in reactions to thermal stimuli supplied for the most part through the air. Most such intangible thermal stimuli experienced are applied to large surfaces, and are diffuse in the sense of not sharply limited in area. On a cold morning we complain "we feel cold," in a hot theatre that "we are too warm"; we refer the excessive cold or warmth to ourselves, and not to the surrounding air. It is in relation to this group of thermal sensations that projection is obscure. Inasmuch as a man's body is in part objective to his own "self," a noumenon, and sensible, coming partly into the range of his various specific sensual fields, thermal sensations can be referred by the "I" to the material "me." Most of the intangible thermal stimuli evoke sensation thus referred. Such sensations are strikingly prone to be "pleasurable" or the reverse. And even here the admixture of tactile quality with thermal stimulus has the effect of imbuing the resultant sensations with a projected quality. The "double touch" which contributes largely to spatial perception of the material "me," is still more potent when thermal sensations are compounded with it. The ear feels cool to the hand, the hand at the same time feels warm to the ear. In this case the sensations, although perceived to be due to the temperatures of the body itself, acquire a peculiar quality of the character of a projection.

It is in the forming of judgments upon this group of unprojected, or only slightly projected, "cold" and "warmth" sensations that "adaptation" often becomes especially deceiving. The oscillations of the physiological zero of temperature rob us of all steady criterion for judgments. Hence, in common parlance, we refer to the environment conditions which are internal, as well as fail to refer to it conditions which belong to it. A person coming in from a windy walk often feels a room uncomfortably warm which is not so to others; exercise has increased the circulation in his skin and tended to warm it, but the moving outer air has rapidly conducted off the extra heat; on entering the house, the stationary air there does this less quickly, and his feeling of warmth is referred to "the oppressive heat of the room." Hence opening windows and sitting in a draught with its accompanying risks; though keeping quiet for five minutes, until the circulation has returned to normal, would attain the same end without danger.³ In the cold stage of the ague-fit, although the blood itself is warmer than usual, the skin, precluded from it by vaso-spasm, and for that reason pallid, shrunken, and cool, develops an intense feeling of chill. The teeth chatter and knees shake. The cold sensation there is not due to unusual coldness of the environment, but to a starving of the skin from its heat by cutting off the internal supply. The patient, however, in spite of himself, refers the causation to the environment; but not the "cold"; he complains "how cold I am." A room often feels at the same time cold to one person, warm to another; just as the same water feels cold to the finger of one hand, warm to a finger of the other hand, the previous thermal conditions of the two hands having been dissimilar. Though neither ear nor hand may at a given

¹ Hermann's "Handbuch," Bd. iii. Abth. 2, S. 249, etc.

³ This nature of the perception is shown perhaps better in other languages than ours, "avoir chaud," "avere freddo," etc.

moment be producing any thermal sensation, finger and ear being each fully adapted to their physiological zero temperatures, on bringing the finger in contact with the ear, the finger may feel the ear to be cool, the ear feel the finger to be warm.

Chiefly among the great group of intactual unprojected thermal sense reactions lie those which reflexly help to regulate the general temperature of the homoiothermous animal. These reactions can scarcely be considered to come within the scope of this chapter so fitly as under that of animal warmth. Although reactions of which the initiation is due to the operation of the afferent mechanism of the specific senses of "cold" and "warmth," it seems certain that some of these reflexes do not directly influence the stream of consciousness. They are unconsciously executed, except when unusually intense. When sufficiently intense to affect consciousness, they are especially liable to assume pleasurable or painful characters of "feeling."

The liminal difference of intensity of stimulus.—Starting from the temperature sensation evoked by an adequate stimulus of threshold intensity, a very considerable range of intensities of sensation can be distinguished by increments of stimuli, and that without otherwise producing any change in the quality of sensation. Between certain limits of temperature the values of the threshold differences are very small. Above, and especially below, those limits the values of the threshold differences become much greater. Fechner, by applying successively to the same area of skin two objects different in temperature but otherwise similar, estimated the smallest difference of temperature (of water) perceptible by the thermal organs of the skin at the area in question. He found the minimal *perceptible* difference smallest with stimuli between the temperatures of 12°·5 C. and 25° C. Using water and the skin of the finger, he discovered that when the finger had been allowed sufficient time in the first specimen of water for, as would now be said, some "adaptation" of its end-organs to the temperature of that water, it could detect differences of temperature to a degree which did not affect his thermometer, although graduated in twentieths of Réaumur units. The range of temperature (12°·5 C. to 25° C.) between which Fechner found the liminal difference smallest must have applied entirely to "cold" sensation, since the skin of the hand possesses normally a temperature ranging between 27° C. and 29° C.¹ Alsberg,² however, found the threshold difference smallest with stimuli (water) between the temperatures of 35° C. and 39° C., a range which, as the highest skin temperature is about 32° C.,³ must have applied to "warmth sensation." It might have been expected that the range of temperatures at which the threshold difference was smallest would have lain close above and below the "adequate temperature." Some observers⁴ have indeed obtained this result, notably Nothnagel, who found the range lie between 27° C. and 33° C.

As with tactual intensity, the threshold difference between two thermal stimuli applied successively to the same area of skin is much less than between stimuli simultaneously applied to similar but not identical skin areas, even if they lie near together.⁵

⁵ Weber, *loc. cit.* ⁶ *Arch. f. Ohrenh.*, 1893, Bd. xxxv. S. 161.

examination of touch, employed the following method for observing the differential limen or the absolute limen of cold sensation. By opening a valve, a steady blast of air at the temperature of the room was allowed to pour from a pressure-bag at a velocity of 14 cms. per second along a lengthy tube of 3.5 mm. diameter. This draught, at 120 cms. away from the end of the tube, was distinctly detectable by the moistened skin of the face to be cool. It was sufficient to just bend a glass-wool fibre held at 90 cms. from the opening of the tube. By measuring the elasticity of the fibre by pressure on a chemical balance, the force of the draught was found, at 90 cms. from the opening, to be much less than .01 mgrm. A thermometer wrapped in moist linen at 90 cms. began to fall after 11 seconds, and soon had fallen .06° C. The sensation of cold was quite clearly perceptible after 7.5 seconds of the draught. The stimulus was probably quite intangible, for it scarcely caused flickering in a candle-flame 110 cms. distant from the mouth of the tube.

Both by the methods of successive stimuli and of simultaneous stimuli, the differential limen of stimulus value is very different in different regions of the skin. This is clear from Weber's and from Nothnagel's observations. Weber¹ determined the degree to which at various regions of the body surface distinction can be made between glass phials filled with oil and then warmed or cooled in water, but applied dry. He sought in this way to estimate the degree of thermal sensitivity of the skin regions. The method is not the best adopted for that purpose; but for the questions under consideration his results are of interest. They were as follows:—

Thermal discrimination is at its maximum in the face, especially in the eyelids and cheeks. The eyelids are more sensitive at the canthi than between. The lips, less sensitive than eyelids and cheeks, are, like the former, more sensitive toward their angles of junction than in the middle. This is the reverse of the arrangement of tactual spatial sense. The thermal sensitivity of the nose is least at its tip, and greatest along the lower part of the outer edge of the nostril. It is very poor inside the nostril: in the external auditory meatus it is, on the contrary, well developed. The skin just in front of the tragus has greater thermal sensitivity than the lip,—again the exact reverse of the distribution of the space-sense of touch. Along the median line of the body, thermal sensitivity is everywhere poor, alike in face, chest, abdomen, and back. Weber found the proximal part of the proximal phalanx of the palmar face of the index finger more sensitive than the corresponding surface of the other fingers; the ball of the thumb more sensitive than the hypotheneal region. The skin over the olecranon he found more sensitive than that of the rest of the arm; the skin over the trochanter major more sensitive than that over the crista ilii.

In considering these results, it must be remembered that Weber does not seem to have paid attention to what Hering² terms "the adequate temperature." There is much evidence that the excitability of a sense organ is at any time partly determined by antecedent stimulation. As the visual organ adjusts itself with a different pitch of excitability, becomes differently attuned, under influence of light and of dark respectively, so the thermal sense organs at different temperatures of the environment. When a skin surface under its living conditions of continual accession of heat and loss of heat generates sensation neither of "cold" or "warmth," it is described as "fully adapted"

¹ *Loc. cit.*, S. 554.

² Hermann's "Handbuch," 1880, Bd. iii. S. 430.

of body surface was renewed by the "difference" method. The results were confirmatory. The differences varied between 2° C. and $1^{\circ}1$ C. for different regions of skin.

It would hardly, perhaps, have been expected that regions endowed with very high absolute sensitivity should be poorly endowed with ability to distinguish difference. Yet a comparison of the performances of the ungual phalanx and nipple shows it to be so. Evidently in testing ability to distinguish, a very complex process is being examined. Absolute sensitivity must, of course, enter into it, but "experience" is probably just as important. The following is an example:—One and the same "cold" stimulus, applied successively to the nipple and the finger, evokes a more intense cold sensation from the former than from the latter, because the "absolute sensitivity" of the nipple is the greater. But with the finger a difference of temperature between two similar objects can be noted, the temperatures of which stand only 2° C. apart, while for detection by the nipple their difference must be 8° C. Speaking generally, the threshold difference is low in value in regions where "touch" possesses strong local sign. As instanced above, it is a fact, elicited by more than one method, that sensitivity to cold and warmth increases as the skin of the limbs is examined in ascending direction from the apex of the limb toward the trunk.

It might have been supposed that that surface of the body habitually protected by clothes would have possessed higher sensitivity to cold than would parts habitually naked. On the contrary, it is found that the face is more sensitive to cold than are many clothed parts of the trunk and limbs. The clothed parts of the body surface are less practised in changes of temperature than the unclothed; the appreciation of degree of change of temperature by the clothed parts has been found correspondingly slight.

Anæmia of the forefinger by holding it above the head diminishes the minimal interval perceptible between two temperatures.¹ Passive hyperæmia seems to affect it little.² Long application of heat or cold greatly damages the discrimination.³

Reaction-time.—On application of a cold object to the skin, the resulting sensation of cold occurs after only a short period of latent excitation.⁴ In its short latency it resembles a "touch." On the contrary, the generation of a warmth sensation is a longer process; the sensation, like that of pain, develops slowly.⁵ When the hand is dipped in cold or hot water, the back of the hand perceives the temperature sooner than does the palm. Weber concludes this is because the palmar epidermis is the thicker.⁶ If both hands are plunged into a deep vessel containing water at 3° to 4° C., and the palms lie toward each other without touching, the cold is felt first by the backs of the hands, but after about eight seconds the feeling of cold is greater in the palms than in the backs; hence from the palms, although a higher maximal cold sensation can be evoked, a longer period of latent excitation is gone through: the difference in all likelihood lies in difference of rate of conduction to the end-organs.

If an object at temperature T be applied to the surface of the epidermis, and θ be the physical temperature of the thermal end-organs, which are at the time at their physiological zero-temperature, θ_1 can represent the temperature which the end-organs will take after a certain duration of the application.

⁶ *Loc. cit.*; see also for the thermo-conductivity of the skin, Klug, *Ztschr. f. Biol.*, 1874, Bd. x. S. 73.

Let it be supposed that the change in temperature is sufficient to cause sensation, e.g. of "warmth." The difference between θ and θ_1 expresses the intensity of the excitation. But θ_1 will not be reached instantaneously. Before it is reached, the end-organs will have possessed a number of different intermediate temperatures— t, t_1, t_2 , etc. If t_3 be the thermal state of liminal difference, that is, just sufficient to evoke sensation, it may perhaps be regarded as that which is just sufficient to be a stimulus at the end-organ. On that supposition, all the time passed between the production of the thermal state t and the thermal state t_3 is lost, not in nervous sensifacient action, but in mere application of the stimulus. The reaction-time, in the ordinary acceptation of the term, commences at the production of t_3 . This period preliminary to the initiation of the sensorial reaction can be reduced by the use of strong thermal stimuli.

The reaction-time differs according as the source of the thermal stimulus comes into actual contact with the skin or not. With strong "intangible" stimuli, the following periods have been found:¹—

¹ Tanzi, "Sulle sensazioni del freddo e del caldo," Milano-Torino, 1886.

These figures confirm the longer reaction period for warmth sensation, that appears to have first been drawn attention to by Herzen.

The quality of "locality" in thermal sensations.—When heat is applied to the skin at separate areas, there is found to be considerable power of "localising" the places of application. The thermal senses of the skin possess, therefore, like the tactile sense, a spatial quality. Rauber¹ investigated the question by placing warmed metal balls in perforated wooden plates, which latter were applied to the skin. He found sensory circles for the "warmth" sense corresponding with Weber's circles for touch. He did not test cold sensations. This has been done by Goldscheider,² who has, moreover, worked not with the average liminal distance, but with "cold spots" and "warmth spots."

With excitation of a cold or a warmth spot, as with that of a touch-spot, there develops, in consciousness, not only a presentation of quality and quantity regarding the stimulus, but also of locality. By applying punctiform stimuli to pairs of cold spots or pairs of warmth spots, a high degree of "local sign" is found to attach to the resultant sensations. Goldscheider found this quality higher for "cold" than for "warmth" spots.

	Cold Spots.	Warmth Spots.
Palm	0·8 mm.	2 mm.
Cheek, forehead, chin	0·8 "	5 "
Back of hand, leg, thigh	3 "	4 "
Upper arm	2 "	3 "
Fore arm	3 "	3 "
Back, abdomen, chest	2 "	5 "

The origin and use of such refinement of localising power for cold and warm stimuli is difficult to understand. It may be that it is necessary in order to obtain perceptions of continuous areas of small dimension. It is to be noted that when a skin surface is excited by heat, the sensation is referred not to a number of individual spots of warmth in the skin, but to a continuous surface,—although the area stimulated is made up of a punctiformly arranged series of sentient places. This is expressed by the overlap of the sensory circles. The more intense the thermal stimulus, the finer the power of localisation (Klug) both for cold and warmth sensations. Two thermo-æsthesiometers at the same temperature, when placed simultaneously on the skin, produce a sensation perceptibly double when they lie nearer together, if their temperature be 5° C. than if it be 20° C. The distance varies little with stimuli between 20° C. and 40° C. The average liminal distance is less with stimuli at 5° C. than with stimuli at 50° C. Beyond that temperature the stimuli become painful. To examine, therefore, whether mere distance of the temperature of the stimulus from that of the skin was the cause of the greater efficiency of the "cold" than of the "warmth" stimulus, Klug applied the two stimuli to the arm in a bath in which its skin-temperature had been lowered. The average liminal distance was then found smaller for stimuli at 50° C. than at 5° C. But the differences obtained in the distance were only small; and the universally richer distribution of "cold" spots than "warmth" spots, together with Goldscheider's positive results, make it clear that localisation is somewhat finer for the cutaneous "cold" sense than for the cutaneous "warmth" sense.

An important point, somewhat allied to that of localisation, has been mentioned above, namely, that simultaneous thermal stimuli, if of the same species, e.g. cold, produce reinforcement of the physiological intensity one of

¹ *Centralbl. f. d. med. Wissensch.*, Berlin, 1869, S. 273.

² *Loc. cit.*

another; and Weber showed that such stimuli, when applied to surfaces near together, mutually reinforce one another more than when farther apart.

Antagonism of sensations of "cold" and "warmth."—If by the thermo-æsthesiometer a sensory circle for cold or warmth has been carefully delimited, and if then two fairly equal thermal stimuli, one cold, one hot, be simultaneously applied within the limits of the circle, a curious sensation results. Czermak, who performed the experiment with use of small test-tubes filled with oil and warmed or cooled, says, "one then distinguishes the sensation due to the cold test-tube quite clearly from that due to the warmed; but, owing to there being no hint of the relative neighbourhood of the two, one is thrown into a peculiar and indescribable confusion," which only disappears when the distance between the two stimuli is sufficiently increased. Klug, using Kronecker's fine-pointed thermo-æsthesiometers, found the average liminal distance not diminished by making one cold, the other warm. When the two points lay at less than that distance, he felt a duplex sensation, but of temporal, not of spatial duplicity. He describes the sensation as alternating cold and warmth,—in fact, resembling the sensation obtained by presenting different colours to identical areas of the two retinæ simultaneously.

Paths of conduction.—The facts mentioned above make it more than probable that the afferent nerve fibres for "cold" and for "warmth" respectively are distinct. The same conclusion is supported by pathological evidence. Herzen¹ found, in experiments on the cat, that after transection of the dorsal spinal white column, the foot on the side of the lesion was not withdrawn when a piece of ice was applied to it, although the animal at once withdrew its opposite foot from contact with a similar stimulus.²

The sundering of the species of cutaneous sensations one from another in spinal disease most frequently takes the form of partial, often severe, impairment of pain and thermal sense, while touch remains intact. It used to be said that in disturbance of cutaneous sense the thermal sensations were the last and least to suffer. Goldscheider³ declares that rather the reverse is true. In tabes, syringomyelia, neuritis, etc., it is not very uncommon to find distinction drawn by the disease between sensations of cold and warmth, the one failing, the other not. Isolated impairment of "warmth" is more common than of "cold."⁴ Certainly the effect of drugs upon skin sensitivity has marked effects on the thermal elements.

THE SKIN AND COMMON SENSATION.

The skin contributes, as might be expected, to so-called "common sensation." Its contributions are especially characteristic in certain pains, sexual feelings, the "feelings" of tickling, shivering, shuddering, and the like. From no part of the body can pain more urgent be provoked than from the skin. A question, arising almost necessarily at the outset in dealing with the physiology of cutaneous pain, regards the relation between it and other sensations of cutaneous origin. Is cutaneous pain the product of a specific sense of pain? Data for complete satisfaction of this problem seem still insufficient. It is necessary, in order

¹ *Arch. f. d. ges. Physiol.*, Bonn, 1866, Bd. xxxvii.

² The conduction paths for thermal sensations are referred to in the article "Spinal Cord," p. 866.

³ *Loc. cit.*

⁴ Schlesinger, "Die Syringomyelia," Wien, 1895.

to state the problem adequately, to include with it some reference to other pains than the cutaneous. The general trend of the evidence will serve to indicate the direction in which the answer to the special case under consideration will in all likelihood ultimately be found.

Some authorities attach to the skin sensory impressions of "pure contact"¹ and of "movement,"² which they regard as different from tactual or thermal. Such sensations, however, in so far as they differ from simple tactual impressions, seem to do so rather because of the nature of complex elaborations from tactual impressions. Hence they will not be dealt with here as specific and distinct from touch. That common sensation arising in the skin, of which the chief characteristic is pain, cannot be so dismissed.

Regarding the physiological nature and mechanism of pain there may be taken one of the three following views—(1) Pain may be a feeling inherent in and appearing under certain circumstances in any, each, and all of the separate senses.³ (2) Or it may be a quality conditionally arising in and limited to certain only of the species of sense.⁴ (3) Or it may itself be a particular species or mode of sensation, the product, and the only product, at least in certain varieties, of a specific sense.⁵ On the last-named view, it should be generated by the reaction of a special neural mechanism, possessing specifically distinct peripheral nerve-ends, and specifically distinct sensorial mechanisms in the central nervous system.

Common experience teaches that a spot of skin, under moderate pressure, gives merely touch, while under extreme pressure it feels pain. The popular and the at first sight most natural, indeed almost intuitive, view of the causation of cutaneous pain, is that which regards it as resulting from excessive stimulation or reaction of the sensifacient apparatus of the tactual and other species of cutaneous sense. In such a supposition the belief is implicit, that a certain extreme degree of excitement in a sensory centre produces pain. Pain on this view is but a character or function common to various species or orders of sense, and not a sensation of species apart and distinct from the reactions of all other senses. On this view the sensations of each sense can among themselves be different, not only in virtue of difference of intensity, of quality (timbre, colour, etc.), of "local sign," etc., but also by difference of "affective tone" in relation to agreeableness and disagreeableness. Such an opinion is consonant with the general experience, that sensations of every species, although in moderation pleasant, become unpleasant when their intensity exceeds a certain degree.

It can be said that lights, sounds, odours, tastes, cold, heat, etc., must, considered as sensations, be "moderate" to be enjoyable. Of conditions that

determine the pleasurable ("positive") or displeasurable ("negative") tone of sensation, among the most powerful are "intensity and duration."¹ An intense light or a piercing note evoke sensory disturbances of distinctly "negative tone." With the minimal sensation the agreeableness is *nil*, but that character reaches its maximum before the total sensation is itself by any means maximal.

Reference is not intended above to the pain in the eye which, apart from visual sensation, can be caused by very strong illumination. That such pain can be caused by light quite apart from any effect upon visual sensation, is proved by its elicitation from totally blind eyes.² It is probably a phenomenon allied to photophobia. Photophobia may occur in the totally blind, and is independent of, although influenced by, the retina and optic nerve. The mechanism of "light-pain" and photophobia is not clear: they are phenomena which led E. H. Weber³ to question whether, recurring to an older view, there are not nerve fibres of common sensation in the optic nerve. Magendie⁴ detected no reactions whatever on scratching the retina in mammals, amphibia, or fish, but in birds, body-movements and contraction of the pupil followed regularly. It is noteworthy that retinitis may run its course completely without pain, whereas inflammatory processes of the conjunctiva produce intense photophobia.

There are, however, certainly other conditions besides mere intensity and duration which can make sensory impressions agreeable and disagreeable. Some sensations of taste, *e.g.* bitter, sour, certain odours, possess an unpleasant character—a "negative tone"—almost at the limen of the sensible intensity of the stimulus. Here the disagreeableness seems to be allied, not to the intensity, but to the "timbre" or "colour" or quality of the sensation. Among all simple sensations it is in those of the highest and most proficient senses, *e.g.* sight, that implication of disagreeable and agreeable seems least an obligatory function of the timbre. Hence one may demur when asked to accept affective tone as an immediate *quale* inherent in all presentation.⁵ When of moderate intensity the majority of simple visual sensations do not, in virtue of mere colour, involve apart from complex associative experience—either delight or pain. Such visual sensations are from the present standpoint "neutral." With the sense of hearing it is different. The concord *c, e, g.* produces a sensation of positive tone, and is as distinctly elicitive of pleasure as are the notes *c* and *d*, simultaneously struck, provocative of urgent disagreeableness, of—as the very name insists—discord. Between its extremes, imbued with "positive" and "negative" tone, the timbre scale (apart from the intensity scale) of sensation extends a neutral zone untinted, so to say, by either pain or pleasure. On this view a pleasant warmth differs from a painful burn, as the affective tone one of colour, *e.g.* orange, from the affective tone of another colour, *e.g.* violet, or as that of one complex tone differs from that of another.

But, in accepting the above view, that pain is but a quality of sensation which, under appropriate circumstances of intensity or quality of stimulus, can arise in the domain of any and each sense, certain difficulties are encountered. It must be admitted that pain arises more frequently and more easily and is much more intense in connection with certain senses than with others. If "sense pain," like "local sign," be considered to be a *quality* of sensation, the admission has to be granted that, although qualities discoverable in a large group of

⁵ Marshall, *Mind*, London and Edinb., 1894, N. S., vol. iii. p. 533; and "Pain, Pleasure, and Æsthetics," London, 1894.

the senses, they are in certain hardly existent at all.¹ "Painful" may therefore be a quality potential to a certain group of senses, but not general and common to each and all the senses. Nor does it seem to stand in such antithesis to "the pleasurable," as to be potential constantly in those species or orders of sensations, in which the latter is existent or potential. That is to say, a pleasure-pain series seems for some senses an unproven attribute. Some species of sensations, *e.g.* certain tastes and odours, seem "unpleasant," even at the threshold of the sensible intensity of their stimuli; and, similarly, others seem in some individuals to possess from very limen up to maximum a pleasurable, certainly no painful, character, *e.g.* the taste of "sweet." If stress be laid on this aspect of the question, it can be urged that some species of sensation are characterised in common by the attribute agreeable, and others in common by the attribute disagreeable; and that neither the one character nor the other are qualities common to all species of sensation.

The disagreeableness of a vivid colour contrast or of discordant notes is akin to pain but is really a degree of "physical pain?" Is it strictly expressible as a fraction of the agonising torture of a scalded limb? "The nerves which subserve smell, taste, hearing, and sight cannot produce pain; violent irritation of the optic nerve produces intense visual sensations but not pure "pain."³ "The pain which we feel when the finger is cut is a wholly different thing from the pain given to the most delicately musical ear by even the most horrible discord."⁴

With regard to smell, the comparatively poor development of olfactory sense in man makes it very hazardous to assert that in that case "disagreeableness" cannot reach an intensity which, on the first-mentioned theory, is a "pain" equal in violence to any cutaneous or other. The fact that, *e.g.* in the case of the skunk, emissions of an odour can protect the emitter from carnivorous foes in its "struggle for existence," is evidence of the violence of the unpleasantness that an olfactory sensation can be plausibly argued to attain.

Pain may be only an extreme case of disagreeableness, but some forms of disagreeableness are much more complex mental states than others. The full scope of the terms "agreeable" and "disagreeable" is too wide for the discussion here. They attach to manifold processes⁵ besides simple sensations and perceptions, processes built on "affective tone," whether "negative" or "positive," and attributed to whatever psychical process, as on a foundation. What psychical process, it can be asked, is not? The sight of blood is disagreeable by reason of associated experience of disagreeable sensations. If the intellectually disagreeable is of later development than the physically disagreeable,⁶ it can be argued that all "disagreeable" has arisen out of the physically painful. "Doubtless in lower animals pain is almost the only stimulus."⁷

Here it is necessary to guard against expanding the set problem by unwary use of the word "pain." This word will be here limited to phenomena of which everyday parlance speaks as bodily or "physical"

⁷ *Ibid.*

pain. "Painful" is the affective colour of many psychical states both more complex and less complex.

There are intellectual processes with negative affective tone, and simple sensations with negative affective tone. Of the latter, those belonging to the projicient senses are less strongly coloured than those of the non-projicient. It is the "sense pains" of the non-projicient senses that constitute bodily or "physical" pain. Physical pain is so eminently obtainable from the skin, that about the question of cutaneous pain discussion as to existence of a specific sense of pain is chiefly turning.

Admitted that the disagreeableness of an intense light or of a discord is not fully comparable with the "pain" of scalded skin, that admission is not tantamount to allowing that cutaneous pain is the product of a specific "pain sense." It can be said that all parts of the body that can produce pain are endowed with nerve fibres normally ministering to a group of senses that can be classed together as yielding *common sensation*, and that these nerve fibres only under stimulation excessive either in intensity or duration or spatial extent, produce pain. By common sensation is understood that sum of sensations referred, not to external agents but to the processes of the animal body. Its "object" is the body itself—the material "me." Sensations derived from the bodily tissues and organs possess strong affective tone; while the sensations of special sense are relatively free from affective tone.

The scope of the term "common sensation" no doubt has varied somewhat with different authorities.¹ Adopted in contradistinction to "special sensation," the ordinary meaning of the word does not immediately explain its technical use. All afferent nerve fibres were considered to supply impressions to the common sensation of consciousness; the nerves of the special senses were considered to supply, over and above the common sensation which they each supplied in common, impressions of special sensation, each peculiarly its own, optic nerve, visual, etc. Magendie's experiments (1825) of scratching the retina with a needle, exciting the eighth cranial nerve, etc., did something toward removing from the special sense nerves the ascription of functions of common sensation. Johann Müller,² no doubt under the influence of Kant's philosophy, brought forward the law of the specific energies of sense. Earlier writings by Purkinje, Elliot, Charles Bell, and Autenrieth had paved the way to this; and the limit of the law has been affected since by the Darwinian principles of evolution and adaptation. J. Müller went so far as not to concede the existence of common sensation (*Gemeingefühl*) as distinct from touch. He reckoned to the category of tactual the sense impressions derived

¹ For instance, compare E. H. Weber, Wagner's "Handwörterbuch," Bd. iii. S. 2, with J. Henle, "Allg. Anat.," Leipzig, 1841, S. 728. By some (e.g. K. Vierordt, "Grundriss," Tübingen, 1877, S. 488), the term is made to include all those sense impressions in which we can discover or observe alteration of our own state of impressibility. By this definition are included in common sensation the so-called "subjective" sensations, originated in the special (so-called "objective") senses by internal stimulation, i.e. by conditions arising in the body itself. In this connection it may be remembered that the excitation of a skin nerve in its course (e.g. faradisation of ulnar trunk at elbow), it was at one time taught evoked pain only, not sensations of touch. To refute the teaching, the experiment has only to be repeated. The sensation obtained is usually not painful, although always "strange." Its strangeness is no doubt explicable by the combination in simultaneous excitement of nerve fibres in groupings never previously experienced, dependent on their mere position in the nerve trunk. Some are included and some left out in unwonted fashion. Hence the punctiform character of the reference. The above wider scope of the term common sensation (*Gemeingefühl in weiterem Sinn*) seems inconvenient and is not adopted here.

² "Zur vergleichenden Physiologie des Gesichtsinnes," 1826; "Ueber die phantastischen Gesichtserscheinungen"; and "Handbuch der Physiol.," 1832 to 1840.

from viscera and muscles. Later, E. H. Weber¹ brought forward reasons for sundering sensations of touch from those of common sensation. Weber was among the earliest (1846) to successfully analyse common sensation into component orders.² He seems to have regarded common sensation as simply the sum of visceral and muscular components severally distinguishable. Wundt insisted on the summation not being simple, but involving the building of a more or less complex superstructure by psychical synthesis, the synthesis in so far resembling a chemical synthesis, in that from it results an entity as individual as the component entities.

Total common sensation is the result of many component sensations. It has at basis multitudinous simple impressions, its raw material, whence in the psychical factory the *cœncæsthesis* is produced. It is the sense of the *afficirte Leiblichkeit*, and is in some ways the antithesis of the Kantian *innere Sinne*. The sensations contributing to it might be supposed to take origin in the most various sensifacient parts and organs of the body. As a matter of fact, it is found that stimuli exciting the apparatus of the special senses, visual and auditory, under ordinary circumstances give but little toward "common sensation." The sensations that arise in internal organs and viscera, on the contrary, contribute a great deal. Hence it may be said that it is built of what have been called³ entoperipheral feelings in contradistinction to the epiperipheral. What indeed the viscera contribute to "sense" goes entirely toward "common sensation"; under ordinary circumstances, however, their total contribution to consciousness is but small. The prevailing aspect of healthy perceptive consciousness looks not toward the material "me" but beyond it, or it may be said has a direction of outlook not of inlook. "Common sensation" plays, therefore, a subordinate rôle in healthy consciousness. The feelings of appetite for food, of need for evacuation of fæces or of urine, etc., all occupy but little of the conscious day. But when visceral sensations are strong, then common sensation plays no subordinate part in consciousness. The forms of special sensation may then be pushed into the background, or attached as mere accessories to the pre-eminent "feeling." This potential intensity—related to emotion—which is latent in visceral sensation will be adverted to again.

Numerous observations, experimental and clinical, from those by Haller⁴ and his pupils, through those by Bichat⁵ and Budge⁶ down to the present day,⁷ show clearly that the viscera, the serous membranes, the mucous membranes, except those lining the mouth, nose, throat, rectum, vagina, and entrance to the urethra, and the abdominal contents, except the kidneys in slight degree, and the generative glands, cannot by irritation with directly and variously applied mechanical, thermal, and chemical stimuli, be demonstrably proven to call forth pain or signs indicative of pain. The kidneys, ovary, and testis, under mechanical compression, do reply, but the first-named does so only very slightly. From their experimental observations on the visceral structures and from

similar on muscles, tendons, and joints, carried out with like negative result, Haller, and also Bichat in part,¹ concluded that these organs are insentient. Clinical experience shows that the viscera may be freely incised in the unanæsthetised patient, ligated, or pinched, without in the most evanescent or slightest degree affecting the attentive consciousness. The movement of the stomach and diaphragm, one against another, with large excursion and considerable speed, cannot under ordinary circumstances be perceived.

Attention cannot be induced to that direction, far less be focussed there. Yet to imagine all these structures insentient were certainly mistaken,—one is misled by the impotence of inadequate stimuli. The heart in its beating produces normally no “feeling,” but it nevertheless possesses the in some ways most powerful afferent nerve in the whole body, and under certain conditions evokes all engrossing pain. The voluntary muscles contain numbers of afferent nerve fibres and sense organs,² and can produce urgent sensation. All parts of the alimentary canal, under the vicissitudes of disease, give evidence of capability to affect sense even with pain. Excitations of the central end of the splanchnic nerve, and of many other visceral nerves, uniformly evoke evidence of pain.³ In the abdominal and thoracic sympathetic cord are numbers of myelinated fibres, which are the axons of nerve cells in the spinal ganglia, contributing to the afferent spinal roots. The white rami communicantes of the sympathetic are afferent as well as efferent, for by them fibres pass from the visceral nerve-chain into the spinal ganglia and roots. I find a lower thoracic white ramus (tenth thoracic) in a small cat to contain about 150 myelinated sensory fibres; such fibres are therefore fairly numerous in the abdominal sympathetic.⁴ They vary much in size, some being amongst the largest fibres in the sympathetic, but more are among the very small ($12\ \mu$ to $1.5\ \mu$ or less in the small cat). Some of the larger probably belong to the Pacini corpuscles, numerous in the neighbourhood of the pancreas, uterus, and elsewhere. The existence of a abundant afferent channels from the viscera into the central nervous system is therefore as definitely proved by physiological research as is the existence of visceral pain demonstrated to bedside observation. Yet the impulses generated in the afferent nerves of the viscera, although they embouch into the central nervous system (*via* the spinal and the vagal ganglia), do not appear under ordinary circumstances to evoke conscious reactions. Some authorities teach that they generate constantly “obscure sensations.” “If the whole of our abdominal viscera were removed, we should be aware of the loss.”⁵ The supposition is one not of course to be tested by experience. Rather than that the viscera constantly generate obscure sensations, it would seem to me that some of them at least initiate intermittently with phasic regularity sensations that are far from obscure, as well as visceromotor, secreto-motor, and other reflexes outside the pale of consciousness. Sensations would seem to arise from the viscera under ordinary circumstances chiefly, as might be expected, in relation to exercise of their normal functions. The functional “activity” of most viscera is phasic; sensations accompanying the “activity” phase seem pleasurable, not the reverse. In the prolonged phase of pause for preparation, preceding the phase of “action,”

¹ Bichat did not deny the sensitivity of muscles. Schiff, however, did so absolutely, “Muskel- und Nervenphysiologie,” Lehr, 1858, and so have others.

³ Bichat, “Anatomie générale,” Paris, 1802; Budge and others.

⁴ There appear to be none in the cervical sympathetic. Bichat remarked on the insensitiveness of the superior cervical ganglion and the cervical sympathetic, “Anatomie générale,” Paris, 1802, tome i. p. 24. Cf. Budge and Waller; also Langley, *Phil. Trans.*, London, 1892, vol. clxxxiii. p. 117. I found all (except seven) the nerve fibres in the cervical sympathetic of the monkey degenerate after section of the motor spinal roots of the lowest cervical and highest six thoracic nerves.

⁵ Foster, “Text-Book of Physiology,” 1891, pt. 4, p. 1421.

the call for repetition of the "activity" of the organ gradually springs up and cumulatively increases. The endings of the afferent visceral nerve fibres are in this phase excited with increasing urgency, by adequate stimuli, of the quality of which we are ignorant, but these stimuli may be in many cases of mechanical kind. Summation perhaps plays a greater part in rendering them effective than in the case of the adequate stimuli of the organs of the special senses. The sensations they evoke seem almost all of them imbued with displeasurable "tone," and they can culminate in physical pain.

An essential constituent of common sensation derives from the locomotor apparatus of the body, *e.g.* muscles, joints, etc. But the contribution by this factor is not so copious as might have been supposed. There is a large diversion of its stream of ingoing impulses to channels feeding the production of presentations of environmental agents. In fact, the sensations from muscles which influence, by their contractions, the various sense organs, may almost be said to be lost in contributing a further quality to the sensations of the sense organs which the muscles in question influence; for these they standardise their spatial *quale*. They, many of them, acquire thus in a secondary manner some projection. But their justifiable inclusion in common sensation is shown by nothing more clearly than by their relation to pain. Under circumstances for the most part exceptional, they contribute "fatigue," "cramp," "rheumatic" pains, etc., to common sensation.

Cutaneous sensation occupies in some ways an intermediate place between the forms of special sensation and of common sensation.¹ Cutaneous sensation has, according to its species, a variable degree of projection, but never that degree attaching to special sensation. The ether vibrations which, impinging on the retina, evoke perception of a light shining at a distance, impinging on the cheek, evoke perception of a warm spot of skin. Even most "touches" are perceived not so much as pure signs of the environment, as of our conscious "self" reacting to an agent. But the position of cutaneous sensations in regard to common sensation will depend on to what extent the cutaneous sensations be regarded as separable into specific kinds. If the view taken in the articles on "touch" and "cold" and "warmth" sensations be accepted, then the specific "warmth" and "cold" senses are, especially the former, further from the special and projectant senses than is the pure "touch sense"; the converse is their order of propinquity to common sensation. On the view that all these three senses can each produce physical pain, all three are clearly contributory to common sensation.

On this view the, as they have been called,² "regular" stimuli provoke sensations less related to common sensation than do irregular excessive stimuli applied to the same cutaneous apparatus. The important point for the present argument is, that on this view the limits of physical pain include certainly several senses, a group of senses. Its most familiar ministers are perhaps cutaneous nerves, but in respect to it other nerves, those of deep structures, have to be placed beside them. Hence the classification of pains into "superficial" and "deep";³ and, on the above view, the existence of the latter class is of itself a guarantee further that non-painful sensations arise from the deep-lying structures of the body.

¹ "I can truthfully say, I feel the paper at the end of this pen; but with pain it is less that I feel pain than that, in Condillac's phrase, 'I am pain'; language recognises this in such diction as 'I ache'" (see Fechner's observation, Wagner's "Handwörterbuch," 1846, Bd. iii. S. 2).

² See A. Fick, "Physiol. des Menschen," Wien, 1882, S. 133.

³ Xavier Bichat, "Sensation externes et internes," "Anatomie générale," Paris, 1802, tome i. p. 165.

Under many circumstances on these deep sensations are grafted "pains." It is customary to consider such circumstances as lead to pain "abnormal," and therefore to treat the "pains" occasioned as reactions to abnormal occurrences. If to do so be but a propitiatory compliment to a well-intentioned scheme that helps to minimise harm, well and good; but with an environment infested by conflict, disease, and mischance, to call such "pains" abnormal reactions is merely a question of personal taste in the adjustment of the relativity of terms. With an organ so open to injury as the skin, the application of a certain percentage of stimuli noxious, from excess of intensity or duration, may be regarded as strictly normal. Of the more sheltered deep structures of the body, to arbitrarily say the same is, at least, as defensible as to say the reverse. The consideration possesses meaning for any attempt to trace the evolutionary history of "pain sensations."

It is obvious that the sensory structures, cutaneous and deep, which possess the power of calling up pain (in that term's restricted sense adhered to here) have as common attribute the non-projection of sensations. The kinds of sensation which the mind most fully projects, the "objective" sensations, as sometimes termed, seem always reactions to objects (noumena) that can affect as identical stimuli simultaneously, more than a single individual mind. Although a sensation obtained from the skin does, in many cases, include perception of an external agent causally connected with the sensation, it seems invariably also to include perception of the "material me" (*afficirte Leiblichkeit*). In such cases the agent acting on the skin is a noumenon that can affect as an identical stimulus successively, but not simultaneously, more than a single mind. The senses which deal with agents not similarly appellat to several minds at once are deficient in projection. I feel the radiant energy from a lamp with the back of my hand, I see it with my eye; the latter's sensation does nothing to remind me of my own existence, the former's calls my attention to my hand. And there are a large number of instances of excitation of cutaneous, muscular, and visceral sense nerves in which no external agent whatever is perceived, and the perception relates exclusively to the "material me." In these cases the stimuli are furnished by objects, agents, which neither successively nor simultaneously can affect, as identical stimuli, more than a single mind. That one is the "I" resident with the particular "me," of whose material the stimulant agents are themselves part (actions). Concerning this category of internally initiated sensations, it will be obvious from the foregoing, that for their description the external world offers no adequate symbols whatsoever. There is no true basis for a convention of terms by which they can be made describable. Some of them, however, after a partial fashion, offer approach to conventional description, in virtue of their frequency among numerous individuals. An empirical standard for comparison of them becomes practicable, in proportion to their frequency and extension among a community. Hence skin-pains are more describable than others, for applications of painful stimuli to the skin are so common as to be—as above urged—"normal." Indeed, the skin may be said to have evolved for itself a special sense of its own injuries. But where, as in consequence of disease, from time to time and from individual to individual, the deep organs vex the "normal" flow of consciousness, sensations are experienced which are, so to say, singularly individual and doomed to remain indescribable. The sensible universe has no suitable symbols for their expression. In this difficulty it is true that with intellectual health the sentient mind reflecting on the body often can, as in the case of projected sensations, rightly interpret that which it does feel. But this it does not with the same assurance, there being no such accessible touchstone of rightness or of wrongness for criterion. Yet one attribute of these sensations, otherwise indescribable though they be, the mind is never at a loss about. There is always distinct in them a pleasurable or a displeasurable "tone."

Our sensations have as their end knowledge of the external world, but knowledge of that world in relation to ourselves. Mind rarely, probably never, perceives any object with absolute indifference, that is, without "feeling." In other words, affective tone is the constant accompaniment of sensation. Every form of common sensation is based on perceptions of an altered condition of the body itself. In connection with this comes the fact that all forms of common sensation possess significantly pre-eminent attributes of physical pleasure or physical pain. These reactions of the sensifacient organs, yielding perception of altered conditions of the material "me," the mind seems to view with less of philosophical indifference than it can usually behold others, *e.g.* those of the so-called "objective" senses. Few forms of common sensation leave the mind "unmoved." All are linked closely to emotion, and, as that term implies, all operate powerfully on motor mechanisms. Certain muscles—the exponents of expression—are almost uncontrollably excited. The reaction plays also upon the local musculature in a manner curiously imperative.

The facility of path of these motor reflexes colligated to pain, hints at their antiquity, or at their having been formed by some neural method particularly able to, as it were, make a good road. Each reaction that employs a neural path seems to smoothe it by sheer act of travel. This is true even of slight impulses—light traffic—and more true of heavy. Pain reactions are to be regarded as very heavy traffic. Their impressions summate with peculiar ease, take correspondingly long periods to subside, and, to judge by their inertia, move generally masses of neural material relatively great. Such impressions might wear a road with quite especial speed. Many spinal reflexes imply, so to say, well-worn habits based on ancient pain reactions. One is almost emboldened to figuratively imagine them as connate memories of the spinal cord. The majority of them seem to be protective reactions that in organisms of high neural type are accompanied by "pain."

Pain seems the psychological adjunct of protective reflexes. A pain reaction is in so far like a nauseous taste attaching to a poison. The temperature at which the skin begins to evoke pain (43° C.) is that at which nerve substance begins to suffer injury.¹ The sensation caused by the pressure of a sharp point (*e.g.* needle) on the skin is felt to be painful just below the pressure sufficient for the instrument to break into the skin, *i.e.* the stimulus becomes painful just before it does injury. True, that the material "me" usually affects little the flow of healthy consciousness. Nevertheless, on the existence of that material "me" depends the very existence of that consciousness. It is the material "me" of which Lotze's trodden worm thinks when it contrasts its own suffering self against the whole remaining universe. The directness of nexus between excitation of pain on the afferent side and certain especially localised movements on the efferent, is argued to be the "instinctive" outcome of this, and of "protective" significance. The plan of defence often lies patent in the character of the movement. The tail is reflexly twitched away from the side to which the painful stimulus is applied.² The pain reflex causes the pinched foot to be withdrawn. The epigastric pain of hunger can be relieved by putting food into the stomach; the faucial pain of thirst by the swallowing of fluid. Both "needs," so long as the cerebral hemispheres are in function,

¹ E. H. Weber, *loc. cit.*

² E. Pfüger, "Die sensorischen Functionen des Rückenmarkes," Berlin, 1853.

excite the active search for food. The drawing in of the muscle of the abdominal wall, which is the motor reply elicitable by the testicle, may be interpreted as protective in reference to its original intra-abdominal location.

How far the pain sensation is a part or an accompaniment of the reflex reaction, which by calling upon motility protects the individual, is questionable. Ordinarily the two are concomitant and colligated. Many¹ hold the motor reaction to be secondary to the mental. There are, however, those who hold that in the case of the "feelings" the psychical effect is secondary to the efferent vascular² and visceral.³ Of the coarser emotions it has been argued by James that the feeling does not cause, but is caused by the bodily expression. The bodily changes, according to him, follow directly the perception of the exciting fact, and our feeling of the same changes as they occur is the emotion. Certain experiments furnish evidence—not highly satisfactory—that all pleasurable states of consciousness are accompanied by bodily movements of extension, and all painful by movements of flexion. These movements may be very slight. Münsterberg⁴ concludes that the feeling of agreeableness is the mental accompaniment and outcome of reflexly produced movements of extension, and disagreeableness of the movements of flexion. Of the pain-feeling and the pain-reflexes which are colligated results of certain stimuli, the latter, the reflexes, seem to persist under conditions of mutilation of the central nervous system, that are by most accepted to preclude the possibility of conscious reactions, and in disease where feeling of pain is lost.⁵ Granting the weight of evidence preponderates against the possession of capacity for pain by animal forms of low neural organisation,⁶ vestiges of the motor reflexes accompanying pain in higher forms are nevertheless possessed by them. The motor part of the total "pain reaction," both somatic and visceral, may have the more ancient evolutionary history. Sense pain of high intensity may therefore be a means comparatively recently evolved, and now in evolution, for the better protection of the higher organisms. It is probable, however, that in the earlier grades of evolution of sense all species of sensation were more equally endowed with affective tone. The skin, unlike the sheltered viscera, is bare to the vicissitudes of the environment. Its more abundant opportunity has led in it to the more complete evolution and education of a sense of pain. Feeling of pain works beneficially for the preservation of the organism⁷ possessing it, and since it is in action before, and is maintained until the end of sexual maturity, favours directly the preservation of the species. In the struggle for existence it is doubtless one of the most potent weapons nature has devised. But it seems to predicate a certain advanced grade of neural organisation. There is little evidence that it is present in lowly organisms. To those possessing it—the higher animal forms—it dispenses an enormous competitive advantage. It is perhaps the primary determinant of "will."⁸ It is noteworthy that in the human race there is some evidence that it is more developed in civilised than in uncivilised populations. The theory of utility is merely a conscious

reckoning upon it.¹ "Economics as a science bases itself upon the conscious choice of pleasure."²

Nothing said above disallows of the term "common sensation" being taken to embrace the whole office of the cutaneous senses, touch, cold, warmth, as well as the senses of the musculo-articular apparatus, and of the viscera, on the assumption that all these share in common the incapacity to "project" their sensations, and to provoke, under conditions of excessive stimulation, pain. On such a view the nerves of tactual and thermal sense, under appropriate circumstances, produce cutaneous pain; and the nerves which furnish the sensory impressions at basis of the perceptions of the "muscular sense" likewise, under appropriate conditions, produce the "ache" of muscular fatigue, the "gnawing" pain of hunger, the "cutting" pains of visceral cramp, etc. So also, on the same view, the feeling of thirst and the pain of cardialgia may both be the manifestations of the same gastric nerve fibres. But on this view the old difficulty encountered above, regarding the specificity of pain, has to be met with again, although in modified form.

Pain as a skin sensation is *sui generis*, incapable of confusion with the sensations evoked by other, usually lesser, stimuli. It is not as if some painful component inherent in cutaneous sensation from the limen upwards increased, and increased disproportionately as the reaction grew more violent. There is no trace of the painful in a moderate "warmth sensation." Though musical notes of different pitch can be confused by a mind not musically trained, there is no chance of confusion in any mind between sensations of, for instance, pure "cold" and "pain." A pain sensation evoked by pressure from the skin does not *quâ* sensation appear to introspection as an intensified touch sensation, though the stimulus for the former may be merely the intenser application of a contact. The degree of warmth sensation that a burn gives need not be more intense as a sensation of "warmth" than is a painless warmth sensation; in fact it is often less so, for the new sensation of pain suppresses sensations that might be simultaneously evoked.

The statement arrived at, therefore, comes to be: If the forms of common sensation as a group be characterised by want of projection and potential pain, among cutaneous sensations are certain which fall into the category of common sensation. The skin, therefore, contributes to common sensation; that is, nerves of common sensation are distributed to the skin. But it does not conversely follow that all cutaneous nerves are nerves of "common sensation." Are the nerves of common sensation identical with those of touch and warmth and cold, or with one or other among them, or with none of them?

The *central* neural mechanism for cutaneous "common sensation," e.g. pain, is certainly largely distinct from that of touch and temperature. This seems clearly indicated on examining both pain and the "feeling" of tickling. Tickling, it is sometimes taught, results from stimulation of the purely tactual nerves. The mechanism of the matter probably is that weak tactual stimuli call into reflex activity unstriated muscles of the skin. The contraction of these excites the feeling of shivering which combines with that of the light touches. In that case it is conceived to be a peculiar psychological elaboration from tactual and muscular impressions. It may be so, and it may stand in somewhat the same relation to the touch spots of the skin as does pain to the pain

¹ See Patten, "Theory of Social Forces," Philadelphia.

² Witmer, "Twentieth Century Practice of Medicine," 1897, vol. xi. p. 919.

spots. It is certainly a form of common sensation, and as such less comparable with a touch perception than a pain. In it a series of light, painless, mechanical stimuli, applied over a surface of skin, evokes hardly controllable action of muscles ordinarily secure to the will's mastery. This recalls the uncontrollable reaction of so-called volitional muscles under pain. Summation of stimuli, which forms a characteristic part of the process of production of pain, plays also a prominent rôle in the production of the tickling "feeling." In both occurs, in consequence of summated sensory stimuli, uncontrollable nervous discharge into a muscular field with elements of triple kind, namely, sympathetic (cardiac and goose-skin reflex),¹ respiratory, and volitional, the last including characteristically the muscles of emotional expression,—indeed, as all three kinds concurrently react along with the emotion, all may in a sense be termed emotional. The involuntary motor nerves played on are sympathetic, e.g. the pilomotor, sudorific, cardiac, vasomotor, etc.² The pulse is altered; the volume of the arm decreases under pain, that of the brain increases. The semi-voluntary are those of respiration; the voluntary, those of expression, and those that move the part which is the seat of application of the stimulus. An ordinary "touch" does not in this way, by a touch-perception, affect the visceral, respiratory, and emotional muscles. The two reactions may be briefly contrasted. A *touch* evokes uncontrollably a perception of some part of the environment, may or may not evoke a movement, and does not affect the visceral and mimetic musculature. A cutaneous *pain* evokes uncontrollably a movement (of defence), and uncontrollably an emotion with its obligate visceral and mimetic movement of expression; it may or it may not evoke a perception of the environment, although it evoke a reference to the body itself.

The *central* lines of propagation of the disturbance, provoked by ordinary touch on the one hand, and by painful touch or tickling touch on the other, seem therefore different. The latter irradiates into motor paths, other than those to which the former travels; and even where the directions of the irradiation in the two cases partially lead toward the same centres, these are reached, in the case of tickling and pain, by lines of approach seemingly less open to inhibition from above than those employed by the reactions of pure tactual or thermal order.

Here may be adduced the well-known observation by Schiff,³ confirmed by Herzen.⁴ If in the lower cervical region the cord be transected, with exclusion of its dorsal columns, each touch or light handling of the skin, behind the segment of transection, calls forth signs that the animal "feels." The rabbit raises its head, moves its "whiskers," opens its eyes, or gives other signs which, taken together, amount to unequivocal evidence. On the other hand, if the touch stimulus be intensified and converted into a painful stimulus, even of the most extreme kind, there is no further response than that evoked at outset by the touch. Similarly, Schiff states, if a nerve trunk be bared and then lightly taken between forceps, there is an initial start, and after that any further pinching or compression of the nerve remains ineffectual. It is argued from Schiff's observation that "painful" impressions are conducted, not *viâ* the long ascending afferent root fibres of the dorsal columns, but *viâ* the grey matter. The experiment certainly shows that if Schiff's interpretation of the signs, as indicating touch and pain, be accepted, conduction for the former occurs along the dorsal white columns, and that the evidence of pain remaining

negative, in spite of employment of strong "painful" stimuli, conduction of pain impressions does not travel along the dorsal white columns. It appears probable that the path for pain involves a spinal relay cell, or several such, instead of the long direct root-ganglion path.

Budge concluded that a powerful stimulus produces—(1) a local reflex, by short fibres entering the grey matter, in the immediate vicinity of the entrance of the afferent root in the cord; and (2) a "feeling" of pain from centres in the bulb, reached by conduction through and up along the grey matter of the spinal cord. That the path of upward conduction for pain lay in the spinal grey matter is a conclusion in which, on the basis of his own experiments, he follows Stilling, Schiff, and Brown-Séguard.¹

Schiff² and also Budge³ concluded from vivisection experiments—in which, as the latter carefully points out, the character of movements is the only guide that the observer has regarding the provocation of pain—that only those fibres of the afferent spinal roots provoke pain, which end soon after entering the cord in the grey matter of the cord. Budge, especially, exhaustively examined by irritation the various portions of the central nervous system, to determine those which, when so examined, seem, as judged by the reactions, to provoke pain. He obtained no evidence of painful reaction from the cerebral hemisphere, including *corpus striatum*. The *optic thalamus* gave dubious indications, which Budge was inclined to attribute to experimental implication of the neighbouring cerebral peduncle. The deeper and median parts of the *corpus quadrigeminum anterius*, he concluded, could occasion severe pain, so also the *corpus quadrigeminum posterius*. From the corpora quadrigemina to the lower end of the fourth ventricle was a region, irritation of which always seemed to evoke pain, unless the irritation were confined to grey matter. Removal of the *corpora quadrigemina* on one side (after ablation of the hemisphere on that side, which was unproductive of effect as regards pain) in the rabbit produced at first marked diminution of sensitivity to pain on the same side of the body (rabbit), followed by hyperalgesia on that side.

Hence Schiff⁴ wrote of the grey matter as "æsthesodic." Budge⁵ describes, as an experiment for demonstrating the insensitivity of grey matter, the pricking with a needle of the grey matter of the calamus scriptorius; the animal remains perfectly unmoved thereby, a touch on the adjoining white matter evokes a violent reaction.

Other experiments which bear on the central path of conduction in the cord, are those in which various degrees of transverse and longitudinal section of the cord have been performed. Stilling, Schiff, and Budge (see above) believed that the impressions eliciting pain crossed to the grey matter, opposite the side of their entrance, and ascended in it to the bulb. They were under influence of Gerlach's supposed network of conducting fibres in the grey matter. For them the grey matter was a continuum, as it is not now believed to be. There is now no evidence of any but short fibres in the grey matter, and any prolonged conduction up it, if possible, would involve transition across many synapses; and every synapse probably introduces a resistance, so that the resistance of such a path, if the path were possible, would probably be enormously high. Experiments show the grey matter incapable of conducting a long distance.⁶ Brown-Séguard,⁷ Ferrier,⁸ and Aldren

Turner,¹ believe that pain impulses cross almost immediately after entrance into the cord, and pass up the opposite half of the spinal cord. Miescher² and Woroschiloff³ arrived at the result that, in the rabbit, the impulses ascend the lateral columns, and I⁴ obtained the same result in the dog, using blood pressure reflexes as sign. Weiss,⁵ Homén,⁶ Osawa,⁷ Mott,⁸ Bottazzi,⁹ and Holtzinger¹⁰ conclude the conduction involves both lateral columns, the tautomeric about as much as the crossed. In all this experimental work on animals the observer has to work through signs of subjective states incomparably inferior in most instances to the verbal communication establishable with an intelligent human subject. Clinical pathology, therefore, can render great service here.

Viuesseux¹¹—a Swiss physician (1818), suffering from spinal disease—noted with surprise that the fingers of his right hand, though analgesic to such degree that they bore without pain any degree of pressure or wounding, could feel and judge a patient's pulse quite well. Since then, especially since E. H. Weber's researches,¹² many cases of "dissociation" paralysis of the skin, have been observed as the result of spinal diseases, including pressure lesions, traumatic injuries, syringomyelia, tabes dorsalis, leprosy, etc. In certain stages of ether narcosis a similar phase of dissociative paralysis occurs.¹³

This sundering of the different species of skin sensations one from another in spinal disease, most frequently takes the form of partial, often severe, impairment of the pain and thermal sensation, while tactual remains normal or nearly so. Mechanical stimuli are felt by the skin with normal delicacy as "touches," while stimuli that normally are painful are felt merely as touches. This, I find, occurs at the edge of an isolated spinal root skin field. It also occurs in diseases of the spinal grey matter (e.g. syringomyelia, gliosis).

In these latter it forms, with certain features of distribution, a pathognomonic condition. Contact with the finger-tip, a brush, the head of a pin, is normally perceived and properly localised; but with this may coexist complete analgesia, to mechanical as well as thermal irritants. The patient no longer feels a pin-prick or a strong faradic current as pain. Ability to distinguish differences of temperature may be totally gone. The sense of pain of the deeper parts is also impaired, so that fractures of the bones are no longer felt to be painful, and extensive surgical operations can be performed on the patient without pain. The mucous membranes often participate in the impairment of temperature sense, so that patients may eat too hot food without noting its harm. Careful observation of the exact size and position of the lesion in the cord producing this condition gives the following indications as to the position of the pain-path. Certain cases¹⁴ seem to prove pretty clearly that destruction limited to one dorsal (posterior) grey cornu in a segment of spinal cord entails loss of sensation for pain (and temperature) in the corresponding *segmental skin field* (not a *peripheral nerve field*) on the same side of the body. Instances show that where both dorsal grey horns have been injured, but one more than the other,

the severer analgesia is on the same side as the severer lesion, but touch has remained good on both sides. This agrees so far with the path traced by Schiff and Budge to short fibres of the spinal root that plunge into the grey horn. The continuation of the path cannot, however, remain long in the grey matter, because the grey matter may be quite destroyed, and hollowed out at a level, and yet no complete analgesia result in the parts further below the site of the lesion.¹ The path therefore leaves the grey matter soon after entering it. In the grey matter a column cell must be introduced into the chain of conduction, because section of posterior roots leads to no degeneration that goes through the grey matter and on into the white beyond.² Laehr³ points out, on the basis of the Brown-Séquard paralysis, that in certain such cases the loss of sensation on the side opposite to the loss of motility is a loss of pain and temperature sensation. The conduction upwards of impulses producing vasomotor reflexes was found by Miescher⁴ and myself⁵ to occur in the ventrolateral parts of each lateral column. It has been suggested that the ventral division of the cerebellar tract (Gowers' tract) is a pain-path.⁶ It may be so, although the connection with the cerebellum does not support this suggestion; yet, because part of the tract ends in the cerebellum, it does not follow that all of it does so. But we do know that the ventral cerebellar tract is partly crossed. There is the bundle of crossed fibres, described by Grunbaum⁷ (by degeneration after median longitudinal section), lying at the periphery between the two cerebellar tracts. Its upward destination is unknown. Even if the pain-path employ these crossed fibres, the pain fibres of the roots do not transgress the median line of the grey matter, but end on their own side. It is quite possible that the path is partly crossed, partly not. The tautomeric segmental effect of the lesions confined to grey matter, and the crossed hemianæsthetic effect of the lesions which include white matter, indicate clearly that outside the grey matter is a collected strand of pain fibres, reinforced from segment to segment by contributions from column cells in the grey matter. The main path so formed may likely enough be a crossed path, but there seems to be an uncrossed as well. Gowers has recorded a case in which a unilateral hæmorrhage in the lateral column at the upper cervical region produced complete analgesia and thermanæsthesia of the opposite side, without disturbance of touch. The path of conduction for warmth impressions, it is suggested, lies near to but is not entirely commingled with that for pain.⁸

The above statements suggest strongly that there is in the spinal cord a more or less distinct "pain-path," into which the impulses generated at certain "skin spots" enter with comparative ease. Among the features of the path are these: It is less open than others to reactions of moderate and brief kind, that is, it requires stimuli intense or long-continued; the efficiency of stimuli that are long-continued is due to the high degree of summing power possessed by the path; the path is largely a crossed path, and soon enters, crosses, and leaves the grey matter; in doing so a column cell is intercalated in the conduction chain. What is the relation, if any, of this path to impulses subserving the pain initiated by deep organs? Is it a skin pain-path or a path for sense pain in general? There is a good deal of evidence in favour of the conduction of the centripetal impulses from muscles by the

long root fibres of the dorsal spinal column, without decussation right up to the dorsal column nuclei. Muscular sensation is not affected by the diseases that implicate the above-described spinal path,—at least, muscular co-ordination is not obviously disturbed by them. The severest muscular cramps and fatigue do not induce associated skin sensations.

Some individuals never have a presentation of a certain sense without the occurrence of a presentation of another sense, hence "coloured audition," "photosms," etc. These are called "secondary sensations," the word sensation being employed in its broad sense to cover presentational perceptions.¹ A somewhat similar phenomenon, also familiar to many, is the "referred" or "associate" sensation, *Mitempfindung*. In its excitement of one sensifacient organ or part produces, besides its own proper sensation, a sensation referred to another part. As not the "reference" but the "association" is the peculiarity, the reference being only the ordinary process, which in this case by its operation calls attention to the association, the term "referred" is not altogether happily applied to the phenomenon. "Sympathetic," the term used at the beginning of this century,² seems better, and is especially appropriate because of the proneness of associate sensations to be of the nature of pain. An often cited associate sensation is the tickling in the nose which is felt on looking at a brilliant light;³ here probably the association is less between the optic nerve and the nasal branches of the trigeminus than between the branches of the trigeminus supplying the eyeball and those supplying the nose. Pain in the shoulder associated with liver disease was similarly regarded, and a fanciful speculation offered in explanation for it by the anthropotomist. What Americans call "the ice-cream nerve"—pain on the forehead on eating a cold substance—is a better example. By applying a "mustard leaf" over the front of the upper part of the sternum, I can produce, in myself, the sensation of a patch of hot, unpleasantly tingling character, referred to the inner side of each upper arm, just above the inner condyle; each patch seems oval, the long axis directed up the arm, and extending for about 3 in. During the phenomenon I cannot really rid myself of the belief that the skin there must be looking red, but no flush is found. In this case the associated sensations and the stimulus applied lie, as shown by delimitations of the cutaneous segmental-nerve areas,⁴ both of them within the same segmental area.

In connection with viscera, the phenomenon takes forms that might almost be spoken of as "illusions of pain." The associate pains—"sympathies" literally—of visceral disease have been recorded, and dwelt on by M. Traube,⁵ Quincke, Hilton,⁶ Brown-Séguard,⁷ Dana,⁸ Head, J. Mackenzie,⁹ and others, but it is especially since the work of Head¹⁰ that the previously isolated facts have been systematically extended and ably correlated, so as to assume scientific importance. Pains are initiated by the afferent nerves of viscera in certain skin areas. The importance of this for the present argument lies in the fact that the central pain-path seems shown by this evidence to be to some extent a

channel leading in common from visceral and from cutaneous afferents. To Head we owe the knowledge that the spatial arrangement of the radiation is, largely at least, of *segmental* character. Each viscus stands in relation with a definite patch of skin. The patches thus marked out do not correspond with any of the areas of distribution of the peripheral nerves, as far as known to gross human anatomy, but resemble and in fact strikingly agree in disposition with the segmental skin areas, found to belong to the spinal nerve roots, *i.e.* spinal ganglia. The segmental character of the "reference," and the likelihood that the connection or communication occurs where the column cell is intercalated, that is, at the synapse in the conduction chain, both suggest that the seat of "reference" is in the spinal grey matter itself.

The spinal ganglia contain, of course, the afferent visceral nerve fibres of the white rami and also the afferent nerve fibres from the skin, etc. Regarding the manner and place of "radiation," Müller, as early as 1834, wrote, "either of two hypotheses may be adopted." The radiation may occur in the spinal ganglion, by escape there of excitement from one nerve cell to another, the conductors being there no longer isolated by protective sheaths. Or, "the sympathetic sensations are the result of the radiation of the irritation from the fibres primarily affected upon the roots of other fibres in the brain or spinal cord, just as in the production of reflex movements impulses conveyed by sensitive nerves into the cord are communicated to motor nerves; the only difference being that, when sympathetic sensations are produced, the radiation of the impulses does not reach motor but only sensory fibres, or, at any rate, acts on sensory at the same time as on motor nerves." "This is another proof that the same sensation is produced at whatever point of its length a nerve fibre is irritated." The mere radiation of an impulse will therefore suffice to produce sympathetic sensations. "The extension of irritation in the spinal cord, from the roots of the sensory to the roots of the motor nerves, and the fact that sensory nerves without ganglia, *e.g.* optic—in the instance where a strong light causes a sensation of tickling in the nose—exhibit radiation of sensations, shows that the radiation must take place not in the ganglia but in the central nervous system."¹ The seat of radiation is considered by Head also to be intraspinal, by Kyri,² however, to be intraganglionic. As above stated, I myself should regard it as at the site of synopsis between the visceral spinal ganglion cells and column cells of the grey matter that continue the thermal-gestic chain of conduction. The referred sensation is not one of touch, but of pain,—is, in fact, a "sympathy." The segmental patch of skin to which the reference is made may be hyperalgesic; generally, not the whole of it, but a part, is also hyperæsthetic to warmth; this is called by Head "the maximal point." In fact, the visceral part of the spinal segment communicates its own excitement to a certain portion of the somatic part of the segment. Thus Head finds that disease of the kidney and ureter cause reference of pain and hyperalgesia in skin, the sensory innervation of which is from the tenth, eleventh, and twelfth thoracic spinal ganglia. Similarly with disease of the cardiac end of the stomach and the skin fields of the sixth and seventh thoracic spinal ganglia. But not all spinal segments innervate viscera. Several neither give fibres to nor receive fibres from the viscera,—that is, possess no white ramus communicans. It is especially in the limb regions that the visceral component of the spinal segment is wanting. Head finds no referred pains in the fifth, sixth, seventh, and eighth cervical, nor in the second, third, or fourth lumbar segments. The afferent nerves of the viscera compose to a certain extent a twofold system,—a cranial and a spinal, the former being the vagus, the latter

¹ "Elements of Physiology," translated by W. Baly, London, 1837, vol. i.

the white rami communicantes. Head shows that affections of the thoracic and abdominal viscera, but not of the pelvic, produce pain and tenderness not only in the body, but also over certain areas of the scalp. These headaches, he finds, stand in direct and constant relation to the position of the area of referred pain and tenderness on the surface of the body. The headache corresponds with this or that dorsal segmental area. The skin areas of referred pain in some cases overlap distinctly but not to the same extent as do the areas of segmental nerves, when delimited by the method of "remaining æsthesia."¹ Head² includes in his considerations the trophic nerves of the skin. "I do not, therefore, think we shall be far wrong in assuming that trophic nerves to the viscera bear a similar relation to the sensory sympathetic fibres as the trophic nerves to the skin bear to the fibres for pain. If this be so, it will help to explain the effect produced by counter-irritation of the skin on the activity of the viscera. Conversely, it will also explain the occasional improvement in pains of a purely nervous origin by some visceral irritation, e.g. the removal of lightning pains over the first, second, third, and fourth sacral areas (rectum) in a tabetic, by the administration of a purge."

Another set of referred pains studied by Head,³ are those in which each organ in the head (nose, eye, ear, teeth, tongue, nostrils, larynx, brain) refers a pain to one or more areas on the surface, where the skin may in consequence become actually tender. Thus lesions, not of the conjunctiva and anterior layer of the cornea, for they cause simply local pain, but of the substantia propria of the cornea, and of all parts of the globus behind it, back to the retina, produce pain, frequently tenderness, of areas of skin over the upper half of the face and the anterior half of the cranium from Head's *maxillary* to his *vertical* areas inclusive.

Again, in the instance of the ear, the meatus auditorius does not cause referred pain, but local pain purely. Lesions of the membrana tympani and middle ear cause referred pain and tenderness over the hyoid area. Tension in the middle ear, such as occurs in the first stage of otitis media before the membrane is perforated, causes referred pain and superficial tenderness over the vertical and occasionally over the parietal area of the scalp, in addition to that over the hyoid area.

Head's discovery of the segmental distribution of the skin areas of hyperalgesia was early confirmed by J. Mackenzie,⁴ and by J. Kyri.⁵ The former has pointed out that the pilomotor nerves over a limited area may be rendered abnormally sensitive by visceral disease,—a "goose-skin" reflex becomes more readily elicitable than in health. The pilomotor efferents belong to the sympathetic,—issuing by the white rami.⁶ The general radiation of a sensation is well exemplified, as J. Müller pointed out, by the associate sensations of the sexual orgasm. For details of the anatomical distribution of Head's areas, the original papers should be consulted.⁷

The central paths of the pain impulses from the skin and viscera are therefore closely connected with one another. The spinal connections of the nerves for warmth and cold, and for trophic disturbances in the skin, must also be in somewhat close association, especially

⁷ *Brain*, *loc. cit.*

those for warmth, with pain. On the other hand, the nerves for pure touch, and perhaps those of the muscular sense, must be fairly separate centrally from those of pain.

It has been pointed out¹ that the sensations of the intellectual senses have a power of cohesion, of integrating; whereas "hunger, thirst, nausea, and visceral feelings in general cohere little with one another and with other feelings, and thus integrate but feebly." They interfere and are incompatible with and even displace other sensations. Cutaneous "pain" soon and easily overpowers, cancels, and obscures other specific qualities of sensations arising simultaneously. We know from experience that from certain stimuli certain specific sensations must under ordinary circumstances arise, yet when pain is added to these they are inhibited, not felt. This argues for the suppression of one reaction by intervention of a second of a different kind, rather than for any alteration of mere intensity in the earlier. It is as if with a certain violence of stimulus a *new* sensation ousted a co-existent from all rôle in consciousness.

The *central* neural mechanism for cutaneous pain is certainly therefore largely distinct from that of touch, and to a certain extent from cold and warmth sensations. There is evidence also that its *peripheral* mechanism is to a certain extent distinct. The existence of separate afferent nerve fibres with specific dolorific end-organs would completely accord with the third hypothesis mentioned above at the outset. The chief arguments in its support can briefly be cited as follows.

There are some regions of the skin that are analgesic, though they possess good tactual sense (*e.g.* the buccal mucosa opposite the second lower molar (Kiesow)).² Other regions exist which are by a number of observers judged to be anæsthetic as regards pure "touch," although acutely sensitive for pain (cornea) (see p. 987). Analysis of the functions of the skin as a sensifacient surface distinguishes within it elemental points, not only for "touch," "cold," and "warmth" sensations, but also others, there is evidence, for "pain." Goldscheider early declared that the "cold spots" and "warmth spots" can by no amount of excitation be proved to initiate pain. On touching one of the latter with a heated cone, a "feeling with high degree of heat quality but without painful quality"³ is produced; although at other places than "temperature spots," contact with the cone-point can be extremely painful. The peculiar "burning" character of the pain produced by contact of the skin with a hot object, is explained as due to the admixture of sensations arising from the stimulated "warmth spots," with pain arising from the stimulated "pain spots." It is stated⁴ that "touch spots" are similarly analgesic, although it is not yet altogether clear that touch of a painful quality cannot be excited from them by intense stimulation. It is to be remembered that the "spots" from which, according to both observers, pure pain can be so easily excited are extremely numerous, and it is difficult so to apply with minute areal limitation an intense mechanical stimulus that it shall not affect "pain spots" in the vicinity of the touch spots.

When a small region, *e.g.* 1 sq. cm. of skin, in which the hairlets

¹ H. Spencer, 'Principles of Psychology,' vol. i. p. 187.

² Kiesow, *Phil. Stud.*, Leipzig, Bd. ix. S. 540; *ibid.*, Bd. xiv. S. 567; v. Frey, *Ber. d. k. sächs. Gesellsch.*, Leipzig, July 1894.

³ *Op. cit.*

⁴ Goldscheider, v. Frey, *op. cit.*

have been cut close, is examined with bristle æsthesiometers (see "Touch Spots"), a certain number, *e.g.* fifteen touch spots are found, all easily detected by using pressure intensities of less than 40 (3-33) grms. per sq. mm. No further touch spots are then revealed by increasing the intensity of stimulation even three- or four-fold. But when the intensity is increased to something over 200 grms. per mm. (occasionally as low as 150), there appear a large number of other "spots," at each of which smart reaction occurs. These spots are scattered pretty evenly, and, unlike touch spots, bear no obvious relation to the position of the hair follicles.¹ The sensation produced at each is pricking and painful, and in many of them the pain caused is, in the opinion of some observers,² quite unattended by any sensation of pressure. From each of these spots, when pricked, very lively, in some cases "hardly bearable," pain is evoked. These spots are called "pain spots" (Goldscheider, *v. Frey*).

Among the advantages of the hair-æsthesiometer (Hensen,³ *v. Frey*⁴) are—(1) Exactitude of local application, *i.e.* "stigmatic stimulation"; (2) impossibility of exceeding with it a certain easily measured intensity, which is its maximum capacity. In practice it is perfectly easy, when the hair is mounted properly, to ensure employing its maximal power at each application. Hensen and *v. Frey* use a chemical balance to calibrate the hair instruments. *v. Frey* takes as index of the stimulus the pressure exerted by the hair into its cross-section, expressed in fractions of a sq. mm. Nagel objects⁵ that a truer index would be the force that has to be exerted to bend the hair. He says that stimuli of unequal pressure but equal force are not perceived—in using the hair-æsthesiometer—to be different.

There are many forms of algesimeter besides the "hair" pattern. A simple needle is the most generally used, and offers many advantages for the clinician. If the needle has actually to enter the skin to evoke pain, that is of itself a sign of hypalgesia in any cutaneous region. The pinching up of a fold of skin will often successfully evoke pain when needle-pricks, however deep, do not. Quantitative results are the object of algesimeters. Björnström's⁶ instrument is a form of pincher, the pressure of which can be read from a scale. Hess's⁷ and Motschutkowsky's⁸ instruments are standard needles, the degree of depth of insertion of which into the skin can be read off on a scale. Bernhardt's method is by faradisation of the skin, the measure of the stimulus being the distance of the secondary coil from the primary.

Differences between the reactions obtainable from pain spots and touch spots are found as follows:—

1. The liminal sensibility of mechanical stimuli (pressure) is higher for pain spots than for touch spots.⁹ This the above-given example illustrated. The ratio $\frac{\text{touch limen}^{10}}{\text{pain limen}}$ varies in different regions of the skin; thus it is $\frac{1}{3}$ for the arm, $\frac{1}{100}$ for the finger-tips. Hence, when both are equally tightly squeezed, a fold of palmar skin gives less pain than a fold from the fore-arm.

⁹ Goldscheider, *op. cit.*

¹⁰ *v. Frey, op. cit.*

The lowest limina for pain are found in the temple¹ and the dorsal skin of the finger-joints.² Next, perhaps, come the tongue-tip and the forehead. The hand on the ulnar side is more sensitive for pain than on the radial. Glans penis, buttock, ankle, are among the least. On the whole, the pelvic region is as poorly sentient to pain as any part of the body surface. Flexor sides are, on the whole, less sensitive than extensor in regard to pain.³ The topography of "pain" in the skin, as regards its degrees of delicacy, certainly differs much from the topography of "touch," but the accounts yielded by various observers with algesimeters of different kinds, are very discrepant.⁴ The following are Bernhardt's figures, obtained by his faradic method; the figures represent the distance of the secondary coil from the primary:—

Tongue-tip	141	Back of hand	99
Cheek	125	Fore-arm	93
Back	116	Instep	92
Sternum	114	Pulp of finger	84
Buttock	111	Palm	75
Thigh	102	Toe-tip	65

Goldscheider has examined the regional distribution of heat-pain.

2. The liminal intensity for electrical stimuli (break-induction shocks applied by unipolar method) is higher for touch spots than for pain-spots.⁵

It is impossible to say whether these electrical stimuli to the skin excite the end-organs or the nerve fibres. The anomalies of the results of electric excitation in various parts of the skin show clearly that the skin is not equipped with organs adapted for such stimuli. In the palm, for the current to suffice to excite touch, it must be applied at the mouths of the sweat glands.⁶

Liminal intensity of pain stimuli is highest where the skin is thick and lies on thick muscle far from bone;⁷ this is with mechanical stimuli, and where the local deformation is not well estimated. Palm, thigh, and ankle, after temple, are parts where the limen is highest.⁸

3. Cooling the skin paralyses the pain spots sooner than the touch spots, although causing preliminary hyperæsthesia of both.⁹

Cocain locally applied to the tongue suppresses touch, taste, cold, warmth, and pain sensations, the order of paralysis in time being earliest temperature sensation, then taste, then touch, and finally pain.¹⁰ According to Shore, pain is suppressed before touch.¹¹ The statement¹² that cocain paralyses in the eyeball only the pain spots, is not confirmed.¹³ The behaviour of cocain in rendering the cornea analgesic, and yet allowing sensations of touch, though impaired, is important for deciding the true position of pain from pain spots. Carbolic acid,¹⁴ in 5 per cent. solution on skin or tongue, acts in the same way as cocain, but not so strongly. By subcutaneous injection in 2·5

¹⁴ Goldscheider, *op. cit.*

per cent. solution, it can locally completely paralyse all endings, including "painful." Chloroform,¹ locally applied with a sponge, after a temporary burning sensation, leaves all forms of sensibility locally lowered. It acts on different sensations in the same order of degree as cocain, but especially suppresses heat-pain. Menthol,² after causing a temporary hyperæsthesia of cold spots, depresses sensibility of all forms. Orthoform,³ in subcutaneous injection, after preliminary local pain, causes local analgesia. Guaiacol acts less quickly, but otherwise similarly and more lastingly, than cocain.⁴

4. The faradisation of pain spots, at any frequency above twenty shocks per second, evokes a continuous sensation; faradisation of touch spots, at rates of 130 shocks per second, evokes a discontinuous vibratory sensation. A similar difference between the length of duration of the reaction is also traceable by single shocks or mechanical stimuli; the pain sensation fades more gradually away.⁵

5. Not only minute, but also regional, distribution is different in the case of the two sets of "spots." The cornea and ocular conjunctiva are rich in pain spots, but have no touch spots; so also the glans penis.⁶ The eyelid sweeps over the cornea without being felt. On the other hand, a patch of mucous membrane inside the cheek is without pain spots,⁷ although provided with touch spots; indeed, the whole of the inside of the mouth is poorly provided with pain spots, although much of it is extremely rich in touch spots. There is a patch of the mucosa of the cheek at which faradic currents, sufficient to violently tetanise the facial muscles and radiate over all the region of the upper jaw, cause no trace of unpleasant sensation at the point of application.

In examining the buccal mucosa for pain by electric stimuli, it must be remembered that there moisture renders stigmatic application difficult, and with increase of area the density of the current falls. Comparison of dolorific effect obtained by stigmatic stimuli elsewhere with this buccal stimulation is therefore complex; the buccal stimuli would be effectually less intense in application.

6. The sensation from a touch spot is referred to the surface of the skin; that from a pain spot seems to radiate into the depth as well as over the skin surface, and is less clearly qualified with "local sign."⁸

7. The "latent period" of skin pain is greatly longer than that of touch.

From clinical pathology there is testimony corroborative of the physiological. A difficulty, however, arises with the pathological evidence. The pain stimulus being of intenser nature, allows the inference that the selective action of disease on the fibres of a peripheral nerve may consist in limiting the range of their response to the stimulus, without causing it to lose its functions altogether. The plausibility of this suggests itself most in the cases where there is analgesia without total anæsthesia of a part. Pressure on the ulnar nerve trunk will cause partial or total anæsthesia for pain and temperature,

⁶ There is a difference of opinion as to whether any touch can be felt on the cornea without pain. Nagel has pointed out that touches can be felt on the conjunctiva and cornea without any painful or disagreeable quality in them. It is the ease with which the corneal endings provoke pain which is denoted by the term "pain spots" as used in the above paragraph. See also Motter, "Diss.," Erlangen, 1878; M. Dessoir, *Arch. f. Physiol.*, Leipzig, 1892, S. 175.

⁸ E. H. Weber, *op. cit.*

with little or no diminution in sensibility to contact, with intact "motor" sensations and normal localisation.¹ But, as a fact, other combinations of selective loss not unfrequently occur, for which mere gradation of injury is not so plausible an explanation; thus, complete loss of temperature sensations in forearm and hand, with pain and contact preserved, due to injury of the shoulder.² On reunion of a cutaneous nerve trunk after trauma, the different specific sensations return at different rates, usually cold before pain and pain before warmth.³ An exhaustive and most interesting analysis of the changes in the sense spots of the arm, due to pressure of a cervical rib on the brachial plexus, has been described from the case of himself by L. F. Barker.⁴ He found groups of sense spots of one kind persisting in places where none of other sense species remained. Most of the sense spots in these selectively anaesthetic areas reacted to normal threshold stimuli, as could be particularly well proved for the pain spots. In places "cold pain" and "warmth pain" were elicitable, but not "cold" or "warmth" sensation; that is, ice gave pain but no cold, a heat of 47° C. also pain but no "warmth" sensation.⁵ The skin had thus in so far been transmuted to the sensory condition of the mucosa of the stomach, where the ice that is painfully cold to the lips causes pain but no sensation whatsoever of cold.

In toxic neuritis,⁶ and in tabes dorsalis, as well as in the above pressure diseases, the injury to the peripheral nerves may act selectively in regard to the pain spots.

It would seem that we may with some probability allocate the pain sense to certain kinds of the multifold structures described as nerve-endings in the skin—(1) The pain-endings lie more superficially than the other endings. This is strongly indicated by the lowness of their threshold electrical stimulus, which cannot be due to a greater electrical excitability of the pain nerve fibres, since when the ulnar trunk is galvanised the touch fibres are the most easily excited. (2) The central part of the cornea appears to be endowed with pain sensation only. It is found to possess histologically only one form of nerve-ending, namely, free nerve filaments ramifying amidst the epithelial cells. It is therefore probable that the free nerve filaments⁷ in the epidermis form the apparatus.

For the present issue the two most distinctive differences between the sensory reactions obtainable at touch spots and pain spots respectively seem (1) the (not universally accepted) absence of painful quality from the maximal reactions of touch spots; (2) the relatively poor tactual quality of the reactions excited at pain spots, although even the minimal reaction is there said to possess painful quality. I cannot unhesitatingly find in my own perceptions that excitation of a pain spot, e.g. by a bristle aesthesiometer, ever evokes pain pure without any tactual sensation. The fact that there coexist in the skin two kinds of sense spots, excitable by the same sort of mechanical stimulus, and that the one kind requires for excitation a very distinctly

higher threshold of intensity of stimulus than does the other, does not supply a final criterion for judging the question under consideration. There may coexist in the skin two sets of true tactual organs, the one more sensitive to touch than the other.

Some observers who admit distinction between "pressure spots" (called here "touch spots") and "pain spots," affirm the perception of a quality of "contact" in skin sensation in addition to qualities of "pressure" and of "pain."¹ They find "contact" quality in the sensations both from "pain spots" and "pressure spots."² Some affirm it also—and I agree with them in this—in the sensations evoked at temperature spots,³ although less prominent in the perception than is the quality of cold or warmth respectively. Tactile and temperature stimuli are, it may be recalled, not invariably discriminable when applied to some regions of the skin of the back. It is true, however, that if one only out of the four sets of end-organs in the skin can evoke the pain psychosis, then that one can quite appropriately be considered a specific "pain organ." Nor in the skin especially is there any teleological difficulty in the acquirement by the body of a specific set of nerve fibres and nerve organs for sensations of pain. Thus it is found that certain forms of common sensation (*e.g.* sexual voluptas, tickling), peculiarly potential of pleasurable emotion, have been evolved in special connection with certain fields of skin which are not pre-eminently sentient for ordinary "touch."

Let it be granted that the above evidence still leaves it open to regard the skin as possessing, apart from tactual and thermal sense, a specific dolorific sense as well. What have the other sensifacient regions of the body, which can as unequivocally as the skin initiate physical pain, to offer in comment upon such a view? There are "deep" pains as certainly as there are cutaneous or "superficial." Deep structures occasioning pain are the organs of bodily movement and the viscera. Are these structures also endowed with specific nerve fibres for a pain-sense. The afferent nerves of the organs of bodily movement are the ministers of the so-called muscular sense. (For detailed account of them and their function, reference must be made to the article on "Muscular Sense"). They are, as regards their distribution to tissue, and probably also the details of their function, divisible into several sub-groups. The pain, which under unusual circumstances is evoked from the parts supplied by this sense, may either express the excessive reaction of specific "muscular sense" nerves, or the reaction of separate pain fibres, admixed with the fibres proper to "muscular sense," just as it was granted, for the argument above, "pain fibres" exist admixed among the other afferent cutaneous nerve fibres.

The stimuli which provoke pain from the deep structures, such as muscles and joints, appear to be mechanical in quality; in fact, the same in kind as those which normally must furnish the impressions at basis of the muscular sense. Haller's⁴ original experiments vouch for the inadequacy of an exhaustive number of chemical and thermal stimuli. More than that, his experiments, together with other observations, show that certain mechanical insults to muscle and tendon are quite impotent to excite pain.

In reading those earlier experiments, one is struck by two circumstances

² Dessoir, 1892, Nagel, 1895, Kiesow, 1896, and, if I understand him correctly, Goldscheider ("Ueber den Schmerz," Berlin, 1894) throughout his analysis of skin senses, 1885-1895.

³ Kiesow, *loc. cit.*

⁴ "De Partibus," Göttingen, 1752.

regarding the mechanical irritations employed, which might detract from their efficiency as excitants, namely—(1) The thoroughly abnormal character of the production of the strains in many cases, *e.g.* twistings, foldings, etc., which the body itself cannot produce; (2) the absence of the opportunity for prolonged summation. Against such negative evidence is the fact that muscles stretched passively for a prolonged time become painful,¹ and that the passive stretching of muscle is a most efficient excitant for normal spinal reflexes through its afferent nerves.² It would appear that only mechanical conditions, akin to such as obtain in muscles during their functional activity, can initiate from them sensation and pain. The structure of muscle spindles certainly points to the adequate stimulus being of a mechanical kind,³ and that of tendon organs points in the same direction.

Extreme and abnormal actions of muscles furnish the best instances of muscular pain. Weber⁴ felt the muscles of his horizontally held arm become painful in 300 seconds, unbearably so in 900 seconds. At the same time contractions as vigorous as those of cramp may be caused without the painful sensation of cramp.⁵ To attribute the sensation of cramp merely to compression of sensory nerves passing through the muscles, and not to sensory nerves of their own, is certainly not permissible. The pain of muscular cramp is distinctly perceived to be in the contracting muscles, that is, is referred to the contracting muscles. The adequate stimulus seems under certain circumstances—and among these excessive duration appears eminently important—to elicit pain from the muscular sense. A specific set of nerve fibres and end organs, devoted solely to production of pain, although to the above extent supported by analogy from the skin, does not appear a warrantable postulate for muscles.

The feeling of muscular fatigue is a form of common sensation that has undoubtedly considerable "negative tone." It presents, in accordance with its amount, practically infinite shades from the scarcely unpleasant up to the extremity of distressful. It is a state certainly largely due to the regularly employed specific nerves of muscular sense. In its relation to them it is well comparable with the feeling of hunger in relation to the visceral nerves.

The viscera offer still another field for analogy. There we find regions of the body, usually only in very subordinate degree sensifacient, that under certain circumstances evoke extremity of pain. The impulses embouching *via* the vagus and afferent spinal roots from the visceral nerves upon the central nervous system appear hardly at all to elicit ordinarily conscious reactions. When abnormally they do so, they seem almost invariably to produce pain as their result. It is as though particular afferent nerves, which usually are not in the strict meaning of the term sensory nerves at all, can on occasion become "sensory," even to the extent of convulsing the whole mind. Some authorities, as above mentioned, teach that the visceral nerves are generating constantly "obscure sensations."⁶ It would rather seem that these nerves intermittently with phasic regularity launch sensory impressions (as well as visceromotor, secreto-motor, and other reflexes) that do not trouble the stream of consciousness at all. These

sensations are all contributory to common sensation, and therefore potentially possess the attribute with which all forms of common sensation are intensely imbued, namely, "affective tone,"—and physical pain is stronger than physical pleasure. The relation of the stomach to the "feeling of hunger" is a helpful instance.

The prominent features of the "feeling" hunger are—(1) peculiar sensations, referred to the epigastrium (stomach); (2) general "sinking" or "feeling of weakness"; (3) desire for food. Regarding the first the sensations are of an ill-localised gnawing character, principally referred to the epigastrium but not confined to that region, for the pharynx shares in them. The nature of the stimulus provoking these local sensations is not clear. It is often said to be "emptiness of the stomach." Introduction of food into the stomach rapidly stops the feeling, even before much absorption of the taken food can have occurred. Hunger is temporarily relieved by introducing non-nutritious material into the stomach. It has been urged, on the other hand, that a rabbit after twenty-four hours' abstinence is very hungry, although its stomach will be then found to still contain much food. It is said to take three days' abstinence to empty the stomach of the domestic rabbit. But here the stomach after abstinence, although distended, is not so distended as before, and the absolute value of the limen of "relaxation stimulus" may legitimately be variously placed. Also, it has been urged that many persons do not feel hungry in the morning after the longest abstinence of the twenty-four hours;—most English do, but few French or German, a difference related to difference in national habit regarding meal-time. In duodenal fistula hunger has been observed as a marked symptom, even when the stomach is full. On the other hand, in gastric catarrh hunger may be absent although the stomach remain empty for hours. The nature of the stimulus causing the hunger sensations, referred to the epigastrium, is therefore not clear. Tension of the stomach wall (or relaxation) is, however, indicated by various of the above evidences as playing some part in it. Normal tensions, and abnormal, are well known to be efficient as stimuli for the afferent nerves of hollow viscera (*e.g.* urinary bladder, heart, etc.). The tension caused by the engorgement of the mucosa with the proper digestive granules developed in the cells, may give rise to this local sensation in the case of the stomach.

As to the sensory nerve channel for the local sensation of hunger, likely enough it is the vagus, but very possibly the stomach receives sensory nerve fibres also from the thoracic spinal ganglia, *viâ* the rami communicantes. After section of both vagus nerves, rabbits continue to feed well, and therefore must have appetite.¹ So also, after section of the cervical cord or of both the splanchnic nerves, and after extirpation of the ganglia cœliaca and meseraica.² Neither the vagus nor the splanchnic afferent channels are therefore necessarily the single channels for the feeling of hunger; but that after their section the local feeling of hunger exists, is only presumed. Section of merely a few muscular nerves would hardly relieve the body from the heavy feeling of fatigue consequent on a long march; would section of the vagi remove the oppression of impending asphyxia? Section of the sensory nerves of the pharynx and œsophagus does not prevent the occurrence of thirst, but moistening the fauces does temporarily allay thirst.

The dog exhibits hunger after complete removal of the stomach,³ so

³ Ludwig and Thanhofer, quoted from Beaunis, "Les sensations internes," Paris, 1889, p. 34.

here is, together with the local excitation, a general condition produced. As to this latter, again, its nature is not clear. A man is usually less hungry after his ten hours' fast, which has included the night's rest, than after a four hours' abstinence in the working day. The stomach is certainly as emptied in the former case as in the latter. But the greater metabolism that has intervened in the latter brings about a general change which causes hunger. To say this change is want of food-material in the body, is merely to restate the problem. It has been argued that it is want of blood or lymph. Where in duodenal fistula, despite replenishment of the stomach with food, hunger develops and persists, it is relieved speedily by introducing the products of gastric digestion into the upper end of the small bowel.¹ Similarly thirst is, without drinking, rapidly assuaged by the injection of fluid into a vein.² These effects resemble the production of, and relief from, general muscular fatigue, given by transfusion of blood in Mosso's well-known experiment.³ The blood is somewhat inspissated in moderate hunger.⁴ The relief occurs so rapidly, that it is argued that it may be due to alteration of the blood rather than of the lymph. How quickly large quantities of fluid may be transferred from the blood to the lymph, is shown by experimental observations.⁵ The feeling of hunger is relieved, is even converted into a pleasurable satiety, before the blood is saturated with absorbed material. The chief use of the local peripheral reference of sensation in hunger seems as an index for regulating the amount of intake, and thus preventing excess. It has been remarked that animals in which the vagi have been cut, so far from not evincing hunger and taking insufficient food, take an excessive quantity. But I have seen in the dog distinct diminution of appetite ensue on double vagotomy, after cervical spinal transection.

The peripheral regions to which the feeling is chiefly referred, stomach and throat, are innervated mainly by the ninth and tenth cranial pairs. "Hunger" feeling (and "thirst" feeling) are held, therefore, to originate in impressions elaborated by the bulbar centres receiving the roots of those nerves. These centres are perhaps specially sensitive to those qualities of the circulating blood which depend on intake of food, much as the bulbar centre receiving the lung branches of the vagus is specially sensitive to the respiratory quality of the blood. It can hardly be supposed that in the nerve cells of these centres impulses are actually initiated by conditions of the blood supplied to them. Meynert, it is true, argued that functional hyperæmia of the brain is felt as pleasurable and anæmic conditions of the brain as the reverse, the central elements perceiving their own nutritive condition.⁶ But the condition of their blood affects the excitability of nerve centres; it may be supposed to increase the excitability of those into which embouch the afferent nerves of the gullet and the stomach. Some nerve centres are remarkably increased in excitability by moderate hunger, just as conversely the knee-jerks are found to be diminished shortly after a heavy meal. The thirst which is caused by some drugs subsides after a time without the taking of liquid into the body; it has been argued here that the effect is due to temporary increased central activity, due to temporary alteration of the blood. It has been several times remarked that the stomach and intestines of fasting animals exhibit remarkably active peristaltic action. A condition of the general blood or lymph can be easily conceived to not only affect the nerve centres centrally, by affecting the nutrition of their ganglion cells, but also by peripheral changes exciting

sensory nerve-endings. It has been urged that a change, *e.g.* a diminution in the volume of the circulating blood, may be perceptible by means of the heart nerves.¹ Deficiency of lymph might certainly induce a relaxation of many membranes to which afferent nerve fibres are distributed, *e.g.* capsules of Pacini corpuscles, etc. Such changes may be thought too weak to produce effect; yet a character of common sensation is a pre-eminent tendency of the impressions building it to fuse, to summate, to cumulate. This is as unmistakable in pain, as in tickling, the sexual "feeling," etc. This explains why mere excessive duration of a stimulus which at the outset lies far below the limen for pain, may bring it up beyond that limen and make it effective, even insufferable, *e.g.* a tight boot or hat. Hence it is impossible to deny that visceral stimuli, that for a short time are of negligible intensity, may, if continued, develop potency for sensation.

From the above it is evident that the nature of the condition of the body which is the source of the feeling of hunger, is not definitely known, nor is the manner in which the condition can react on sense. Nevertheless, the kind of condition which excites the "feeling" is clear enough. It is a condition in which requisite supply of material for maintaining normal life is withheld, in which injury is threatened, and to which the *dativus incommodi* of the grammarians is applicable. A need arises like the *besoin de respirer*, and becomes irpressible, *i.e.* excites to action. Hunger eventually becomes painful, even more than, conversely, satiety is pleasant. The dogs from which the cerebral hemispheres had been removed by Goltz became restless as feeding-time drew near. This restlessness subsided when the usual quantity of food had been taken, and the dogs then invariably, "refused" further quantities of food. In other words, the restlessness was part of the hunger reflex, and so far, like the movements of "swallowing" brought out by food placed in contact with the dog's muzzle, could only be excited in the hungry state. So also the male pigeon, after removal of the hemispheres, will in spring coo all day long, and show distinct signs of sexual excitement. But his activity is entirely indifferent toward the hen-bird placed near; he leaves her unnoticed. The muscular restlessness (the motor adjunct of the "hunt" for food) stands evidently in the same relation to this visceral sensation of painful "tone" as does the flexion of the hip and knee (withdrawal of the foot) in relation to the cutaneous sensation of painful "tone" initiated by a pinch of the foot.

The use of the discussing of the feeling of hunger to the argument here is, that it broadly indicates how the production of painful sensations by the same visceral afferent nerves as those ordinarily employed in unpainful and in even unconscious neural reflex reactions, comes about. That in some instances the visceral pain is due to tension, forms, to my thinking, not a difficulty, but merely indicates that the normal adequate stimulus is of a mechanical kind.²

A further difficulty for supposing that the viscera are provided with specific nervous apparatus for a "pain-sense," is the following:—

"It may happen to a man to suffer pain in a particular region or tissue of the body once only in the course of his lifetime, or possibly not even once; nay, we may suppose that in this or that region or tissue pain is felt once only in one individual among a large number of persons."³ How, if this pain requires, to carry it out, a special mechanism, including special afferent nerve fibres, can, in the case in

¹ Budge, *Nova acta phys.-med. Acad. nat. curios*, 1860, tomo xxvii.; "Physiologie," Leipzig, 1862, S. 815.

² See C. A. Strong, *Psychol. Rev.*, N. Y. and London, 1896, vol. iii. p. 64, *contra* H. R. Marshall, *ibid.*, 1895, vol. ii. p. 594. Cf. also E. H. Weber, Wagner's "Handwörterbuch," Bd. iii. (2) S. 580.

³ M. Foster, "Text-Book of Physiology," London, 1900, part iv.

question, such a mechanism of pain have originated? Or, when originated, be preserved intact (although unused whole generations through), in order occasionally, perhaps once in a lifetime, to come into use?

This difficulty is in the main, though not entirely, avoided by the view that visceral pain results from *excessive* stimulation of afferent structures normally employed for reflex actions, accompanied only in some instances by sensations at all, and not, under usual circumstances, by feelings of physical pain.

Further, it must be remembered that some of the most salient pains of visceral disease are of the nature of "sympathies," "associate" or "referred" sensations (*Mitempfindungen*).¹ These are clearly merely adjuncts of excessive neural reaction,—not always the effect of excessive stimulation,—and yield no support to a hypothesis of specific visceral pain-nerves. The visceral nerves seem connected with the central neural mechanism for pain only through a path offering high resistance. The central paths of pain are probably in all cases high-resistance paths, but the resistance seems different in degree in different pain-paths. It seems lowest in a certain set of the cutaneous paths. The resistance, it seems, can be overcome in various ways, by intensifying the stimulus, and also by repeating it (summation). When nerve impulses are enabled, *e.g.* by summation, to travel high-resistance paths, they show a tendency to escape to neighbouring channels. Borrowing language from electrical terminology, the tension of the charges seems to be high, and the ordinarily efficient insulation then allows some leakage. In physiological parlance, by virtue of the neural laws of irradiation and intermingling (overlap), the visceral afferent nerves, thrown into excitement by excitation excessive in intensity or duration (conditions in which pains arise) impart excitement to juxtaposed nervous apparatus, and especially to the dolorific nerves of the skin. There is nothing in the so-called referred pains of the viscera, either in regard to their mechanism or their occurrence, that argues for the existence of specific pain-nerves in the viscera.

As far, therefore, as analogy from the pains of the viscera and the organs of muscular sense can guide, we are not given warranty for an expectation that cutaneous pain shall be the outcome of the stimulation of specific "pain-nerves." And if that supposition be adopted, logical justice leads to the following dilemma. The *adequate* stimuli for *touch* and *thermal sense* can evoke *pain* from the skin. A persistent touch, *e.g.* the light pressure of a hat, not painful at first, may in time become so. According to Weber, the merely areal increase of application of heat to the skin can convert a non-painful heat stimulus into a painful. Those who infer that painful cutaneous sensations are called up only by specific pain-nerves will be consequent, if they suppose that the skin possesses at least two species² of pain fibres, equipped with specific end-organs, for which tangible and thermal stimuli respectively are adequate. Analgesia for tactile stimuli sometimes co-exists in the same skin with hyperalgesia for thermal stimuli.³ Painful mechanical stimuli have been in similar experiments noted to elicit wholly different reflexes from those evoked by painful thermal stimuli.⁴

Weber felt this difficulty when he adopted the long-current opinion that nerves of "touch" and thermal sense yield pain when excited not mediately

¹ See above, p. 981.

² From the analogy of the existence of separate nerve-endings in the skin for sensation of "cold" and "warmth" it would be probable that more than two, namely, three species of pain-endings in skin would be demanded for pains from mechanical and thermal stimuli. Two is, however, taken in the text as the smaller hypothesis.

³ Strong, *Psychol. Rev.*, N. Y. and London, 1896, vol. iii.

⁴ E. Bruecke, "Vorlesungen ueber Physiologie," Wien, 1874, Bd. ii. S. 240.

through their end-organs but immediately along their course. He argued that the pain felt when the ulnar nerve is cooled by holding the elbow long enough in ice-cold water, is caused by excitation of the nerves of temperature sense. But in that experiment, sensations tactual and thermal as well as dolorous, arise, referred to the peripheral distribution of the ulnar trunk. The experiment admits just as well of explanation by the hypothesis of special pain nerves irritable in their course.

It may be argued, however, that even on the view of the existence of *specific* pain end-organs in the skin, it is not obligatory to suppose that, though they respond equally both to tangible and thermal stimuli, they are in reality of more than a single kind. These stimuli are of the nature of general nerve excitants. They only excite the pain sensations when they are applied in relatively high intensity, and excite it *cæteris paribus* in proportion to the height of grade of their intensity. Such excitants of sufficient intensity, when applied to any naked nerve fibre, motor as well as sensory, and in its course, as well as at its ramified endings, will excite it. What is necessary, therefore, in the skin is that the endings of the hypothetical specific pain-nerves should be amenable both to tangible and thermal stimuli, and this might possibly be the case in one of two ways. They might possess end-organs so highly differentiated in regard to specific nerve energy, that any stimulus affecting them at all irritated pain-reaction. Or they might, while their central connections obeyed to the letter the well-worn law of specific nerve energies, be provided with peripheral end-organs so little differentiated as to allow with facility a considerable range of quality of general nerve excitants to play upon them with tolerable effect. The main difficulty is that the effect is so great. Choice between the two views will depend largely upon the relative value attached to two different functions seeming to belong to every sensifacient end-organ. The sensorial end-organ is an apparatus by which an afferent nerve fibre is rendered distinctively amenable to some particular physical agent, and at the same time rendered less amenable to, *i.e.* is shielded from, other excitants. It lowers the value of the limen of one particular kind of stimulus, it heightens the value of the limen of stimuli of other kinds.

Especially in regard to the latter result of adaptation, has the original Müllerian law of specific nerve energies required reconsideration. The Blix-Goldscheider cold spots of the skin evoking cold sensations reply¹ to stimuli of pressure and heat as well as of cold; that is, non-adequate as well as adequate stimuli fairly easily evoke from them their specific sensation. On the other hand, there are in the tongue individual papillæ from which only a certain suitable set of tasteable substances can evoke a sensation,—always the specific sensation,—and all other stimuli fail to evoke any sensation whatsoever.² The warmth spots of the skin are in the condition of these tongue papillæ; but it may be that the pain spots are more in the condition of the cutaneous cold spots in this respect, and even overpass them. Somewhat against this is the histological evidence of the skin regions which are pre-eminently dolorific, pre-eminently possessing so-called “naked” nerve fibril sensorial endings. If simplicity of histological structure in a sensorial end-organ be any guide to absence from it of functional differentiation, histology indicates the explanation of the presumed amenity of pain spots to various

¹ Denied by M. Dessoir and Nagel, affirmed by Goldscheider, v. Frey, and Kiesow. My own experience on this point supports the latter group of observers, and would include faradisation.

² Oehrwall, *Skandin. Arch. f. Physiol.*, Leipzig, 1891, Bd. ii. S. 1; cf. Kiesow, *Phil. Stud.*, Leipzig, 1898, Bd. xiv. S. 591.

physical stimuli, by want of differentiation rather than height of differentiation of end-organ as the more probable.

On the other hand, instead of supposing that the hypothetical specific pain nerves are each and all normally and delicately amenable to a range of variety of stimuli, for whose appreciation elsewhere a whole series of sense organs is required, it may be answered that there is no objection to supposing that the skin has two or three different species of specific pain nerves. For this belief there appears at present no decisive evidence, but there is the analogy with muscular and visceral nerves.

On the hypothesis of the existence of a specific pain-sense it would be expected that excitation of the cerebral cortex would give rise to some evidence of production of pain. The cerebral cortex, which contains, as is known, fields for the termination of so to say each avenue of sense, should on that view excite pain sensations. This does not appear in fact to be the case. The well-known experiments of Haller, Bichat, Budge, etc., besides bedside evidence, and the opportunities of electrical excitation, do not bear out the expectation. Epilepsy, so far as I can learn, hardly ever includes in its prodromata a "pain" aura,¹ although other orders of sensation—visual, auditory, tactual, thermal, gustatory, and odorous—seem each laid under contribution.

On the other hand, the dogs from which Goltz had removed the cerebral hemispheres reacted to "painful" stimuli in a way which was interpreted as evidence of the persistence of physical pain. Such evidence is, however, after all, equivocal for the point, as is the reflex vocalisation noted in the rat—and I have heard it in the monkey—elicitable even in the first hour after cerebral ablation, anterior to the corpora quadrigemina. We reflect that in this condition the contrast of the sensible world as "me" and "the rest" seems from other evidence gone, and the animal has become "impersonal." In all these cases the working of the machinery of expression is but a dubitable sign for the actual existence of the feeling which is under ordinary conditions "expressed."

On the whole, it would appear as if the deep sensory nerves, the visceral and the musculo-articular, and of the superficial sensory nerves, the cutaneous, possess the power of evoking physical pain; and it appears significant for this fact that these are the sensory channels which inform the sentient self of the condition of that half of its sensible universe, its bodily "me belonging to self." It is impossible to think that the normal functions of three sets of afferent nerves of such different distribution and physiology as the visceral, musculo-articular, and cutaneous, are all the same, although the dolorific actions from them appear so similar. Bodily pain would therefore seem less a single specific order of sensation than, like local sign, a quality attaching in common to a certain non-universal group of specific sensations. Pain has no one specific stimulus with which it can be correlated. This view of course relinquishes the conception of any specific pain-sense, also, strictly speaking, of "pain" nerve fibres. But I recognise that it may be convenient to distinguish, when certain apparatus especially readily ministers to pain, some nerves as "dolorific" or "pain-nerves"; as in the skin where certain nerves develop sensations with pain quality dominant, almost to the exclusion of all other (as muscle nerves evoke dominant local sign). This usage will at least serve as a

¹ See, as a rare instance, the case given by Pierce Clark, *Am. Journ. Insan.*, Utica, N. Y., July 1897.

protest against the teaching that pain stimuli and pain sensations are agents and reactions lying beyond the sacred pale of "normal" life.

Having discarded the supposition of separate afferent nerve fibres with their specific end-organs, entrusted specifically with carrying "painful" impressions to a "pain centre," it is finally worth considering what meaning can be still attached to the phrase "pain centre." There might exist such a specific pain centre, to be reached by currents of overflow from other sense centres, when the violence of their inner excitement had surpassed a certain pitch. Or, again, a certain extreme degree of inner excitement might superimpose the feeling of pain upon the sensation elaborated by each of the sense centres itself,¹ although unequally in degree in the centres of the different senses.

The rate at which agreeableness and disagreeableness vary with intensity of a sensation, may roughly be represented by a curve about a horizontal line marking the threshold of sensibility. If below the line be disagreeable, the curve at starting from the horizontal rises, at first more slowly than sensational intensity, then faster, and reaches its maximum distance above, that is, on the agreeable side of neutrality, before sensation is near its acme. After its maximum the agreeableness soon drops and sinks below the horizontal zero level into the realm of the disagreeable or painful. Into this it plunges, becoming, after a certain depth, finally asymptotic to the horizontal level. For some sensations—as bitter, sour, and certain smells—the curve does not ascend at all, but enters the realm of disagreeable from its outset. Among these sensations must be included those from the pain spots of the skin. The sensation of pain spots seems to resemble most nearly in this respect such olfactory sensations as in highly osmotic animals certain odours, *e.g.* that of the skunk, evoke. How intimately vexation of the stream of consciousness by pain stands in relation to intensity of the stimulus, is no way shown better than by simply increasing the number of nerve fibres, under application of a stimulus non-painful when at work upon a limited number. Minuteness of local application of stimuli to the skin does not appear to have yet reached a degree at which it becomes probable that the sensation is caused by excitation of a single nerve fibre alone. The nerve fibres to the skin are in their distribution very intermingled. I found that in most regions of skin, every, even small area, obtains nerve fibres from two successive spinal roots, and in not a few regions of skin the number of spinal roots furnishing the areas is three.² Hence in a skin field where only one root remains, punctiform stimulation at the field's edge is less bound up with pain than that nearer the field's centre, the latter implicating a greater number of nerve fibres. In regard to the pain produced by cold and warm stimuli size of the skin-surface, *i.e.* the number of the sensifacient nerve-endings influences in the directest manner the product of the sensation. A finger-joint can be kept comfortably in water at 48°·7 C., but the whole hand plunged into the same water soon becomes painful. Similarly with water at 6°·2 C. The "touch spots" in a skin area do not work all from the same sensibility limes; increase of pressure on the same field will, within limits, excite fewer touch-organs if light than if heavier.

That the seat of the neurosis underlying the painful in a sensation is not identical with that of the production of the regular form of the sensation, seems shown by the evidence given of the difference of the central paths of conduction for pain and for touch. The grounds were given above for the belief that the pain-path involves especially the spinal grey matter and the white matter immediately abutting upon that. In connection with this is the prominent part which summation plays in the production of pain.

¹ Lotze, "Med. Psychol.," S. 245 ff.

² *Phil. Trans.*, London, 1892.

Pain sensations summate at less frequency than touch sensations, and even more easily than muscle twitches.

Richet¹ has pointed out that, in faradising the skin, a distance of the secondary coil from the primary can be found at which neither single make-shocks nor break-shocks are perceptible, but a rapid series of these individually imperceptible shocks evokes a strongly unpleasant sensation. In certain clinical cases,² rhythmic repetition of a liminal stimulus, e.g. touches with a brush or needle point, after a certain number of seconds, evokes a pain which swells wavelike to a crisis and then subsides, often recrudescing to a second or even third crisis. When the point of a pin is lightly pressed on the skin, there succeeds, after the immediate pricking feeling, an interval without sensation, followed by a second pricking feeling. This second sensation, which has been termed the "secondary," differs from the first in having no touch-quality mixed with it; it seems "to come from within." No "secondary sensation" follows stimulation with a single induction shock; it does, however, follow when a short series, or even two induction shocks,³ are applied for not less than $\frac{1}{2}$ of a second. It is therefore due to summation in the latter case, and probably in the former also.

The inertia of the organs for pain seems peculiarly great. Faradic excitation, with shocks at higher rate of frequency than 20 per second, causes continuous sensation of pain, and the period of latent excitation for pain is relatively long. I found that by focussing the heat-rays from a lamp upon a skin area of about 25 sq. mm. (on the back of the hand), and allowing a perforated screen to intermittently intercept the radiation, the heat-pain begins to be perceptibly intermittent when, the times of play and of interception being equal, the intermittence falls below the rate of thirteen per minute. An intensity of this intermittent radiation stimuli, at first not painful and yielding sensations strikingly discrete, soon becomes dolorific, and then the sensations remain discrete no longer but are fused more or less together.

Weber⁴ counted the seconds elapsing before the finger- or tongue-tip had to be withdrawn on account of pain from water at various temperatures. The warmth gradually became painful in many instances when not so at first,—e.g. with water at 44° Reaumur, whence the finger was withdrawn in from twenty-one to twenty-eight seconds. He found the fingers of the left hand slightly more sensitive than those of the right. The rounded end of an iron rod, four Paris lines ($\frac{1}{3}$ in.) thick, cooled to 3°·2 Reaumur, and applied to the forehead eleven lines from the median plane evoked painful sensation in ten seconds; that is, the sensation caused began to be painful in ten seconds, and similarly, from the upper eyelid, in eight seconds became insufferable. In these cases pain almost is summation.

"When all the spinal paths are in normal condition, impulses of moderate strength will take the simple white paths, and only impulses of excessive strength will overflow into the branching side paths through the grey matter."⁵ The essential part of this idea is (1) a summing path offering high resistance to conduction, and (2) a low resistance path of more mobile neural protoplasm, possessing less inertia. To identify the one with grey matter, the other with white, seems unnecessary and unfortunate. Every conduction path in the nervous system is composed both of grey and white matter, inasmuch as every nerve fibre is but the process of a nerve cell, and every nervous impulse is but a wave of change which travels a concatenation of nerve cells, and every (or almost every) synapse between nerve cells occurs in the grey matter. It is more useful to interpret the suggestion rather in the sense that when nervous

impulses are strong, they overflow from their ordinary channels of direct and facile conduction toward mechanisms of conscious reaction into channels less direct with consciousness, the latter being composed of a greater number of conducting neurones than the former. It is well known that the general rule of arrangement in the spinal cord is, that long nerve fibres lie outside, short nerve fibres inside next to the grey matter. Some of these latter are extremely short, and all belong to "relay cells." It is this sheet of short relay fibres, immediately abutting on the grey matter, that pain impulses—to judge from experimental and other data—especially in one part of their course employ. These short cell-paths, abutting on the spinal grey matter, effect their mutual linkage there. We know summation in connection with the nervous system only as a property attaching to cell-chains, often, it is true, to simple two-link chains. Hence summation may be a function of the transmission of impulses from one cell to another,—in short, a function depending on the synapse. It is in accord with this to find that a conducting chain of a particularly high number of links, *i.e.* built up of more nerve cells than usual, exhibits summation particularly markedly. That is, the inertia of the pain apparatus may be a peculiarity of the reaction of the "pain" nerve cell, or, on the other hand, may be simply the outcome of its consisting of many nerve cells. That pains are badly localised (E. H. Weber), thus painful touches not so well as less painful, harmonises also with the same general conception.

The physiological apparatus for cutaneous pain takes, as compared with that of other skin senses, a long time to get into movement, and when once moved requires, in comparison with other apparatus, a long time to return to equilibrium.

Connected with summation must be the phenomenon of delayed pain sensation¹ commonly met with in tabetic cases. The pain produced by a prick with a needle is perceived only after a lapse of an abnormally long time; even five seconds may intervene between prick and pain. The sensations of touch and pain are thus isolated, a clear interval separating the two. The patient replies to the single prick with a double response "now," followed by "ah!" corresponding with the "touch" and the "pain." Schiff² described a similar phenomenon as occurring in experiments where partial transection of the spinal cord has trespassed on the grey matter and narrowed it. According to him, the delay increased proportionally with the encroachment on the grey matter, just as the wave of conduction was delayed in the bell of medusa where the tissue was encroached upon, and the path narrowed, in Romanes' experiments.³ Compression of a nerve trunk has also the effect of delaying the sensory reaction for which it is afferent. I myself met very marked instances of delay in experiments,⁴ when dealing with the analysis of sensory nerves into their separate root components. For instance, the reflex from a digital nerve which received afferent fibres from the seventh and eighth cervical roots, and from the first thoracic, was much *delayed* in occurrence after section of the first thoracic and eighth cervical dorsal (afferent) roots; the latency was sometimes more than three seconds. Clinical observation⁵ has also detected the delay in injury or disease of peripheral nerves. Schiff's reference of it to narrowing the grey matter is a suggestion applicable, therefore, to only part of the problem. In my own experiments there was similarly a narrowing of the conduction path, but the path was entirely a peripheral one. The explanation is probably connected with the increase of intensity of reaction obtained in so many cases

by increase of the extent of the stimulus, *i.e.* by simple increase of the *number* of nerve fibres excited (cf. "Cutaneous Senses of Cold and Warmth," p. 956).

The stimuli which evoke pain may be characterised as "excessive." It might almost be asserted that "excess" is that quality of a stimulus in virtue of which it becomes "adequate" for the sense of pain. "Excessive" in this application connotes "harmful," or "to be avoided," *e.g.* by muscular action for resistance or escape. The "excess" of the stimulus may lie in its intensity, or in its extensity (spatial or temporal).

The conclusions thus reached may be briefly stated thus:—Affective tone is an attribute of all sensation, and among the attribute tones of skin sensation is skin-pain. Affective tone inheres more intensely in senses which refer to the body than in those which refer to the environment, that is, it is strongest in the non-projicient senses. It is therefore strong in the cutaneous senses, and in them is inversely as their projicience, therefore least in touch spots, more in thermal spots, most in the so-called "pain spots." The sensations from pain spots have weak tactual quality and strong affective quality, especially of negative tone. The pain produced by heat is probably evoked from "pain spots," and not from thermal spots; the pain produced from "pain spots" is produced not only by mechanical stimuli, but probably also by thermal, chemical, and electrical stimuli. Stimuli evoking skin-pain are broadly such as injure or threaten injury to the skin; the skin may be said to have gone far toward developing a special sense of its own injuries. The central conducting path concerned with these skin feelings seems a side-path into which the impressions from the various skin spots embouch with various ease, those from the "pain spots" especially easily. The physiological reactions connected with this side-path are characterised by tendency to "summation," tendency to "collateral irradiation," slow culmination and slow subsidence. They often involve with their own activity that of adjacent sensory channels (associate pains, referred pains). and almost invariably of motor centres of visceral, facial and other muscles of expression (emotional discharge).

Can bodily pains be of central nervous origin? The dog from which the cerebral hemispheres have been removed gives reactions, interpreted¹ as evidencing pain. Budge and others² have examined by experiment the effect of stimuli to various parts of the brain, with a view to discovering which parts can give rise to painful sensation, and which not. The result of their observations, chiefly made on the rabbit, has been negative as regards evidence of pain from all parts above the optic thalami. From the optic thalami the evidence was equivocal; what there was Budge was inclined to attribute to the adjoining *crus cerebri*. From the *corpora quadragemina* down to the lower end of the rhomb-encephalon inclusive, signs of pain were easily evoked. Pathology seems to prove the production of pain by irritative lesions of the thalamus. Support is lent by the close connection found clinically³ and experimentally⁴ between the thalamus and bodily expression of emotion.

³ Nothnagel, Meynert, Rosenbach, Kiritzow, Mingazzini.

⁴ Bechterew, Outanskow, Mislawski.

In one case¹ a boring, tearing pain in one half of the body, accompanied by motor weakness the day following its onset, led to suicide two years after the attack. A lesion was found post-mortem in the thalamus (*nucleus externus*), adjoining the posterior third of the posterior segment of the internal capsule, in the hemisphere opposite to the hemialgesia. In another instance² there was "severe pain for a number of years in the right side of the body, and for five years weakness of the right side, with involuntary movements of the right hand and sometimes leg. On movement of the parts, pain could be produced in arm and leg throughout, but while at rest pain was chiefly in elbow and knee. The tactual sense was intact, although there was slight hyperæsthesia. Localisation power and the temperature and muscle senses were intact, except slight numbness to cold. There was a high degree of hyperalgesia to pressure, percussion, and all passive movements. A vertical section through the pulvinar of the left thalamus displayed on the edge of the middle and posterior third a round pea-sized cyst, filled, and a web of connective tissue, lying in the immediate neighbourhood of the internal capsule." In another case,³ a solitary tubercle in the right half of the pons was the only lesion found to account for severe pains existing in the left limbs, with complete anæsthesia of their skin, "anæsthesia dolorosa."

Cognition and feeling seem almost concomitant. To abstract either from other can only be done as a conventional simplification for logical purposes. There is therefore no *a priori* reason for expecting cognition and feeling to be respectively adjunct to spatially separate cerebral organs. As regards pain and the cortex, some argue that the feeling of bodily pain is elaborated in the Rolandic region, and that thence are initiated emotional movements, respiratory, vascular, and facial, etc. Pain aura in epilepsy seems to be very rare.⁴ It has been suggested⁵ that the severe pains of hysterical and hypochondriacal patients are, in some instances, of cortical origin. Witmer⁶ had a "painless" man for some time under observation. He had worked at a show as "the human pincushion." "He could be cut with a knife, or stuck with pins or needles, without showing the slightest sign of pain. I have known him to hold a red-hot coin in his hand without wincing, until it had burnt itself deep into the flesh. It is impossible to say positively whether this subject inhibited the expression of pain, or whether he inhibited the pain itself. He said he felt pain on ordinary occasions, when he had not made up his mind to be insensible to pain, but he reported that when once he had decided not to feel pain of the stimulus, the pain was no longer felt. There were areas of the skin which he could not render insensible to pain. I am inclined to believe he inhibited the sensation of pain, and not its external manifestations." Kant describes that he learnt to inhibit the pains of his gouty attacks.⁷ Cases of hysteria present phenomena analogous to the above. Pain disorders are much more readily produced by hypnotic suggestion than are disorders of any of the other senses,⁸ except perhaps the muscular.

THE MUSCULAR SENSE.

BY C. S. SHERRINGTON.

CONTENTS.—Definition of "Muscular Sense," p. 1002—Views regarding the nature of Muscular Sense, p. 1002—Charles Bell's "Sixth Sense," p. 1006—The Peripheral Apparatus of the Muscular Sense; Histological Data, p. 1006—Nerves of Muscles and Tendons, p. 1007—End-Bulbs and Pacinian Corpuscles, p. 1007—Hypotheses as to the Mode of Excitation of the Peripheral End-Organs of the Muscular Sense, p. 1009—Muscle-Reflexes, p. 1011—The Performances of Muscular Sense, p. 1013—Perception of Posture, p. 1013—Perception of Passive Movement, p. 1014—Perception of Active Movement, p. 1016—Objective Effects of Loss of Muscular Sense upon "Willed Movement," p. 1018—Subconscious Character of Reactions of Muscular Sense, p. 1019—Probable Importance of Tonus for Co-ordination, p. 1020—Apæsthesia produces Ataxy of "Willed Movement," p. 1020—Sensory-paralysis, p. 1021—Perception of Resistance, p. 1021—The Liminal Stimulus, p. 1021—The Liminal Difference, p. 1022—"Adaptation," p. 1024—Interpretation of Results, p. 1024—Fusion of Muscular with other Sensations, p. 1024.

IT is somewhat difficult to present a concise definition of the term "muscular sense." Authorities have not been perfectly concordant in their use of the term. It may perhaps best be taken to include all *reactions on sense arising in motor organs and their accessories.*

VIEWS REGARDING THE NATURE OF MUSCULAR SENSE.

At the outset of any inquiry into muscular sense arises a question omissible for other senses. In the very expression "a sense" physiology elsewhere postulates existence of an organ or organs placed peripherally, that is, outside the central nervous system, whence afferent channels convey to intrinsic "centres" impulses which there initiate the physiological and psychological reactions of the sense. In the case of the muscular sense, the existence of peripheral sense organs has been by many denied.

The view which dispenses with peripheral organs and afferent nerves for the muscular sense has had powerful adherents (Bain, Helmholtz, Lewes, Mach). It supposes that during movement, *e.g.* a willed movement, the outgoing current of impulses from brain to muscle is accompanied by a "sensation of innervation." Where a movement is to be precise, we do become, in fact, acutely aware immediately in advance of the amount and direction it is to assume. The very discharge into the motor nerves seems thus itself to possess a sensual quality.

An objection to this hypothesis is that it sunders sharply the sensations of passive from those of active movement, whereas there is strong ground for believing the two intimately allied; see below, p. 1016.

Different exponents of "sensation of innervation" suggest different views of its mechanism. The discharge of motor nerve cells, as *per se* of sensual quality, is one suggestion (J. Müller,¹ Helmholtz,² Wernicke,³ and formerly Wundt).⁴ Another regards the motor nerve cell as possessing cellulifugal branches besides its axon, and supposes the discharge of the cell in that way to run centripetally in the nervous system as well as outwardly; among these, Meynert,⁵ H. Munk,⁶ Exner,⁷ and formerly, if I mistake not, Bastian.⁸ For others, again, the motor nerve fibre itself is the site of reflux impulses from as well as to muscle (Arnold,⁹ Lewes¹⁰), at once the afferent, and efferent channel for the "sensori-motor circuit" of Charles Bell.¹¹ The "sensation of innervation" theory is connected with, but should be sharply distinguished from, that cortical revival of sensible and remembered effects of past movements, which seems to form the initiatory phase of the process of willed muscular action. As a component of the muscular sense (kinæsthetic) factor of a willed movement, Bastian¹² recognises a central process, revival of a kinæsthetic image, and a peripheral process consisting of guiding kinæsthetic impressions, which flow in from muscle, etc., and from eye, and influence the motor discharge, although in a subconscious way. The former component is psychologically a memory image of the sensations that accompanied the movement when executed formerly, and especially when in process of being learnt. To this position Münsterberg¹³ stands near. For Wundt,¹⁴ centro-motor elements lie in connection with centro-sensory, and these latter are excited not only by influent impulses generated by peripheral muscular sense organs, but also by the motor discharge in the centro-motor elements along their central connections. This superficially approaches the immediate consciousness of one's own movement, championed by Trendelenberg¹⁵ and George,¹⁶ and combatted by Lotze¹⁷ and Harless.¹⁸ A difference between Bastian and Wundt lies in the former supposing that for the guiding kinæsthesia there collaborate peripherally arising impressions with remembered peripherally arisen; while the latter supposes peripherally arising sensations to combine with centrally arising, not distinctly stating those to be kinæsthetic revivals. For Wundt the motor cerebral cell presumably reacts by cellulifugal processes upon sensory cerebral cells; Bastian years ago made a similar suggestion for the motor cornual cells of the spinal cord, and Exner carries the latter notion to extended use in the text and schemata of his recent "Entwurf."⁷

Since Hume, it has been admitted that the perceived results of our volition are the outward ends obtained, and not the inward action of the neuromuscular machinery. But discrimination between weights is found possible

when the movements are brought about by direct faradisation of the nerve trunks and muscles.¹ The liminal difference is, however, then much greater than under volition. It is less under faradisation of the nerve than under galvanisation of the nerve, and less under galvanisation of the nerve than of the muscle; but even with nerve faradisation it is 2.5 times greater than with volition. Waller¹ considers this amount of discrimination no greater than can be accounted for by touch alone.

Wundt, when upholding the "sensation of innervation," appealed to the "heaviness" of a paretic limb. But it can be replied that a paretic limb feels heavy because its movements are hampered as when weighted. Vulpian and also Ferrier² have pointed out that when a hemiplegic patient tries to close his paralysed hand, he in his endeavour, without willing to do so, performs the action with the sound one. The muscles of the glottis and the respiratory muscles invariably become active under effort; as the effort increases, its motor discharge becomes more and more diffuse.

A phenomenon cited by Helmholtz is the following:—"When the right external rectus is paralysed, the right eye can no longer rotate to the right. So long as it turns only to the nasal side it makes regular movements, and the correct position of objects is perceived. When it should be rotated outwardly, however, it stays still in the primary position, and the objects appear flying to the right, although the position of eye and retinal image are unaltered." The left sound eye is covered. "In such a case," Helmholtz³ goes on to say, "the exertion of the will is followed neither by actual movement of the eye, nor by contraction of the muscle in question, nor even by increased tension in it. The act of will produced absolutely no effect beyond the nervous system, and yet we judge of the direction of the line of vision, as if the will had exercised its normal effects. We believe it to have moved to the right, and, since the retinal image is unchanged, we attribute to the object the same movement we have erroneously ascribed to the eye. . . . These phenomena leave no room for doubt that we only judge the direction of the line of sight by the effort of will with which we strive to change the position of our eyes. . . . We feel, then, what impulse of the will, and how strong a one, we apply to turn the eye into a given position." But the interpretation neglects (G. E. Müller, W. James) the movement of the covered eyeball as a source of peripheral sensation.

Not only is evidence of sensation of innervation unconvincing, but facts it fails to explain are explicable by the counter view of peripheral sense organs. Of a patient in which the entire arms and trunk down to the navel were insensible, superficially and deeply, but the arms not paralysed, it was noted as follows:—"We⁴ take three bottles,—two empty weighing 250 grms. each, the third full of Hg and weighing 1850 grms. The patient declares he finds them all weigh alike. An experiment was performed, in which he could be informed neither by sight nor by hearing. He even declared, holding in his hand the bottle full of mercury, that he found it have no weight. We place successively in his hand (his eyes bandaged), a piece of modelling wax, a stick of wood, a thick rubber tube, and newspaper folded lengthwise. These he squeezes. He feels no difference of resistance; he does not even perceive that anything is in his hand."

³ I quote from W. James' translation in "Principles of Psychology," vol. ii. p. 507, which is from the 1st edition of the "Physiol. Optik." The passage remains unaltered in the 2nd edition, p. 744 (1896), which is a part of the volume lying beyond that revised by Helmholtz before his last illness.

⁴ Gley et Maxilier, trans. by W. James, *Rev. phil.*, Paris, tome xxiii. p. 442.

But there are differences in the effect of anæsthesia on motor power. In some cases the anæsthetic patients cannot move their limbs at all; in some they cannot move them when their eyes are shut.¹ In some, accurate movement is only possible by help of visual perceptions; with closed eyes ataxy becomes extreme. But there is a class of cases in which, although a limb has lost all sensitivity even for passive movement, voluntary movements can be accurately executed even when the eyes are closed. The patients can, for example, write accurately at will although their eyes are closed, and though they have no feeling of the writing taking place, and do not know when it begins or stops.² This class is formed of hysterical and hypnotic cases. At first sight these examples furnish the strongest evidence in favour of the "feeling of innervation" view. No other guiding impressions resident or remote appear to exist. Appeal to the speaking intelligence of the patient does not give evidence of any. But those who have especially studied these cases urge that the condition is not one of true or physiological anæsthesia. They regard these patients as victims of divided consciousness; a part of their consciousness containing, for instance, the kinæsthesia of a limb or lateral part of the body, becomes split off from the remaining consciousness. In the split-off part the kinæsthetic impressions and sensations may nevertheless remain to produce their usual effects, including co-ordination of movement.

The thumb and the three outer fingers are kept fully extended by pressing their tips down on a table edge, and the index is flexed fully except at its end joint, at which, under the circumstances, flexion is mechanically impossible. If, then, the effort to flex the end be made without looking at the finger, most persons believe the movement intended is carried out. The peripheral sensations of the existing position are overcome by those of the flexed position revived for the initiation of willed movement.³ Similarly, Exner's illusion,—biting on an unyielding plate giving sense of penetration, although no movement is really effected. Loeb's⁴ interesting observations on willed movements seem to me to illustrate rather than two simultaneous movements are not, when asymmetrically placed, appreciable very delicately in regard to extent and direction, and that judgment of them is easily biased by the precurrent kinæsthetic idea revived in the willing of the movement. They seem to me to show a somewhat surprising deficiency in muscular sense working under certain conditions, but not to prove that that sense is based on "feeling of innervation," still less to disprove that it is based on centripetal impressions excited in the acting peripheral organs during the movement.

Our conclusion is therefore that "sensation of innervation"—provided that memory revivals of muscular sensations of peripheral origin be not included under that term—remains unproven. Many psychologists argue for it; many, however, do not accept it.⁵

A second view held regarding "muscular sense" considers it to result from sensations derived from the sense organs of the other "five senses," and to have, strictly speaking, no apparatus of its own. Changes in tension of the skin (Schiff) at flexures, etc., are reported by the cutaneous afferent nerves, and yield perceptions of the movements they accompany, of postures, etc. The delicacy of the "five senses" is such that in unsuspected ways they make us aware of the effects of even minute movements (Hensen).⁶ A grave objection to this view

is the very slight impairment of muscular sense which follows cutaneous anæsthesia, and the very great impairment following injury to the deep sensory nerves of a limb, in spite of visual assistance.

There remains, then, a *third* view, namely, that the muscular sense is based on a specific set of sensations obtained by specific sense organs in muscles, tendons, joints, and all the accessory organs of movement. To this view adherence is given in the following account.

Charles Bell¹ was the first to definitely postulate the existence of a muscular sense on a physiological parity with the other senses. After his writings it began to be referred to as the sixth sense. He was not, of course, the first to suppose that consciousness of the positions and movements of the body and of its parts is based on sensations. Neither did he, in speaking of "muscular sense," suggest that the muscles are the exclusive site of origin of its sensations; but he was the first to postulate the existence of special afferent peripheral nerves for impulses evoked by the movements and postures of the body.

It is obvious that any extensive action of the skeletal musculature must, when it occurs, affect various organs of sense. Such effects may be separated into "resident" and "remote."² The hand when moved at the wrist-joint provokes mechanically, by tensions and relaxations of muscles and of their tendons, ligaments, and the like, a number of sensory end-organs belonging to those structures. It also affects, by stretching and flexing the skin, sense organs within it. If the movement bring the part against an object, or against another part of the subject, touch, and in the latter case the so-called "double touch," results. Its movement may bring the part moved into the field of vision. These last-named tactual and visual effects constitute the "remote" results; on the contrary, the sensations of muscle and joint—in fact, of the motor organs in play—are the "resident" effects.

We may treat of the muscular sense as of other senses. The parts of its apparatus may be distinguished as peripheral, internuncial, and central; among its phenomena may be distinguished centripetal impulses; sense impressions, sense perceptions, judgments, and ideas.

THE PERIPHERAL APPARATUS OF THE MUSCULAR SENSE.

Under this heading may be included the afferent nervous apparatus of the locomotor organs, muscles, joints, and bones. Evidence that structures are afferent may be indirect, *e.g.* inferred from histology, or direct, obtainable by physiological experiment. To begin with the histological evidence.

Nerves of bone.—Bones are indubitably well supplied with nerves,—the long, the short, and the flat bones alike. The nerve fibres are derived, according to Kölliker's³ summary, from the spinal roots and from the sympathetic. One-third of the fibres measure above 10 μ diameter. They "branch and end in a manner that quite recalls the behaviour of sensory spinal fibres" (Kölliker).⁴ In my degeneration experiments on the nerves of the limb, I found many sound myelinated fibres in the nerve perforating the tibia, though all motor root fibres and all sympathetic myelinated fibres had been destroyed by degeneration.⁵

Periosteum.—The periosteum is supplied with nerves, though sparsely.

⁴ *Ibid.*, S. 313.

⁵ Sherrington, *Journ. Physiol.*, Cambridge and London, 1894, vol. xvii.

The fibres measure $9\ \mu$ – $4\ \mu$, and undergo terminal subdivision (*e.g.* in *fossa infraspinata scapulae hominis*).¹ The periosteum near the ends of bones, where it abuts on the joint and ligaments, conveys nerves destined for the latter.

Nerves of the muscles and tendons.—The nerves of muscles derive large numbers of their fibres from the spinal ganglia. In the limb muscles of the monkey and cat I found from a half to a quarter of all the nerve fibres to be sensory.² The size of the sensory nerve fibres varies between $18\ \mu$ and $2\ \mu$

FIG. 370.—Transverse sections of a nerve-twig supplying a portion of the *vastus medialis* muscle (knee-jerk muscle) of the cat. From micro-photographs of osmic acid preparations. 1. Normal condition of the nerve. 2. Condition three months after severance of all the ventral spinal roots, and of the corresponding spinal ganglia contributing to the nerve. No myelinate nerve fibres remain. 3. Condition three months after severance of all the ventral spinal roots, the spinal ganglia remaining intact. A number of healthy nerve fibres both large and small remain. These belong to the spinal ganglia, and are afferent.

or less. These sensory fibres end in end organs—muscle spindles,³ Golgi-organs,⁴ modified Pacini-organs,⁵ Pacini-organs.⁶

Interosseous membrane.—Between the limb bones the *nervi interossei* of the leg and forearms give numerous twigs to those membranes. The nerve fibres end in free endings (Kölliker), in end-bulbs and in Pacini bodies.

Muscle spindles.—Hassall (1851) seems to have earliest noted these structures. They were first distinctly described by Kölliker (1862) and by Kuhne (1863).

⁶ Rauber, *Festschr. f. Bischoff*, 1883; Sherrington, *Proc. Roy. Soc. London*, 1897, vol. lx.; Ruffini, *loc. cit.*, and *Sperimentale (Accad. med.-fis. fiorentina)*, Firenze, April 1897; *Brain*, London, 1897, vol. xx.

The last-named gave them the name here adopted. They were not known to be sensorial until Ruffini (1892) succeeded in histologically analysing their nerve-endings, and I (1893) in tracing the majority of the nerve fibres to the spinal ganglia. The muscle spindle is a fusiform organ, in which for clearness of description I distinguish an *equatorial* and two *polar* regions. Along its axis lies a bundle of striated muscle fibres, two to ten in number. In the monkey and man it is rare to find a single intrafusal muscle fibre only. I have seen in man as many as twelve muscle fibres in one spindle. In the lizard and snake,¹ however, the muscle spindle contains usually but a single fibre. The intrafusal muscle fibres differ from ordinary muscle fibres in being smaller and not undergoing any marked degenerative change after destruction of the nerve trunk innervating the muscle.² They seem in some respects extreme instances of the red variety of muscle fibre, but the intrafusal fibres are even in the very reddest muscles of the rabbit smaller than are the ordinary fibres of those muscles. They contain many central nuclei, and at the equatorial regions of the spindle a richly nucleated core of non-striated material encroaches on the striated structure of the fibre, leaving only a peripheral striped sheet, which recalls that of a developing fibre; and in places even that peripheral zone may be wanting. The intrafusal muscle bundle emerges from the capsules sometimes at both ends, often only at the distal pole, it having in the latter case ended in tendon while still within the capsule. The capsule consists of fibrous membranes, which externally are connected with the well-developed sheath of Henle of the entering nerve fibres. At the poles the capsule merges into *perimysium internum*. It is separated internally from the intrafusal muscle bundle by a space, the periaxial space, widest in the equatorial region. The intrafusal muscle bundle is supplied by numerous nerve fibres, some of which are probably motor. The most obvious nerve-ending is one in which a large myelinated fibre having crossed the periaxial space, lost its myelin, and divided dichotomously more than once, terminates in a ribbon-shaped axis cylinder, which winds many times round an intrafusal muscle fibre forming close coils. This is the "annulo-spiral ribbon" ending of Ruffini. Another form of ending, also sensorial, is Ruffini's "flower-spray" ending, which coexists with the annulo-spiral.³ Both these kinds of endings are situated in the equatorial region, but outside that region are found nerve-endings, somewhat like ordinary motor end-plates; these are probably motor. The motor nerve fibres of skeletal muscle are as a rule larger than sensory nerve fibres; in the spindles the sensory nerve fibres are larger fibres than the motor. Cipollone⁴ has recently shown that an intrafusal muscle fibre in the lizard commonly has not one but two motor end-plates, one at each end of it. Just as, unlike other fibres of skeletal muscle, the intrafusal muscle fibres do not undergo degeneration after destruction of the nerve trunk,⁵ so also, unlike other muscle fibres, they do not participate in the hypertrophy produced by functional exercise.⁶ Muscle spindles have now been studied in various animal types (e.g. frog, lizard, pigeon, rat, guinea-pig, rabbit, cat, dog, monkey, man, etc.). Those of the frog and lizard are smallest and structurally simplest, and often contain but one muscle fibre apiece.⁷ Those of the monkey and man are largest and most complex, and rarely contain but a single muscle fibre. In the cat and monkey I found it not uncommon for the spindles to be conjoined in pairs and even triplets. Their tendon-bundles with special frequency enter into Golgi-organs,⁸ with these again possess accessory Pacini

bodies of simple type.¹ They are not equally distributed through the musculature. Huber² agrees with me in thinking that they are disproportionately frequent in the small distal muscles of the limbs. Kölliker noted fifteen spindles in each belly of the *omohyoideus*. I failed to find³ any at all in the following muscles:—*Recti* and *obliqui oculi*, *levator palpebræ superioris*, the intrinsic muscles of the tongue and larynx. Cipollone⁴ notes their absence from the muscles of facial expression, although present in the masticatory muscles (pterygoids, masseter).

Kühne⁵ has insisted on certain resemblances between the muscle spindle and the electric organ, which is stated to be derived from muscular tissue. Kerschner⁶ argues the muscle spindle to be an organ in which the "action current" of muscle forms the stimulus to the sensory nerve fibres.

The Golgi-organ of tendons.—These sensorial end-organs were earliest described by Rollett,⁷ but for the first time fully by Golgi, who studied them in mammals, birds, and reptiles. The organ consists of terminal arborisations of one or of two myelinated nerve fibres, the arborisations permeating as a richly branching tree, the thickness of a tendon bundle, which is somewhat sharply marked off from the surrounding tendon bundles. The terminal arborisation is of great size and complexity, and extends in some cases for 500 μ along the tendon bundle. The organ has often a distinct capsule, and is well supplied with blood vessels. Like the muscle spindles, they seem particularly large and complex in the higher mammals. The tendon bundle in which the Golgi-organ lies can often be traced to receive the insertions of muscle fibres that belong to muscle spindles. The Golgi-organ affects particularly that region of the general tendon which adjoins the flesh of the muscle. These organs are found in the tendons of the eye muscles, which, as I have pointed out, are muscles devoid of spindles; but the great number of sensory nerve-endings in the eye muscles are smaller and simpler than the ordinary tendon organs.

Large end-bulbs, or, as they are called by the Italian authorities, "modified Pacinian bodies," are also met in muscle tendons, especially in the sheaths of tendons, and of the muscles. For description of them reference can be made to Ciaccio,⁸ Mazzoni,⁹ or Ruffini.¹⁰

Pacinian corpuscles occur in connection with tendons, also in the septa, and in the *perimysium internum* of muscles, and even embedded in the fleshy tissue.¹¹

The individual contributions toward muscular sense of these different sets of end-organs can only be conjectured. In the skeletal muscles there are, as we have seen, three sets of sensory organs, *e.g.* muscle spindles, tendon organs, Pacini corpuscles modified and typical. The fact that of these, one set, the spindles, are contractile, suggests that they function in signalling active movements rather than passive. Throughout the body it is remarkable how great a part mechanical actions play as stimuli to protoplasm. It has been argued that the action current is the immediate physical stimulus for the sensorial endings in muscle. That is plausible, although some of the arguments brought forward, such as the initiation of the kinæsthetic idea in the latent period of the muscular response, are weak. The possibility that the immediate stimulus consists of chemical products of the muscle has been discussed by G. E. Müller and Schumann,¹² but remains little more than a suggestion. If suggestion is profitable, it seems to me more likely that the immediate stimulus of the muscle spindle is of a mechanical kind, produced by the change in form of the

muscle fibre when it contracts. It is true that change of form of the spindle must occur to some extent, not only when the muscle shortens, owing to contraction, but also when its points of attachment are approximated by other causes (*e.g.* passive movement). But the change is, for the same degree of approximation of its attachments, not quite the same when passively obtained, either as to extent or character. The rectilinear course of the fibres is not so maintained. When the ankle of the frog is fully plantar-flexed, the sural muscle lies actually in folds. But the muscle spindle is peculiar among sensory end-organs, in that the part to which the actual nerve-ending is applied is not only contractile but extensible. Each lengthening and shortening of the muscle, within degrees which do not overstep the limits of extensibility and elasticity of the muscle fibres, changes the figure of the intrafusal muscle fibres. Ruffini's annulo-spiral ending is a form of nerve-ending special to the spindle. There is no ground for thinking the nerve fibril as extensible and elastic as a muscle fibre. The tendril-like rings of the nerve fibril must, if so, be subject to strain when the muscle fibre they clasp becomes thicker, and when they are pulled apart from each other as the muscle fibre elongates. It is noteworthy, however, that in some cases the muscle fibre, to judge from its less distinct striation there, is less contractile at the place of the nerve-ending than elsewhere. The striated and fibrillated substance of the fibre is there largely replaced by the voluminous nuclei I have described; these lie in a central core of finely granular material, surrounded only by a striated zone, recalling the appearance of a Purkinje cardiac fibre. In some cases the striation of the muscle fibres seems to fail at the nerve-ending, though in many it is perfectly continuous throughout.

Beside changes in form, changes in tension must also occur in the spindles; in the tendon organs the changes in tension must be much greater than the change in form, the tendon bundle being but little extensible or elastic. Its tension will wax and wane with the tension throughout the muscle. The stimulus for the tendon organ may well be mechanical; the nerve-endings that penetrate the little tendon bundle (Golgi's *tendinetta*) of the organ may be compressed as the muscle contracts or is passively stretched. It is easy to understand how the organs might react under both passive and active movements of the limb. The Pacini corpuscle is often interpreted as being adapted for stimulation by compression. The modified form is more usual in muscles than is the typical form. It occurs in some places, *e.g.* sheaths of muscles, where there is likelihood of its being laterally compressed. The ordinary Pacini, embedded in muscle, is admirably placed for being compressed, especially when, as sometimes, seated in the retiring angle between a septum or aponeurosis and obliquely inserted muscle bundles.

From the above we might expect tension to largely determine muscular sense perceptions. It must be admitted, however, that observations showing that the liminal excursion for passive movements is practically unaffected by the initial position of the joint, is against tension being of such great importance. The same position or movement of a joint may involve very different degrees of tension, according as it is favoured or hindered by outward forces (traction of weight, etc.), including muscular; yet the limen of judgment remains the same; the weighting of one of the compared hands makes, according to Loeb, very little difference to the illusions he studied as to excursion and direction of "willed" movements. This difficulty in the way of regarding the perceptions of muscular sense as based on elemental sensations of tension, may be partly met by supposing that, while some of the sense organs have tension for adequate stimulus, some have change of form with or apart from tension. Impressions from tension-organs (isometric), checked against simultaneous impressions from form-organs (isotonic) or organs of joints, might supply a judgment based on their ratio, which might give the required ideas. One and the same sensation of muscle-form or of joint-movement, summed with

one and the same sensation of tension of muscle (including tendon), would, if memorable, make a kinæsthetic complex for judging and standardising comparable complexes.¹ Sense organs of joints certainly contribute importantly to the various kinds of muscular sense perceptions.

The skin does not much assist muscular sense. Cutaneous anæsthesia inflicts little injury on the sense of movement or posture. That it has some influence, however, is undeniable. Of two equal weights, one hollow and therefore the larger, lifted successively, the larger seems the lighter,² even if the test be made when the eyes are shut. Tested with the eyes open,³ the larger weight seems more distinctly the lighter than when touch is appealed to apart from vision. A pound of lead is, as regards sensation, heavier than is a pound of feathers.

Sensitivity of muscles, joints, and bones, as evidenced by reflexes.—The muscular structures, including tendon, appear insensitive under many mechanical, thermal, electrical, and chemical stimuli, known to be efficient in other cases.

Haller and his pupils concluded that neither tendon nor muscle is sentient. Bichat considered the former slightly sensitive. Schiff,⁴ Bernstein,⁵ and Bloch⁶ have all, more recently, maintained the insensibility of muscle. Rollett,⁷ after finding nerve-endings in tendon, tried to elicit reflexes from tendons, but failed to obtain any. Reflexes can, however, be initiated from these structures. One very constantly obtainable is initiated by compressing the tibialis anticus tendon (cat) just above the annular ligament; the response is given by the adductor muscle of the thigh.

The tendon reflexes are misleadingly so called. Thus, in their prototype the "knee-jerk," the tendon is not necessary to the reaction, and the reaction has so short a latency that it cannot be reflex. There are, however, nearly thirty named "tendon reflexes" studied in the human body, and some of these may be true reflexes. It is not possible to decide the point until the latent period has been measured in each instance.

From the muscles themselves, in spite of former negative results, there is now evidence of the obtaining of reflexes. Vasomotor reflexes can be evoked by kneading exposed muscles in the curarised rabbit.⁸ The effect is usually a fall of general blood pressure. Electrical stimulation of the muscles and nerves less constantly produces a fall, often a rise. The knee-jerk can be inhibited by stretching or compressing any of the hamstring muscles,⁹ even when the muscle is completely freed from all connection with the body except through its nerve trunk and its blood vessels. I noted movements of the opposite eye and pricking of the ears (cat), produced by gently stretching the inferior oblique muscle, freed from all connections but its nerve and blood vessels, and suspended between two pairs of ivory-tipped forceps.¹⁰ A twitch can be evoked from the tibialis anticus, isolated but for nerve and blood vessels, by jarring it, especially lengthwise. The sudden relaxation of a passively stretched muscle I have often seen evoke a reflex, e.g. the

letting go of the stretched sural triceps often causes reflex contraction of the pretibial muscles.

Contrary to older observations,¹ it now seems proven that feeble reflexes can be elicited by irritation of joint surfaces, mechanical or thermal. Goldscheider² found the effect increase the deeper he penetrated towards the bone. Striking the articular end of a bone elicits reflexes, but these are not truly joint reflexes, for they persist after all the nerves to the *end* of the bone have been destroyed.³ So also with periosteal reflexes, they are not truly elicited from the nerve-endings in periosteum. Both these latter sources of reflexes—reflexogenous regions, as they are sometimes termed—are really dependent on distant bone, to which the mechanical shock is conveyed, and there excites the nerves distributed. Sternberg has obtained reflex contraction of the pretibial muscles (in rabbit) by tapping the bared or lower-cut surface of the tibia, after the lower part of that bone has been severed from the upper by exsection of a piece from the shaft.

In other experiments, direct excitation of the proximal ends of the nerves of muscles, etc., has been employed. Vasomotor reflexes have been observed to result. In the cat, as I have shown,⁴ the excitation of the proximal end of the cut nerve trunk of the group of hamstring muscles—a nerve trunk of exclusively muscular distribution—reflexly affects the innervation of the antagonistic *vastus* and *crureus* to the extent of temporarily abolishing the knee-jerk dependent on the spinal tonus of those muscles. Similarly,⁵ excitation of the same nerve trunk causes reflex inhibition of the rigid spasm of the *extensor cruris*, occurring under “decerebrate rigidity.” Stimulation of the central end of a twig of this nerve trunk, the rest of the trunk being uncut, produces reflex contraction of the remainder of the hamstring group, and reflex relaxation of the already contracted antagonistic group, the extensors of the knee.

This is a result comparable with that seen in the self-regulative innervation of the respiratory muscles,⁶ and with that given by the afferent nerve of the heart muscle, which inhibits reflexly the constrictors of the arterioles, *i.e.* the antagonistic muscle. The depressor nerve stands in some respects as prototype of the sensory nerves of all muscle. The vasomotor reflex, following excitation of a muscle by kneading, is said to be invariably lowering of general arterial blood pressure.⁷ Certainly that result does often ensue, but not invariably on exciting directly the nerve of a muscle electrically; I have then seen the blood pressure rise as frequently as fall. Alteration of pulse frequency is noted among the effects,⁸ the frequency is at first lessened (through the *vagus* centre), and later increased (through the *nervus accelerans*).⁹ It is easy to affect respiratory rhythm by excitation of the central ends of muscular nerves.

That the nerves of muscle are competent to produce pain, is proved by the pain of muscular cramp and other facts. Attempts to assign the pain to the dragging upon or the compression of nerve trunks coursing through or on or between muscles, or to their stimulation by “action currents” of muscles, fail for obvious reasons. It is difficult to satisfy one’s self that such reflex effects as these, vaso-

motor and respiratory, are elicited by intensities of stimulus not beyond the bounds of normal, or exaggerated, so as to be dolorous. To discriminate between the two possibilities, I have stimulated the peripheral ends of the cut motor roots of the nerves of the hamstring muscles (cat), the afferent roots remaining intact. It is then found that even when the anæsthesia is shallow the muscles can be thrown into a very vigorous and complete tetanic contraction, maintained even for 30 seconds, or more, without producing noticeable effect on the general arterial blood pressure or on respiratory rhythm. When the stimulation is increased sufficiently, and the contraction is therefore very severe, slight effects on blood pressure and respiration are obtainable, but the attendant risk of some escape of the stimulating current to the sensory roots is not entirely excluded.

From the point of view of muscular sense proper, more interesting than the reflex effects upon vasomotor and respiratory mechanisms, are those upon the local musculature. These latter exemplify certain degrees of co-ordination, including "reciprocal innervation." From skin and the cutaneous nerves similar reflexes can be excited, although it would seem less readily.

THE PERFORMANCES OF MUSCULAR SENSE.

The perceptions of muscular sense may be grouped into (i.) those of posture, (ii.) of passive movement, (iii.) of active movement, and (iv.) those of resistance to movement. Changes in consciousness accompany all movements of the body which occur at speeds above a certain liminal, and over distances of beyond a certain liminal extent. Most movements of the body alter the position of one part of it relatively to another, as well as alter the body's position relatively to its environment, without altering the mutual space-relationship between different parts of the body. The latter class may, from the physiological point of view, be termed "solely extra-relative." All these kinds of movements are perceptible by the mind, in virtue of the space perceptions with which it is furnished, by the combined labours of the senses of sight, touch, and the organs of the labyrinthine and muscular senses. But with solely extra-relative movements the muscular sense is usually little concerned, and consideration of them can be omitted from any brief exposition of "muscular sense."

Perception of posture.—This is not the place to discuss how the position of the body, considered as a whole, in reference to the earth's centre, and contradistinguished from all else which is "environment," is perceived. For that, much else besides the muscular sense is instrumental. To that, the muscular sense contributes limited perceptions of the relative positions of the corporeal parts, *e.g.* of the limbs, their joints, etc. The muscular sense is no doubt a large contributor toward the perception of the mechanical equilibrium of the body, and in that way toward the regulation and maintenance of its stability. The necessary corrective movements that, during locomotion, prevent gravity pulling us prone, or as we sit, stand, or maintain postures natural to us (our *usustatus*, *ususitus*, *usumotus*), involve perceptions of the relative position of our corporeal parts are guided by—one might almost say supplied by—the muscular sense. These perceptions, though not for the most part "objects" of attention, determine actions, and can be attended to at once, should need arise. That in the dark one hand, passively placed, can be touched on any desired finger-tip by a finger of the other hand, illustrates our possession of a sense of posture largely

provided by "muscular sense." Posture, passively maintained, is found to be nearly as accurately perceived as when actively maintained. Sense of posture is very defective in limbs the sensory nerve roots of which are diseased. The appreciation of difference between postures of the limb is not so delicate as to account for the minute alterations—less than an angular degree—at a joint perceived in Goldscheider's experiments. There the perception is one of *movement* rather than of successive assumption of different postures,—an important distinction, paralleled in the visual and tactual senses.

Besides purely muscular, articular sensations also probably contribute to perception of posture. This has been said¹ to be shown by the position of the fingers being as sensible when the muscles are paralysed as when they are normal,—but in reality such observations fail to prove or negative the assertion.

Perception of passive movement.—The minimal adequate stimulus for sense of passive movement may be expressed in angular measurement of a movement about a joint. Leyden found that movements of $\cdot 5^\circ$ to 1° at the hip-joint are perceptible;² but we owe most of the measurements on this subject to the careful work of Goldscheider.³ The liminal excursion for the shoulder-joint is $\cdot 2^\circ$ to $\cdot 4^\circ$, the speed of movement not being less than $\cdot 3^\circ$ per second. Degree of sensitivity, as judged by the size of the liminal excursion, places the joints in the following order,⁴ beginning with the least sensitive:—

Ankle-joint	$1^\circ 15-1^\circ 30$
Second interphalangeal	$1^\circ 03-1^\circ 26$
First	$0^\circ 72-1^\circ 05$
Hip	$0^\circ 5 -0^\circ 79$
Knee	$0^\circ 5 -0^\circ 70$
Elbow	$0^\circ 4 -0^\circ 61$
Metacarpo-phalangeal	$0^\circ 34-0^\circ 43$
Wrist	$0^\circ 26-0^\circ 42$
Shoulder	$0^\circ 22-0^\circ 42$

Arranging the joints in order of speed of movement required for the limen of perceptible excursion, the list is as follows,⁴ beginning with the least sensitive:—

First phalangeal joint	$12^\circ 5$	per second.
Wrist	$3^\circ-9^\circ$	"
Metacarpo-phalangeal	4°	"
Ankle	$2^\circ-3^\circ 5$	"
Hip	$1^\circ 6-3^\circ 2$	"
Knee	$1^\circ-2^\circ 5$	"
Elbow	$0^\circ 7-1^\circ 4$	"
Shoulder	$0^\circ 3-1^\circ$	"

A much smaller ($\frac{1}{4}$), and especially a much slower ($\frac{1}{16}$), movement is just noticeable at the great proximal joints of the limb than at the small peripheral. The delicacy of sense of movement progressively

¹ Duchenne, "Conscience musculaire," Paris, 1853.

² *Virchow's Archiv*, 1869, Bd. xlvii. S. 32.

³ Goldscheider excluded cutaneous sensations of pressure, as far as possible, by casing the segment of the limb in a gutta-percha sheath filled with water. The limb was moved by hydraulic means, and the movement was recorded graphically on a magnified scale upon a rotating cylinder, so that its time and its amplitude of excursion were known.

⁴ Goldscheider, *Arch. f. Physiol.*, Leipzig, 1889.

diminishes from the attached base to the free apex of the arm. The natural movements at a joint are usually slow, in proportion as the lever working at that joint is long. The natural movements at the shoulder and knee are slower than those at the digital joints. Movements of such speed as those of the fingers in writing hardly occur at hip or at shoulder. Speed and excursion mutually support one another as provocative of sensation. A movement too slow to be felt, if of small excursion, becomes sensible if its excursion be prolonged. With equal movements nearly liminal in amplitude, an increase of speed of execution converts an imperceptible into a perceptible. By multiplying together the liminal excursions and the least speeds necessary to obtain them, numerical measures of the liminal performance of the muscular sense are obtained, and these, as far as concerns passive movements of the upper limb, run as follows:—

Proximal interphalangeal joint	8923-13440
Metacarpo-phalangeal	1224-1548
Wrist	806-3654
Elbow	280-854
Shoulder	110-420

The performances by the shoulder are, when thus reckoned, more than forty times as delicate as those by the fingers.

Goldscheider, mainly on account of the disturbance and defect of the sense of passive movement occasioned by faradisation of the joints, concluded that the deep sensitiveness of joints is a chief sensory element in the production of perception of passive movement. Touch and vision are not essential to the perception of the movements. Goldscheider denied importance to the afferent nerves of muscle, because the liminal angle for a joint remains the same for various initial positions; but this is not a very cogent argument.

The liminal speeds for given joints starting from various initial positions are exemplified as follows:—

Shoulder with arm horizontal	0°·35	per second
„ with arm 45° below horizontal	0°·30	„
„ „ above horizontal (not a pure movement at shoulder but involving scapula and vertebral column as well)	0°·33	„
Hip-joint, thigh at 180° with trunk, the leg extended	0°·45-0°·36	„
„ thigh at 90° with trunk	0°·3 -0°·25	„
„ thigh at 180° with trunk, and at the same time abducted 40°	0°·5	„
„ thigh at 90° with trunk, and at the same time abducted 40°	0°·33	„
„ thigh at 50° with trunk	0°·6	„
„ thigh nearly fully extended, thigh adducted to 40°	0°·38	„
„ thigh at 180° with trunk—adduction	0°·42	„
„ „ „ —abduction	0°·6	„
„ thigh at 90° with trunk—adduction	0°·6	„
„ „ „ —abduction	0°·8	„
Knee-joint flexed at 90°	0°·5	„
„ flexed at 70°	0°·9	„
Ankle-joint flexed at 90°	0°·9	„
„ flexed at 150°	1°·4	„

That Goldscheider is justified in giving an important rôle to joints in the sense of passive movement, is borne out by the inferiority of accuracy of perception of passive movement, when the limb, e.g. the leg is stretched sufficiently to just separate the joint surfaces¹ one from another, as compared with the accuracy when the joint surfaces play normally over one another. That active movements are slightly better perceived than are passive, may in part be due to the greater compression at joints which accompanies the former, evoking presumably more joint sensation. But the sensations derived from muscles and tendons are certainly also largely contributory to perceptions of passive movement.

Just as sensation of movement seems an elementary product of vision and of touch, so also in the muscular sense. An image in the periphery of the visual field may remain unseen, so long as it does not move, but should it move it will occasion a sensation forthwith,—a perception referred to “something moving.” Two points of contact with the skin, if both within the liminal distance of sensible separation, are not distinguished as differing in locality, but if one of the points move over skin, though the movement be even *toward* the other, its alteration of locality is felt at once, and a sensation of movement results, though entirely within the limit of a single “Weber-circle.” The feeling of *movement* of a finger is obtainable from a finger in which the sense of posture has been (temporarily) quite obliterated by strong faradisation. A movement is easily felt to have occurred, even when the direction in which the part has been moved is not perceived. The importance of the speed of movement for perception of movements of approximately liminal perceptibility is hardly intelligible if the perception depends purely on inference from sensations of locality, of comparison between two sensations, one of the *locus a quo* and a second of the *locus ad quem*. In the case of the fingers the duration of liminal movements, perceptible as movements, is so short (.02 second) that it is almost impossible for two sensations, one of end and one of beginning, to be differentiated and dealt with. These arguments, brought forward by Goldscheider, seem to me to justify the supposition that simple sense-fusions of “movement” can be yielded by the muscular just as by visual and tactual sense. But this does not, of course, alter the probability, amounting in some cases to certainty, that in many of our usual passive movements the excursion and duration of which are far greater than the almost liminal movements studied by Goldscheider, our perceptions of them include perceptions of the initial posture, of the ultimate posture, and of intermediate positions also, and supply the basis for judgments.

Perception of active movement.—The accuracy of judgment of actively performed movements, that is, of movements occasioned by active contraction of the muscles, is almost always examined in the form of “willed” movement, and is based only in part on the performances of the muscular sense. In experiments on the sensible limen of willed movement, as regards excursion and speed, Goldscheider found the liminal value slightly finer than for passive, although the difference was almost negligible. Thus the average for the end finger-joint with active movement is 1°02–1°09, for the passive 1°0–1°8. That active movements are slightly better perceived than passive, may in part be due to the compression at joints that accompanies active movements more than passive, and therefore generates presumably more joint-sensation.

It is possible to execute subliminal willed movements, that is, willed movements so small in excursion as to be insensible to muscular sense. These can be evoked by thinking vividly of the movement.

¹ Lewinsky, *Virchow's Archiv*, 1879, Bd. lxxvii. S. 145.

Amount of active movement, its extent and direction, is under many circumstances erroneously judged. A subject desired to compress a dynamometer half a dozen times in succession, with all his strength, is surprised to find he has not exerted the same force at last as at first.¹ In Loeb's² experiments, one arm was required to perform a movement of similar extent and direction to a movement simultaneously performed by the other, but from an initial position asymmetrical with the latter's. The discrepancy between the movement executed and that judged to have been made, illustrates the shortcomings of the muscular sense under certain conditions. Loeb found the discrepancy in extent and direction between the willed movement and the executed movement, as shown by the difference between the copying movement and the copied movement, vary proportionately with the degree of shortening of the muscle at the commencement of the copying act. The shorter the active muscle already was at outset of the movement, the greater the deficit in its extent of performance, as compared with the intended movement, as measured by that of the movement copied,—in other words, the more its actual performance was over-valued; and conversely. He found that analogous conditions similarly distort the perception of direction of movement.

In view of observations by E. H. Hering and myself,³ it would be preferable were these results to be stated, not in terms of degrees of shortening of a muscle, but in distance from limit of movement in a particular direction. Thus the sensible effects of lengthening (relaxation) of muscles would be included as well as those of shortening (contraction). From Loeb's research the initial position of the joint appears of importance from the point of view of active (willed) movement, though Goldscheider showed it affects little the sensible limen of passive movement. An illusion studied by Loeb is this: from symmetrical points the two hands are moved simultaneously, horizontally in the same direction, *e.g.* both toward the right, with the intention that both should traverse the same rectilinear distance; the hand moving inward toward the median plane of the body is then found to traverse a greater distance than the other. The high delicacy of perception of movement, both passive and active, revealed by Goldscheider's work, contrasts with the large errors of estimation of amount and direction of movement instanced by such illusions as these. This argues for existence of a sensation of movement *per se* as an elemental product of the muscular sense, and not as a judgment based on comparison of discrete sensations of position. The extent of the illusions seems partly due to simultaneity being a relatively disadvantageous condition for comparison between perceptions. When the willed movement is a successive, not a simultaneous, imitation, the error is not so great. The error varies considerably with the individual. Also in Loeb's illusions there is the bias given to the judgment by the intention to make the movements equal. But the lack of definiteness of the muscular sensations received is strikingly illustrated.⁴

A person stands, eyes shut, facing a vertical screen. A and B are two points on the screen that are placed symmetrically with regard to the median vertical plane of the body, and each about 25 cms. from that plane. The vertical heights of the two points are the same. The person has to outline, eyes shut, two similar simple figures, simultaneously with both hands. The hands are to be moved simultaneously in the same direction, *e.g.* both to right, and the figures are to be made as nearly as possible identical. The left hand starts from point A, the right from B. Ascending or descending parts of the

¹ Delbœuf, *Rev. phil.*, Paris, 1881, tome xii. p. 526.

² *Arch. f. d. ges. Physiol.*, Bonn, 1890, Bd. xli.; 1892, Bd. xlvi.

³ *Ibid.*, 1897, Bd. lxxviii.

⁴ *Ibid.*, 1892, Bd. xlvi.

outlines are drawn fairly equal. If, then, the attempt be repeated but with the starting-point B considerably above A, the ascending part of the outline of the right-hand figure is smaller than the corresponding of the left-hand figure; the descending part, on the contrary, is longer.

Symmetrical muscular movements executed with the intent to be, and after performance judged to be, equal, show habitual preponderance of one side, right or left, in different persons (Stanley Hall), and this without dependence on right-handedness or left-handedness,¹ but rather upon muscular development due to influence of occupation. Bloch, however, states that, in measuring the number of pages of a book between the finger and thumb, the distance is under-estimated by the left hand with right-handed people, but by the right hand with left-handed people.

It seems that speed of movement is not very correctly judged. In the above-mentioned illusions the total duration of the movement is equal, and the speed of movement is not detected to be different. Loeb found that the weighting of a hand—thereby introducing a resistance—did not much affect the result. He concluded from this that mere tension of muscle was not a chief basis for the sensation. Exner's illusion² points in the same direction. If a plate of vulcanite be placed between the teeth and bitten upon, the sensation given is as though the jaws moved perceptibly toward one another, although the plate be really quite unyielding; the illusion is obtained of the teeth sinking slightly into the substance bitten. Sternberg's illusion³ mentioned above is comparable with these.

OBJECTIVE EFFECTS OF LOSS OF MUSCULAR SENSE UPON "WILLED" MOVEMENTS.

The office of the muscular sense in regard to willed movement can also be studied to a certain and fortunate degree objectively. It is found that the destruction of sensitivity in particular regions brings about objectively observable disturbances of movement. A region totally deprived of sensation by section of its afferent nerves, is termed *apæsthetic*, and the effects of apæsthesia upon the musculature of the part are three—(1) paralysis, (2) ataxia, (3) atonia. Certain elementary adjustments of muscular action occur reflexly without awakening attention or in the slightest degree seeming to trouble at all the stream of consciousness. Yet these have, inferiorly and remotely, relationship to the highest achievements of the muscular sense, such as the manipulative finesse of the human thumb and finger. The muscular sense embraces the part played by sources of afference in the taxis of muscular activity, even where the reactions lie not amenable to introspection. The physiologist derives a certain advantage from this, in that it offers an objective mode of studying the activities of the afferent apparatus of muscular sense by watching the objective effects of it on the characters of muscular movements.

The unconscious reflex actions of the adult may be taken to represent those reactions accruing to him phylogenetically or ontogenetically, which, though of ancient origin, have with little metamorphosis remained on the average useful to him as an adult member of his species. As to

¹ M. Cremer, "Inang. Diss.," Würzburg, 1887.

² See Sternberg, *Arch. f. d. ges. Physiol.*, Bonn, 1895, Bd. lix.

³ *Ibid.*

how consciousness comes not to be involved in them, there are several probabilities to offer. Unhesitating fatality and speed are characters which consciousness might only impede, though, for certain nervous reactions, these very characters would be beneficial to the race. Another suggestion would be, that division of attention appears, from the constitution of mind, to undermine all exquisiteness of performance.

Excitation of the afferent nerve fibres in the nerve trunk of a skeletal muscle produces, apart from and more readily than those general reflexes, vasomotor, etc., above-mentioned, special reflexes upon the local musculature. The above-mentioned general reflexes are only positively indicative of that degree of common sensation in which sense-feeling is dominant and painful. The local reflex effects on the musculature obtained from afferent muscle nerves by weaker stimuli, are more special in character, and more significant for the study of muscular sense, especially in its relation to co-ordination. If, when the cranio-spinal axis has been transected just in front of the pons, and "decerebrate rigidity" has set in, the purely muscular nerve trunk of one of the flexor muscles of the knee is cut, and its central end excited by ligation or faradisation, the existing strong tonic contraction of the extensor muscles of the knee is at once relaxed,¹ and the fellow-muscles of the flexor group, previously inactive and flaccid, are at the same time thrown into contraction. The same result may be brought about also by stretching or compressing the muscles themselves, so long as their afferent nerves are intact. The excitation of the sensory nerve fibres from the flexor muscles, besides provoking contraction of the fellow-flexors, inhibits the contraction (and even the tonus) of the antagonist group. In this experiment the sensory impulses arising in one muscle influence the activity of the motor nerve cells governing its fellow-muscles, and of those governing its antagonists, augmenting the former, diminishing and even annulling the latter. Acting thus, the centripetal impulses from the muscle produce an important item of spatial co-ordination, which I have termed "*reciprocal innervation*."² This effect of the centripetal impulses from the muscle is not accompanied, it would seem, by psychosis. Kinæsthesia, in the psychological sense, seems precluded where the whole cerebrum had been removed. Muscular "sensations" can hardly have been present; indeed, similar observations can be made even when the whole brain has been cut off by transection at the top of the spinal cord itself. The co-ordination of the movements of the spinal frog is suggestive of regulation by afferent nerves,—probably muscular. I found the initial posture of the limb in the spinal animal (*e.g.* frog) distinctly affect the character of the reflex movement elicitable from the limb even in the absence of cutaneous organs. The co-ordination was therefore evoked by impulses from the peripheral organs and nerves of muscular sense, in the absence of all the nervous machinery from which one is accustomed to consider consciousness indissoluble.

How little ordinary consciousness is involved by the lower performances of muscular sense, is instanced by the untying of the hands during sleep, even although the knots used for confining them be of a quite complex kind. The two distinct cortical regions related to the movements of the eyeballs accords with the evidence mentioned above in favour of the regulation of those movements by intrinsic muscular sensations (frontal cortex), as well as by visual (retinal) sensations (occipital cortex).

¹ Sherrington, *Proc. Roy. Soc. London*, 1893, vol. lii.

² *Ibid.*, 1896, vol. lix.

Another influence exerted by "afference" ("*Centripetalität*," H. E. Hering) upon the motor innervation of skeletal muscle has to be remembered. The blocking all afferent channels lowers the muscular tonus, as seen in the excessive passive mobility of the limb, and in the delay of rigor mortis in its muscles.¹

The mechanical tension of a muscle which results from its reflex tonus seems important² for the proper execution of its rôle in a combined movement. The action of a muscle A, if unprevented by external resistances, inevitably produces centripetal impulses, which react on the neural tonus, and therefore on the mechanical tension of its antagonist muscles B. More than that, the action of the muscle A, if unprevented by external resistance, inevitably not only stretches its antagonist B passively, but in so doing causes a discharge of centripetal impulses in B, by mechanically exciting B's end-organs, and that discharge modifies, probably usually augments, the neural tonus of B. This regulates the course of the movement, and is preparatory to a next step in the sequence of movement, usually of the reverse direction to the initiatory.

Probably, however, there are other factors still in the ataxy of an apæsthetic limb. Its ataxy is different to that of cerebellar disturbance, and that of disseminated sclerosis. Analysis of it discovers disturbance in the extent, the direction, and the speed of the movement as compared with a normal movement of similar intention. The apæsthetic limb of the frog is flung upward, much as the leg of the tabetic patient is in walking advanced too high and too far.³ I have seen the apæsthetic fore-limb of a cat, when raised to assist the mouth in the management of a large morsel, oftentimes miss the cat's mouth, and even its head altogether.⁴ Similarly in the working of the hand, although it itself retain a large part of its sensorial innervation, if the rest of the limb be apæsthetic, it often misses the object at which it grasps, and may pass an inch or so to one side of its intended goal.⁵ The limb can be seen to swerve from side to side in the progress of its movement. The speed of normal willed movements has been shown to be uniform from soon after start to close upon finish.⁶ The jerky movements of afferent ataxy are obviously not carried out with even approximately uniform velocity.

The centripetal impulses, loss of which produces loss of skeletal tonus, arise not in the skin but in the deep tissues. Those afferent channels, rupture of which produces this ataxia, are not principally cutaneous. A frog in which the hind-limbs have been rendered apæsthetic, exhibits marked ataxia in those limbs; but a frog from which the skin of the hind-limbs has been removed,⁷ moves with no obvious want of precision. The bird in which the skin of the foot has been insensitised by nerve section, will sleep perfectly balanced on the insensitive foot.⁸ The horse which goes lame from tenderness of the hoof, trots normally after neurotomy has rendered the whole foot insen-

sitive. Cocainisation of the vocal cords does not hamper the management of the voice.¹ The cocainised eyeballs can be well trained in any desired direction in a perfectly dark room.² In *tabes dorsalis*, in which the chief lesion concerns the afferent roots, locomotor ataxy is a characteristic, and in this disease the early loss of the knee-jerk indicates the early breakdown of the afferent nerve fibres of the muscles of the lower limb. Besides the consequent loss of tension, the loss of what Bastian calls "guiding" sensations is probably a factor in the inco-ordination.

To the organs of muscular sense is largely traceable local "feeling of fatigue." In *tabes dorsalis* the patient is often abnormally resistant to the induction of this feeling in certain groups of muscles, even on prolonged exercise of them (compare above, pp. 972 and 990).

Finally, there is the phenomenon of senso-paralysis. Charles Bell noted that after section of the supramaxillary (purely afferent) divisions of both *trigemini*, power to use the upper lip for prehension (ass) is lost. In the monkey the "grasp" of hand or foot is lost in an apæsthetic limb.³ These instances suffice to indicate that in their relation to afference some movements stand very differently to others.

Exner finds it impossible, without the help from a retinal image, to at all accurately converge the eyes for an object, which, though unseen, *e.g.* in a dark room, has its direction and distance well perceived, since it is held before one in one's hand.

Perception of resistance.—Muscles are physiological machines for antagonising various forces by elastic tension. In so doing, certain changes in consciousness are brought about, and among these is a "sense of resistance." To hold between the fingers a thread that carries a weight, gives a sensation as of the existence outside the fingers of a something only describable as offering resistance. It is, however, difficult to think of "resistance" as a quite elementary sensation. It can perhaps be simplest thought of as sensation of tension; but discrimination between resistances is based on ratios between degrees of tension sensations and other sensations, such as posture, excursion, and speed of movement, and on touch. More accurate judgment of the weight of an object can be found by lifting it than by allowing it simply to rest on the supported hand. Touch is contributory, but the basis of the judgment seems to be those sensations accompanying the muscular action which are called kinæsthetic. When the finger presses down the beam of a balance, counterweighted by weights ranging between 200 and 2000 grms., a constant fractional increase of about $\frac{1}{15}$ is found to be the liminal sensible difference, if active movement of the finger be not employed, but that fraction falls to $\frac{1}{10}$ when the finger is pressed down by willed movement.⁴

Liminal stimulus.—The load affording the limen of sensible resistance for the elevators of the shoulder has been found⁵ to be in a given case 7.5 grms., hung at the tip of the forefinger, the arm being horizontal and joint movement limited to the shoulder. With movement at the elbow only, the load had to be increased to 9 grms.; and with movement in the finger only, to

24 grms. The static leverage being taken into account, the observations indicate that the delicacy of perception of resistance as measured by the minimum perceptible is greater for peripheral than for proximal segments of the limb.

Liminal difference.—H. E. Weber, measuring the just noticeable difference between weights successively lifted by the same arm, found that difference one-fortieth part of the lesser of the two weights compared. The law which he had previously induced from observations on tactile stimuli, he therefore recognised as applicable to the muscular appreciation of resistances. That law states that the increase of stimulus required to be perceptible as an increase is not any fixed quantity, but one that bears a constant ratio to the total stimulus.

Weber's observations on the application of his *law* to kinæsthetic sensations rest on experiments that deal with only a small number of compared weights. He attempted to exclude participation of touch in the discrimination by hanging the weight in a cloth, the gathered ends of which were compressed as tightly as possible between the fingers. In that way he sought to keep the tactile stimulus maximal and invariable throughout. Since then fuller series and stricter methods have been pursued. Fechner in his historical research¹ recorded 24,576 separate judgments on weights of vessels, which could be filled in various degree and lifted each by a wooden handle. Hitzig's² kinæsthesiometer has been frequently employed; it is a set of balls outwardly alike, but individually loaded so as to be of different weights. Merkel³ used pressure on a balance-beam; Jacobi⁴ preferred a form of steel-yard, one end of which was lifted by the hand. Goldscheider⁵ employed a weight attached by a cord running over a pulley. Langlois and Richet⁶ observed as index to the fineness of the muscular sense in the respiratory mechanism, the smallest rise in the mercury column of a manometer which caused perceptible impediment to the expiration of the observer.

The observations obtained by these methods can be dealt with by—(1) The methods of just discernible differences; (2) the method of average error; (3) the method of right and wrong answers; (4) the method of intervals apparently equal; or (5) the method of doubling the stimulus. These methods have been already alluded to.

In Jacobi's observations,⁷ the liminal difference remained pretty constantly $\frac{1}{20}$ throughout a long range of weights. Experiment finds, in fact, that in the muscular, as in the other senses, the liminal difference is not expressible throughout the range of even work-a-day stimuli as a constant fraction of the total stimulus. Experiments in Hering's laboratory⁸ on the liftings of eleven weights, ranging from 250 to 2750 grms., showed the liminal sensible increment to vary from $\frac{1}{21}$ at 250 grms. to $\frac{1}{14}$ at 2500 grms.; at 2750 grms. to rise to $\frac{1}{8}$ again. Merkel found that for weights below 200 grms. and above 2000 grms., and moved by the finger, the discriminative power was less than for the range between those figures. On the contrary, neither Fechner,⁹ nor Müller and Schumann¹⁰ found the discriminative delicacy decline with weights even far heavier than 2 kilos.

The following fractions express the results of actual observations:—

Observer.	Standard Weight in Grms.	Liminal Difference.
Fechner.	300	$\frac{1}{51.1}$
	500	$\frac{1}{58.8}$
	1000	$\frac{1}{74.6}$
	1500	$\frac{1}{75.2}$
	2000	$\frac{1}{70.4}$
	3000	$\frac{1}{76.9}$
G. E. Muller and Schumann	496	$\frac{1}{28.8}$
	1071	$\frac{1}{26.6}$
	2131	$\frac{1}{33.8}$
	3221	$\frac{1}{43.4}$

In comparing a weight—the so-called “standard weight”—with others, it is not a matter of indifference whether the lifting of the standard precede or follow that of the weight to be judged against it. Hence the well-known “time error.” There is a tendency to undervalue the succeeding weight of the pair. This tendency is stronger with shorter intervals between the successive lifts than with longer, and with heavier weights than with lighter. It appears when the comparison is between right and left hand lifts, though not so markedly as with lifts confined to right or left alone. Fatigue affects the time error in the direction of reducing it. An explanation offered for the time error is that, especially when the successive lifts follow each other rapidly, the motor organs are still in some degree of excitement, or at any rate the path is smoothed and favourably prepared for repetition, when the second impulse to lift occurs; hence more innervation is employed than is intended, and the weight is judged to move more easily. That it occurs with alternate-handed experiments is one more instance of the smoothing a motor path on one side by use of the symmetrical motor path on the opposite, *e.g.* of the collaboration of right and left hemispheres. On this view of the causation of the time error the effect of fatigue is obvious. There is also a spatial error. The weights to be lifted cannot be so placed as to lie to hand in quite the same manner. The difference of the position from which the weight is to be picked up exerts a complex influence.¹

Discrimination is usually sharper when weights are compared in ascending order, *i.e.* from lighter to heavier than *vice versa*. G. E. Müller and Schumann have pointed out the great influence of precurrent effect upon the judgment of a succeeding one. A weight, 826 grms., when compared ten times, with all precautions for rendering judgment unbiassed, against a “standard” weight 626 grms., was once pronounced the lighter, twice pronounced equal,

¹ Sunkel, “Inaug. Diss.,” Marburg, 1890.

and on seven occasions the heavier. A weight, 876 grms., compared with that of 626 grms., was on all of ten occasions judged the heavier. The "standard" weight, 626 grms., and a weight of 2476 grms., were then lifted alternately, each of them thirty times, the "standard" weight preceding the heavier weight. The "standard" was then thrice lifted alternately with weights 926 grms., 876 grms., 826 grms. Then the standard was lifted ten times alternating with the weight 2476 grms.; and finally, thrice in alternation with weights 926, 876, and 826. The ten alternatives with the 2476 weight, and the three with the 926, 876, and 826, were then once more gone through. In the latter part of the experiment the weight 876 grms. was thrice judged to be lighter than 626 grms., and seven times to be equal with it; and weight 926 grms. was on nine occasions judged equal to weight 626 grms., and once judged to be lighter than it. This phenomenon is an example of what is termed "adaptation" or "adjustment."

The motor innervation having become "adapted" for a heavier weight, the perceptions obtained from the peripherally arising impressions resemble in judgment such as would arise under usual circumstances, were a lighter weight than that actually raised to be the object of a smaller effort. Under the more intense motor innervation the weight is *actually* lifted as *quickly* as a lighter weight would be were the motor innervation less intense.

Hering¹ has pointed out how manifold must be the sensations on which estimation of lifted weights is built. Comparisons of perceptions of the speed with which the lifted weights are moved, of the fields of muscular action invoked to maintain the balance of the body as the weight is moved, as well as of skin sensations of pressure and pull, all play a part. A light weight taken up in expectation of its being a heavy one seems to "fly up." An onlooker can often, by watching the speed of lift, tell whether the weight under trial is lighter or heavier than the "standard." Indeed, discrimination between the weights, by lifting them, may be less a matter of discrimination between kinæsthetic sensations of tension than between kinæsthetic sensations of movement-speeds.² But Loeb's experiments (above-mentioned) show that discrimination of *speed* of willed movement is poor. Movement as such is perceived by the muscular sense. A further datum has been insisted on by Jacobi, namely, the latent period of the movement; that is, the length of interval between the signal for willing of the movement and the commencement of the movement which is willed. For a given weight a definite latency corresponds with a definite innervation force, and with equal efforts the latency is proportional to the amount of the weight. Again, the momentum of the mass moved, and the facility with which the initiated movement can be arrested, may also be a factor in forming the judgment, and will vary with the load lifted. A term "sense of tension" may have to replace "sense of resistance." Of observations on sensible muscle-tensions few exist. Sense of resistance to muscular action may be based on compared sensations of joint movements and of changes of muscle-tension, with or without comparison with sensations signifying changes of muscle form. In these ways may be obtained the distinct perceptions we have of the different ways—with ease, or against difficulty—in which the same posture is maintained, or movements identical as regards excursion and velocity are executed.

FUSION OF MUSCULAR SENSATIONS WITH OTHER SENSATIONS.

The perceptions furnished by the muscular sense deal largely with the mutual relations between motile parts. By collaboration of muscular sense with certain other senses (especially sight and touch), those

¹ In a letter to Fechner.

² G. E. Müller and Schumann, *Arch. f. d. ges. Physiol.*, Bonn, 1889, Bd. xlv.; Sunkel, "Inaug. Diss., Marburg," 1890.

senses gain spatial quality measurable in terms of the intensities of the muscular sensations.

Concomitant muscular sensations have been regarded as endowing sensations of other modality with spatial quality. Lotze developed his scheme of "local signs"¹ from the supposition that visual space-perception rests on measurement of retinal differences in terms of intensities of muscular sensations afforded by muscular movements required, when the various retinal points are replaced by the fovea for purposes of attentional vision. Münsterberg² goes so far as to write, "Every content of consciousness requires a muscular impression"; and it has been said "only when we move a limb do we become conscious of its existence."³

A longer line can be visually just distinguished to be longer than a shorter when the difference amounts to $\frac{1}{50}$ of the length of the latter. If we look through a horizontal slit toward a white screen, and without being able to see any other objects perceive a vertical thread, each eye will of itself take up such a position that the image of the thread falls on the yellow spot. The visual axes intersect at the thread. On bringing the thread nearer or removing it farther from the eyes, the angle of intersection of the visual axes is changed as the eyes follow the thread. If the thread is moved very little, the rotation of the eyes is so slight that the accompanying movement sensation is not noticeable. It is found that the increment of movement, which just suffices to cause noticeable sensation, amounts to approximately $\frac{1}{50}$ of the total excursion counted from the parallel position as zero. That perception of spatial magnitude is thus directly proportional to the liminal difference of sensation of movement possessed by the eye, suggests that the sensation of movement serves as criterion for the space-perception.

Again, we possess the finest sensitivity of our eyeball movements when the visual axes are practically parallel,—a rotation of about 1' is then noticeable. If we suspend two black threads near together in front of a white screen, and fixate them with one eye, and then retire gradually from them, though keeping them constantly fixated, the apparent distance between the threads constantly lessens as the retinal image grows smaller. At a certain distance the two threads appear one. There is a certain magnitude of the retinal image of two points (*i.e.* a certain magnitude of the visual angle between them) below which they cannot be perceived as separate. The two images fuse to one at the moment when the distance between their retinal images is so small that the eye has to turn only about 1' in order to bring first one thread and then the other on the same retinal point. The limit to which the eye can attain in cognition of spatial distance is identical with the limit of its apprehension of the sensation of its own movement.

These are quoted as instances of the grounds upon which the fusion of muscular sensations of various intensity with perceptions of certain other senses is regarded as endowing the latter with the quality of "space."

THE DIOPTRIC SYSTEM.

Static and dynamic refraction.—In the first part of this article the refractive apparatus of the eye will be considered,—first in a condition of rest, and then as adjusted to vision at different distances and with different luminosities.

In order to study the formation of the retinal image, and the conditions by which it is modified, it is necessary to simplify the complex optical system of the eye, and reduce it mathematically to a pair of surfaces,—Listing's schematic eye,—or, still further, to a single surface,—Listing's reduced eye. For this reduction certain data are necessary, namely, the radii of curvature of the refractive surfaces, the distances of these surfaces from one another, and the refractive indices of the transparent media. The cornea and the aqueous humour are so nearly of the same refractive index, that the refraction at the posterior corneal surface may be neglected, and this leaves three surfaces needing investigation, namely, the anterior surface of the cornea, and the anterior and posterior surfaces of the lens.

The ophthalmometer.—The radii of curvature and the distances of the surfaces from one another might be determined on the dead eye, but, owing to the alteration caused by the diminution of the intra-ocular pressure at death, this is not satisfactory. One difficulty in their measurement during life arises from the unavoidable movements of the living eye, but this difficulty has been overcome by the *ophthalmometer* first devised by Helmholtz, in which the image reflected from any of the refractive surfaces of the eye may be measured, and the curvature calculated from its size.

The principle upon which Helmholtz's instrument depends, is the apparent deviation of an object seen obliquely through a glass plate.

In Fig. 371 an observer at l will see O through the plate aa as if it were situated at O' , and through the plate bb , at O'' . An object seen through the two plates will appear doubled, the double images deviating in opposite directions. The amount of deviation of each depends on the thickness of the plate h on the angle of incidence, and on the refractive index.

$$OO' = h \frac{\sin(\alpha - \beta)}{\cos \beta}$$

If the angle the plates make with one another be so adjusted that the two images just touch at their inner edges, the distance $O'O''$ will be equal to the diameter of the object, each image having been moved outwards through half its diameter.

Radius of curvature of the cornea.

—In order to find the curvature of the cornea, the eye to be examined is placed about 2 metres from the ophthalmometer, in front of which is a screen bearing two luminous objects, a and b , in Fig. 372, the distance between a and b being about half a metre. Four points of light will be seen reflected from the cornea, and the plates are adjusted till the two middle points coincide, so that only three points are seen. The size of the image β may be calculated by the formula given (or more commonly in practice is found from a table prepared for the instrument), and the radius of curvature of the cornea is calculated from

the formula $r = \frac{2x\beta}{y}$ where x = the distance between the cornea and the object ab , and y = the size of the object, namely, the distance between a and b .

By this method Helmholtz found the radius of the central part to be 7.829 mm. Other investigators have given rather smaller figures.

FIG. 371.

FIG. 372.

In another form of ophthalmometer, devised by Coccius, the plates are replaced by a double image prism, and the images are brought into apposition

by altering the size of the object; β is then a constant for the instrument; and γ being found, the radius is calculated from the same formula. In Landolt's ophthalmometer the doubling of the object is brought about by means of two prisms, while in the instrument of Mandelstamm and Schöler the reflected image is directly measured by means of microscope and micrometer.

Position and curvature of the anterior lens surface.—The distance between the anterior surface of the cornea and the anterior surface of the lens was measured by Donders with the corneal microscope. In

FIG. 373.

the method used by Helmholtz advantage was taken of the facts that the anterior lens surface corresponds with the plane of the pupil, and that the reflected image of an object in the corneal axis appears to lie behind the cornea at a distance equal to half its radius of curvature. With the ophthalmometer at g' in Fig. 373, the corneal reflection of a luminous object at b is doubled.

FIG. 374.

The pupil will be seen double at the same time, and a fixation point, f , is moved till a position of the observed eyeball is found at which the doubled corneal images correspond with the edges of the doubled pupil (Fig. 374). This is repeated with the ophthalmometer at g'' , and the point where the lines $g'a$ and $g''a$ intersect will show the position of the pupil. In calculating the position, account has to be taken of the difference between the real

and apparent positions of the pupil and of the angle fah , between the corneal axis and the line of vision (see p. 1031). The distance is found to be about 3.6 mm., the figures given by different investigators varying from 2.9 to 4.0 mm.

The image of the anterior lens surface is too faint and ill-defined to give satisfactory results by doubling, and Helmholtz determined the curvature of this surface by making the lens and corneal images of the same size. This was done by having luminous objects of different sizes for cornea and lens. The size of a reflected image being proportional to the focal distance of the reflecting surface, the radius of curvature of the lens can be calculated from the sizes of the objects, and the known radius of the cornea. When the eye is accommodated for distant objects, it has been found to be about 10 mm., the figures of different observers varying from 7·9 to 11·9 mm.

Position and curvature of the posterior lens surface.—The position of the posterior lens surface is found by producing a light reflection from the surface, and then exchanging the position of the luminous object and the observing eye. In each case it is arranged that the lens image shall be covered by a corneal reflected image, and the position of the lens image will then be at the point of section of the two lines of vision of the observer passing through the two corneal images. The position of the latter being found, the position of the lens image may be calculated, and is about 7·5 mm. behind the cornea.

The curvature of the posterior surface may be found in the same way as that of the anterior, or the apparent size of the reflected image from the posterior surface may be measured, and the real size calculated from the properties of the refractive media lying in front of it.¹ The radius is about 6 mm., when the eye is accommodated for distant vision.

The cardinal points.—In addition to the above data, it is necessary to know the refractive indices of the media. The index of the aqueous is approximately equal to that of the vitreous, measurements on fresh eyes by Hirschberg, using Abbe's refractometer, giving that of the aqueous as 1·337, of the vitreous 1·336. The index of the lens varies in its different layers, the refractive power being greatest at the nucleus, and diminishing outwards. The mean index adopted by Listing, derived from the results of Helmholtz and Krause, was 1·4545; but other investigators have given smaller values. In calculating the schematic eye, Listing used rather larger values than those given above for the distances between the refractive surfaces and for the radius of the cornea, and calculated the following positions of the cardinal points:—The anterior principal focus 12·8326 mm. in front of the anterior surface of the cornea; the posterior principal focus 14·6470 mm. behind the posterior surface of the lens; the first principal point 2·1746 mm., the second 2·5724 mm., behind the anterior corneal surface; and the first nodal point 7·580 mm., the second 3·602 mm. in front of the posterior surface of the lens. In the reduced eye, the foci are the same as those of the schematic eye, while the single principal point is 2·3448 mm. behind the anterior surface of the cornea, and the single nodal point 4·764 mm. in front of the posterior surface of the lens.

Centre of rotation of eyeball.—This may also be found with the aid of the ophthalmometer. The instrument is placed in the middle of a graduated horizontal arc, along which a fixation point can be moved. A fine hair is suspended vertically in front of the observed

¹ For more detailed description of these and the previous methods, refer to *Arch. f. Opth.*, 1855, Bd. i. Abth. 2, S. 1; "Handbuch f. d. ges. Augenh.," 1874, Bd. iii. S. 204, etc.; or "Traite complet d'opht.," by de Wecker and Landolt, 1880, tome i. p. 738.

eye, which is rotated till the hair covers first one and then the other border of the cornea. The angle through which the eyeball has moved, namely, the angle xyx' in Fig. 375, may be read off on the scale, and is about 56° . The diameter of the cornea yy' may be found with the ophthalmometer by doubling the cornea, by altering the plates till the doubled images from the centre of the cornea correspond with the edges of the

FIG. 375.—Donders.

doubled cornea (as in Fig. 374, with the difference that the circles represent the doubled cornea, and not the pupil). The angle yxz and the side yz being known, xz , the distance from the centre of rotation to the basis of the cornea, may be found, and the height of the cornea, *i.e.* 2.6 mm., being added, will give the distance of the centre of rotation behind the summit of the cornea. By this method Donders¹ found the distance in emmetropic eyes to average 13.54 mm. In myopic eyes the centre was found to be 14.52 mm., and in hypermetropic 13.22 mm. behind the anterior corneal surface.

According to J. J. Müller² and Berlin,³ the centre of rotation is not a fixed point, and recedes from the cornea when the lines of fixation are directed upwards. The former determined the path of a definite point of the cornea during movement of the eyeball, while the latter arranged a number of fine objects, so that they appeared in line with one another in different positions of the eyeball, the point of section of the different lines corresponding with the centre of rotation.

Optical irregularities.—Before considering some further points

FIG. 376.—Landolt.

about the refractive system, certain definitions will be necessary. The optical axis of the eyeball (aa' in Fig. 376) is the line which passes

¹ "Accommodation and Refraction of the Eye," 1864, p. 181.

² *Arch. f. Opth.*, 1868, Bd. xiv. Abth. 3, S. 183.

³ *Ibid.*, 1871, Bd. xvii. Abth. 2, S. 150.

through the nodal point and the centre of rotation of the eyeball. If the different refractive surfaces were exactly centred, as we shall see is not the case, it would pass through the summits of the three chief curved surfaces. The line of vision of is the line passing from the fovea centralis through the nodal point of the reduced eye, and continued to the point of fixation external to the eyeball. The line of fixation om is the line passing from the external fixation point to the centre of rotation of the eyeball. A fourth line, called by Helmholtz¹ the *Visirlinie*, passes from the point of fixation to the centre of the pupil; owing to the frequent eccentricity of the pupil, this may differ considerably from the lines of vision and fixation.

The cornea is ellipsoidal,² and the major axis of the corneal ellipse, el , may not correspond to the summit of the cornea. The angle between the line of vision and the major axis of the corneal ellipse is known as the angle α (*axe* in Fig. 376); the angle between the optic axis and the line of fixation, as the angle γ .

The deviation of the line of vision from the optical axis, and the imperfect centring of the eye, are shown by the following experiment of Helmholtz.³ In Fig. 377, ab is a graduated scale with apertures at a and b ; the observer at a sees the three images of a light at b , reflected from cornea and lens of an eye at d . If the line of vision corresponds with the optical axis, the observer should see the anterior lens image midway between the others, when the observed eye is directed to the centre of the scale, c . It is found that the point of fixation has to be shifted to one side, *i.e.* the nasal side of cd , and slightly above the plane abd . If the eye were properly centred, and the observer and light at a and b exchanged places, the anterior lens image should still be midway between the others. In none of the eyes examined by Helmholtz was this the case, and this observation has been confirmed by Tscherning.⁴

FIG. 377.

As shown by the experiment described, the optic axis cuts the posterior pole of the eyeball on the inner side of the yellow spot and slightly above it. The angles α and γ may be determined with the ophthalmometer. A light to serve as object for the reflected image is placed over the instrument, which is furnished with a graduated arc and movable fixation point. The position of the eyeball is found which gives an image exactly in the centre of the cornea, *i.e.* the cornea

¹ "Handbuch d. physiol. Optik," 2te Aufl., Hamburg u. Leipzig, 1896, S. 115.

² The generally accepted view, that the cornea is ellipsoidal, has been denied by Sulzer (*Arch. d'ophth.*, Paris, 1891, tome xi. p. 419) and others. The form of the surface has been determined by calculation from observations of the curvature at a certain number of points. From examination of a large number of points of the corneal surface with the ophthalmometer of Javal and Schiötz, Sulzer came to the conclusion that the central part is approximately spherical; that at a certain distance from the centre the cornea becomes flatter, the nasal side more than the temporal, and the upper more than the lower half.

³ "Handbuch d. physiol. Optik," 2te Aufl., S. 108.

⁴ *Ztschr. f. Psychol. u. Physiol. d. Sinnesorg.*, Hamburg u. Leipzig, 1892, Bd. iii. S. 475.

is doubled by altering the plates till the reflected images of the flame fall on opposite edges of the cornea, as shown in Fig. 374. The position of the fixation point on the graduated arc will give the angle γ , and the angle α may be calculated, since in Fig. 378, vc , the distance from the centre of rotation to the graduated arc, is known, and also kc , the distance from the nodal point to the centre of rotation. The method is not strictly accurate, for the centre of the cornea does not, as already mentioned, necessarily correspond with the corneal axis, and modifications of the method have been devised to overcome this difficulty.¹

FIG. 378.

According to Donders,² in emmetropic eyes the angle α is about 5° , so that, when the lines of vision are parallel, the optic axes would diverge 10° . The deviation was found to be greater in hypermetropic, and less in myopic eyes, in which the deviation may be nil, and the optic axes may even converge.

If the optic axis and the axis of the corneal ellipse coincide, the angles α and γ vary together, and the difference between them diminishes, the further the point of fixation is from the eye. In addition to the three reflected images used in the ophthalmometric methods, a fourth may be observed reflected from the posterior surface of the cornea. It may be seen by placing the flame well on one side, and magnifying the corneal image with a lens.

An entoptic image may also be seen, owing to the fact that a certain amount of the light reflected from the posterior surface of the lens is reflected again from the posterior surface of the cornea. The light from the anterior surface of the lens comes to a focus near the posterior surface of the lens,³ and, owing to its distance from the retina, is not observed entoptically. The light from the posterior surface of the lens, when again reflected, comes to a focus near the retina, and gives rise to an entoptic image. When a flame is held on one side of the line of vision in a dark room, a faint inverted image may be seen on the opposite side of the line of vision, which moves in the opposite direction to that of the flame. This image may in some cases be the basis of the occurrence of monocular diplopia.

Myopia and hypermetropia.—Theoretically, myopia might be due to the curvature of any of the refractive surfaces being greater than normal, to increase of the refractive index of one of the media, or to elongation of the eyeball. Similarly, hypermetropia might be due to diminished curvature, diminished refractive index, or to shortening of the eyeball. In nearly all cases, change in the shape of the eyeball is believed to be the most important factor, although altered curvature may account for many slight examples of these defects. It has been suggested that cases of transitory myopia in certain inflammatory conditions of the eyeball may be due to increased refractive index of the aqueous. The refraction may differ in the two eyes, and this condition is known as anisometropia.

Astigmatism.—This term is employed for two kinds of defect,

¹ *Arch. f. Ophth.*, 1865, Bd. xi. Abth. 2, S. 257.

² "Anomalies of Accommodation and Refraction," 1864, p. 183.

³ *Ztschr. f. Psychol. u. Physiol. d. Sinnesorg.*, Hamburg u. Leipzig, 1892, Bd. iii. S. 429.

namely, for irregularities of cornea or lens,—irregular astigmatism; and for differences in the refraction of different meridians of the corneal and lens surfaces,—regular astigmatism. One kind of irregular astigmatism is due to the structure of the lens, and shows itself in the “star-like” appearance of any minute luminous point. In most eyes, again, a fine luminous line appears, when carefully examined, to be doubled; or multiplied still more. This may be observed well in the case of the horns of the new moon. This appearance is supposed to be the basis of some of the recorded cases of monocular diplopia or polyopia.

Regular astigmatism may depend on a defect either of the lens or of the cornea, the latter being the more common. The existence and amount of corneal astigmatism may be determined by a modification of the ophthalmometer devised by Javal and Schiötz.¹ Thomas Young² discovered that the defect in his own case was due to the condition of the lens, by finding that it persisted when the refractive power of the cornea was abolished by covering it with a layer of water. The meridians of greatest and least refraction are always at right angles to one another, but may be at any angle to a vertical section through the eyeball. The defect prevents the occurrence of a true punctiform focus, and produces two linear foci, and between them an interfocal region, in one part of which the focus is approximately circular. This circular focus lies nearer the anterior than the posterior linear focus. In the average emmetropic eye the vertical meridian is more convex than the horizontal, the difference not amounting to more than .5 D, and in most cases of marked astigmatism the vertical is also the more convex meridian.

Chromatic aberration.—The difference of focus for the ends of the spectrum was calculated by Helmholtz.³ Using Listing’s reduced eye, and assuming that its refraction is equal to that of water, he found a difference of .434 mm., so that an eye accommodated for red at infinite distance would be accommodated for violet at a distance of 71.3 cm. Matthiessen⁴ found the distance between the two foci still greater (.58 to .62 mm.); and Einthoven,⁵ who has recently calculated the cardinal points of the eye for different parts of the spectrum, also finds the values with the reduced eye too small. Einthoven found that there was no appreciable difference in the position of the posterior nodal point for different colours.

The effect of this difference of focus may be most readily observed on looking, with inexact accommodation, through violet glass transmitting red rays, especially with a half-covered pupil. It is also seen with fine black or white lines. It is much increased when the pupil is dilated. It is said that chromatic aberration is more easily observed by emmetropic and hypermetropic than by myopic eyes.

ACCOMMODATION.

Changes in lens.—The changes which have been observed during accommodation will first be described. The anterior surface of the lens increases in curvature, while the curvature of the posterior surface

¹ “Beitr. z. Psychol. u. Physiol. d. Sinnesorg.” (Helmholtz Festgruss), Hamburg and Leipzig, 1891, S. 39.

² *Phil. Trans.*, London; 1801, p. 57.

³ “Handbuch d. physiol. Optik,” 2te Aufl., S. 157.

⁴ *Compt. rend. Acad. d. sc.*, Paris, 1847, tome xxiv. p. 875.

⁵ *Arch. f. d. ges. Physiol.*, Bonn, 1896, Bd. lxii. S. 166.

is very slightly altered. This may be observed by means of the reflected images seen with the phakoscope, and the amount of change may be accurately measured with the ophthalmometer. The central point of the anterior surface is found to move forwards, the amount of movement averaging .5 mm. The radius of curvature of the anterior surface diminishes from an average of 10 mm. to one of 6 mm., while in cases of hypermetropia the increase of curvature may be even greater. Knapp¹ found that in four individuals the amount of accommodation, calculated from the change of curvature of the lens, agreed fairly closely with the actually observed range of accommodation.

According to Tscherning,² however, the increase of curvature does not take place uniformly over the whole anterior surface, but is greater for its central part. He came to this conclusion after repeating an experiment of Thomas Young, in which he used a plano-convex lens with squares marked out on the plane surface,—the aberroscope. On holding this 10 cm. from the eye, and looking at a light, most individuals see the outer lines curved with the convexity inwards, while, on accommodating, the curved lines become straight or even curved outwards. Tscherning regards this as showing that in its resting state the refraction is greater at the periphery of the lens than at the centre, while during accommodation the increase of refraction is relatively less at the periphery, so that the whole lens may become equally refractive, or the central part even more refractive than the periphery. With more exact measurements, by means of his ophthalmophakometer, Tscherning found that while the radius of curvature of the central parts altered from 10 mm. to 5 or 6 mm. during accommodation, a point on the periphery, 1.4 mm. from the centre, only showed a radius of 8 mm. during accommodation, while in the more peripheral parts there was actual and not merely relative flattening.³ Crzellitzer⁴ has since repeated and confirmed these observations.

The curvature of the posterior surface is found to be very slightly increased, the observations of numerous workers showing a change from about 6 mm. to 5 mm. in radius.

Most investigators have found no alteration in the position of the lens, *i.e.* the position of the posterior surface. Reich⁵ and Tscherning⁶ have, however, each described slight recession of the posterior surface, about .1 mm., and Hensen and Voelckers⁷ observed recession of the lens in animals, shown by the movements of a style placed against its posterior surface. Tscherning also described a slight movement downward of the lens during accommodation. The question has been very thoroughly investigated by Hess,⁸ who finds that, when the eye is accommodated, there is considerable mobility of the lens. In cases of absent iris (after iridectomy) under the influence of eserine, Hess observed a marked shaking of the lens with every movement of the head, the phenomenon disappearing after instillation of atropin. The movement was most marked with the head inclined backwards. For observations on the normal eye, Hess took advantage of the fact that eserine acts on the

⁸ *Arch. f. Ophth.*, 1896, Bd. xlii. Abth. 1, S. 288.

ciliary muscle before it affects the iris, and applied eserine after using homatropin. The normal eye showed similar marked shaking, the observation being especially striking when opacities of the lens existed. The shaking was also observed subjectively. On moving the head from side to side, and then stopping the movement, an observed needle appeared to make three or four oscillations after cessation of movement of the head. The same phenomenon was observed in entoptic observation of the lens. The mobility of the lens during marked accommodation, produced voluntarily or by means of eserine, was ascribed by Hess to slackening of the suspensory ligament. Hess¹ also confirmed Tscherning's observation of a downward movement of the lens during accommodation, but found further that the direction of the movement depended on the position of the head, and that the movement did not occur when the head was inclined so that the iris was horizontal, showing that it was due to gravity. The movement of the lens was determined by the apparent movement of a point of light which moved with the head, and had a constant position relative to the eye; during strong accommodation there was an apparent rise of the point of light, showing a downward movement of the retinal point stimulated. The amount of movement of the lens, with strong voluntary accommodation, was found to be about .3 mm., while in the eserinated eye, on moving the head from shoulder to shoulder through an angle of 180°, the displacement of the lens amounted to 1 mm.

Hess also found a certain amount of mobility in the antero-posterior direction, and investigated its amount by determining the near point with the head inclined forwards and backwards. With voluntary accommodation he found in several individuals that in the two positions of the head, the near point varied to an extent corresponding to a difference of refraction of .34 D to .48 D, and calculated that this corresponded to a displacement of the lens antero-posteriorly of .15 to .21 mm. With the eye well under the influence of eserine, the refraction, as shown by the near point, changed to the extent of .61 to .81 D, showing a displacement of the lens of .26 to .36 mm. With relaxed accommodation no change in the near point with altered position of the head could be observed. Hess suggests that the previous observations of recession of the posterior lens surface may have been due to the position of the head.

Crzelltizer² has confirmed the observations as to the shaking of the lens, but supposes that this is due to a muscular tremor and not to slackness of the zonula. This explanation cannot, however, apply to the other observations of Hess.

Several observers have noted irregularities of the border of the lens in albinos and in cases of absent iris, such as might be due to greater pressure on certain parts than on others. Hess³ observed that this appearance, which he describes in most cases as a wavy border, becomes quite uniform after the instillation of eserine. When the lens is observed from in front in similar cases, its outer zone is seen as a circular band, bright by reflected, dark by transmitted light. This appearance is due to total reflection, and has been used as an indication of change of shape of the lens. The breadth of the border depends on the angle at which the two lens surfaces meet, increased breadth showing increased

¹ *Arch. f. Ophth.*, 1897, Bd. xliii. S. 477.

² *Arch. f. Ophth.*, 1896, Bd. xlii. Abth. 1, S. 288.

³ *Loc. cit.*, S. 90.

thickness of the lens. The border becomes broader during accommodation, and it is said that the lens can also be observed to diminish in size concentrically.¹

Changes in suspensory apparatus.—The free mobility of the lens, and the changes observed in the regularity of its edge, are evidence that the suspensory ligament is slack during accommodation. In cases of absent iris, a fine radially striated appearance may be observed in the position of the ligament, and Hess found that this striation became indistinct after the use of eserine. In animals, Hensen and Voelckers² found that a style placed behind the ligament showed that it became slack during accommodation. Schön³ has objected that this is only true of the fold of the ligament which runs to the posterior surface of the lens, which he supposes to become bent on itself, while the anterior stronger process remains tense.

The behaviour of the ciliary processes during accommodation has been much discussed. When observed from in front in albinos and in cases of absent iris, Becker⁴ noted recession in near vision, but most other observers have seen the processes move forwards, and at the same time approach the optic axis. They are also said to swell slightly. When observed in animals through a window in the sclerotic, the ciliary region is seen to sink inwards during accommodation (Hensen and Voelckers).² The space seen between the ciliary processes and the edge of the lens appears to remain approximately constant during accommodation (Hjort,⁵ Hess).

Hensen and Voelckers⁶ found that during accommodation the choroid moved forwards. They obtained this result in an extirpated human eye as well as in animals. They found that a needle showed a movement of the choroid, amounting to $\frac{1}{2}$ mm. at the equator of the eyeball, diminishing from this point, so that no movement was observed in the ciliary and macular regions. The retina moved with the choroid. The circular or oval phosphene, seen on sudden relaxation of an accommodative effort in the dark, has been ascribed to the movement of the choroid. It is probably due to traction near the posterior pole of the eyeball, for Berlin⁷ found that, when produced simultaneously with an ordinary pressure phosphene, the latter appeared outside the ring of the accommodation phosphene.

In addition to the associated contraction of the pupil during accommodation, the iris is pushed forwards by the bulging lens. If the eyeball is observed laterally, the pupillary edge may be seen to move forwards while the peripheral zone recedes. Helmholtz⁸ found the amount of movement forwards about .4 mm.

Tscherning⁹ observed a greater recession of the middle than of the outermost zone of the iris, but other observers have failed to confirm this.

Thomas Young¹⁰ found that his range of accommodation was as great when his cornea was covered with water as under normal conditions, and

¹⁰ *Phil. Trans.*, London, 1801, p. 57.

also observed no changes during accommodation in the images reflected from the cornea. Later measurements with the ophthalmometer have failed to show any change in the radius of curvature of the cornea.

Intra-ocular pressure.—The condition of intra-ocular pressure during accommodation has been the subject of much difference of opinion. According to one view, the pressure in the vitreous rises while that of the aqueous falls during accommodation. This view is based chiefly on cases described by Förster.¹ In cases in which the anterior chamber had been opened, the cornea was noticed to flatten during accommodation, pointing to lessened pressure within; while, in a case of perforation of the cornea, the aqueous filling the opening receded during accommodation. In these cases the general intra-ocular tension was abnormally lowered, and it is doubtful whether the same phenomena would occur in the normal eye, and this doubt is increased by the fact that Förster notes that they occurred after the use of atropin. Manometrical observations, however, in both cavities of the eyeball during accommodation have failed to show any noticeable difference,² while it has been found that injection of fluid into one cavity raises the pressure of both equally. The free mobility of the lens during strong accommodation, described by Hess, would be impossible if there were any difference of pressure in front of and behind the suspensory ligament.

Hensen and Voelckers³ found that in animals an artificial protrusion of the vitreous through a puncture increased during accommodation.

Nervous mechanism.—The chief point of interest is the supposed function of the sympathetic as the nerve of accommodation for far vision. Jessop⁴ observed recession of the anterior lens surface on stimulating the long ciliary nerves, after the ciliary muscle had been moderately contracted by pilocarpin. Morat and Doyon⁵ assert that when the sympathetic is stimulated in a dog or cat, under the influence of morphia or pilocarpin, the anterior lens image enlarges, and that a needle placed against the anterior lens surface indicates flattening of the lens. They ascribed this effect to the inhibitory influence of the sympathetic on the ciliary muscle. On the other hand, Langley and Anderson⁶ failed to observe either movement of the choroid, backward movement of the anterior lens surface, enlargement of lens images, or increase of distance between them. Heese⁷ also failed to obtain any separation of the lens images on stimulation of the sympathetic. In the cat, with which animal Morat and Doyon obtained their most marked results, Heese noticed a diffused halo round the lens image, which he ascribed to dispersion rendered more obvious by the dilatation of the pupil, and supposed that this may have misled the French observers.

Unequal and meridional accommodation.—By the former term is meant accommodation of a different amount in the two eyes; by the latter, of a different amount in the two meridians of the same (astigmatic) eye. Observations of Hering and Donders are generally held to have disproved the existence of the former, but A. E. Fick⁸ has recently attempted to show that

¹ *Klin. Monatsbl. f. Augenh.*, 1864, Bd. ii. S. 368.

⁸ *Arch. Ophth.*, N.Y., 1889, vol. xviii. p. 292.

it occurs in cases of unequal refraction. He combined printed type in the stereoscope, arranging that the gaps in the type presented to one eye should be supplied by that presented to the other eye, and found that the print could be read with a difference of 2 to 3 D. Hess¹ has, however, by means of careful stereoscopic experiments, shown that the older view is probably correct. He used fine threads at slightly different distances, so that they would be seen lying side by side in binocular vision, and found a difference of distance amounting to .25 D was sufficient to render one of the two threads indistinct or even invisible. He found that cases of slight anisometropia showed no more evidence of unequal accommodation than did normal vision; when fully corrected, a difference of .5 D was not compensated for by accommodation. Hess ascribes Fick's results partly to the use of too coarse tests, and partly to his neglect of the influence of the pupil. It is possible in myopia for a distant object to appear more distinct with the eye accommodated for near vision than with the unaccommodated eye, owing to the contracted pupil in the former case more than compensating for the increased diffusion circle.

Hess also calls attention to the influence of rivalry in such experiments (see p. 1122).

Greiff² investigated the same question by a different and very simple method. If an opaque body is held before the eyes, part of the visual field will be seen by one eye, part by the other eye, and part by both eyes. With different refraction in the two eyes, one part of the field will be indistinct if the difference is not compensated for by accommodation; and Greiff found by this method that both in natural and artificial anisometropia there was not the slightest evidence of unequal accommodation.

The evidence seems also to be against the existence of meridional accommodation. Its occurrence has been advocated (1) on the ground of experiments in which astigmatism is imitated by means of glasses, (2) on account of the marked and often sudden changes of vision which occur in cases of natural astigmatism, and (3) because astigmatism is sometimes found to have increased after instillation of atropin. Hess³ has recently failed to find any evidence of unequal contraction of the ciliary muscle sufficient to overcome astigmatism of a fraction of a dioptré. Astigmatics often assist vision by closing the eyelids, so as to convert the palpebral aperture into a slit, and this fact may explain some of the cases which have been brought forward in favour of meridional accommodation. Hess has called attention to another possibility. It has generally been supposed that astigmatics always accommodate for one or other of their linear foci. Hess finds that this is not the case, but that accommodation normally occurs for that point in the interfocal region where the focus is approximately circular. Using a photographic apparatus rendered astigmatic by a cylindrical lens, Hess⁴ found that the clearest image occurred at the circular focus; and careful observations of the eyes of astigmatics showed that, when they saw most distinctly, their refraction was adjusted approximately to the circular focus. The variations in astigmatic vision, which have been ascribed to meridional accommodation, may very well have been due to variations in the adjustment of the eye to different parts of the interfocal region. If meridional accommodation occur in cases of astigmatism, it might be expected to lead to anatomical changes in the form of localised hypertrophies of the ciliary muscle. No such appearances have been recorded.

Theories of accommodation.—In the widely accepted theory of Helmholtz, it is supposed that during relaxation of accommodation the suspensory ligament is in a state of tension, thereby compress-

¹ *Arch. f. Ophth.*, 1889, Bd. xxxv. Abth. 1, S. 157.

² *Arch. f. Augenh.*, Wiesbaden, 1891, Bd. xxiii. S. 371.

⁴ *Loc. cit.* Refer to Hess's paper for the photographs illustrating this.

ing the anterior surface of the lens. The longitudinal fibres of the ciliary muscle are supposed to have their more fixed attachment in front, and on contraction to pull the choroid forward, relaxing the ligament, and releasing the pressure on the lens. The circular fibres are supposed to prevent distortion of the ciliary processes by making them follow the retreating lens.

The observations of Hensen and Voelckers on animals are all in favour of this theory, and especially the occurrence of movement of the choroid forwards. The recent observations of Hess seem to afford convincing evidence in favour of the main feature of the theory, namely, slackening of the suspensory ligament during accommodation. Recently the theory has been attacked in several quarters; one objection made by Schön is based on the supposed difference of pressure in the aqueous and vitreous humours in the eye adjusted for near vision. Schön points out that the ability of the contracting ciliary muscle to pull the choroid forwards depends on the intra-ocular pressure, and that it is impossible that both rise of pressure in the vitreous and slackening of the suspensory ligament should take place from the same cause. As we have seen, however, there is no satisfactory evidence that the pressure in the vitreous becomes higher than that in the aqueous humour.

The greatest difficulty of the Helmholtz theory lies in the rôle assigned to the circular fibres. It has been found by Iwanoff¹ that the circular fibres are hypertrophied in cases of hypermetropia, in which accommodation has been over-used, and are atrophied in myopia, in which less than the normal effort is required. This change is said not to be constant, but such changes are only to be expected in those cases in which the refractive anomaly has been left uncorrected. If this observation is accepted, the circular fibres must be of more importance than is assigned to them by the theory. On the other hand, the circular fibres are absent or almost absent in nearly all mammals in whom the mechanism of accommodation is probably of essentially the same nature as in man. Schön has objected that numerous pathological conditions associated with hypermetropia and over-action of accommodation are not intelligible if the process of accommodation is one of relaxation of tension.

When accommodation was found to depend on a change in the form of the lens, Cramer supposed that the increased curvature of the central part of the lens was brought about by means of the pressure of the iris on the peripheral parts. This was soon disproved by the observation that accommodation took place quite normally when the iris was absent, but this flattening of the periphery of the lens by pressure and bulging of the centre is the essential feature of the two recent theories of Tscherning and Schön.

Tscherning² supposes that the posterior attachment of the meridional fibres of the ciliary muscle is more fixed than the anterior, and that when these fibres contract they pull on the suspensory ligament, rendering it more tense, thereby flattening the peripheral parts of the lens, while the centre becomes more convex. He states that when traction is made on the suspensory ligament in the extirpated eye, the change in shape of the lens corresponds to that taking place during accommodation. Crzelltizer, however, who has devised a special ap-

¹ *Arch. f. Ophth.*, 1869, Bd. xv. Abth. 3, S. 284.

² *Arch. de physiol. norm. et path.*, Paris, 1894, tome vi. p. 40.

paratus for exerting uniformly circular traction on the zonula, failed to make satisfactory observations on the peripheral parts of the lens.

Tscherning neglects in his theory the circular fibres of the ciliary muscle. In Schön's theory,¹ on the other hand, they play an important part. Schön supposes that the zonula becomes more tense during accommodation, being compressed by the ring fibres, assisted by contraction of the meridional fibres. He regards the lens capsule, zonula, and choroid, as together forming an elastic and continuous covering of the globular eyeball, and the result of circular pressure round one pole of this globe would cause protrusion of the part within the ring of pressure, namely, the anterior lens surface. The posterior surface of the lens would be prevented from altering in form by the increased pressure in the vitreous, which Schön supposes to be present. While Schön's theory is satisfactory in supplying the circular fibres with a function, it goes too far, for it leaves the other parts of the muscle—the only parts existing in most animals—without any direct function in accommodation.² The theories of both Schön and Tscherning involve increased tension of the suspensory ligament during accommodation. Schön supposes that the observation of Hensen and Voelckers, showing relaxation of the zonula, arises from the folding upon itself of the posterior fold of the ligament, and does not concern the more important fold going to the anterior surface of the capsule. Both theories must fall, if Hess has given a correct explanation of his observations.

Before the changes in the lens were described by Helmholtz, one of the favourite theories was, that accommodation for near objects depended on increase in length of the antero-posterior diameter of the eyeball, brought about by the external pressure of the contraction of the extra-ocular muscles associated with convergence, together with internal traction by the ciliary muscle. On the discovery of the lens changes, the theory was discarded, but it has recently been supposed to be a subsidiary factor, and to be the explanation of the apparent accommodation which has been observed in cases of aphakia, and also when the ciliary apparatus is supposed to be completely paralysed by atropin. Knapp's observations show that in normal conditions the changes in the lens are sufficient wholly to account for the range of accommodation. Any change in the shape of the eyeball would be accompanied by change in the curvature of the cornea; all agree that the latter does not occur in normal eyes, and Silex³ has found no change in a boy who seemed to have some power of accommodation after removal of the lens.

Accommodation in birds, reptiles, amphibia, fishes, and cephalopods.—The comparative physiology of accommodation has been very thoroughly investigated by Beer. In birds⁴ he has found that the cornea consists of two distinct lamellæ, and that Crampton's muscle produces retraction of the inner or posterior lamella. In some birds (owls, hawks, buzzards) he found with the ophthalmometer that the peripheral parts of the cornea were flattened, while the curvature of the central part increased. The lens showed increased curvature on stimulation of the ciliary muscle. On dividing the ligamentum pectinatum, the lens was found to have increased its curvature, and stimulation of the muscle then had no influence on the curvature. There was no

⁴ *Arch. f. d. ges. Physiol.*, Bonn, 1893, Bd. liii. S. 175.

appreciable alteration in the curvature of the posterior surface of the lens. Beer concluded that in far vision the anterior surface of the lens is compressed by traction exerted by the ciliary processes (which in the bird are directly attached to the lens capsule). This traction is kept up by the tension of the ligamentum pectinatum; when the ciliary muscle contracts, it draws back the inner lamella of the cornea, and the tension of the ligamentum pectinatum being relaxed, the anterior lens surface is allowed to become more convex. This mechanism has the same principle as that formulated by Helmholtz for the human eye, but differs greatly in its details. In some birds the same mechanism supplements the increased refraction of the lens by increasing the curvature of the central part of the cornea.

In reptiles (except snakes), Beer¹ found that the mechanism of accommodation closely resembles that of birds. In most snakes, on the other hand, no change in the form of the lens was observed, but a forward movement of the whole lens was found to take place. This movement was brought about by means of a striped muscle composed of circular fibres, which exerts pressure on the vitreous during contraction, and forces forward the most movable part of the wall of the vitreous chamber, namely, the lens. When the vitreous chamber has been opened, contraction of the muscle causes retraction of the lens. Among the snakes examined, only one was found (*Tropidonotus tessellatus*) in which the anterior surface of the lens became more convex, but this change was also probably accompanied by a bodily movement of the lens forwards. Most of the amphibia examined² were found to accommodate in the same way as snakes, by means of a forward movement of the lens. Some were found to be approximately emmetropic in air, others in water; but in no case was the amount of accommodation present sufficient to enable an animal to see distinctly in both media. In some snakes and amphibia, the power of accommodation seemed to be absent.

In fishes, Beer found the mechanism to be of an absolutely different nature.³ It had previously been found that the fish is myopic in water, and Beer confirmed this, using the methods of skiascopy and direct ophthalmoscopy, the myopia varying from about 3 to 12 D in water in most fishes, and from 40 to 90 D in air. With the ophthalmoscope Beer found a decrease of the myopia on electrical stimulation of the eye. With the phakoscope and ophthalmometer he found no change in the curvature of the lens, but distinct movement of the lens backwards and slightly to the temporal side during stimulation. He found that this movement was due to the campanula, which could be seen to contract; while retraction of the lens did not occur after cutting the campanula or its tendon. The lateral movement of the lens was due to the position of the campanula on the temporal side, and through the space between the pupil and the lens Beer was able to observe a corresponding lateral movement of the retinal image. This mechanism seemed to be limited to the Teleostean fishes; no movement of the lens could be detected in the Elasmobranchs examined.

In Teleostean fishes, the eye when at rest is shown to be adjusted for near vision, and accommodation for far vision is brought about by movement of the lens backwards. Beer⁴ has found that this is also true of the cephalopod eye, though the mechanism of retraction is different. The determination of the refraction was very difficult, but Beer satisfied himself by skiascopy that myopia existed at rest, varying from 2 to 10 D, being greatest in the octopods. On electrical stimulation the myopia decreased; no alteration in the curvature of the lens could be detected; and, by means of a needle in the lens, graphic tracings, showing retraction of the lens during stimulation, were obtained. The retraction was found to be due to the ring muscle first

¹ *Arch. f. d. ges. Physiol.*, Bonn, 1898, Bd. lxxix. S. 507.

described by Langer, in which the fibres run meridionally, and on contraction pull the lens backwards. Beer found that the increased pressure on the chamber behind the lens, due to the contraction of this muscle, produced bulging of the lax posterior pole of the eyeball, but that the recession of the retina so caused was too small to neutralise the recession of the lens. Both in fishes and cephalopods the iris was found to have no influence on the process of accommodation. There is no evidence of anything like a mechanism of accommodation in the compound form of eye.

THE PUPIL.

Pupillometry.—In measuring the size of the pupil, it must be remembered that it is magnified by the refractive action of the cornea and aqueous humour. The methods ordinarily used have the disadvantage that they involve the near approach of an object to the eye, and consequent shading. This difficulty may be overcome for exact measurements by the use of a telescope with a scale (Schadow¹), or by observing the image of the pupil reflected from a mirror. Schirmer² used the image reflected from one side of a prism seen against a scale, which was reflected internally from another side of the prism which had been covered with mercury. Hess³ employs a method in which the virtual image of a scale appears in the plane of the pupil. The most exact method is with the ophthalmometer, on the same principle as described on p. 1030 (Fig. 374). Two other special methods are useful under certain circumstances. One first employed by Bellarminoff⁴ is to photograph the pupil under different conditions, and for this the magnesium flashlight has been used by du Bois-Reymond⁵ and Haycraft. The other method first employed by A. Fick⁶ is to observe the entoptic image of the pupil. A fine hole in a screen at a short distance from the eye will be seen as a diffusion circle, which varies in size with the size of the pupil. If two such holes are used, at such a distance from one another that the two diffusion circles just touch, the diameter of the pupil is approximately equal to the distance between the two holes. The exact relation is influenced by the distance of the holes from the eye, and to a considerable extent by the condition of refraction of the eye. The method is especially useful as a means of detecting slight changes in the size of the pupil; when the circles just touch, enlargement of the pupil will make them overlap, and contraction will make them separate from one another.

Changes in the pupil.—Change in the size of the pupil takes place under four chief conditions, namely (1) with change in the illumination; (2) with change in convergence and accommodation; (3) in response to sensory stimuli in different parts of the body; and (4) in connection with psychical changes, and especially emotional conditions. The pupil is also affected by various drugs and in various abnormal conditions of the nervous system.

The amount of contraction depends on the intensity of the light falling on the eye, and Haycraft⁷ has recently shown, using the photographic flash light method, that the relation is of the same kind as that

⁷ In a communication to the Physiological Society not yet published.

existing between stimulus and sensation, namely, that the amount of contraction of the pupil is proportional to the logarithm of the intensity. Schirmer¹ found the condition of adaptation of the eye to be of great importance, and that, in different conditions of adaptation of the two eyes, the same illumination may contract the pupil of one, and dilate that of the other eye. With maximal adaptation to the dark, Schirmer found that the pupil maintained the same diameter, usually between 3 and 4 mm., within wide ranges of illumination (*i.e.* between 100 and 1100 mc.).² Schirmer has proposed to call this the physiological pupil-width, and Silberkuhl³ has employed it for measurements of the pupil under different conditions. The pupil is said to contract more when light falls on the central retina than on the periphery. This is probably true under ordinary conditions, but has not been investigated in dark adaptation, when a different result would probably be obtained (see p. 1083). The size of the retinal area stimulated has been found to be of influence, but there are no exact observations on this point also. The pupil has been said to become smaller and to contract less with advancing age. It is also said to be larger in myopic than in emmetropic and hypermetropic eyes, but Schadow⁴ and Silberkuhl⁵ have failed to find any appreciable difference. Silberkuhl found no difference in cases of unequal refraction.

Each pupil contracts not only when light falls directly upon it, but also when light falls on the pupil of the other eye. These reactions are known as the *direct* and *consensual* reactions respectively.⁶ It is said that the consensual reaction takes place somewhat later than the direct, but this point seems to be doubtful.

The contraction of the pupil with accommodation and convergence is an associated movement. Following E. H. Weber, it is often supposed that the contraction is especially associated with convergence, but this is not the case. The pupil contracts with accommodation without any change in convergence, as well as with convergence without accommodation. The latter may be shown by experiments with prismatic glasses, while the former is shown by an experiment due to Hering,⁷ in which the pupil is observed by the entoptic method. Each eye looks through a fine hole in a screen, so that a binocularly combined image is seen; if a second hole is made in each screen, in one above and in the other below the original hole, three pupillary diffusion circles may be observed in a line, and are seen to change in size when the accommodation is changed without alteration of convergence. According to a recent paper, however, by Verwoort,⁸ this result is due to the imperfect exclusion of convergence; and this author believes that Weber was right in associating the reaction of the pupil with convergence (see p. 1131, for the relation between accommodation and convergence).

Mechanism of contraction.—The contraction of the pupil, due to the action of the sphincter muscle, depends, in birds and mammals, upon a reflex starting from the retina, and having its centre in the floor of the aqueduct of Sylvius. In fishes and amphibia, the pupil con-

⁵ *Loc. cit.*

⁶ Steinach (*Arch. f. d. ges. Physiol.*, Bonn, 1890, Bd. xlvii. S. 289) has found that the consensual reaction does not occur in animals with total decussation of the optic nerves in the chiasma.

⁷ "Lehre v. binoc. Sehen," 1868, S. 134.

⁸ *Arch. f. Ophth.*, 1899, Bd. xlix. S. 348.

tracts to light in an extirpated eyeball. It has been disputed whether this is due to direct action on the iris or to an intra-ocular reflex. Steinach¹ has shown that the reaction is greatly influenced by the state of the eye, and is very marked when the animal has previously been kept for some time in the dark. The iris of the extirpated eye will then contract to light, when the whole of the posterior pole of the eye, including the retina, has been removed by cauterisation. With local stimulation of the pupil by light, Steinach found that the contraction began at the part stimulated and slowly spread to other parts. The reaction, however, did not occur on stimulation of the peripheral part of the iris, and was limited to the part near the pupillary border. In the eel, salamander, and frog, Steinach found that the muscle fibres of the sphincter were pigmented, fine yellowish brown pigment granules appearing to lie between the muscle fibrillæ, and he ascribes the influence of light to its direct action on the pigment. Steinach investigated the influence of the different parts of the spectrum, and found that this corresponded with the absorption of the pigment, the maximum effect being in the green about *F*, while the red end of the spectrum as far as *C* produced no contraction.

Mechanism of dilatation.—There has been till recently much uncertainty as to the cause of the dilatation of the pupil. It has been ascribed to the contraction of radial muscular fibres, to inhibition of the sphincter, and to vaso-constriction, acting either by emptying the iris of blood, or by producing longitudinal contraction of its radial arteries. Langley and Anderson² have shown that there is a substance in the iris which contracts radially, but have left it an open question whether this substance is in the form of unstriped muscle fibres. They found that local stimulation of the sclerotic produced dislocation of the pupil, which could only be explained by radial contraction, and that local dilatation of the pupil might be observed to occur simultaneously with local contraction of the sphincter. They found that a strip of iris, isolated except at its ciliary attachment, shortened on stimulation of the cervical sympathetic to as much as half its length; and they showed that this shortening was not accompanied by any appreciable change in the blood vessels. Heese,³ about the same time, took tracings of the contraction of radial strips of the iris with the sphincter removed, and on stimulation of the cervical sympathetic obtained curves, corresponding, as regards form and latent period, with those of unstriped muscle fibres. The question still remains, whether this radial contraction is accompanied by simultaneous inhibition of the sphincter. Langley and Anderson failed to obtain any evidence of relaxation of the sphincter on stimulation of the sympathetic. Waymouth Reid⁴ has, however, found definite differences in the electrical variation of a demarcation current, when the electrodes are placed concentrically near the pupil and radially near the periphery of the iris. When the third nerve was stimulated, there was a negative variation in the concentric position and a positive variation in the radial position; when the sympathetic was stimulated, the concentric position gave a positive, the radial gave a negative, variation. Reid concludes that contraction of the sphincter is accompanied by inhibition of the radial contractile substance, and that contraction of the latter is accompanied by inhibition of the sphincter.

THE RETINA AND VISUAL SENSATIONS.

PHYSIOLOGICAL RETINAL PROCESSES.

Visual purple.—The most obvious change which occurs when light acts upon the retina is the bleaching of the visual purple or rhodopsin contained in the outer limbs of the rods. The existence of this substance was first described by Boll in 1876, and its properties have been most fully investigated by Kühne.¹ In the process of bleaching an intermediate substance, visual yellow is formed. Visual purple varies in colour to some extent in different animals, inclining more to violet in some, including man. The red colour in some cases is ascribed by Kühne to mixture with visual yellow. Green rods occur amongst the others in amphibia. The bleaching is limited to the part of the retina on which light falls, and produces an optogram, or image of an external object, both in the living and the recently killed animal. The eye should be kept from the light for ten minutes, then exposed for about three minutes in a room lighted by one window, so that an image of the window falls on the retina; the eyeball should then be extirpated by the light of a sodium flame, and the retina laid in a 4 per cent. solution of alum. The eye of a recently killed animal will then show a well-defined colourless optogram, while in an eye exposed during life it will be still pink and less sharply defined.

The bleaching of visual purple during life cannot be brought about in any other way than by the direct action of light. Exposure of one eye only to light does not lead to any change in the purple colour of the other eye, nor is any change produced by exposure of the body to light.

Regeneration of visual purple takes place in both the living and extirpated eye, when kept in the dark; it also occurs in red light. Boll² supposed that red light acts as a stimulus to regeneration, but from experiments with optograms Kühne found that, with moderate intensities, regeneration takes place at the same rate in red light as in the dark, and with brighter red light more slowly. Regeneration seems to depend upon some substance derived from the pigment epithelium, to which Kühne has given the name rhodophyllin. If a piece of the retina be separated from the underlying pigment layer, bleached by light, and then replaced on the pigment, regeneration takes place, and even without replacement regeneration may occur, probably owing to the particles of pigment retained between the rods. In some cases this takes place when no pigment seems to be present, especially in the lower half of a retina placed vertically, and Kühne supposes that in this auto-regeneration, which takes place very slowly, rhodophyllin is present in the rods. Regeneration is uninfluenced by light applied to the other eye, or to another part of the same eye. Both bleaching and regeneration are thus independent of the nervous system, and visual purple has been found to be present a year after division of the optic nerves. Regeneration is hastened by pilocarpin and muscarin, probable owing to increase of the secretory activity of the pigment epithelium.

Rhodophyllin is apparently, like visual purple itself, soluble in bile salts, for a solution of visual purple in bile salts is capable of regeneration after

¹ *Untersuch. a. d. physiol. Inst. d. Univ. Heidelberg*, 1878–82.

² *Arch. f. Physiol.*, Leipzig, 1877, S. 4.

bleaching, and the process may be repeated two or three times. Boll supposed that the regenerating substance is derived from the coloured globules of the epithelial cells, and described the globules after regeneration as more faintly coloured. But no definite relation has been found by other observers between the action of light and the condition of either the coloured globules or the myeloid granules of the pigment epithelium. Regeneration takes place when there is no pigment, as in the albino rabbit, and in those mammals (man, ox, pig) in which there are no fat globules in the epithelium.

The times necessary for bleaching and regeneration of visual purple have been determined. In the living frog ten minutes' exposure to strong sunlight is necessary, while regeneration requires one to two hours; in a warm-blooded animal bleaching is far more rapid,—according to Kühne, sixty times more rapid than in the frog. Solution of visual purple from the frog and mammal, however, bleach in about the same time. The difference in the two animals may depend partly on the temperature, partly on the much greater length of the rods in the frog, and consequent greater thickness of the purple layer. The size of the pupil is also of influence. Kühne found by experiments on the rabbit with one pupil dilated by atropin, that the amount of bleaching differed greatly in the two eyes. The effect of temperature on the time of bleaching differed to some extent in solutions obtained from the frog and rabbit, and Kühne supposes that there are different visual purples as there are different hæmoglobins.

In order to investigate the absorption spectrum of visual purple, the retina must be treated with a solution of bile salts. Owing to the fact that bile has

FIG. 379.—Kühne.

a powerful solvent action on red blood corpuscles, the solution of visual purple so obtained is mixed with hæmoglobin, especially in man and other mammals.¹ Kühne² has recently described two methods for separating the hæmoglobin. In one, bile salts and visual purple are precipitated by an excess of magnesium sulphate,

leaving the hæmoglobin in solution; in the other, a retina which has been hardened in alum is left for some hours in a 10 per cent. solution of sodium chloride, after which treatment with bile salts extracts visual purple only. No observations have yet been recorded on the spectrum of human visual purple dissolved with these precautions. The spectra of visual purple and visual yellow of the frog are shown in Fig. 379.

Köttgen and Abelsdorff³ have determined the absorption of visual purple in a large number of animals. They found that in mammals, birds (owl), and amphibia, the maximum absorption took place at 500 λ , while in fishes the maximum was at 540 λ . The curves representing the absorption in the two classes are shown in Fig. 380. Kühne's new method was not used, but the differences seem to be too great to be explained by the presence of hæmoglobin in one and not in the other. Köttgen and Abelsdorff failed to obtain any evidence of the existence of visual yellow in their investigations.

The influence of coloured light on visual purple is of great importance in relation to its possible function in colour vision. The red of the spectrum has least action, and, as already mentioned, in moderate intensity does

¹ In the frog a pure solution may be obtained, owing to the vessels in this animal being limited to the hyaloid (Kühne).

² *Ztschr. f. Biol.*, 1895, Bd. xxxii. S. 21.

³ *Ztschr. f. Psychol. u. Physiol. d. Sinnesorg.*, Hamburg u. Leipzig, 1896, Bd. xii. S. 161.

not hinder regeneration. When sufficiently intense, it acts, however, on visual purple, and will in time completely bleach the retina. That yellow light is also of very slight influence, is shown by the use of the sodium flame in experimental investigations on visual purple; its action, however, is greater than that of red light. Visual purple is most rapidly bleached by the part of the spectrum between *D* and *E*, and from the maximum of action in this part of the spectrum there is a gradual diminution with diminishing wave-length. Kühne investigated whether the slighter activity of the violet end was due to greater spreading out

FIG. 380.

of that end in the prismatic spectrum and consequent smaller intensity, but experiments with a grating spectrum also showed the greatest activity of the yellow-green rays. The degree of activity corresponds with the degree of absorption of monochromatic light by visual purple (Fig. 379). Visual yellow is acted on more strongly by the violet end in correspondence with its absorption spectrum, and consequently visual yellow is often absent as an intermediate product when visual purple is bleached by light of short wave-length. Fuchs and Kreidl¹ have found that the Röntgen rays have no influence on the visual purple of the frog, and Pergens² found that this was also the case after removal of the lens in *Leuciscus rutilus*. Gatti³ has found that the rays have no influence on the regeneration of visual purple. Fuchs and Kreidl found, on the other hand, that the yellow-green fluorescent light from the tube bleached visual purple very slowly.

The whitish-green fluorescence of the retina in ultra-violet light depends on the rods and on the bleached visual purple. The unbleached rod layer fluoresces very slightly and with a bluish tint; when completely colourless, the fluorescence is much stronger and greenish in appearance. Visual yellow, on the other hand, appears to be completely devoid of fluorescence. The cones and the rods about the ora serrata, which have no purple, do not fluoresce, and under ultra-violet rays the fovea appears as a dark spot. It is difficult to determine whether the solution of visual purple is fluorescent, since the bile in which it is dissolved fluoresces strongly (Ewald and Kühne).⁴

The function of visual purple will be considered later in connection with the theories of light and colour vision. It will be sufficient to

¹ *Centralbl. f. Physiol.*, Leipzig u. Wien, 1896, Bd. x. S. 249.

² *Klin. Monatsbl. f. Augenh.*, Stuttgart, 1897, Bd. xxxv. S. 354.

⁴ *Untersuch. u. d. physiol. Inst. d. Univ. Heidelberg*, Bd. i. S. 139.

mention here the experiment of Kühne¹ on the vision of frogs whose visual purple had been completely bleached. He found that they could evidently see, were able to catch flies in bright sunlight, and behaved very differently from blind frogs. He found that the great majority of normal frogs put themselves under green in preference to blue glass, when differences of temperature and intensity were excluded. Bleached frogs also preferred green glass, while blind frogs were found indiscriminately under each.

Other changes in rods.—In addition to the changes in colour, the outer limbs of the rods have been observed to change in size under the action of light. In frogs kept in the dark, there are distinct spaces between the rods; the distances, according to v. Hornbostel,² varying from $\cdot 5$ to $\cdot 8 \mu$; in frogs exposed to the light, the rods are separated only by narrow lines. The swelling, however, is only perceptible after nearly one hour's exposure. No increase in diameter occurs in red light.

Angelucci³ and Gradenigo⁴ describe contraction of the inner limbs of the rods under the action of light, so that they become shorter and thicker. In the dove, under the other hand, Stort⁵ described the inner limb as longer and thinner in the retina exposed to light.

The pigment epithelium.—The changes produced in the pigment epithelium by the action of light were first studied by Kühne, Boll, and Angelucci. In the eye of a frog which has been kept in the dark, the pigment layer separates easily from the rod and cone layer, and the brown pigment is found heaped up in the body of the epithelial cell and round the outer extremities of the rods, not reaching beyond the outer third of the length of the rod. In an eye which has been illuminated, the epithelium and rods are separated with difficulty; the body of the epithelial cell contains much less pigment, so that the nucleus is clearly seen; and the pigment is much more abundant between the outer limbs of the rods, and extends also between the inner limbs as far as the *membrana limitans externa*. In birds and mammals the pigment layer naturally separates more easily than in the frog, but in them the pigment shows the same change of distribution under the influence of light and dark. In the frog, about ten minutes of illumination are needed to bring the pigment to the *membrana limitans externa*, while one and a half to two hours are necessary for return to the dark position; these times correspond very closely with those necessary for bleaching and regeneration of visual purple respectively in the same animal, and point to the close connection of the two processes. The pigment, however, differs from visual purple in its behaviour to coloured light, the movement forwards taking place actively in red light. According to Angelucci,⁶ the violet end of the spectrum is that which acts with the greatest intensity, and there is, according to him, a gradual increase in the movement forwards with decreasing wave-length of the light used. According to A. E. Fick,⁷ the forward movement of the pigment, once set up by a short exposure to light, goes on in the dark. He found that frogs from the dark exposed to the light for one minute, and then kept in the dark for twenty minutes, showed forward position

of pigment, while in those killed immediately after the minute's exposure there was little change from the dark position. The forward position was found in frogs when respiration had been interfered with, either by keeping them in closed vessels or under water, or by mixing CO² with the air breathed. In nearly all cases the lower half of the retina showed a more forward position of the pigment than the upper half, and Fick believes that this is due not only to the fact that the lower part of the retina is usually more exposed to light, but also to a greater tendency to forward movement.

The influence of the nervous system on the movement of the pigment will be considered in connection with the movements of the cones.

The cones.—The movement of the cones under the action of light was observed later by Engelmann and van Genderen Stort.¹ While investigating the recession of the pigment in frogs in the dark, it was noticed that the cones were situated between the outer limbs of the rods, and not close to the external limiting membrane, as had been previously described. They were found to occupy the latter position in frogs exposed to the light. The change was found to be constant and to depend on contraction and relaxation of the inner part of the inner limb of the cone, which Engelmann named the cone-myoid. In the dark position, the ellipsoidal body of the cone is situated between the outer limbs as far back as the retracted pigment, and connected with the nucleus of the cone in the external nuclear layer by a narrow process,—the elongated cone-myoid. In the light position, the body of the internal limb was directly continuous with the nuclear portion. The degree of lengthening observed was greater the more speedy the process of hardening for examination, the cone-myoid having a tendency to contract on the action of the hardening reagent. The greatest difference in length was observed in frogs and fishes; it was less marked, though distinctly present, in birds and mammals. The contraction with light took place rapidly, the maximal contraction occurring in a few minutes; extension in the dark was more gradual. In the twin cones observed in the frog's retina, only one of the two showed differences of length. The degree of action of the different parts of the spectrum was not very fully investigated, but the violet end appears to be the most active. The influence of the coloured globules found in the outer ends of the inner limbs of the cones of birds and some reptiles was investigated. The degree of contraction did not seem to depend on the globules, for in the tortoise, with intensely coloured globules, very little, if any, change in length was observed. It was found that cones with red globules were affected most by green light, but, on the other hand, in the red area of the dove's retina, the cones with small red globules scattered through the whole length of the internal limb, shortened less actively than others in green light. The cones with orange, yellow, or green globules showed in general no distinctive action.

The Röntgen rays have no influence on the movements of cones or of pigment, both being found in the dark position when the retina has been exposed in a dark box to their influence (Pergens, Gatti).

Influence of nervous system on movements.—It has already been stated that the bleaching of visual purple is confined to the eye that is acted on by light. This is not the case with the movement

¹ *Arch. f. d. ges. Physiol.*, Bonn, 1885, Bd. xxxv. S. 498; and *Arch. f. Ophth.*, 1888, Bd. xxxiii. Abth. 3, S. 229.

of the pigment and cones. Engelmann¹ found that if only one eye of a frog was exposed to light, both eyes showed the forward position both of pigment and cones. After removal of the brain, the changes were limited to the eye acted on. Engelmann concluded that there were centrifugal "retino-motor" fibres in the optic nerve. The same position as that due to light was also brought about by means of strychnin, and by the application of tetanising currents to the eye. Engelmann also found that the same forward movement occurred on stimulation of the skin. A frog with the anterior half of the body protected from light, and the posterior half exposed, showed the light position, especially of the pigment. A. E. Fick² objected that variations in the position of pigment occurred in dark frogs; that results similar to those of Engelmann occurred after section of the optic nerve; and that the experiment showing the influence of skin stimulation was vitiated by the interference with respiration caused by the covering of the anterior half of the animal. Fick only observed the position of the pigment. Nahmacher³ observed the position of the cones in a large number of frogs. He used chemical stimulation of various parts with and without previous section of the optic nerve. After stimulation of the optic chiasma, he found forward position in 82·3 per cent. of the cases in which the optic nerve had not been divided, and only 18·4 per cent. in those with divided nerve. Further evidence in favour of centrifugal influence was derived by Engelmann from the electrical behaviour of the two eyes, and the weight of evidence seems to be distinctly in favour of the existence of "retino-motor" fibres in the optic nerve.

There seems now to be definite anatomical evidence of the existence of such centrifugal fibres, which pass from the nerve fibre layer directly into the inner reticular layer, and then either terminate in free endings near the border of the inner nuclear layer (Ramón y Cayal),⁴ or join the cells in that layer (Dogiel).

Microchemistry.—Certain other differences between a retina which has, and one which has not, been exposed to light have been noted. The reaction of the former is said to be acid, that of the latter alkaline. Birnbacher⁵ found the illuminated retina stained yellow with eosin, while the dark retina was coloured an intense pink. With Biondi-stain the cones of the former were coloured green, those of the latter yellow. Dor⁶ has tried the effect of coloured light; with red light he found a difference in the staining of rods and cones; while with blue light there was no such difference. The rod and cone nuclei have been described as differing greatly in the illuminated and non-illuminated retina, being round and deficient in chromatin in the former, elongated and with abundant chromatin in the latter case (Mann,⁶ Pergens⁷).

Retinal currents.—The electrical condition of the retina, and its modifications on the action of light, have been much investigated, but their exact nature is still undetermined. When the optic nerve is connected directly with the retina, a current of rest is indicated; if connection is made with the outer side of the retina, *i.e.* with the rods, the nerve is positive, the retina negative; if, on the other hand, the

⁷ *Ann. Soc. roy. d. sc. méd. et nat. de Bruxelles*, 1896, tome v. p. 389.

inner nerve fibre side of the retina is connected, the retina is positive, the nerve negative. If the inner and outer side of the retina are connected, the former is positive, the latter negative.

If the optic nerve is connected with the eyeball, the direction of the current varies with the part of the eyeball; if with the cornea, the nerve is negative; if with the sclerotic, the nerve is positive. This is probably due to the fact that when connection is made with the sclerotic, the effect is the same as if it were connected with the rods; while in the case of the cornea, conduction takes place through the ocular media to the inner surface of the retina.

When light falls on the retina, this current undergoes a more or less complicated variation. When the isolated retina is employed, the changes are as shown in Fig. 381; on the action of light, a positive succeeded by a negative variation; on cutting off light, a positive variation. The relative amount of the variations depends on the condition of the retina; in some cases the negative variation is considerable, while the preceding positive phase is very slightly marked; in other cases the negative phase is not sufficient to bring the current back to the condi-

FIG. 381.—Steiner and Kühne. FIG. 382.—Steiner and Kühne. FIG. 383.—Steiner and Kühne.

tion at the time of the stimulus (Fig. 382). According to Kühne and Steiner,¹ this occurs when the retina is especially fresh, and they regarded it as probably the nearest approach to the normal condition; and this seems more probable from the fact that when the whole eyeball is used the negative phase is entirely absent (Fig. 383); and this phase is probably due to injury in removal of the retina. The retina is extremely sensitive to light, and shows a change with light of an intensity only just sufficient to produce sensation in the living eye. The duration of the light stimulus is of influence on the variation; the three changes described also occur with instantaneous illumination, and according to Fuchs² the positive phase is much shorter with instantaneous than with longer illumination.

Holmgren³ found that the retinal current did not depend on visual purple, and that the changes occurred in bleached eyes; but, according to Kühne and Steiner,⁴ the reaction is more intense when visual purple is present, while the bleached eye showed a marked negative phase, and sometimes even absence of the positive phase. These changes may, however, have been due to fatigue changes other than those of visual

⁴ *Ibid.*, Bd. iii. S. 354.

purple. The times taken by the various phases have been studied by Fuchs; he found a latent period of '0004 to '0061 sec.; a duration of the positive phase varying from '007 to '0181 sec.; the time to the end of the negative phase varied from '0089 to '0352 sec.

Engelmann and v. Grijns¹ found that light applied to one eye of a frog caused, after a short latent period, a marked variation of the current in the other eye, the change being an increase in the negativity of the equator in relation to the cornea. The same result is obtained with chemical stimulation of one eye. Conduction by the glandular skin of the head was excluded. The influence of other movements was also excluded by the use of curari, which was found not to prevent the movement of cones and pigment.

The effect of coloured light on the electrical variation is a point of very great importance which has not yet been satisfactorily investigated. Dewar and M'Kendrick² found that yellow light produced the largest variation, green next, and then red and blue. These and similar results obtained by other observers are probably dependent on the different intensities of the coloured lights. All colours appear to give a variation in the same direction.

Dewar and M'Kendrick³ found that the relation between luminosity of the stimulus and electrical variation was approximately the same as that existing between stimulus and sensation. When the luminosity increased from one to a hundred units, the variation was multiplied from three to six times. Waller⁴ has investigated the relation more thoroughly, and has found a logarithmic relation between stimulus and variation.

VISUAL SENSATIONS.

Introductory.—The facts of light and colour vision will now be considered, avoiding, as far as possible, reference to the physiological structures and processes concerned, and only those general and theoretical questions will be discussed which do not involve any special theory of vision. After the facts have been described, an account will be given of the known relations between visual sensations and retinal elements, and of the chief physiological theories of vision.

Visual sensations may be divided into three groups, namely, sensations of light, of colour, and of form. The perception of form is closely associated with other kinds of spatial perception, in which binocular vision and movements of the eyes are the chief physiological factors, and will be more fully dealt with in the last part of this article. In this part it will only be considered in so far as it seems to be a function of the retina without movement, as in the discrimination of two points. The sensibility for light or luminosity is very closely associated with that for colour, but the two will be considered separately as far as possible.

The character of a sensation which follows stimulation of the retina always depends on two factors,—the nature of the stimulus, and the condition of the part of the retina stimulated. Each of these factors is complex, and consequently the character of the sensation may be influenced by many circumstances, including the nature of previous stimulation of the retina; the size and position of the area stimulated; the duration of the stimulus, and the rate at which individual stimuli

¹ "Beitr. z. Psych. u. Phys. Sinn.," 1891, S. 197.

³ *Ibid.*, p. 156.

⁴ *Brain*, London, 1895, vol. xviii. p. 200; also more recently in *Proc. Roy. Soc. London*, 1900.

succeed one another; the nature of the stimulation of other parts of the same retina, of the other retina, and even of other sense organs. The influence of abnormal conditions of the retina¹ forms an important division of the subject. In addition to visual sensations arising in the usual way from stimulation by light, those due to mechanical or electrical stimulation of the eyeball have also to be considered.

Sensations of light are capable of being arranged in a continuous series, passing from the deepest black or dark to the brightest white or light; the sensations are said to differ from one another in brightness or luminosity.

Sensations of colour, on the other hand, differ from each other in three ways,—in colour-tone or hue, in brightness or shade, and in saturation or tint.

By degree of saturation is meant the extent to which a sensation of colour is fused with one belonging to the black-white series. Spectral colours have a high degree of purity or saturation, but it is possible to experience sensations of more than spectral saturation (see p. 1059).

The three characteristics of colour sensations correspond to three differences in the physical nature of the light stimulating the eye, namely, wave-length, intensity, and complexity. The correspondence, however, is not exact, and it is important to use the three physical terms only when speaking of the stimulus, and to reserve the terms, colour-tone, brightness, and saturation or purity for the sensations. It is often useful to follow the example of painters, and to speak of the colours depending on long wave-length as warm, and of those of short wave-length as cold colours.

Colour-tone, brightness, and saturation do not vary independently of one another. Brücke² found that addition of white light to a coloured light alters its colour-tone, changing it towards red, and ascribed this to a preponderance of long-wave rays in white light, which is not noticed under ordinary conditions, but becomes noticeable when the light is added to another colour. Rood,³ on the other hand, found that the only colour which remained unchanged was a greenish yellow; those on the long-wave side become more red on diminution of saturation, while those on the short-wave side deviated towards violet. He notes that all the changes were such as would be produced by the addition of violet. Alteration of brightness affects colour-tone and saturation. This, however, is closely connected with adaptation of the eye, and must be considered later.

Quantitative standards.—In order to compare the sensibility of one part of the retina with another, or of the same part under different conditions, certain methods of exact estimation have been employed. One of these is to determine the minimal stimulus capable of being perceived, the threshold of sensibility. In the use of colourless light there is only one such threshold; coloured light at low intensities appears colourless (see p. 1079), and consequently one has here to distinguish between the point at which the coloured light is seen as light, the absolute threshold, and the point at which its colour can be recognised, the specific or chromatic threshold. The interval between

¹ For the sake of brevity, the word "retina" is here and elsewhere frequently used instead of "cerebro-retinal apparatus." Since we are almost wholly ignorant in what part of the sensory system the changes determining the specific nature of a sensation take place, the latter term would be more accurate.

² *Sitzungsbd. d. k. Akad. d. Wissensch.*, Wien, 1865, Bd. li. Abth. 2, S. 461.

³ *Am. Journ. Sc.*, New Haven, 1880, vol. xx. p. 81.

the two thresholds is sometimes called the photo-chromatic interval, and differs in extent for different colours, being absent, or almost absent, in the case of red, and greatest for green, light. Another method of comparing sensibility is to find the amount by which a stimulus must be increased or decreased, in order to give a sensation which is perceived as different. The just perceptible difference or threshold of discrimination is a unit which is very commonly used in the measurement of sensibility. In the case of colourless light, this threshold is again only of one kind; for coloured light the threshold of discrimination may be determined for differences of colour-tone, brightness, and saturation.

It is also necessary to have some standard by means of which to compare different colours in respect of brightness. This is a matter of considerable difficulty, and the methods which have been devised depend on certain peculiarities of vision; the subject of hetero-chromatic photometry must be postponed till these have been considered.

A method of comparing different colours in respect of saturation, which is due to Hering, may be mentioned now, as it is capable of being employed without reference to the special theory in connection with which it is used by Hering. Under certain conditions a coloured light may appear colourless, and the white or grey with which a coloured light is matched under these conditions is known as its white "value" (*Valenz*). For the present the white value of a given light may be defined as the light with which it would be matched when seen with the dark-adapted eye at a low intensity (see p. 1078).

The number of colour-tones which can be discriminated in the spectrum is about 160, and others have to be added for the purple series. It has been found that the eye is most sensitive to change of colour-tone at two places, about the lines *D* and *F*, and is less sensitive between and on either side of these points. According to König,¹ the just perceptible difference at 640λ is 1.28λ ; at 590λ , $.26 \lambda$; at 540λ , $.68 \lambda$; at 490λ , $.16 \lambda$; and at 430λ it is 1.06λ . Uthoff² obtained similar results, while others have found the degree of sensitiveness at *D* as great as or greater than at *F*.

The number of degrees of brightness and saturation of a given colour-tone, which can be discriminated, has not been satisfactorily determined. Taking more or less rough estimates, v. Kries³ has calculated that the total number of different light and colour sensations which we are capable of experiencing would amount to about 500,000.

Limits of the spectrum.—It has been much disputed whether the limitation of the visible spectrum is due to insensitiveness of the retina to infra-red and ultra-violet rays, or whether the invisibility is due to absorption before reaching the retina. As regards the red end, this question seems to have been decided by Aschkinass,⁴ who has investigated the absorption of the ocular media by means of a spectrolometer, and found that the absorption at the visible limit only amounts to 5 per cent., and that complete absorption does not occur till 1400λ . At the other end the limitation seems to be to a considerable extent due to absorption; the limits of different individuals vary here much more than at the red end, and are probably due to differences of pigmentation of the yellow spot and of the lens. The spectrum

¹ *Arch. f. Ophth.*, 1884, Bd. xxx. Abth. 2, S. 178.

² *Arch. f. Physiol.*, Leipzig, 1889, S. 171.

³ *Ibid.*, 1882, Suppl., S. 58.

⁴ *Ztschr. f. Psychol. u. Physiol. d. Sinnesorg.*, Hamburg u. Leipzig, 1896, Bd. xi. S. 44.

shortens at this end with increasing age, apparently owing to increased pigmentation.

According to Helmholtz,¹ the ultra-violet spectrum as far as the line *R*, is visible under normal conditions, being indigo blue with slight and bluish grey with greater intensity. Its visibility is said to be increased by removal of the lens,² and it is said that this part of the spectrum then appears nearly or quite colourless. In cases in which the lens has been removed, it is also said that Röntgen rays give rise to a visual sensation, but the evidence for this is unsatisfactory. The invisibility of the infra-red rays is probably due to insensitiveness of the retina, while the ultra-violet rays fail to be seen, partly, at any rate, owing to absorption by the ocular media.

The exact limits of the visible spectrum show a certain amount of variation in individuals with normal vision, and greater variations in abnormal vision.

Visual acuity.—This is usually defined by the smallest visual angle which the line between two points must subtend, in order that the points may be distinguished as two. It has also been defined by the smallest angle at which the eye can recognise the form of an object. In practice it is most commonly tested by the power of distinguishing letters, the visual acuity being expressed by the formula $V = \frac{d}{D}$, where *D* is the distance at which the letters employed subtend an angle of five minutes, and *d* is the greatest distance at which these letters can be recognised, thus $V = \frac{5}{5}$ means that letters which subtend an angle of five minutes at 5 metres can be read at 5 metres. Such a method, though generally in use, is not satisfactory physiologically, for the perception of the form of relatively complicated objects like letters involves other than retinal factors, and Guillery³ has proposed as the test of visual acuity the smallest extent of a black point on a white ground which can be perceived at a given distance, and finds that this method gives satisfactory results. Such a point has been called the "physiological point" (Aubert). The subject of visual acuity is one of great practical importance, for it has become customary to use it much more largely as a test of the condition of the retina than either the light or colour sense.

The relation between visual acuity and intensity of illumination has been much investigated. The acuity increases with increased brightness, and this fact has been made the basis of a method of colour photometry (p. 1077). According to Posch,⁴ visual acuity increases rather more quickly than the logarithm of the intensity of illumination, and König⁵ has recently found a similar logarithmic relation. König also finds that at very low luminosities the relation between acuity and intensity differs from that at ordinary luminosities.

Extension and sensibility.—There is a definite relation between the extent of the retina stimulated and the brightness of the resulting sensation. Förster⁶ was the first to point out that brightness and visual angle supplement each other; that the smaller the one the greater must the other be in order that perception shall take place. According to Charpentier,⁷ this relation only holds for areas below a

⁷ "La lumière et les couleurs," Paris, 1888, p. 138.

certain limit, corresponding approximately to the dimensions of the fovea. Not only is the threshold of stimulation thus influenced by the size of the retinal area, but also the threshold of discrimination for light and colour. Donders¹ proposed to use the visual angle as the readiest means of measuring the colour sense, and Guillery has recently applied this method in the investigation of the sensitiveness of different parts of the retina (p. 1086). Within certain limits it seems as if a definite amount of light stimulating the retina produces the same sensory effect, whether it is spread over many or concentrated on a few retinal elements.²

It has been found that when coloured light stimulates a very small area of the retina, it may appear colourless, *i.e.* there is a photochromatic interval for stimulation of small extent. This was investigated especially by Aubert,³ who found the appearance of colour depended greatly on the nature of the background,—yellow appearing, very early on a dark, very late on a bright, background, while green appeared equally soon on both. The disappearance of the colour of small areas depends partly on the intensity of the colour, and has been made the basis of a method of colour photometry. The question is, however, complicated by the difference between vision with the fovea and with the surrounding part of the retina.

If a small field of coloured light is reduced in size till it appears colourless, it has been found that its colour may be restored, if other equally small areas are simultaneously illuminated with the same light.⁴ It seems as if a subliminal excitation in one retinal area were capable of being reinforced by similar excitations in other parts of the retina (see p. 1066).

ADAPTATION AND INDUCTION.

Adaptation.—The two chief factors on which the excitability of a given area of the retina depends, are the nature of the preceding stimulation and the condition of the surrounding retina.

The condition of excitability of the retina, depending upon the nature of the stimulation, is called adaptation. The visual apparatus has the power of adjusting itself to differences of illumination, just as it has to differences of distance. The adjustment to differences of illumination depends on two factors,—the size of the pupil, and the condition of excitability of the retina. The relation between the condition of the pupil and retinal adaptation is not yet quite clear. Schirmer⁵ has shown that the two are connected, the size of the pupil depending on the illumination to which the eye has previously been exposed, as well as on the existing illumination (see p. 1043).

Retinal adaptation was first studied by Aubert,⁶ who investigated the extent to which the sensitiveness to minimal stimulation was affected by complete exclusion of light from the eye. He found that the increase was rapid at first, the sensitiveness being multiplied fifteen to twenty times in the first two minutes. The increase took place more slowly later, and the sensitiveness had almost reached its maximum in about

¹ *Arch. f. Ophth.*, 1877, Bd. xxiii. Abth. 4, S. 282.

² Abney has recently (*Proc. Roy. Soc. London*, 1897, vol. lxi. p. 330) found a definite relation between the threshold and the diameter of the retinal area stimulated, the smallest diameter, and not the area, being the determining factor.

³ "Physiol. d. Netzhaut," Breslau, 1865, S. 108.

⁴ See A. E. Fick, *Arch. f. d. ges. Physiol.*, Bonn, 1888, Bd. xliii. S. 445.

⁵ *Arch. f. Ophth.*, 1894, Bd. xl. Abth. 5, S. 8.

⁶ "Physiol. d. Netzhaut," Breslau, 1865, S. 25.

twenty minutes, but continued to increase slightly for two hours, when it was thirty-five times greater than at first. Charpentier¹ found the rapidity of the increase corresponded to that described by Aubert, but described the amount of increase as much greater, the eye completely adapted to darkness being able to see light one thousand (in one case two thousand five hundred) times less intense than after exposure to bright light. In adapting the eye to various illuminations, he found that the sensitiveness increased much more rapidly as complete darkness was approached. According to Charpentier, the increase of sensitiveness is wholly due to the retinal condition, and is unaffected by differences in the size of the pupil. Adaptation to bright illumination after being in the dark, takes place much more rapidly than adaptation to darkness.

One effect of dark adaptation is to increase the vividness of the intrinsic light of the retina, and this increase may introduce difficulties in ascertaining the threshold of sensibility for light. The two effects do not necessarily increase *pari passu*, and Aubert thought it probable that they were independent of one another, the intrinsic light being of central origin, while the increase of sensitiveness is due to the condition of the retina (p. 1096).

The retina is not only capable of adaptation to difference of luminosity, but also to differences of colour. The light which enters the eye is always more or less coloured. If coloured glasses are worn, the retina becomes adapted to the colour, and objects after a time again appear colourless. When the glasses are removed, objects appear coloured in the colour complementary to that of the glasses, and it is not till the eye has become again adapted to white light that objects appear colourless. Brücke² has shown that in the normal condition our eyes are always more or less adapted to red, owing to the light which passes through the iris and sclerotic, the effect being especially great with lateral illumination. It is then much more noticeable, because different in the two eyes. A mixture of red and green which is yellow in daylight, will appear reddish to the eye adapted to the dark. This source of error may be minimised by wearing a black, funnel-shaped shade to keep off lateral light when experiments in colour vision are carried out in a lighted room.

After-images. — When the adaptation is local, the appearances which occur are known as after-images, and may be seen in the absence of any objective light stimulus. When a limited surface is accurately fixed, it may appear to become brighter or darker according to circumstances; if coloured, it may appear to change in colour-tone, brightness, or saturation. If after a certain period of fixation the eyes are closed or directed to a grey surface, larger than the fixed surface, a part of the visual field will be seen, corresponding in form to the latter. This after-image may be of the same brightness as the original, or the reverse, and is known as positive or negative, in the same sense as in photography. If coloured, it may be of the same colour as the original, or it may be complementary. The term negative is often applied to the latter, but it is better to limit that term to denote brightness, and to speak of coloured images as homochromatic or complementary. The after-image of a colourless surface may be coloured, usually in some variety of green, and that of a coloured surface may not be exactly comple-

¹ "La lumière et les couleurs," Paris, 1888, p. 150.

² *Ann. d. Phys. u. Chem.*, Leipzig, 1851, Bd. lxxxiv. S. 418.

mentary to the original. This anomalous coloration is usually due to the abnormal nature of the white light used, or to the influence of the light passing through the sclerotic and iris. After-images are very delicate means of observing slight differences of colour, partly owing to their relatively low degree of brightness, which permits slight differences of colour to be discriminated, partly to the absence of differences of marking and texture, which in many surfaces mask slight differences of colour. It is usually possible to get rid of anomalous colour by excluding lateral light. In some cases, however, it is possible that unusual coloration may be due to an abnormal condition of the retina (Hilbert).¹

If a fixed surface is gradually replaced by a different surface, the change which has been taking place during fixation may gradually pass into the after-image. If the change is sudden, there is in the ordinary method of observation an interval between the disappearance of the surface and the appearance of the negative or complementary image. This interval is partly filled up by phenomena to be described later, requiring special means of observation. If the eyes are kept steadily fixed, the after-image may be observed to undergo periodical variations. The negative (or complementary) image disappears and reappears, the intervals being sometimes observed to be occupied by a positive (or homochromatic) image. Plateau,² who first described the appearance, observed nine variations, and a still larger number may be seen. The earlier variations occur at intervals of about three to four seconds, the later variations more rapidly, and the latter resemble in many respects the variations of minimal sensations which have been usually ascribed to variations of attention. These periodical variations of after-images were referred by Helmholtz³ to movements of the eyes. They do not, however, accompany the ordinary blinking movements of the eyelids, and the regularity of their occurrence is against this supposition. After-images are, however, influenced by movements of the eyes. Any sudden movement, or sudden change of accommodation, will make an after-image disappear; but during gradual changes after-images may be kept steadily in view.

The shortest time of exposure necessary to produce an after-image effect is very small. A coloured patch on a rotating disc will give rise, at certain rates, and with bright illumination, to a ring in the complementary colour of the patch. The after-image effect is strong enough to more than neutralise the effect of the original excitation, and shows that the complementary image occurs with exposure of a small fraction of a second.

According to Exner,⁴ there are three parts of the spectrum which are much less altered in appearance by fatigue than other parts, namely, red from the end of the spectrum to between the lines *C* and *D*, green between *E* and *b*, and blue about *G*. On the other hand, v. Kries⁵ found yellow, green, and blue least changed in colour-tone, red and yellow-green changing their hue in the direction of yellow, blue-green and violet in the direction of blue. Hess⁶ found that the appearance of a spectral light after fatigue corresponded in general to that of a mixture of this light with the complementary of the

¹ *Ztschr. f. Psychol. u. Physiol. d. Sinnesorg.*, Hamburg u. Leipzig, 1893, Bd. iv. S. 74.

³ "Handbuch d. physiol. Optik," 1867, S. 364.

⁴ *Arch. f. d. ges. Physiol.*, Bonn, 1868, Bd. i. S. 375.

⁵ *Arch. f. Physiol.*, Leipzig, 1882, Suppl., S. 113.

⁶ *Arch. f. Ophth.*, 1890, Bd. xxxvi. Abth. 1, S. 1.

fatiguing light. If the eye is exposed to a coloured light, and then exposed to its complementary light, the latter appears more saturated.

Burch¹ has recently found that when light of great intensity is used, characteristic fatigue effects are produced with four parts of the spectrum, namely, red from *A* to *B*; green in the neighbourhood of *E*; blue about half-way between *F* and *G*; and violet at and beyond *H*. In each case the eye is found to be blind to the fatiguing colour; thus after fatigue to green, the red of the spectrum is seen to pass directly into the blue. Fatigue to yellow caused disappearance of both red and green, so that only blue and violet were left. After fatigue by three of the four parts of the spectrum only one colour was seen. The red so obtained extended from *A* to a little beyond *b*; the green from *C* nearly as far as *G*.

Persistent positive image.—Under certain conditions, a positive after-image is seen, which persists for a considerable time. It differs from the ordinary after-image in not undergoing the definite periodical variations of the latter, although similar irregular variations may be observed as it becomes faint. Such a positive image is seen with the dark-adapted eye, and may be very well seen soon after waking. It occurs with very short stimulation.

The most marked positive image is that which occurs after very intense stimulation. It is bright and well-defined when the eyes are closed, but appears as a dark cloud when seen against a bright surface. Its duration depends on the intensity of the stimulus, and it may persist for minutes or hours. In its later stages it may become coloured, and may also undergo irregular variations. In cases of very intense stimulation, a similar phenomenon has been observed to persist for very long periods, and even for life; and there does not appear to be any clear distinction between this definitely pathological phenomenon and the ordinary persistent image. The latter possibly only occurs when the stimulation has been sufficiently intense to disturb the normal functions of the retina.

Another phenomenon which has been observed with strong stimulation of the retina, is coloured waning of the after-image (*farbiges Abklingen*). The image of white light may be seen to appear in a succession of colours, beginning with bright greenish blue, passing on to blue, violet, pink, and then changing to a dirty orange and yellow-green. The exact nature of the coloration varies with the intensity and duration of the stimulus. The colours have been referred to differences of persistence (p. 1068), and may also in some cases be connected with the colour adaptation of the retina.

Corona of after-image.—The after-image change in a retinal area influences and is influenced by the changes going on in surrounding parts of the retina. The most marked instance of this is the corona of an after-image. If a white patch on a black ground is fixed, the black after-image will be seen to be surrounded by a light halo. If watched, this halo may be seen to vary; at one moment it is a narrow border, at the next it broadens out, and undergoes periodical changes analogous to those of the after-image itself. If one fixes two white patches separated from one another by a narrow black strip, the part of the after-image corresponding to the strip appears very bright, and may be regarded as due to the superposition of two halos. In he

¹ *Journ. Physiol.*, Cambridge and London, 1898, vol. xxii. p. xii. and *Phil. Trans.*, London, 1899, vol. cxci. p. 1.

after-image of a black patch on a white ground, the black corona of the light after-image is much less marked. Similar appearances occur in coloured images.

On the other hand, the after-image change in a limited part of the visual field is influenced by the brightness of the surrounding parts. This was described by Hering under the name of induction. When black and white surfaces adjoin one another, the black may be observed to become brighter and the white darker on fixation. A grey patch on a ground brighter than itself will appear to become lighter when fixed; on a ground darker than itself it will appear to become darker. Martius has recently called attention to this phenomenon, and proposed it as a method of colour photometry (p. 1078).

Contrast.—The facts just given are closely connected with the subject of contrast. These appearances may be regarded as examples of reciprocal action of retinal areas on one another, and this reciprocal action is the basis of contrast. Contrast may be simultaneous or successive. Two adjoining or neighbouring parts of the visual field are influenced in their brightness and colour by this reciprocal action. This action is so rapid as to be almost instantaneous, and is then known as simultaneous contrast. During longer observation, the difference between the two parts of the field may become considerably greater, and this successive contrast is due, partly to the change mentioned at the end of the last section (Hering's successive induction), partly to movement of the eye, and consequent development of after-image effects.

Pure simultaneous contrast is most marked at first, and if steady fixation is kept up, rapidly diminishes. It is also most marked when the contrasting surfaces join one another. This maximum effect of contrast at the line of junction, however, must not be confused with marked borders, which occur during fixation, and are due to slight involuntary movements of the eyes, and consequent stimulation by one surface of the border of the retinal area previously exposed to the other surface.

FIG. 384.—Hering.

Simultaneous contrast occurs both for light and colour. Simultaneous light contrast is shown in a striking manner by an arrangement, such as in Fig. 384, in which a grey cross is placed on a surface, half of white paper and half of black velvet. The two parts of the cross will be seen to differ greatly in apparent brightness. A grey, observed against a variable background, changes in apparent brightness with every change of the background; and it may be shown, by looking through a small aperture, that these changes in brightness are not due to variations in the size of the pupil. It is an interesting example of light contrast, that a change in the illumination of a room which is not directly observed, may show itself as a change in the apparent brightness of a shadow, although there may have been no change in the actual illumination of the shadow. The delicacy of Rumford's method of photometry depends on contrast, the shadows showing slight changes of brightness much more readily than the surrounding illuminated surface.

Simultaneous colour contrast shows itself most readily on a grey

surface adjoining a coloured surface, especially when the grey surface is of medium intensity. The contrast effect is much aided by the absence of other differences between the contrasting surfaces. Differences of texture or of glaze, inequalities of surface, and similar details, obscure colour contrast very greatly. Nearly all grey papers are more or less coloured, but the colour may not be obvious on simple inspection, and may only become apparent when a disc made of the paper is rotated. A rapidly-rotating disc presents a uniform surface, which is better adapted for the discrimination of slight coloration. Hering ascribes to the same factor the visibility at a distance of a grease spot on cloth, which is imperceptible when looked at closely. It is for the same reason that colour contrast appears so well on a rotating disc, and that contrast is so much favoured by covering the induced and inducing surfaces with transparent tissue paper. The same factor also accounts for the distinctness of contrast effects in the after-image. If the after-image of Fig. 384 is observed, the two parts of the cross will be found to differ in brightness more than in the original.

It was formerly believed that contrast occurred most readily with moderate degrees of saturation, and it was supposed that the favourable effect of covering the contrasting surfaces with tissue paper was due to lessened saturation. Rollett¹ and Hering,² on the other hand, found that contrast increased with saturation. The subject has been quantitatively studied by Kirschmann,³ and by Pretori and Sachs.⁴ Two chief methods have been used. A surface coloured by contrast may be compared with an objectively coloured field; or advantage may be taken of the fact that the effect of a saturated surface on a less saturated surface of the same colour is to abolish the colour of the less saturated surface, and the contrast effect may be measured by finding the amount of colour in the less saturated surface which can just be neutralised. The latter method has been found to be the more satisfactory, and the above observers agree in finding that the contrast effect increases with increase of saturation of the inducing surface. According to Kirschmann, the former seemed approximately to increase in arithmetical, when the saturation increased in geometrical, progression. Pretori and Sachs found a definite relation between the white value of the reacting surface and the amount of colour that could be neutralised, the two increasing proportionally.

The influence of the extent of the contrast inducing surface was also investigated quantitatively by Kirschmann, who used two discs at a certain distance from one another. In the case of brightness contrast, it was found that the contrast effect increased with increase of extent of the inducing surface, the relation between the two being approximately logarithmic. Colour contrast was also found to increase with extent of the inducing surface, and apparently in the same ratio as brightness contrast.

If two surfaces of different colour adjoin a third suitable surface, the latter may be seen to be coloured by contrast, in the colour which is complementary to that which would be produced by mixture of the two inducing colours.

⁴ *Arch. f. d. ges. Physiol.*, Bonn, 1895, Bd. lx. S. 71.

Irradiation.—When a black square on a white ground is compared with a white square of the same size on a black ground, the white square seems the larger. This depends on irradiation, and is seen under various conditions. It is the cause of the apparent notch seen in the edge of a dark object against a flame. Owing to its relatively extensive contour, print is a favourable object for observing the influence of irradiation. The phenomenon has been ascribed to various causes, such as propagation of the physiological process to surrounding elements, spherical aberration, and diffraction at the pupil. There is little doubt that it is a physical phenomenon due to diffusion, for it is much more marked with a large pupil. Printed type appears very considerably reduced in size with a pupil dilated by atropin, and is restored to its normal appearance by means of a small artificial pupil.¹ Irradiation has also been referred to chromatic aberration, but it is said to occur with monochromatic light.

Homochromatic induction.²—Under certain circumstances, an induced colour may be of the same hue as the inducing colour. This occurs especially with small black or white surfaces on a strongly coloured ground. This homochromatic induction probably depends simply on dispersed light (Blix³). Aars⁴ has recently described a form of colour mixture which depends on the same phenomenon. He found that a narrow band of colour seen from a distance is altered in colour-tone when it separates two larger coloured surfaces, the induction being homochromatic. The phenomenon occurred most readily with inducing colours of short wave-length, a fact in favour of dependence on dispersion; and the mixture described by Aars is essentially of the same nature as that which occurs on mixing pigments together.

Temporal and spatial induction.—Both after-image and simultaneous contrast may be regarded as manifestations of a process of physiological induction. Stimulation of any retinal area induces an altered condition of excitability in that area (temporal induction), and an altered condition in surrounding areas (spatial induction). The change in the appearance of a surface during fixation, the after-image, and successive contrast, are examples of temporal induction. Simultaneous contrast, and some other appearances which depend on reciprocal action of different retinal areas, are examples of spatial or areal induction. The corona of an after-image depends on both temporal and spatial induction.

Hering⁵ has used induction in a different and more limited sense. By simultaneous induction he means the change during fixation in adjoining black and white surfaces; by successive induction, the persistence of the change after removal of the stimulating surfaces.

Theory of after-image.—There have been two chief rival theories of after-image. In the theory first advanced by Scherffer, of which Fechner and Helmholtz have been the chief advocates, it is supposed that after-images are due to fatigue; that the retina is relatively passive; that in the case of light the after-image is due to general diminished activity of the fatigued area; while in the case of colour it is due to

¹ *Mind*, London and Edinb., 1896, vol. , p. 71.

² This phenomenon has been named by Blix, "isochromatic induction." Isochromatic is not only a term used in physics in a different sense, but is also incorrect in this connection, meaning rather "of equal colour value."

⁴ *Ber. internat. Cong. Psychol.*, München, 1896, S. 188.

⁵ "Zur Lehre vom Lichtsinn," S. 36.

visibility of those rays to which the area has not been fatigued. An after-image seen in complete darkness is ascribed to visibility of part of the intrinsic light of the retina.

The other view, advocated by Plateau and Hering, ascribes a more active rôle to the retina, and supposes that a condition is set up antagonistic in nature to the original excitation. Plateau supposed that the variations of an after-image were due to an oscillatory process in the retina on its way to a state of rest.

The great difficulty of the former view lies in explaining the brightness of the after-images which may be seen in complete darkness. The brilliancy of these, and especially of coloured images, may be very considerable. On the fatigue hypothesis, the latter are explained as due to part of the intrinsic light, that part corresponding to the exciting rays being absent. The brightness of such an image is, however, much greater than that of the whole intrinsic light, even after prolonged stay in the dark. That the brightness of an image should be greater than that light of which it is a part, would seem an insuperable difficulty to the fatigue hypothesis, but Helmholtz brought in the influence of contrast to explain it. We have nothing with which to compare the intrinsic light of the retina, while the after-image is seen against the darker background corresponding to the rest of the retina, and its apparent brightness is heightened by contrast, *i.e.* the phenomenon is explained on psychological grounds.

Another objection to the fatigue hypothesis is, that after-images are observed most readily in the early morning, when the liability to fatigue should be slight. They also occur especially well in the young and vigorous. The periodical variations of after-images cannot be explained by fatigue, especially the appearance of a positive image between two negative phases.

Hering has devised a number of experiments directed against the fatigue explanation.¹ If a small saturated red disc on a somewhat darker grey ground is fixed, and after an interval both disc and ground are shaded, the disc will appear bluish green and much brighter than the ground.² In this experiment the retinal area in question is still being objectively stimulated by red light. The blue-green after-image would on the fatigue hypothesis be due to the visibility of part of the small amount of white light reflected by the red disc.

Hering has compared an after-image with objective light of the same colour. On the white half of a black and white surface he placed a small red disc 5 mm. from the line of junction of the black and white halves; on the black ground, 10 cm. from this line, a blue-green disc. After fixation of the line of junction close to the red disc for one minute, he fixed a point on the black surface 5 mm. from the blue-green disc, so that the subjective blue-green image could be compared with the objective blue-green disc. With suitable general illumination the after-image appeared brighter and more saturated than the disc. Here an area of the retina "fatigued" to red produces a brighter and more saturated blue-green sensation than one previously allowed to rest by exposure for one minute to a black surface, and then stimulated by blue-green light. According to Hering, this can only be due to some inherent capacity of the visual organ. The nature of this capacity must be left till his special theory is considered.

¹ For these and numerous other after-image and contrast experiments, see *Arch. f. d. ges. Physiol.*, Bonn, Bd. xliii. S. 264 and 329.

² This experiment was also carried out by Plateau, to whom it was suggested by Wheatstone (*Bull. Acad. roy. de méd. de Belg.*, Bruxelles, 1875, tome xxxix. p. 100).

The seat of after-images is another question of interest. The influence of movement of the eyeball upon after-images, and the fact that pressure on the eyeball hinders the appearance of an after-image (p. 1098), have been supposed to be in favour of their peripheral origin. Rimpler¹ found that the sensations arising from stimulation of the stump of the optic nerve, after extirpation of the eyeball, were not followed by after-images. On the other hand, Parinaud² has argued in favour of a central seat, from the fact that after excitation of one eye, a negative after-image may be seen in the other eye. This, however, is simply due to the difficulty of knowing with which eye we are receiving an impression (see p. 1136). Parinaud also states that after-images do not appear to move when the eyeball is mechanically displaced, but this observation is very doubtful.

Theory of contrast.—The old view of Johannes Müller, that contrast depended on reciprocal action of retinal areas, was at one time almost completely neglected. Contrast was referred by Helmholtz to purely psychological factors, and especially to supposed processes of unconscious inference.

In the case of colour contrast, Helmholtz's mode of explanation may be illustrated by what is usually known as Meyer's experiment, although in its essentials it was described by J. Müller.³ If a small patch of grey paper is placed on a coloured (green) surface, it becomes tinged with the complementary colour (pink) by contrast. This pink coloration is greatly increased by covering with transparent tissue paper. Helmholtz⁴ supposed that, in looking at such a surface, we seem to be looking at a background through a coloured (green) medium, the grey patch appears part of the background, and is regarded as an object seen through the green medium. It is a matter of experience that an object which appears white through a green medium must be pink, and the patch is therefore seen as pink. If a grey patch, corresponding in intensity to that under the tissue paper, is held in front of the cover, it is very little, or not at all, coloured by contrast; and, according to Helmholtz, this is due to the fact that it is regarded as an independent object, and is therefore not affected in the same way as if it were part of the background.

The mirror contrast experiment of Ragona Scina, and the colour contrast produced by rotating such a disc as Fig. 385, were explained on the same lines. In the case of the latter, the explanation was somewhat forced, it being supposed that the colours of the disc were regarded as variations of a uniform colour, such as might be produced by shadows, coloured reflections, staining by coloured liquids, or soiling by coloured powders. "In order to produce an objectively grey spot on a greenish surface, a reddish pigment would be required." Coloured shadows were regarded by Helmholtz as giving the most convincing evidence in favour of the psychological nature of contrast. On a surface illuminated both by daylight and lamplight, a shadow thrown by an object from the yellow lamplight will appear blue by contrast. Helmholtz observed through a tube the border of the coloured shadow, and, when the blue colour had developed, moved the tube, so that the eye was wholly exposed to the shadow. He found that the blue colour persisted, although there was now no contrast inducing light, and disappeared on removing the tube from the eye. It was supposed that the blue colour, produced by the illusion of judgment, persisted till removal of the tube allowed comparison with other colours, and rendered a new judgment possible.

² *Gaz. d. hôp.*, Paris, 1882, p. 459.

³ "Handbuch d. Physiol.," 1837, Bd. ii. S. 369.

⁴ "Handbuch d. physiol. Optik," 1867, S. 407.

This mode of psychological explanation has been criticised by Hering, and its application to these phenomena shown conclusively, by means of variations of the experiments, to be unwarranted.¹ In the case of all, the contrast colour may, by suitable means, be made so intense, that observers, unaware of the nature of the experiment, may not know which is the objective and which the subjective colour. In the case of Meyer's experiment, the fact that the grey patch in front of the cover is so little affected by contrast, is due to the effect of differences of texture, etc., obscuring the colour difference. Hering found that if the grey patch was carefully covered with tissue paper, so that it exactly resembled the other patch, both showed the contrast colour equally well. Another argument used by Helmholtz was, that a black line marking off the patch from the surrounding area, much diminished the contrast colour ;

FIG. 385.—The shaded rings represent the coloured portions of the disc. The other rings give on rotation a grey of medium brightness which is coloured by contrast.

but this is to be expected if, as generally acknowledged, contrast colour is most marked immediately adjoining the inducing surface. In the case of mirror contrast, Hering has devised a form of the experiment in which observers may see the most pronounced contrast effects, while wholly unaware that they are looking through a coloured medium.

Hering has shown that Helmholtz's results with the coloured shadow are due to the lack of careful fixation, and to the effect of successive contrast. After steady fixation through a tube of the line of junction of the illuminated surface and blue shadow, the after-image is seen on removing into the shadow, or on extinguishing the yellow light, the blue colour showing in the half previously illuminated, while the half previously rendered blue by contrast becomes colourless, or may even be tinged yellow. On removal of the tube, or better, on opening the tube so as not to disturb fixation, the after-image is still seen on the larger background.

Hering² has devised a binocular experiment which conclusively disproves

¹ *Arch. f. d. ges. Physiol.*, Bonn, 1887, Bd. xl. S. 172 ; and Bd. xli. S. 1 and 358.

² *Ztschr. f. Psychol. u. Physiol. d. Sinnesorg.*, Hamburg u. Leipzig, 1890, Bd. i. S. 18.

the explanation of Helmholtz. One eye looks through red and the other through blue glass at a white surface, which appears violet, owing to binocular colour mixture (p. 1124); a black patch on the white surface is doubled by converging the eyes for a nearer point, and the double images seen against the violet ground are coloured differently by contrast,—that seen by one eye being blue-green, and that seen by the other, yellow. This experiment would show that two separate illusions of judgment may occur simultaneously, one for each eye. The occurrence of mixture of contrast colours is also in favour of their physiological origin.

A simple but striking experiment, illustrating both temporal and spatial induction, is given by Hering.¹ Place two broad white strips of paper on black velvet, so that a strip of the black, about 5 mm. wide, is left between them. If a point is fixed on the black strip, this will be seen to become lighter, and, on removing the white strips to one side, after fixation for thirty seconds, the black strip will become much brighter, and, with suitable adjustment of the general illumination, may appear brighter than the objective white strips. The surfaces previously covered by the white strip are black by successive contrast, but the blackness does not seem great enough to account for the brightness of the middle strip. The same appearance may be observed with closed eyes. Hering regards the experiment as showing that the visual organ, by its own inherent capacity, can produce a greater brightness in one part of the field than is produced in another part by white light.

This experiment is still more striking if coloured (red) strips on a black ground are used. On removing the red strips, a red after-image is seen corresponding to the black strip between them, and this occurs when the green colour of the surrounding surface produced by successive contrast is hardly noticeable. This appearance is obviously closely related to the corona of the after-image.

According to Hering, the reciprocal relation of retinal areas is a fact of the most fundamental importance in vision. Its function is to counteract the effect of their regularly diffused light which surrounds every retinal image, and the reciprocity is therefore most marked at the junction of the reacting surfaces. That objects are seen with sharp outlines is due to this reciprocal action, and to the production of a retinal condition opposed in nature to the original excitation. Hering regards it as incredible that a phenomenon of such fundamental importance as contrast should not depend on some physiological mode of relation between retinal (cerebro-retinal) areas. The nature of this physiological relation will be discussed later.

Plateau,² who advocated a physiological explanation of both after-image and contrast, referred them to oscillations in time and space respectively. The periodical variations of an after-image were examples of the former kind of oscillation, while he regarded irradiation and contrast as due to a similar oscillatory condition, passing outwards in the retina from the place of stimulation.

The phenomenon described on p. 1056, in which subliminal excitation in a small retinal area is reinforced by stimulation of other areas of the retina by the same kind of light, seems to be an instance of induction opposed in nature to the ordinary form. It ceases, however, to be contradictory, if one assumes that the opposed state induced in the retina by stimulation of one part, reacts on the inducing surface. When a number of small retinal areas are stimulated, the induced change will be more intense than in the case of only one area, and the effect of the reaction may be sufficient to raise the colour of the small areas above the threshold.

¹ *Arch. f. d. ges. Physiol.*, Bonn, 1888, Bd. xliii. S. 266.

² *Bull. Acad. roy. de méd. de Belg.*, Bruxelles, 1876, tome xlii. p. 684.

While there is now no doubt that the general phenomenon of contrast may be referred to a process of physiological induction, there are certain features of contrast which are at present wholly unintelligible physiologically, and these can only be expressed as facts in psychological terms. Thus, the obscuration of slight differences of colour or brightness in two objects by other differences, such as inequalities of surface and differences of texture, can only at present be given as a psychological fact. Waller¹ has described an experiment, in which, when a coloured surface is placed on either side of the middle third of a grey strip, the contrast colour in the strip is barely perceptible. If, now, the middle third is marked off by placing a pin across the strip at each end, the contrast colour appears distinctly. One can only give this as an example of the psychological fact that colour contrast is favoured when the induced surface is sharply marked off from surrounding parts. Sherrington² has pointed out that individuals may see a difference of colour between two surfaces, due to contrast, until they are convinced that the two surfaces are objectively alike, and may then fail any longer to see the difference in colour. In this, as in other cases, the psychological factors tend to mask the appearances which depend on the physiological reciprocity of adjoining retinal areas.

THE DURATION OF STIMULUS AND SENSATION.

Duration and sensibility.—In the section on after-image the factor "duration" has been to some extent considered. In this case, however, attention was limited to the altered condition of sensibility which remains for considerable periods after retinal stimulation. In this and the following sections facts will be considered which illustrate the relation of the duration of the stimulus to the duration of the sensation. However short the duration of the stimulus, the sensation which arises lasts for an appreciable time, and this phenomenon may be termed persistence of vision. It has also been termed positive after-image, but it would probably be better to limit the term "after-image" to those more or less prolonged manifestations dealt with in the previous sections.

It has been found that the threshold of sensibility depends upon the duration of the stimulus within certain limits, *i.e.* for durations between .002 and .125 sec. (Charpentier).³ A feeble light of short duration, which is below the threshold of stimulation, may become visible by increasing its duration; the duration necessary within the limits mentioned being inversely proportional to the intensity, so that doubling duration has the same effect on sensibility as doubling intensity. For these short intervals the effects of light on the retina appear to accumulate as they do on a photographic plate. The same inverse relation also holds between intensity and extent of retina stimulated (p. 1055), so that summation of feeble stimuli seems to occur both in time and space, and, according to Charpentier, for a given sensation a certain amount of light is necessary, and within the limits it matters little whether this amount is extended over a larger or smaller area, or reaches the eye in a longer or shorter time. Adaptation of the retina to the dark shortens the duration necessary for a sensation in the same way that it lowers the threshold. According to Charpentier, with very short duration coloured light is seen as colourless, *i.e.* for coloured light there is an interval between the absolute and chromatic thresholds of duration, but this has

¹ *Journ. Physiol.*, Cambridge and London, 1891, vol. xii. p. xlv.

² *Ibid.*, 1897, vol. xxi. p. 41.

³ *Arch. d'opht.*, Paris, 1890, tome x. p. 108.

been denied. According to Kunkel, there is a photo-chromatic interval as regards duration in the case of green and blue, but not in the case of red.

Persistence of vision.—When the retina is affected by a momentary light-stimulus of ordinary intensity, the sensory process, owing to inertia, takes a certain time in reaching its maximum, and then fades away, rapidly at first, more gradually later. These three periods may be known as the periods of rise or waxing (*Anklingen*), maximum, and fall or waning (*Abklingen*) of the sensory curve. The period of rise has been most fully investigated by Exner,¹ who used an instrument devised by Helmholtz. Two surfaces were exposed in rapid succession,—the first, a white square on a black surface; the second, a uniform white surface. It was found that if the first excitation had reached its maximum, while the second was still in the period of rise, the appearance would be that of a light square on a dark ground; if, on the other hand, both had passed the maximum, the first excitation would have fallen to a lower level than the second, and the appearance would be that of a dark square on a light ground. Between these two appearances there would be a moment at which the surface would appear uniform, and this appearance would correspond to a condition when one excitation had not quite reached the maximum, while the other had just passed it. By this method Exner found that the time taken in reaching the maximum varied with the intensity. The more intense the stimulus, the more rapid the rise of the sensory curve, and the relation between the two appeared to be such that if the intensity increased in geometrical progression, the time in which the curve reached its maximum decreased in arithmetical progression. The period of waxing in the case of different colours was determined by Kunkel² using Exner's method. He determined the times for red, green, and blue; when these colours were made of approximately equal brightness, he found that the period of rise was shortest for red and longest for green, the times taken in reaching the maximum for red, blue, or green being '0573 sec., '0916 sec., and '133 sec. respectively.

The periods of maximum and of fall are not capable of such exact investigation. By varying the intensity of his two excitations, Exner endeavoured to determine the course of the curve and the total duration of the sensory process, and found the maximum to be of very short duration followed by a gradual fall, the total duration varying with the intensity, the size of the retinal image, and the part of the retina stimulated. It is probable that the period of waning is different for different colours, but there are no exact data on this point.

Talbot-Plateau law.—One of the chief methods which has been employed to investigate the nature of the sensory curve is that of intermittent retinal stimulation. When momentary stimuli follow one another with sufficient rapidity, the effect is a continuous sensation of uniform brightness. The brightness of this sensation is that which would have arisen if the amount of light intermittently reaching the retina had been uniformly distributed over the whole period of stimulation. This proposition, which is known as the law of Talbot³ and Plateau,⁴ has been experimentally investigated. Helmholtz found

¹ *Sitzungsb. d. k. Akad. d. Wissensch.*, Wien, 1868, Bd. lviii. Abth. 2, S. 601.

² *Arch. f. d. ges. Physiol.*, Bonn, 1874, Bd. ix. S. 197.

³ *London, Edinburgh, and Dublin Phil. Mag.*, London, 1834, Ser. 3, vol. v. p. 327.

⁴ *Ann. d. Phys. u. Chem.*, Leipzig, 1835, Bd. xxxv. S. 457.

that a disc, such as in Fig. 386, on rotation gave a uniform grey, and that the brightness of the grey was the same as that of a surface obtained by mixing the double images of black and white strips, doubled by means of a piece of Iceland spar.¹ The law has been found to be approximately true for moderate intensities, though Fick² found that there were slight deviations. For low intensities continuous illumination gave a brighter sensation than intermittent; with stronger illumination, intermittent illumination had the greater effect, while at the upper limit of intensity employed by him the law held good. Investigators of this question have usually employed discs seen by reflected light. O. Grünbaum,³ using direct light, has found that the law does not hold above a certain intensity, the brightness of a light diminished in intensity by rotating before it alternate

FIG. 386.

open and black sectors being greater than that of the same light diminished to an equal degree in physical intensity by means of Nicol's prisms.

Flicker sensation.—When the intermittent stimulation is not sufficiently rapid to cause complete fusion, a characteristic flickering appearance is seen, and the point at which this flicker passes into a continuous sensation has been used as a means of determining the conditions which influence visual persistence. The flickering appearance alters in character with the rate of stimulation. With slow rates of rotation of a disc divided into sectors, these can at first be distinguished; increase of the rate produces a coarse and unpleasant flicker, accompanied at certain rates by a peculiar glittering appearance, and this gradually passes into a fine tremulous appearance before complete fusion occurs. Some observers have used the point of cessation of the coarse, others of the fine flicker, and it has not yet been clearly established that the two points of transition follow the same laws. It is difficult to make a clear distinction between coarse and fine flicker, and the point of cessation of the latter is that with which the most satisfactory results may be obtained.

The point of fusion depends in the first place on intensity; being raised by increase of intensity, *i.e.* more rapid stimulation is required. It has been supposed that as the intensity is increased in geometrical progression, the rapidity of stimulation necessary for fusion increases in arithmetical progression, so that with high luminosities the point of fusion is not appreciably affected by further increase. Grünbaum has found that this is only true up to a certain limit, and that as intensity is increased, a point is reached at which the point of fusion begins to fall. This only occurs when the stimulus has reached a considerable intensity, corresponding with that at which the same observer finds the Talbot-Plateau law no longer holds good. It seems probable that both changes are connected with the prolonged positive or blinding image

¹ "Handbuch d. phys. Optik," 2te Aufl., S. 483.

² *Arch. f. Anat., Physiol. u. wissenschaft. Med.*, 1863, S. 754.

³ *Journ. Physiol.*, Cambridge and London, 1898, vol. xxii. p. 433.

which follows intense stimulation of the retina (p. 1059). It is here supposed that periods of stimulation alternate with periods of complete absence of stimulation. Flicker also occurs when periods of greater and less excitation alternate, and the point of fusion is then lowered by diminution of the difference of intensity in the two periods.

There are different opinions as to the influence of the relative duration of the periods of excitation and non-excitation. Charpentier¹ found that increase of duration of the stimulation raised the point of fusion, while Marbe² found the point of fusion lowered when the more intense stimulus was prolonged in relation to the less intense.

FIG. 387.—Sherrington.

Sherrington³ has recently shown that the factors described in the previous sections as spatial and temporal induction, have an enormous influence on the point of fusion. Using a yellow, blue, and black disc (shown in Fig. 387), in which *Bl* and *Bk'* were of the same objective brightness as *Bl'* and *Bk'*, he found that the rate at which flicker ceased in the two rings differed very greatly; *Bl Bk'* requiring a much higher rate than *Bl' Bk*, the brightness of *Bl* and the darkness of *Bk'* being increased by simultaneous contrast, or spatial induction. By means of this and similar experiments, he shows conclusively that the point of cessation of flicker depends on what one may call the "physiological" intensity, and not on the physical intensity, and also furnishes a conclusive proof that simultaneous contrast rests upon a physiological basis. By means of the disc shown in Fig. 388, Sherrington further shows that temporal induction influences the point of fusion. If this disc be rotated in the same direction as a clock hand, flicker persists longer

¹ *Arch. d'opht.*, Paris, 1890, tome x. p. 340.

² *Phil. Stud.*, Leipzig, 1896, Bd. xii. S. 279.

³ *Journ. Physiol.*, Cambridge and London, 1897, vol. xxi. p. 33.

in the ring corresponding with the white space between the two black teeth, and with the black tooth between the two white notches than in the two rings enclosing it; on reversing the direction of rotation, flicker ceases sooner in this middle ring. In this experiment, the whiteness and blackness of the teeth and notches are intensified by contrast, and the effect of changing the direction of rotation shows that the fusion takes place less readily when ordinary white precedes intensified black, and ordinary black precedes intensified white, than in the opposite order. In the one case the intensified black and white have been preceded by ordinary black and white respectively, which will, by lowering sensi-

FIG. 388.—Sherrington.

bility, have lessened their intensification; while, in the other case, the intensified black and white will have been preceded by white and black respectively, and this, by increasing sensibility, will further augment the intensification due to spatial induction, and bring about an increased difference in the physiological intensities of the successive stimuli.

The influence of contrast or induction thus demonstrated by Sherrington gives a clue to a difficulty in regard to flicker which has been much discussed. Filehne¹ found that if discs of black and white sectors were rotated, the number of sectors on the disc was of influence. If a disc with four sectors be rotated n times per second in order to produce fusion, a disc with sixty-four sectors might be expected to require $\frac{n}{16}$ rotations to eliminate flicker. A higher number is, however, found necessary. His results have been confirmed by other observers. The size of the aperture through which the rotatory disc is observed is found to be of influence. The phenomenon has been explained by the fact that in the slower rotation necessary with the larger number of sectors, the movement of the contours is of influence (Marbe),² or that

¹ *Arch. f. Ophth.*, 1885, Bd. xxxi. Abth. 2, S. 20.

² *Loc. cit.*, p. 238.

it depends on movement of the eyes, and therefore becomes much less marked if the disc is observed through a slit (Schenck).¹ Grünbaum² has recently worked out a definite relation between the breadth of the sector and the diameter of the aperture through which the disc is observed, and there is little doubt that the phenomenon is due to the influence of contrast. The larger the breadth of the aperture in relation to that of the individual sector, the larger will be the fraction of the total revolution of the disc during which black and white will be exposed simultaneously, and will, by reciprocal intensification of each other, increase the rapidity of stimulation necessary to abolish flicker.

Two other factors found to be of importance are the size and position of the retinal area stimulated. Exner³ found that the duration of the sensory process varied with the size of the retinal image; the duration decreasing in arithmetical, when the size increased in geometrical, progression; and Charpentier⁴ similarly found that increase in the size of the retinal image raised the point of fusion. These observers have also found that flicker disappears less readily on the peripheral retina, especially in the dark-adapted eye, while Exner found that fusion took place more readily for the fovea than for an area 1.33 mm. from it. Bellarminoff⁵ has further found a higher frequency necessary for fusion on the nasal than on the temporal half of the retina for certain kinds of light. Exner⁶ found the point of fusion to be lowered by pressure on the eyeball (p. 1098).

Increase in the size of the retinal image and removal of the image to the peripheral retina act in the same way as increase of intensity; and the influence of these factors, and of adaptation, induction, and duration of the stimulus, all seem to be instances of a general law, that the point of fusion of intermittent stimuli, so as to produce a continuous sensation, depends, not on the physical intensities of the stimuli, but on their physiological intensities, as determined by the condition and nature of the stimulated retinal area.

The previous considerations have applied to colourless sensations. The point of fusion in the case of colour sensations seems to depend wholly upon the brightness of the colour, and to be independent of its colour tone. If coloured light stimulates the retina intermittently, it is found that the brighter the colour, the greater is the rate of stimulation necessary to cause fusion. This has led to the adoption of flicker as the basis of a method of heterochromatic photometry; and the subject will be more fully considered later, when we come to the means of determining the brightness of a colour.

Recurrent images.—It has so far been assumed that the course of the sensory curve is a simple rise and fall. Facts must now be considered which show that the curve is more complex, and that in nearly all conditions of stimulation there is a secondary process, which takes place later than that already considered, and gives rise to what may best be known as a recurrent image, to distinguish it from the after-images described on p. 1057. The recurrent image was first noticed by Purkinje,⁷ as an elliptical strip following a moving light. It has usually been

⁷ "Beobachtungen u. Versuche z. Phys. d. Sinn.," S. 111.

observed by moving the source of stimulation, when the recurrent appears to follow at a certain distance the primary image; this may be done most readily by means of a revolving mirror. The same phenomenon may also be observed with a momentary stationary stimulus. By the former method some observers have described the recurrent as immediately following the primary image, while others have seen the two separated by a dark interval. This difference has been shown by Charpentier¹ and v. Kries² to depend on the intensity of the stimulus, and on the adaptation of the eye.

Most observers have described the interval as about $\frac{1}{2}$ second; according to Charpentier it may vary from $\frac{1}{4}$ to $\frac{1}{30}$ second with intensity. By altering intensity alone v. Kries did not produce so great a difference, and he regards the length of the interval as chiefly dependent on adaptation. He found that in complete dark-adaptation the recurrent image followed the original immediately, and was brighter than to the light-adapted eye. v. Kries believes, however, that the two appearances do not depend simply on shortening of the interval, and he states that, with moderate dark-adaptation, two images may be seen, one following immediately, the other at an interval. The duration of the stimulus is also of influence; increased duration shortens the interval, and lengthens the recurrent image (Bosscha).³ The size of the recurrent image varies with intensity (Charpentier), attaining with strong light five or six times the size of the original.

The coloration of the image has been differently described. Some have seen it as colourless, whatever the nature of the stimulus; others as faintly complementary, others as violet or reddish. Hess,⁴ on the other hand, describes it as having the same colour as the original, but so faint that it can only be detected by comparing double images. According to Charpentier, it is violet with low, colourless with high, intensity; while v. Kries describes the ordinary image as faintly complementary, the image of the dark-adapted eye as colourless.

The interval between the original and recurrent image has been described as of abnormal darkness (Bidwell), or as faintly tinged in the complementary colour (Hess).

When coloured light is used for stimulation, the recurrent image varies with the part of the spectrum. Bidwell⁵ and v. Kries have failed to see any recurrent image following spectral red, and according to others it is very faint with this part of the spectrum. The brightest image is obtained by using green light, and, according to Hess, the curve representing the brightness of the image for different parts of the spectrum corresponds closely with the curve of brightness of the spectrum for the dark-adapted eye at low intensity.

v. Kries has found that the image is not seen in direct vision; that, as the moving image crosses the region of central vision, it disappears momentarily; and, using the stationary method, he has found that the region of the visual field in which it is absent has a diameter of 35 to 38 mm. at 1 metre distance.⁶ v. Kries has also found that there

⁵ *Proc. Roy. Soc. London*, 1894, vol. lvi. p. 132.

⁶ Hess (*Arch. f. Ophth.*, 1897, Bd. xliv. S. 445) denies this, while others (Samojloff and Hamaker) have confirmed v. Kries' observation. Hess also denies that the influence of adaptation is as described by v. Kries.

was no recurrent image in a case of night blindness, and in one of total colour-blindness.

Hamaker¹ has recently brought forward evidence which shows that the phenomenon is more complex than has been supposed. In addition to the recurrent image, several observers have seen others, and Hamaker clearly distinguishes four stages: the primary original image, followed immediately by a short "tail"; a secondary image, separated from the former by a dark interval; a tertiary image, lasting for two or three seconds; and a quaternary image, which is probably identical with the ordinary negative after-image. Some of the discrepancies between different observers may have been due to confusion between the secondary and tertiary images. The influence of adaptation and of other conditions is not the same for the two images.

In this and previous sections, four distinct phenomena have been distinguished which are ordinarily classed together as after-images, namely, the negative image due to local adaptation; the quasi-pathological positive image; the persistence due to inertia; and the recurrent image of Purkinje. These are four quite distinct conditions, and it has been a great source of confusion in the past, that they have all had the same name. The term after-image should be confined to the phenomenon due to local adaptation, while the other three phenomena should be termed the persistent positive image, retinal persistence, and the recurrent image. A fifth phenomenon, which is sometimes confused with after-image, is the memory-image, which in many individuals (of the visual type) not only remains after the impression, but may be recalled.

Charpentier's band.—Another phenomenon pointing to the complexity of the sensory curve, is that known as Charpentier's dark band.² If a black disc which has a white sector is rotated slowly in strong illumination, the side of the white sector which first penetrates the black ground shows a black band separated from the black ground by a similar white band. The band occurs about $\frac{1}{7}$ of a second after the beginning of the passage of the white, and lasts about the same time. It may often be seen to be followed by a series of similar less distinct black bands at uniform distance. Charpentier ascribes these bands to retinal oscillations, which he supposes to have a constant rapidity, each total oscillation lasting about $\frac{1}{3}$ of a second. The oscillations are supposed to be of two kinds, one more rapid being polarised in the direction of the yellow spot, while the other radiates in all directions.

Other appearances with intermittent stimulation.—Some other phenomena of interest occur with intermittent retinal stimulation. The flicker which occurs before complete fusion is, at a certain stage, of a glittering character, and gives the appearance of a brightness considerably greater than that of the continuous sensation; the Talbot-Plateau law being only true after complete fusion. Brücke³ described the maximum brightness with black and white sectors as occurring when there were 17.6 stimuli per second, and ascribed the appearance to the reinforcement of each white sector by the positive (recurrent) image of the preceding sector.

Exner⁴ described certain subjective appearances with intermittent stimulation as occurring especially with red, green, and blue light, while other colours appeared to be decomposed by this means, violet light

giving a red and blue figure. These appearances required intense light, and Burch¹ has recently described the spectrum as showing the three colours, red, green, and blue, most strongly with intermittent light of great intensity.

Another phenomenon which has lately attracted much attention is the appearance of colours, when a disc of black and white sectors is rotated. These colours were first observed by Fechner² in 1838, and are often called by his name. He used a disc, shown in Fig. 389,³ and found that different individuals varied greatly in the distinctness with which they saw the colours. The most usual appearance which accompanies flicker at a certain stage is one of a more or less definite pattern in yellow and blue. The colours distinctly increase in vividness with prolonged observation and with the brightness of the illumination. In recent modifications of this experiment the appearance of colour has been found to be more definite, if narrow black bands are placed on the

white sectors, or, better still, if such bands are observed through a gap in the disc. All gradations of colour may be observed depending on the relative position of the black sectors, the white sectors, and the bands. The most definite colour which is seen is red, and Bidwell⁴ has shown that this is the same phenomenon as one described by him, in which a bright object on a dark background appears, when suddenly exposed, to be surrounded by a narrow red border lasting about $\frac{1}{10}$ of a second. With brighter illumination a distinct blue-green appears,

FIG. 389.

and Bidwell⁵ has referred this to the after-image of the red effect. This appears to be an instance of the phenomenon already mentioned, in which the after-image effect may neutralise or overpower the colour of the original excitation to which it owes its origin. Some of these subjective colours are said to be visible with monochromatic illumination.

Fechner explained the phenomenon by supposing that the different colours made their appearance at different rates, in the same way that the coloured waning of after-images showed that they disappeared at certain rates. This explanation was adopted by Helmholtz,⁶ who supposed that the process in the case of red and violet was more rapid than for green, a supposition confirmed later by Kunkel (see p. 1068).

¹ *Journ. Physiol.*, Cambridge and London, 1897, vol. xxi. p. 431.

² *Ann. d. Phys. u. Chem.*, Leipzig, 1838, Bd. xlv. S. 227.

³ Fechner calls attention to the fact that, when this figure is revolved slowly in the direction of the arrow, the black seems to extend beyond its limits; when in the opposite direction, the black seems to shrink, the latter effect being the more marked.

⁴ *Proc. Roy. Soc. London*, 1896, vol. lx. p. 368.

⁵ *Ibid.*, 1897, vol. lxi. p. 268.

⁶ "Handbuch d. phys. Optik," 1867, S. 380.

It is doubtful whether the coloured bands can be explained in this way, although the distinctness of the red in Bidwell's experiments is to be expected if this colour reaches its maximum with the rapidity ascribed to it by Kunkel.

Theory of fusion with intermittent stimulation.—At first sight the most obvious explanation of fusion of discontinuous stimuli, so as to produce a continuous sensation, is derived from the analogy of muscular tetanus. The rise and fall of the sensory curve takes an appreciable time, and if a new stimulus comes in before the curve due to the previous stimulus has had time to fall, the result would be a continuous line; the occurrence of flicker would then be due to the fact that a slower rate allowed the individual curve to fall slightly before the second stimulus arrived. If this were the case, however, the intensity of the resulting sensation, with complete fusion, should be the same as that of each individual sensation at or near to its maximum. The fact known as the law of Talbot and Plateau seems therefore to negative this simple view, and renders necessary some other explanation. In order to reconcile the fusion of intermittent stimuli with the Talbot-Plateau law, it seems necessary to adopt the assumption that a less intense stimulus, occurring at a certain interval after a more intense stimulus, acts immediately in preventing the excitation set up by the former from reaching its maximum, and leads to a state of oscillation about a mean excitation, which may produce the appearance of flicker, or if slight enough may be unnoticed (remain below the threshold), and lead to the appearance of continuity in the sensory process.

As in the case of after-image, persistence has been ascribed to both peripheral and central processes. Exner¹ found that with intermittent electrical stimulation of the eyeball, light sensations were still discontinuous with a rapidity of sixty per second, while, with stimulation by light, fusion took place with about twenty-four stimuli per second. Assuming that the electrical stimuli acted on the optic nerve fibres, Exner regarded the above fact as proof of the retinal origin of persistence. Filehne² objected that, under certain conditions, sixty or more light stimuli per second give a discontinuous sensation; and Grünbaum³ has shown that the figure is still higher. Exner's proof, then, loses its validity; and there is at present no definite evidence as to the seat of visual persistence. Sherrington has shown the dependence of persistence on spatial induction or contrast, and, consequently, if the latter is central, the former must be so also. The seat of induction generally, however, is also still an open question.

THE BRIGHTNESS OF COLOUR SENSATIONS.

Colour photometry.—Numerous methods have now been devised to enable different colours to be compared in respect of brightness. The difficulty in doing this is enhanced by the fact that the relative brightness of different colours varies with the absolute intensity, a fact first noted by Purkinje, and usually known by his name.

The most widely employed method of colour photometry has been the simple direct comparison of coloured with colourless light. This method was employed by Fraunhofer in 1817, and the extensive researches of Abney⁴ and König⁵ on

¹ *Arch. f. d. ges. Physiol.*, Bonn, 1875, Bd. xi. S. 414.

² *Arch. f. Ophth.*, 1885, Bd. xxxi. Abth. 2, S. 20.

⁵ "Beitr. z. Psych. u. Phys. d. Sinn.," 1891, S. 311.

the brightness curves of normal and abnormal vision are based on this direct comparison. At first sight it seems very difficult to say with any degree of accuracy that a coloured field has the same brightness as a colourless field; and some, including Helmholtz, have been unable to make satisfactory observations of this kind, but most of those who have used the method agree that it is practicable, and gives more consistent results than might be expected from its purely subjective nature. Rood¹ and Abney tested their results by mixing two complementaries, of which they had determined the white equivalents, and found that the grey so produced was equal to the sum of the white equivalents of the components.

As might be expected, this direct method of comparison appears to be especially easy in the more simple colour system of the colour-blind.

The direct method must, however, always be more or less arbitrary; G. E. Müller² has lately objected that certain colours have a "penetrative" quality, which may be confused with brightness; and it is certainly very dangerous to draw conclusions in respect to slight individual differences of colour vision from such a method. Numerous indirect methods have now been described to determine the relative brightness in a more objective way.

One of these methods, devised by Vierordt,³ consists in finding the amount of white light which must be added to a coloured light, to render the colour of the latter imperceptible. It is, in fact, a method by which the brightness of a part of the spectrum is determined by finding its threshold of saturation. Vierordt's scale of intensities for the spectrum agrees roughly with Fraunhofer's. A similar method was employed by Draper⁴ with very different results. This observer found that with the prismatic spectrum red was the brightest colour, while with the diffraction spectrum all parts were equally bright, all colours disappearing with the same amount of added white light.

Another method is based on the principle that the degree of visual acuity depends upon intensity. This is interesting as the earliest method employed, having been used by Herschel in 1800,⁵ who determined the distinctness with which he could with the microscope observe fine details of opaque objects illuminated by the different parts of the spectrum, and placed the maximum intensity in the yellow and green. This method has been most thoroughly investigated by Macé de Lépinay and Nicati,⁶ who found for the longer wave half of the spectrum that it gave results agreeing fairly with those of Fraunhofer and Vierordt. They considered two lights as equally bright when the visual acuity in them was of the same value.

One of the most satisfactory methods is known as flicker photometry. The point at which intermittent stimuli give rise to a continuous sensation seems to depend on brightness and to be independent of colour-tone. The measurement of the intensity of sensation by means of time was suggested by Talbot⁷ in 1834, and was first put in practice by Schafhäütl⁸ and Rood.⁹ Probably the most simple application of the method is to rotate open sectors before a field half-filled with the colour whose brightness is to be determined, while the other half shows colourless light which can be varied in intensity. The two halves are judged to be equally bright, when both show a just perceptible flicker. Results obtained by this method agree closely with those obtained by other methods, and fairly closely with those derived from direct comparison.

⁸ *Abhandl. d. bayr. Akad.*, 1855, Bd. vii. S. 467.

⁹ *Am. Journ. Sc.*, New Haven, 1893, vol. xli. p. 173.

A very simple allied method¹ depends on a phenomenon described by Jastrow. If a rod be moved in front of a rotating disc on which a colour and a grey are being mixed, coloured bands will be seen following the rod, except with a certain grey in the case of each colour. The grey found to give no bands with a given colour agrees very closely with that which ceases to flicker at the same time as that colour.

Another method differing in principle is to determine the distance at which small areas of different colours become invisible. This has lately been used by Haycraft² with results agreeing very closely with those of the flicker method.

The dependence of the amount of contraction of the pupil on intensity is the principle of another method, first advocated as a general photometric method by Gorham.³ The size of the pupil is observed entoptically, and this method has, in the case of coloured papers, been found to give results closely agreeing with the flicker method.⁴ A different application of the method has been made by Haycraft,⁵ who measured the size of the pupil, when exposed to different parts of the spectrum, on photograms obtained by the flash-light, and obtained a curve of luminosity of the spectrum agreeing with that of flicker.

Another method proposed by Martius⁶ depends on the fact that a coloured patch becomes darker on fixation when on a background darker than itself, lighter when on a lighter ground. Accordingly, the intensity of a grey on which a coloured patch appears to become neither lighter or darker may be taken as a measure of the brightness of the colour. Martius found it more convenient to use a grey patch on a coloured ground owing to absence of disturbance by the complementary colour of the after-image, and the brightness of a series of coloured papers was found by this method to agree fairly with the results of Fraunhofer and Vierordt. The results, however, differ considerably from those of other methods.

The various methods which have been described give results which, on the whole, agree with one another. Haycraft found a close agreement between the flicker and distance methods, and the flicker, band, and pupil methods also give concordant results, and agree approximately with the results of direct comparison. The assumption that the attribute which is being measured by these methods is brightness, rests partly on the correspondence with direct comparison, but more on the fact that a method, such as flicker, seems to be reliable as a means of determining the brightness of different physical lights of the same colour, in which case its results can be checked by the ordinary physical methods of photometry. As it measures brightness in that case, we may conclude that it also measures brightness in the case of lights of different colours, although it is difficult to exclude the possibility that it may also be in some degree affected by the wave-length. In the section on retinal persistence and flicker, it was stated that probably flicker depends wholly on intensity and not on wave-length, and this statement rests to a great extent on the reliability of flicker as a photometric test.

Purkinje's phenomenon.—One difficulty of colour photometry is at the same time a phenomenon of great interest. The relative brightness of different colours varies with the absolute intensity. Purkinje observed that a red and a blue, which appeared equally bright with ordinary illumination, differed in brightness at lower intensities, the

¹ *Journ. Physiol.*, Cambridge and London, 1897, vol. xxii. p. 137.

² *Ibid.*, vol. xxi. p. 126.

⁵ Communication to Physiological Society, not yet published.

⁶ "Beitr. z. Psych. u. Phil.," Leipzig, 1896, Bd. i. S. 95.

blue becoming the brighter. This is a special case of a more general phenomenon, which has since been named after Purkinje, namely, that with decrease of the intensity of the spectrum, the short wave end becomes relatively brighter. The question how far this change is a function of the altered intensity as such, and how far of the altered condition of adaptation of the eye, will be considered later.

It has already been stated that, with the exception of red, all colours appear colourless at a low intensity, and Purkinje's phenomenon attains its maximum effect when the intensity has been so far reduced as to produce a colourless spectrum. The brightest part of the spectrum is then found to be in the green at *E*, or slightly on the violet side of *E*, instead of about *D*, as at ordinary luminosities. The fact that the interval between the absolute and chromatic thresholds is greatest for green, stands in relation to this phenomenon. Further, the red end of the spectrum is shortened, and is relatively much darker than in the

FIG. 390.—In this figure the red end of the spectrum is on the right-hand side, the blue on the left. The ordinates show the number of revolutions of a semi-disc per second which were found necessary to extinguish flicker. The upper curve represents a bright spectrum, the lower a dark spectrum, and the middle curve one of intermediate intensity.—Haycraft.

ordinary spectrum, while the violet end is relatively brighter. The curve of luminosity, as determined by flicker, is given in Fig. 390 together with the curves of luminosity at ordinary intensities, and in an intermediate condition.

The order in which the colours disappear on lowering the intensity of the spectrum is said to be that yellow and blue go first, violet then becoming invisible, while green persists longest. If the intensity of a spectrum is increased above the ordinary limits, it also becomes colourless, and under these circumstances yellow and blue persist, after red, green, and violet have disappeared.

The loss of colour at high or low intensities does not take place suddenly, but is preceded by a gradual decrease of saturation. Hering has pointed out that if a red and blue be compared while the intensity

is being gradually lowered, the blue will appear to become whiter and the red blacker, and the difference in saturation is in Hering's opinion the basis of the changes in apparent intensity.

Most of the work on Purkinje's phenomenon has been done by direct comparison of the brightness of different colours. Macé and Nicati used the acuity method of colour photometry, and Haycraft has recently investigated Purkinje's phenomenon for coloured papers by the flicker and distance methods. The distance method gave curves for the different colours which agreed very closely with those obtained by the flicker method. One point about which there is difference of opinion concerns the upper limit of Purkinje's phenomenon, and it is also doubtful whether the relative brightness of different parts of the spectrum varies to any appreciable extent at ordinary luminosities. This and other questions require investigation with spectral colours, and with one of the objective methods of colour photometry; probably flicker photometry would give the most satisfactory results.

We may now return to consider whether Purkinje's phenomenon is a function of intensity or of adaptation. It is generally agreed that adaptation of the eye to the dark is a necessary condition for the favourable observation of the phenomenon, but, according to Hering,¹ it is the essential factor. He varied the two conditions independently of one another, using two adjoining rooms separated by a partition, with round holes filled with coloured glass. By altering the illumination of a screen in one room, the intensity of the coloured patches could be varied, while by alteration of the illumination of the other room the eyes of the observer in this room could be brought to any degree of adaptation. It was found that if the eye remained in a condition of light-adaptation, red and blue when lowered in intensity became gradually blacker without change in relative brightness. Of the two, the red retained its colour slightly the longer, and appeared slightly brighter. On the other hand, adaptation of the eye to the dark brings about the phenomenon, without any change in the actual illumination of the patches themselves, the blue becoming whiter and brighter than the red. Hering points out that, in addition to the ordinary adaptation on prolonged stay in the dark, a momentary adaptation occurs on lowering the illumination, and this also produces the Purkinje phenomenon, though in a less marked degree than with prolonged adaptation.

Weber's law.—The relation of the difference of stimulus, which produces a just perceptible difference of sensation, to the total stimulus, has been frequently investigated for vision. The method most widely employed has been to observe the point at which a shadow illuminated by one light just disappears (or becomes visible) against a background illuminated by two lights. In 1760, Bouguer found by this method that the difference was independent of the absolute intensity. Another method is to use Masson's disc, a white disc on which there is a narrow black band, which gives a grey ring on rotation. The breadth of the band is found, which gives a just perceptible ring with different illuminations. The results of star photometry have also been used, on the supposition that the differences between the different magnitudes represent equal differences of sensation, but this method does not appear to be satisfactory. The difference of stimulus necessary for a just perceptible difference of sensation presents great variations, which

¹ *Arch. f. d. ges. Physiol.*, Bonn, 1895, Bd. 1x. S. 519.

probably depend chiefly on the method of the investigator. It is generally put at $\frac{1}{10}$ of the total stimulus, but the delicacy of discrimination appears to be greater, the figure given by Helmholtz being $\frac{1}{107}$; by Aubert, $\frac{1}{88}$; by Schirmer, $\frac{1}{217}$; and by Ole Bull, $\frac{1}{40}$. In some individuals, the delicacy of discrimination is even higher than this.

Aubert,¹ using the shadow method, found that as the illumination diminished the threshold of discrimination increased; and Helmholtz,² using Masson's discs, found a similar departure from Weber's law at low luminosities. Kräpelin³ and Schirmer,⁴ on the other hand, found that the threshold of discrimination is constant when due attention is paid to adaptation, and that, with maximal adaptation to the illumination at which the observations are made, Weber's law is true within wide limits. Kräpelin found that the results were uninfluenced by the size of the pupil.

MIXTURE.

Colour mixture.—The mixture which occurs when an area of the retina is simultaneously stimulated by different kinds of light, may be effected in several ways. In an old method, due to Lambert, a coloured patch is placed on each side of a plate of glass held vertically, so that one patch is seen by reflected, the other by transmitted, light. The relative intensities of the two components may be varied by varying the angle at which the line of vision cuts the glass.

Mixture due to double refraction may be seen if two patches are observed through a crystal of Iceland spar, so that two of the four patches produced coincide.

In pigment colours the most usual method is by means of the colour wheel,—a method depending upon visual persistence. Spectral colours may be allowed directly to combine on a retinal area, or may be converged by means of a lens on a screen.

The colour triangle.—The representation of the facts of colour mixture by means of a geometrical diagram is due to Newton. He adopted a circle with its circumference divided into parts corresponding to the colours of the spectrum. At the centre of gravity of each of the segments corresponding to these parts, he placed a circle, with its area proportional to the amount of light of each colour entering a given mixture. The point in the diagram representing the centre of gravity of all these circles gives the nature of the mixture. A radius drawn through it gives the hue, and the distance of the point from the centre the degree of saturation.

This method of calculating the results of colour mixture was verified experimentally by Maxwell. In a colour diagram each point represents a colour. The resultant of a mixture of any two colours is found by dividing the line joining the two points of the diagram inversely as the quantity of each; thus the resultant of mixture of two parts of red with

FIG. 391.

¹ "Physiol. d. Netzhaut," S. 52.

² "Handbuch d. physiol. Optik," 1867, S. 315.

³ *Phil. Stud.*, Leipzig, 1885, Bd. ii. S. 306.

⁴ *Arch. f. Ophth.*, 1890, Bd. xxxvi. Abth. 3, S. 121.

one of green would be represented in Fig. 391 by o when $og = 2 or$; if R = quantity of red and G = quantity of green, $R \times ro = G \times og$.

If this resultant colour is mixed with a third (B), the resultant of the mixture of the three will be on the line ob , at a point determined by the quantities of each. Maxwell found that by taking these components in different proportions, one may determine the colour corresponding to every point of the triangle of which the three colours form the angles. If three suitable spectral colours are chosen, it will be possible to represent all other colours by means of such a triangle. Complementary colours in such a diagram will be placed at a distance from one another, and the resultant of their mixture to form white will be represented by a definite position within the triangle; the lines joining any two complementaries must pass through this definite point; the lines joining the point for white with any point of one side of the triangle will represent all degrees of saturation of the colour of that point from spectral purity to white. In Fig. 391, if O and B are complementaries and mixed together in approximately equal proportions to match white, w will represent the point for white, and points between o and w will represent orange in its various grades of saturation. The fact that it is possible to find three colours, and by means of their geometrical representation to deduce the results of their mixture in any proportions, is the basis of one of the chief theories of colour vision, and will be returned to in that connection and also in connection with colour blindness.

Laws of colour mixture.—The validity of this procedure depends on certain assumptions which were formulated by Grassmann,¹ as follows:—

1. Every impression of light may be imitated by mixing a homogeneous colour of a certain intensity with colourless light of a certain intensity.

2. If one of the two mingling lights be continuously altered (whilst the other remains unchanged), the impression of the mixed light also continuously changes.

3. Two colours, each of which has a constant tint and a constant intensity of the intermixed white, also give constant mixed colours, no matter of what homogeneous colours they may be composed.

A fourth assumption which Grassmann regarded as less well established was—

4. The total intensity of a mixture is the sum of the intensities of the lights mixed.

Grassmann's propositions have been investigated experimentally. The third and fourth are those about which there is most doubt. The third proposition implies that a mixture good at one intensity should hold good for all intensities, *i.e.* multiplication of both sides of an equation by the same factor should not affect the validity of the equation. According to several observers, this proposition is not true, and the alteration of an equation with altered intensity is usually described as a departure from Newton's law or rule.

The most marked examples of this deviation occur in the colour-blind, and will be considered later (p. 1090). According to König and his followers, it also occurs in normal vision. Thus Tonn² found that the complementary to a red of 670.8λ varied with the intensity, shifting from 511.8λ to 547.3λ when the intensity was reduced to a fortieth. The complementary to 586.5λ , on the other hand, showed no change

¹ London, Edinb. and Dublin Phil. Mag., London, 1854, Ser. 4, vol. vii. p. 254.

² Ztschr. f. Psychol. u. Physiol. d. Sinnesorg., Hamburg u. Leipzig, 1894, Bd. vii. S. 279.

with intensity. The alteration of an equation with intensity is, according to Ebbinghaus¹ and Franklin,² shown by matching a grey, formed by mixture from red and blue-green with one formed from yellow and blue. If these greys are made of equal intensity with ordinary illumination, it is found that, on lowering the illumination, the grey from the red and blue-green becomes decidedly the brighter, and the grey derived from blue and yellow requires a considerable addition of white light to enable it again to match the other. According to Hering,³ these changes with intensity do not occur if the fields used are of small extent, and are ascribed by him to the influence of the macular pigment; to differences in its absorption at different intensities.⁴

The experimental investigation of Grassmann's fourth proposition has been rendered difficult by our want of a suitable means of determining the intensities of the components in colour mixture. Rood and Abney, using single direct comparison of coloured with colourless light as a test of brightness, have confirmed Grassmann's fourth proposition, but the subject requires reinvestigation, with the aid of more satisfactory methods of colour photometry.

When two spectral colours, which lie nearer to one another in the spectrum than complementary colours, are mixed, the resultant has the tone of an intermediate part of the spectrum, but is generally less saturated, and usually the less saturated, the farther apart the two colours. The smallest loss of saturation occurs when warm colours are mixed, while the greatest loss of saturation occurs when green is one of the components of the mixture.

Another proposition, which may be added to those of Grassmann, has been enunciated by v. Kries⁵ and Hering.⁶ Colour mixtures good for one condition of retinal excitability are good for all conditions of excitability. A match between red and blue-green on the one side, and yellow and blue on the other, holds good after adaptation of the eye to red, as well as in the natural condition. With marked dark-adaptation, however, this rule may possibly be no longer true.

VISION OF DIFFERENT REGIONS OF THE RETINA.

Light sense of peripheral retina.—One of the factors which determines the character of the sensation due to a certain stimulus is the region of the retina stimulated. The peripheral retina will first be compared with the central region taken as a whole, and then the special differences will be considered which occur in the central region, characterising the vision of the fovea and macula. Both sets of differences may be considered under the three heads of light, colour, and form.

The condition of adaptation is of the greatest importance in relation to the sensibility to light. Those observers who have not paid any special attention to adaptation have found a gradual decrease of sensitiveness from centre to periphery, while in dark-adaptation the threshold of

¹ *Ztschr. f. Psychol. u. Physiol. d. Sinnesorg.*, Hamburg u. Leipzig, 1893, Bd. v. S. 173.

² *Proc. internat. Cong. exp. Psych.*, London, 1892, p. 104.

³ *Arch. f. d. ges. Physiol.*, Bonn, 1893, Bd. xlvii. S. 277.

⁴ In a recent paper (*ibid.*, 1898, Bd. lxx. S. 297) Tschermak, working under Hering, has found changes in colourless matches with alteration of adaptation, and ascribes the deviations to this factor, and not to the direct influence of altered intensity.

⁵ *Arch. f. Physiol.*, Leipzig, 1878, S. 517.

⁶ *Arch. f. d. ges. Physiol.*, Bonn, 1888, Bd. xlii. S. 488.

sensibility is the same in the central (except fovea) and peripheral retina, and also in different parts of the latter.

Some observers have employed the threshold as the test, and others the just observable difference, while Guillery has used the extent of the retinal image which enables discrimination of difference. No observer has compared the threshold and difference methods, both with and without dark-adaptation.

According to Schön,¹ there is a marked difference between the light sensibility of the nasal and temporal halves of the retina. He found that a point 45° from the fovea on the temporal side required, for the production of a sensation of a certain degree of brightness, three times as much light as the corresponding point on the nasal side. Guillery has also found the temporal half less sensitive, but the difference he describes is very much less than that of Schön. Neither observer mentions the conditions of adaptation.

Exner and Bellarminow have found that flicker is more marked in the periphery than in the centre of the visual field, and have inferred from this that the sensation produced by a definite stimulus is there more intense. Bellarminow, further, has found that flicker occurs more readily with stimulation of the nasal than of the temporal half, thus supporting the view of Schön. Schön has advanced a theory of binocular vision founded on this difference between the temporal and nasal halves of the retina (p. 1138).

Colour-sense of periphery.—The colour vision of the peripheral retina has been investigated by many observers with very divergent results. The divergency depends to a very great extent on neglect of such factors as adaptation, the brightness and degree of saturation of the coloured light employed, the size of the area stimulated, and the nature of the background. The sensibility is generally tested by passing over the retina from periphery to centre, or *vice versa*, patches of coloured light, and noting, first, the limits where the different colours begin or cease to be perceived; and, secondly, the changes in colour-tone, saturation, or brightness which the patches appear to undergo. In general, it may be said that the brighter and more saturated the colour, and the larger the area stimulated, the greater is the distance from the centre at which a colour can be recognised. It is generally agreed that at ordinary intensities no colours are perceived at the extreme periphery, all being perceived as some shade of grey, depending on the kind of light and on the background; but, according to many observers, including Landolt² and Charpentier,³ all colours can be recognised as far peripherally as white, if the light is made sufficiently intense.

According to Hering, the grey with which a given colour is matched at the extreme periphery of the retina is the same as the grey with which it is matched at a low intensity, and he has used this match as one means of determining the white value of a colour. v. Kries⁴ has lately determined the white value of both pigment and spectral lights for the periphery of the retina and for the dark, and found a great difference between the two, the periphery values corresponding fairly well with the normal brightness values by heterochromatic photometry.

³ "La lumière et les couleurs," Paris, 1888, p. 183.

⁴ *Centralbl. f. Physiol.*, Leipzig u. Wien, 1897, Bd. x. S. 745.

There is considerable difference of opinion on the question of the exact limits of the fields for different colours, but there is now fairly general agreement in placing the limits for blue and yellow distinctly outside those for red and green. Nearly all agree that the limits are not fixed, and are greatly influenced by intensity and the other factors mentioned.

Another important feature of peripheral colour vision is the change in tone which a coloured light appears to undergo as it passes over the retina from centre to periphery. Here again there is fairly general agreement that blue and yellow become colourless without undergoing any change in tone, while reds and greens pass through a stage in which they are seen as yellow or blue before becoming colourless. Violet is seen as blue, orange as yellow. Some observers, however, have seen yellow change to green peripherally.

On passing a large number of pigment colours over the retina from periphery to centre, Hess¹ found that nearly all showed change of colour-tone. The colours fell into two groups: one group appeared yellow and the other blue in the periphery. Each of these groups could be again divided into those which appeared red and those which appeared green as they approached the centre. In addition to these four groups, Hess found four colours which showed no change in colour-tone: these four colours formed two complementary pairs, yellow and blue, red and green. The red and green which did not change in tone were found with more difficulty than the yellow and blue, nearly all the pigments used showing a yellow or blue tone at some time in their course over the retina. The red which showed no change was bluer than the red of the spectrum. With spectral colours the same general changes were observed, but only three kinds of light could be found which showed no change in tone, in the yellow at 574.5λ , in the green at 495λ , and in the blue at 471λ . In order to produce a constant red, a certain amount of blue had to be mixed with the extreme red of the spectrum, the latter always being seen as yellow on the peripheral retina. As in the case of pigment colours, the constant yellow and blue, and red and green of the spectrum were found to be complementary pairs.

Hess also investigated the peripheral limits for the colours which did not change in tone, and found that both the white value and the "colour value" were of influence. A green and red pigment were said to have the same colour value when they had to be mixed together in equal proportions in order to make grey. When the white and colour values were made equal, Hess found that the peripheral limit of the unchangeable red corresponded with that of the green, and of the yellow with the blue. According to Hering and Hess, the outermost zone of the retina is relatively insensitive to all colours, the middle zone is insensitive to red and green, and only the central zone has normal colour vision. These zones are often spoken of as zones of total colour-blindness, of red-green blindness, and of normal colour vision respectively, but by this it is not meant that the zones are absolutely insensitive. It would, as Hess suggests, be more correct to speak of them as zones with weak colour-sense, since, with sufficiently strong intensity, all colours can be perceived to the extreme periphery. Hegg² has more recently confirmed Hess's conclusion, that the borders for red and green coincide when attention is paid to equal chromatic and white values. He found the

¹ *Arch. f. Ophth.*, 1889, Bd. xxxv. Abth. 4, S. 1.

² *Ibid.*, 1892, Bd. xxxviii. Abth. 3, S. 145.

limit for yellow about 1° smaller than that for blue, and refers this to the difference of dispersion of the two kinds of light.

Guillery¹ has recently investigated the colour-sense of the peripheral retina, by using as his measure the extent of the retinal image which enables the colour to be recognised. He found for each colour gradual increase necessary from centre to periphery. The figures for yellow and blue showed a close agreement, but differed considerably from those for red and green, which corresponded well with each other, thus confirming the result of Hess by an entirely different method. It may be mentioned here that the photochromatic interval is found to be greater for the peripheral than for the central retina, and that Hess found that a colour equation good for the central (extramacular) region also held good for the periphery.

Visual acuity of peripheral retina.—The difference between central and peripheral retina in respect of visual acuity, is far greater than for other kinds of retinal sensibility. It has been tested by finding the distance at which two points can be discriminated, and also by means of letters. Grönouw² and Guillery³ have also used lately the size of the "physiological point" as a test. Acuity is most intense in direct vision, and drops very rapidly at first, and then more slowly towards the periphery. The low degree of acuity in the periphery can be greatly improved by practice (Dobrowsky and Gaine⁴), differing in this respect from the sensibility for light and colour. The diminished acuity has been referred to four factors,—anatomical differences, want of practice, greater spherical aberration, and diminished intensity in indirect vision. It is probable that the first three of these causes all take part in the production of the difference. Koester⁵ has found that, with dark-adaptation, visual acuity is equally good in all parts of the retina, except in the fovea where it is lowered; while in light-adaptation there is an enormous increase for central vision.

Macular vision.—So far, in comparing the peripheral with the central retina, it has been assumed that the central area has uniform sensibility. This is very far from being the case. The macula, and still more the fovea, differ in their behaviour both to light and colour stimuli from that part of the central region around them which for distinction may be called the "paracentral" region.

The influence of the macula is chiefly due to its yellow pigmentation, and shows itself chiefly in colour mixture, the relative intensity of different parts of the spectrum being altered owing to the absorptive action being greater for some colours than for others. The relative degree in which the different parts of the spectrum are absorbed by the pigment of the extirpated retina was studied by Sachs.⁶ Hering had previously found no absorption of red, and Sachs found the absorption still very slight at *D*, with a slight increase between *D* and *E*, which became more rapid between *E* and *F*, reaching a maximum near *F*, then falling off slightly to the end of the violet. The influence of the macula on colour matches has been studied by Hering.⁷ He found that

⁷ *Ibid.*, 1893, Bd. liv. S. 277.

a large colourless field, produced by mixture of spectral red and blue-green, became red if reduced in size, and that a similar small colourless field became green if increased in size. Placing a screen with two apertures before such a colourless field, he found that one aperture fixed directly appeared redder and darker than the other seen indirectly. Hering explains the changes which take place in the relative intensity of colour matches on alteration of the absolute intensity by the influence of macular pigmentation (p. 1083). Breuer¹ has recently compared colour equations for the central and paracentral regions, and found that his results were in agreement with the measurements of Sachs.

Foveal vision.—If the area of the central region used in direct vision is still further reduced in size, several striking differences are found to exist between its behaviour and that of the paracentral region. The observation of the nature of vision with this region is impeded by the great difficulty of guaranteeing accurate fixation. There seems to be an instinctive tendency to look at a luminous point in such a way as to see it most distinctly, and in experiments on foveal vision this tendency has to be overcome. It is an old observation of astronomers (Herschel, Arago) that faint stars are seen best when observed indirectly, and it is now generally agreed that the threshold of stimulation for light is higher for the fovea than for surrounding parts. This diminished sensitiveness to light seems to extend to the whole of the macula, but is much more marked in its central part. Breuer found that the amount of light absorbed by the macular pigment, which probably extends throughout the foveal region, was not great enough to account for the loss of sensitiveness shown by the fovea. The difference of sensitiveness between the fovea and surrounding part is greatly increased in dark-adaptation of the eye.

The colour vision of the fovea is approximately normal. Several observers have described it as less sensitive for colour than the rest of the retina, especially for blue, and König² has lately described the fovea as blue-blind. It is a fact that a small blue field of low intensity may become invisible on direct fixation, and this is probably due to the influence of the macular pigment, which probably extends to the fovea, supplemented by the low sensibility to light of that region. At ordinary intensities, there is no doubt that blue is well perceived in foveal vision.

A feature in which the fovea has, however, a distinctive character is the absence or diminution of the photochromatic interval which occurs for the rest of the retina. According to A. E. Fick,³ Parinaud,⁴ and König,⁵ there is no interval between the absolute and specific thresholds for coloured light in the fovea, while others (Charpentier⁶ and Koster⁷) find that it exists, though less marked than in indirect vision.

A disputed point is whether Purkinje's phenomenon occurs in the fovea. In addition to the ordinary difficulties, its investigation is rendered unsatisfactory by the difficulty of comparison of different colours as regards brightness, especially for very small areas; but, according to König⁸ and v. Kries,⁹ Purkinje's phenomenon is not true of the fovea, and v. Kries notes that a small

¹ *Ztschr. f. Psychol. u. Physiol. d. Sinnesorg.*, Hamburg u. Leipzig, 1897, Bd. xiii. S. 464.

⁹ *Loc. cit.*

blue field loses greatly in intensity on approaching the fovea, while a similar red field does not. Hering¹ has found that small fields of red and green, which appear equally bright when fixed centrally, become of different brightness when observed indirectly, and points out that Purkinje's phenomenon may be produced by a change from centre to periphery of the retina.

The alteration of a colour match, with diminution of the intensity, does not, according to v. Kries, take place in foveal vision (see pp. 1090 and 1104). Hering² has stated that the deviations from Newton's law become less marked the smaller the area of the retina stimulated, and are absent when the field is made sufficiently small. Another feature of foveal vision, according to v. Kries,³ is the absence of the recurrent image of Purkinje (p. 1073).

Wilbrand⁴ and Franklin⁵ have described in the normal eye the existence of a small blind area in the neighbourhood of the fixation point, its exact position and shape varying in different observers.

COLOUR-BLINDNESS, ETC.

Colour-blindness.—This is by far the most important abnormality of vision, from the theoretical point of view. It is customary to distinguish between congenital and acquired colour-blindness. The former has been more fully studied, and its varieties seem to be better defined, than those due to disease, although for theoretical purposes the latter have advantages that the others lack. Congenital colour-blindness occurs in three chief forms: a rare form, in which all colours are confused, usually known as total colour-blindness, or monochromatic vision; the common form, in which there is confusion between red and green; and a very rare form, in which yellow is confused with blue. The latter forms are often classed together as examples of dichromatic vision.

Total colour-blindness.—There are now on record a considerable number of cases of this defect, which are undoubtedly congenital. Any colour may be confused with any other,—red with green, and yellow with blue. The spectrum is seen as a band of light differing in its different parts in brightness only; and by suitable adjustment of the relative intensities a match may be made between any two parts. The red end is in all, or nearly all, cases considerably shortened, while the violet end has the same limit as to the normal eye. A most striking feature is the nature of the curve of luminosity shown in Fig. 392. The brightest part of the spectrum in nearly all cases⁶ is the green about the line *E*, the actual maximum varying with the source of illumination, while the red end is relatively darker, the violet end relatively brighter than in the normal eye. As Hering⁷ was the first to point out, the curve of luminosity corresponds with the curve of luminosity of the normal eye at low intensities and with dark-adaptation. Matches made by Hering with dark-adapted eye were found to be good for his case of total colour-blindness, with the exception of slight differences in the blue and violet, probably referable to slight differences of macular pigmentation. This correspondence has been abundantly confirmed by other observers.

⁴ "Die Erholungsausdehnung des Gesichtsfeldes," 1896, S. 42.

⁵ *Sitzungsb. d. k. Akad. d. Wissensch.*, Berlin, 1894, S. 589.

⁶ The most definite exception is a case described by Magnus (*Centrabl. f. prakt. Augenh.*, Leipzig, 1880, Bd. iv. S. 373), in which the maximum brightness was at *D*.

⁷ *Arch. f. d. ges. Physiol.*, Bonn, 1892, Bd. xlix. S. 563.

v. Kries¹ has found that the curve of luminosity of total colour-blindness is not affected by change of intensity, and that colour equations are also not affected by change of intensity. Uthoff² has found that the equation of Ebbinghaus and Franklin (p. 1083), which is correct for the normal eye, is not so for the achromatic eye, the mixture of red and blue-green being much the brighter; in fact, the appearance of this match to the achromatic eye is the same as that found for the normal eye in the condition of dark adaptation.

Nearly all the recorded cases have presented certain features which are not found in other forms of colour-blindness, namely, diminished visual acuity, photophobia, and nystagmus. Their presence has led to total

FIG. 392.—König.

colour-blindness being regarded as a pathological condition, originating probably in early life, and differing altogether in nature from the common form of colour-blindness. As will be seen later (p. 1102), however, there is a possible explanation of these features, which makes them consistent with a developmental rather than a strictly pathological anomaly. The diminution of visual acuity seems to exist only for ordinary illumination; with feeble light, vision may be as acute or even more acute than normal, especially at first, and the visual acuity in different parts of the retina shows a very close agreement with that of the normal eye when adapted to the dark. The photophobia seems to be nearly always present in some degree; nystagmus has been recorded in most cases. Nettleship³ found a central scotoma of considerable extent in several cases of this kind, and a small absolute central scotoma has been found by many recent observers. One feature in which this differs from the common form of colour-blindness is its frequent occurrence in females. It may occur in several members of one family.

Red-green blindness.—In considering the common form of colour-blindness, it is especially difficult to avoid terms which imply theory, but

¹ *Ztschr. f. Psychol. u. Physiol. d. Sinnesorg.*, Hamburg u. Leipzig, 1897, Bd. xiii. S. 295.

² *Ibid.*, 1899, Bd. xx. S. 326.

³ *St. Thomas's Hosp. Rep.*, London, 1880, vol. x. p. 37.

since there is no doubt that the most obvious characteristic is confusion between red and green, the condition may, without prejudice, be spoken of as red-green blindness. It is now generally agreed that to individuals with this defect the spectrum is divided into two parts, separated by an interval which can be matched with white, known as the neutral band. In most cases the neutral band is very narrow, and its existence can only be demonstrated with a spectrum in which each part is free from mixture with other rays, or it may be demonstrated more roughly by finding where the colour of one end passes into that of the other. This neutral band is situated in the green or blue-green, somewhere between the lines *b* and *F*, the wave-lengths 505λ and 492λ . In other cases the neutral band is broader, and more easily demonstrated. On either side of the neutral band the spectrum appears to be of one colour, differing in its different parts in brightness and saturation only. By suitable adjustment of intensities any part of one half can be matched with any other part of that half, and a match may also be made between two parts of one half by adding white light to the one that appears more saturated. The colour of each half appears to increase in saturation from the middle outwards. Further, in all cases of this defect, it is possible to find a red and a green, each of which may be matched with white; this may be done with spectral, and less easily with pigment colours; the red which is so matched is one in which a certain amount of blue has to be added to the extreme red of the spectrum. In any given case the red and green so found are complementary, and mixed together make white to the normal eye.

Another feature common to all cases of red-green blindness is, that a colour equation which is good for normal vision is good for dichromatic vision.

Cases of red-green blindness seem to show the changes in colour matches with alteration of intensity more distinctly than in normal vision. The first observation of the kind was made by Preyer,¹ who found that the match between the neutral band and white was no longer good on change of intensity, the neutral band shifting its position towards violet when the intensity was increased. This was confirmed by König and Brodhun,² and denied by Hering, who pointed out, however, the great difficulty of determining the position of the neutral band, owing to its varying with the character of the source of light and the colour adaptation of the eye; while, if the eye is adapted to the dark in order to get rid of the latter factor, there is great diminution of the sensitiveness for slight differences of colour upon which the determination of the neutral point depends.

Brodhun³ investigated the influence of intensity on a number of equations in which a mixture of light of 615λ and 460λ was matched with intermediate parts of the spectrum. He found that a match with light of 480λ was not affected by change of intensity, but, as the wave-length of the homogeneous light increased, marked changes occurred; thus, with an intensity of one unit, light of 560λ was matched with a mixture of 49 parts of 615λ , and 428 parts of 460λ ; while, with an intensity of 32 units, the proportions were 76 and 11.4 respectively.

¹ *Arch. f. d. ges. Physiol.*, Bonn, 1881, Bd. xxv. S. 41.

² *Sitzungsb. d. k. Akad. d. Wissensch.*, Berlin, 1887, S. 311.

³ *Ztschr. f. Psychol. u. Physiol. d. Sinnesorg.*, Hamburg u. Leipzig, 1893, Bd. v. S. 323.

Hering¹ has objected to the results of König and Brodhun, that they were made with too large a field, and he found that with so small a field that the area stimulated was limited to the macula, matches at one intensity were good for any other. v. Kries and Nagel,² using a small field without absolutely accurate fixation, have compared equations with the eye adapted to bright light and to darkness, and have found a very marked difference in the two conditions. With a still smaller field, and with accurate central fixation, it was found that there was a central area of the visual field in which there was no deviation from Newton's law, and a match was good at all intensities. Two dichromats (Nagel and Stark) were able to measure this central region, and found that at 1 metre from the eye its vertical diameter was between 30 and 40 mm., these limits corresponding closely with those of foveal vision.

The two kinds of red-green blindness.—The features described are common to all cases in which red and green are confused. In respect of certain other features, these cases fall into two groups, which, in accordance with a special theory, have commonly been known as red-blind and green-blind. In the present state of the subject it is better to use terms which do not involve theory, and v. Kries has lately suggested that the names *protanopic* and *deutanopic* shall be substituted for red-blind and green-blind. These names have the disadvantage that they give no clue to the nature of the difference of vision in the two groups. The most obvious difference is in the relative brightness of the red end of the spectrum. To one group it is very dark, or even black (*i.e.* the spectrum is shortened), while to the other its brightness is approximately as great as to the normal eye, and this difference may be expressed by the terms *scoterythrous* and *photerythrous*.³ In the scoterythrous group the spectrum is more or less shortened at the red end, the amount of shortening being, however, influenced by intensity and by adaptation, especially adaptation to red. Consequently, a colour-blind case must always be compared with a case of normal vision under exactly similar conditions. In this group the maximum brightness is shifted towards *E*, as compared with normal vision. According to Abney, it is about 559 λ . In the photerythrous group the maximum brightness is about *D*, and the spectrum has approximately the same relative brightness and the same red limit as in normal vision.

The neutral band has been said to be nearer the violet end in the scoterythrous group, but this does not seem to be the case. In all cases it lies between 505 and 492 λ , but König found that its position varied within these limits, independently of the other differences. According to v. Kries, the differences in the two groups only amount to 4 to 6 λ , and this may easily be obscured by the factors mentioned in the last section.

It is a point of great theoretical importance, whether these two groups are sharply marked off from one another, or whether they are connected by transitional cases. As regards shortening, maximum brightness, and neutral band, there is no definite evidence in favour of a distinct separation without transitional cases; but in the case of certain other features the evidence appears to be conclusive.

² *Ztschr. f. Psychol. u. Physiol. d. Sinnesorg.*, Hamburg u. Leipzig, 1896, Bd. xii. S. 1.

³ I am indebted to Dr. Verrall of Trinity College, Cambridge, for suggesting these designations. They do not imply that either group see red, but only that the light which is red to the normal eye is relatively dark to one and relatively light to the other group.

In 1879, v. Kries and Küster¹ determined the amounts of spectral red and blue necessary to match a certain blue-green, and found that the cases examined fell into two sharply-defined groups. Recently, v. Kries² has determined in twenty cases the amount of lithium-red necessary to match sodium-yellow, and has found two distinct groups, the members of each differing very little from one another but very greatly from those of the other group, *i.e.* to ten parts of the yellow the members of one group required 36.3 to 40 parts of red light, while those of the other varied from 196 to 225.

Donders³ compared the relative intensities of lithium-red, sodium-yellow, and thallium-green in twenty cases of colour-blindness, and found that they fell into two widely separated groups, the relative intensities of the three lights showing a close correspondence in photerythrous and normal vision.

In two scoterythrous and two photerythrous cases, v. Kries⁴ obtained matches of a mixture of blue and red light with a number of intermediate homogeneous lights. Representing the amounts of red and blue light respectively by curves, v. Kries found that the red curves of the two scoterythrous cases corresponded closely with each other, and similarly those of the two photerythrous cases; but the red curves of the two groups differed greatly from one another, the former having its maximum at 571 λ , while that of the latter was at 603 λ . The blue curves of all four, on the other hand, showed a much closer correspondence with each other.

According to Hering and Hess, there is an almost exact correspondence between the vision of total colour-blindness and that of the extreme periphery of the normal retina, and also between red-green blindness and the red-green blind zone of the normal eye. Hess found that colour matches good for his red-green blind zone were good for two red-green blind cases of the photerythrous type.

v. Kries⁵ has lately brought forward evidence of a very different relation between the two. He finds that the curve of brightness of the spectrum at the extreme periphery of the normal eye corresponds closely with that for the paracentral region, the maximum brightness being between 608 λ and 589 λ , while the curve differs enormously from that of congenital total colour-blindness. He finds that the periphery values of the normal eye differ very greatly from those of the scoterythrous group of red-green blindness, the curve of the latter having its maximum at 558 λ . The values of a photerythrous case agree much more closely with the normal, but show a greater deviation than is found between different cases of normal vision. Polimanti⁶ has also found that the values obtained by the flicker method for lights between 664 λ and 526 λ differ in the normal and colour-blind eyes. This was especially marked in a scoterythrous case, in whom the maximal value (*i.e.* brightness) was at 565 λ by the flicker method, while the maximum for a normal eye was at 589 λ . A photerythrous case agreed much more closely with the normal, the maximum being in this case, however, displaced somewhat towards the red end of the spectrum.

Weak colour-vision and individual variations.—In addition to

these well-defined cases, others are met with which seem to show weakness rather than absence of certain colour sensations. They behave in the same way as in the complete form, but only confuse colours when they possess a low degree of intensity or saturation. Such cases, as might be expected, differ from the more complete cases in the limits of the spectrum and in the form of their luminosity curves.

Again, besides these intermediate cases, others occur in which there does not seem to be any confusion of colours, but which are in certain ways anomalous. These cases are often described as individual variations. They were first observed by Rayleigh,¹ who found that if a number of individuals matched a mixture of spectral red and green with spectral yellow, some required a much larger proportion of green than the others, while some, on the other hand, required a much larger proportion of red. The yellows matched by such individuals appear very different to the normal eye. In addition to these marked variations, slight differences occur, and these may often be found between the two eyes of the same individual.

The subject has been fully investigated by Donders² and Hering.³ Donders examined the proportions in which light corresponding to the lithium and thallium lines was mixed to match sodium light. In sixty cases, fifty-six gave results agreeing fairly, the variations being within moderate limits. In the other four cases the proportions were very different, the proportion of green to red being very much larger, 48:50 as compared with 23:77. Donders, however, unlike Rayleigh, found that these cases showed a weakened colour-sense of the same kind as in the common form of colour-blindness. Donders then examined several cases of weak colour-sense, and found that, as regards the match in question, five belonged to the second category, requiring a larger proportion of green; three other cases of weak colour-sense, on the other hand, belonged to the first category; while one case, belonging to the second category as regards Rayleigh's match, appeared to have normal colour-vision. In the complete form of red-green blindness, it was found that Rayleigh's match was no longer possible.

Donders supposed that the results depended on a difference in the relative intensities of lithium and thallium light, but found that this was much less than could account for the condition.

Maxwell⁴ found that considerable variations occurred in the colour equations made by different individuals, and referred them to corresponding differences in macular pigmentation. This explanation has been applied and developed by Hering, not only for individual variations, but also to explain the two forms of red-green blindness. His investigations will be considered later in connection with his theory.

Blue-yellow blindness.—Cases in which there is confusion between yellow and blue are very rare. The two chief cases have been recorded by v. Vintschgau⁵ and Hering,⁶ and by Donders.⁷ The first case was very completely investigated. It was found that both yellow and blue could be matched with grey and with each other, while a match could not be made between red and green. The spectrum was shortened at each end. There was a broad neutral grey band in the yellow, extending from 598 λ to 568 λ , and the short wave-end also pre-

⁷ *Brit. Med. Journ.*, London, 1880, vol. ii. p. 768.

sented a neutral region beyond the point where colour could be perceived. The most saturated green was seen at 532λ , and the place of maximum brightness was more towards the red end, between 558λ and 565λ . The case recorded by Donders was very similar, the spectrum being shortened at each end, and the neutral band in the yellow was even broader than in the other case, extending to one-third of the length of the spectrum.

Unilateral cases.—The subjective nature of the sensations experienced by the congenitally colour-blind can, in ordinary cases, only be a matter of speculation. Individuals, who see the spectrum from the red end to the neutral band in only one colour, may nevertheless, under many circumstances, distinguish red from yellow and yellow from green, but accurate observers recognise that they are enabled to do this owing to differences of saturation. Red is especially distinguished as a dark colour with a very high degree of saturation. Most observers, such as Dr. Pole,¹ who has given a classical account of his own condition, believe that the two colours they experience correspond to the yellow and blue of the normal eye. A few cases have been recorded in which the congenital defect was unilateral, and the sensations of the defective could be compared with those of the normal eye. One such case investigated by v. Hippel² and Holmgren,³ was of the ordinary type, in which red and green are confused. There is some doubt as to the subgroup to which this subject belonged; according to Holmgren, he was a typical example of the group in which the spectrum is shortened at the red end; while, according to v. Hippel,⁴ he could distinctly see as far as the rubidium line γ , which he called faint yellow. Both agree that the two colours of this case corresponded with the yellow and blue of the normal eye, the yellow corresponding to the colour of D , and the blue to the indium or caesium line of the normal eye.

In another unilateral case recorded by Holmgren, blue and yellow were confused; the neutral band was just on the green side of D ; the two colours compared with those of the normal eye were red and green, the red corresponding to carmine and the green inclining to blue. There was no sensation corresponding to the yellow of the normal eye.

In a third unilateral case recorded by Becker,⁵ the condition was one of total or almost total colour-blindness. The defect was said to have existed from an early age. All colours were confused, with the exception of brown, which seems to have been correctly recognised. The case differed in several respects from typical total colour-blindness. There was no shortening of the red end, and slight shortening at the violet end. The point of maximum brightness was almost exactly at the sodium line. Visual acuity was normal, and no mention is made of photophobia or nystagmus.

In other unilateral cases which have been described, the defect was probably acquired.

Acquired colour-blindness.—As regards the subjective nature of the sensations experienced, it might be expected that acquired cases would be more useful than congenital, since the individual would have the memory of his normal vision as a standard. These cases, however, have been much less fully studied. Acquired colour-blindness

¹ *Phil. Trans.*, London, 1859, vol. cxlix. p. 323.

occurs in two chief forms; and it may begin by peripheral constriction of the colour fields, the defect spreading inwards, or as a central scotoma spreading outwards. In both cases red and green seem to be almost always the first colours to go, blue and yellow remaining. In acquired total colour-blindness the evidence seems to be in favour of the maximum brightness being at *D*, and not at *E*, as in the congenital form.

One distinction of importance in localised defects of retinal sensibility may be mentioned here. These defects usually occur either as cases of hemianopia or as scotomata, usually central. In some cases there is complete absence of vision in the defective part of the retina; the condition resembles that of the blind spot; and often the patient may only be made aware of his defect by special means, although in the case of hemianopia the defect is usually marked enough to attract attention spontaneously. In other cases the defective part of the field may be occupied by a cloud (*Schwarzsehen*). This appears to be common in central scotoma, but does not seem to have been recorded in hemianopia.

Santonin vision.—Abnormalities of colour-vision are found under certain other conditions. A normal individual, who has worn coloured spectacles, or been in coloured illumination for a long time, will confuse colours in a way that may resemble colour-blindness. More important is the condition produced by certain drugs, and especially by santonin. This produces yellow vision in bright light, and violet vision in the dark, while in bright light, black objects often appear to have violet borders. The violet has been regarded as an after-image effect, but it seems to occur when the eyes have been altogether kept in the dark after taking the drug. The violet end of the spectrum is shortened. There does not appear to be any marked change in other parts of the spectrum, nor anything corresponding to the neutral band of yellow-blue blindness; in fact, some observers have described the yellow of the spectrum as more intense than normal. Haidinger's brushes, and especially the yellow part, become more distinct than normally; and a definite yellow spot may be seen at the fixation point, apparently corresponding to the macula (König).¹ Schultze² supposed that the santonin effect depends upon coloration of the macula, and in favour of this is the increase in the distinctness of Haidinger's brushes, which probably depend upon the yellow spot; while, according to Preyer,³ the shortening of the violet end of the spectrum only occurs with direct vision, the violet of the spectrum again becoming visible when observed indirectly. Rose,⁴ on the other hand, advocated the view that it depends on an affection of the nervous system, and failed to find coloration of any part of the eye sufficient to account for the phenomena. It seems probable that the condition is of a different nature to yellow-blue blindness.

Picric acid is said also to produce yellow vision, and yellow vision has been described in jaundice.

Night-blindness and the vision of albinos.—Night-blindness is a condition of theoretical interest. It occurs in several abnormal conditions of the retina and choroid, but is especially well marked in retinitis pigmentosa, in which the retinal pigment layer appears to be chiefly and primarily affected. It also occurs after exposure to too strong light,

³ *Arch. f. d. ges. Physiol.*, Bonn, 1868, Bd. i. S. 299.

⁴ *Virchow's Archiv.*, 1860, Bd. xviii. S. 29.

especially in lowered conditions of nutrition, and has also been observed in connection with diseases of the liver (Parinaud).¹ There seems to be little doubt that the essential feature of the condition is abnormal slowness of dark-adaptation. It has been found that a night-blind individual may attain the same degree of sensitiveness at low intensities as normal, but requires for it a much longer period of adaptation.

Schirmer² objects to the view that night-blindness depends simply on adaptation of abnormal slowness, on the ground that, immediately after going into feeble illumination, the night-blind see much worse than normal individuals. This may, however, be connected with the momentary adaptation described by Hering (p. 1080). Treitel³ found that the bright-adapted eye, when placed suddenly in feeble illumination, behaved in many ways like the night-blind eye.

Photophobia, such as that which occurs in albinos, may be regarded as an abnormal condition of the upper limit of adaptation. It does not disappear with a small artificial pupil. Schirmer⁴ has found that in this condition the threshold is normal, and dark-adaptation takes place normally in both rate and extent.

Subjective colour sensations.—The most frequent of these is red vision, or erythroptasia. It has frequently been described as occurring after removal of the lens for cataract and after strong stimulation, such as that of light reflected from snow. It has been observed in conjunction with night-blindness. It has been produced experimentally by Fuchs⁵ by exposure to snow-light with an artificially dilated pupil. The white squares of a black and white chessboard pattern appeared red, while the black squares were greenish. The condition has been referred to entoptic vision of visual purple, but no satisfactory explanation is yet forthcoming.

Cases of other kinds of subjective colour-vision have been described, such as green vision (Somya),⁶ either affecting the whole visual field or in the form of coloured globes. Blue vision often occurs after removal of the lens for cataract. It is connected with the yellow coloration of the lens.

Intrinsic light (of the retina?).—This increases in intensity with dark-adaptation of the eye, and the variations in its appearance have been described by Aubert.⁷ Aubert regarded it as probably of central origin, and the same view has been advocated by others. Filehne⁸ found that the intrinsic light was continuous over the central scotoma of the visual field which existed in his own eye, and since his defect was probably due to affection of the nervous path, rather than of the retina, he held this to point to the central origin of the intrinsic light. It has been suggested (Dufour)⁹ that absence of vision and cloudy vision (p. 1095) may be characteristic of cortical and subcortical hemianopia respectively; and if found to be so, the fact would point to the central origin of the intrinsic light, but the clinical evidence on this point is at present scanty and conflicting.

The relation of after-image to the intrinsic light of the retina has been already mentioned. According to Helmholtz, after-images are modifications of intrinsic light; according to others, they are independent phenomena, the former being of peripheral, the latter of central origin (G. E. Müller).¹

Electrical stimulation of eye.—Not only is the eye stimulated by variations in the strength of a constant current applied to it, but, during the passage of the current, sensations arise whose quality depends upon the direction of the current. With an ascending current² the visual field becomes brighter, with a descending current the field becomes darker, even when its brightness is only due to the intrinsic light of the retina. The field is also coloured, the exact nature of the coloration having been described in different ways. With an ascending current, violet has usually been seen; with a descending current, a yellow—reddish according to Helmholtz;³ greenish according to recent careful experiments by G. E. Müller,⁴ and a number of good observers. The position of the optic disc is dark in the former case, bright and bluish in the latter, effects due apparently to spatial induction. When the stimulation ceases, the bright violet field becomes dark and yellowish; the dark yellow field becomes bright and bluish (temporal induction). The sensation which arises on sudden closing of the current has a higher intensity, but has the same character as that which continues after closure (Purkinje, G. E. Müller); thus, with closure of ascending and opening of descending current, there is a bright violet flash; with opening of ascending and closure of descending current, there is a dark greenish-yellow sensation.

An interesting point, determined by G. E. Müller, is that the condition of retinal adaptation does not appreciably influence the effect of electrical stimulation.

Mechanical stimulation and pressure blindness.—The phosphene produced by localised pressure on the accessible parts of the eyeball is blue and yellow, this being in agreement with the greater peripheral extension of the fields for these colours.

The results of mechanical stimulation of the optic nerve are very important in relation to the doctrine of specific nervous energy. It is generally supposed that when the optic nerve is cut during extirpation of the eyeball, in a conscious individual, a flash of light is experienced. This belief rests only on tradition. In 1882, Schmidt-Rimpler⁵ found that no flash occurred in several cases in which the eyeball was removed without an anæsthetic, and there is no satisfactory evidence that mechanical stimulation of the nerve produces a light sensation. On the other hand, Schmidt-Rimpler found that electrical stimulation of the stump of the optic nerve after extirpation, produced in some cases a light sensation, which was described by one individual as of the same nature as that which he had seen when treated by electricity before removal of the eyeball.

If mechanical pressure is exerted on the eyeball for some time, a condition almost amounting to blindness is induced, in which objects can

⁵ *Centrabl. f. d. med. Wissensch.*, Berlin, 1882, Bd. xx. S. 1.

no longer be distinguished (Donders). Exner¹ found that if a field half white and half black be observed while the eyeball is being pressed, the white half becomes quite dark. If a white square is then placed on the black half, it will be seen. Exner explained this experiment by supposing that, while looking at the white half, the store of material in the retina had been used up, and, owing to interference with blood supply, could not be regenerated, while on the black half the retinal material was not used up, and permitted vision of the white square. Kühne² has pointed out that the vision of the white square may be due to its greater distinctness, owing to contrast on the black ground, and found that pressure might produce blindness without the presence of light. Exner also found that pressure on the eyeball influenced the point of fusion of intermittent retinal stimuli; a black and white disc, which still flickers to a normal eye, appearing grey to a pressed eye. He found that it prevented the appearance of after-images and shortened the existence of those already present.

BINOCULAR PHENOMENA.

Adaptation.—Certain binocular relations are of importance in connection with the theories of light and colour sensation. The condition of adaptation of one eye is independent of that of the other eye. It has been clearly established that dark-adaptation of one eye does not increase the sensibility of the other eye. Charpentier³ at first thought that it did so, but found that the apparent increase of intensity was due to the consensual increase in the size of the pupil admitting more light to the eye, and was absent with a small artificial pupil.

Binocular contrast.—The influence of stimulation of one retina upon the condition of the other is best shown by producing double images of a white strip on a black ground. If, now, a coloured glass is held before one eye, and a grey glass before the other, the strip seen by the latter will appear in the colour complementary to that of the glass. Another method is to hold before one eye a card with a small hole, which will also be coloured complementarily to the colour of a glass held before the other eye. When the colour stimulus applied to the one eye is removed, the colour of the strip or of the hole will change to the colour of the glass, and this contrast colour is more marked than that which is seen at first, *i.e.* binocular contrast is more marked during the after-image effect than during the original excitation.

Another example of binocular colour contrast is known as Fechner's side-window experiment. If one stands so that light falls laterally on one eye, and a white strip of paper be doubled against a dark ground, it will be seen that the strip belonging to the more illuminated eye is darker than that belonging to the other eye, while the former is tinged green and the latter red. These features become more marked the longer the difference between the illumination of the two eyes is allowed to last. The darkness of the strip seen by one eye is explained by the "fatigue" of this eye being greater than that of the other. The different coloration of the two strips is explained partly by the fact that the light which passes through the sclerotic of the more illuminated eye, acquires a red colour (see p. 1057), and partly by binocular contrast. As

¹ *Arch. f. d. ges. Physiol.*, Bonn, 1878, Bd. xvi. S. 407; and 1879, Bd. xx. S. 614.

² *Untersuch. a. d. physiol. Inst. d. Univ.*, Heidelberg, 1882, Bd. ii. S. 46.

³ "La lumière et les couleurs," Paris, 1888, p. 177.

Hering points out, binocular contrast gives a very delicate means of determining the condition of excitability, *i.e.* of adaptation of the two eyes.

Ebbinghaus¹ has described an after-image seen by one eye after stimulation of the other eye, the after-image being of the same colour as the original; and the same phenomenon, as already mentioned, may be seen in connection with binocular contrast. This kind of after-image must be distinguished from the negative after-image which is ascribed to one eye after stimulation of the other, this phenomenon depending simply on the difficulty of telling with which eye an observation is being made (see p. 1136).

The subject of binocular colour mixture will be discussed later.

In order to explain the phenomena of binocular contrast, it is necessary either to assume a sympathetic relation between the two retinae or to ascribe them to cerebral processes. The movements, described by Engelmann, of the cones and pigment in one eye, when light is applied to the other eye, give a possible physiological basis for the retinal origin of the phenomena; but these movements probably take place too slowly, even in warm-blooded animals, to explain the almost instantaneous occurrence of binocular contrast. On the other hand, Engelmann and v. Grijs found that the electrical variation of the opposite eye occurred after a short latent period (p. 1052), and a retinal process underlying this may be the basis of the phenomenon. The alternative is that binocular contrast depends on a cerebral process, and since there seems little reason to differentiate the binocular from the ordinary form of colour contrast, this alternative would render probable the central origin of contrast generally.

FUNCTIONS OF THE RETINAL STRUCTURES.

The sensitive layer.—The facts of light and colour-vision having been reviewed, their relation to retinal structures and processes may now be considered. The chief theories of vision are based on the hypothetical existence of certain visual substances, and do not attempt to identify these substances with any known retinal structures. Quite apart from these theories, however, there are some grounds for assigning certain visual functions to certain retinal structures. The reasons which establish the rod and cone layer as the primarily sensitive part of the retina may be dealt with first.

The changes which have been described in the rods, cones, and pigment epithelium may be taken as evidence that these structures are the sensitive elements of the retina, and that the chief processes by which light vibrations are transformed into nervous impulses take place in them. Further evidence is derived from the entoptic appearances known as Purkinje's figures. These are due to shadows thrown by the retinal vessels on the sensitive elements behind, and are under ordinary circumstances invisible, owing to local adaptation. The distance of the elements behind the vessels may be calculated from the apparent movement of the figures on moving the source of illumination. Purkinje described three methods of seeing the figures: by concentrating light with

FIG. 393.

¹ *Arch. f. d. ges. Physiol.*, Bonn, 1890, Bd. xvi. S. 498.

a lens on the sclerotic, the point of light being as fine as possible and at some distance from the cornea (Fig. 393); by illuminating the eye laterally, so that the light enters the pupil and produces an image on the nasal side of the retina, while the light from this lateral image in its turn throws shadows of the retinal vessels (Fig. 394); and, thirdly, by holding a card against a brightly illuminated background, with a small hole in the anterior focus of the eye. In each case the source of illumination should be moved; by the first and third methods the apparent vertical movement of the figures will be in the same direction as the movement of the source of illumination; by the second method it will be in the opposite direction. In calculating the position of the sensitive elements, the first method is

FIG. 394.

the most satisfactory, and was used by Heinrich Müller, to whom we owe the experiment. In Fig. 393, $\alpha\beta$ may be calculated directly from AB , the apparent movement on a screen at a known distance; if $b\beta$ and aa be joined, their point of intersection, v , will give the position of the vessel. Müller measured the distance, bv and av , on frozen eyeballs, and took the mean of the variations met with; the distances, av and βv , could then be calculated. In his own eye the distance thus ascertained varied from $\cdot 17$ to $\cdot 32$ mm., for the eye of three other observers from $\cdot 19$ to $\cdot 33$. The distance between the vessels and

the rod and cone layer in man was found to be between $\cdot 2$ and $\cdot 3$ mm.

König and Zumft¹ have made use of a modification of Purkinje's third method to determine the depth of the sensitive elements for white and monochromatic lights. They held a screen with two holes closely before the eye, and obtained two shadow figures of the same vessel. These were projected on a scale, and the depth of the sensitive layer calculated from the distance of the projected figures on the scale and that between the two holes. They give the following figures:—For white light the distance from the vessel to the sensitive layer was $\cdot 4120$ mm.; for light of 670λ , $\cdot 4402$ mm.; of 535λ , $\cdot 4141$ mm.; of 434λ , $\cdot 3643$ mm. Satisfactory results were only obtained with one observer. They seemed to show that the greater the wave-length, the more deeply seated is the sensitive layer. The difference between their extreme measurements, namely, $\cdot 0759$ mm., is rather more than the thickness of the rod and cone layer, and König supposes that red light may act on the retinal pigment.

Leber and Koster² were unable to obtain two images with two holes, as in König's method, and also failed to confirm his results by another method. From König's results it should follow that Purkinje's images, projected on a field half red and half blue, should show a difference of parallax; their relative rapidity should be as $22 : 19$. They failed to observe any difference, although they found by separate experiments that a difference of $22 : 19$ in rapidity was capable of being perceived.

Evidence as to the seat of the sensitive elements of the retina has also been derived from the degree of delicacy of local discrimination in the retina. The visual angle necessary to enable two points to be distinguished has been tested by observations on stars and on fine parallel lines. The figures obtained by different observers vary from $50''$

¹ *Sitzungsber. d. k. Akad. d. Wissensch.*, Berlin, 1894, S. 439.

² *Arch. f. Ophth.*, 1895, Bd xli. Abth. 1, S. 1.

to 147.5". With fine black wires against the sky, separated from each other by a distance corresponding to the diameter of the wires, Helmholtz found for his own eye an angle of 63".75 necessary for discrimination. This corresponds in Listing's eye to a retinal distance of .00463 mm. The thickness of the cones in the macula has been determined by several observers, the figures given varying from .0015 (H. Müller) to .0054 (Kölliker). In making his observations, Helmholtz noticed at a certain distance the appearances shown in Fig. 395, *A*. He explained the appearance by the arrangement of the cones, as is shown in Fig. 395, *B*.

FIG. 395.

From the figures above obtained Helmholtz calculated the number of cones which should be found on a square millimetre, namely, 13,466; and this agrees very closely with the number of cones in a square millimetre of the fovea as counted by Sulzer,¹ about 13,500. Observations obtained by du Bois-Reymond² also agree very closely. This observer determined the distance at which a number of (460) holes in a sheet of metal were discriminated when looked at against the sky, and found that in different observers the points were perceived when they ranged from 7400 to 14,900 per square millimetre of the retinal surface. These observations, together with the nature of the vision of the peripheral retina, make it most probable that visual acuity is dependent on the cones, *i.e.* at ordinary luminosities.

Function of visual purple.—Till comparatively recently, no systematic attempt had been made to bring visual sensations into relation with any known retinal substances. When visual purple was discovered, it was hoped that it would become the basis of the physiological theory of vision, but its absence from the place of most distinct vision was so great a difficulty that it was soon neglected as an important factor in vision.

In 1867, however, before visual purple was discovered, the occurrence of rods alone in nocturnal animals had led Max Schultze³ to the conclusion that rods were in some way concerned with vision at low intensities. The chemical behaviour and great instability of visual purple suggested the same idea to Kühne.⁴ Parinaud⁵ was led by the consideration of pathological night-blindness to regard visual purple as the basis of vision at low intensities, and found this confirmed by the nature of foveal vision. Charpentier⁶ held at one time similar views. More recently the same idea has been much more fully developed, especially by v. Kries,⁷ who appears to have independently reached conclusions identical with those of Parinaud.

According to this view, the great increase of sensitiveness to light of the dark-adapted eye is due to accumulation of visual purple. The fact that adaptation to brightness takes place with much greater rapidity than to darkness, agrees with the fact that visual purple is bleached so much more rapidly than it is regenerated; and there is, further, a rough correspondence between the rates of the two processes,

⁷ *Ztschr. f. Psychol. u. Physiol. d. Sinnesorg.*, Hamburg u. Leipzig, 1895, Bd. ix. S. 81.

although much importance cannot be attached to this, owing to the fact that our knowledge of the rapidity of the changes in visual purple is derived chiefly from observations on cold-blooded animals.

The difference between the absolute and the chromatic thresholds for coloured light would be due to the sensitiveness of visual purple at low intensities being greater than that of the chromatic apparatus; and it is in accordance with this view that there should be no photochromatic interval for red light, which does not act appreciably on visual purple. Purkinje's phenomenon (p. 1078) would be due to the greater action of light of short wave-length on visual purple.

If vision with the dark-adapted eye at low intensities depends wholly on visual purple, the curve of luminosity of the spectrum should correspond with the curve of absorption of visual purple. In the absence of observations on the spectrum of human visual purple in a pure condition, this point is at present undecided.

The similar spectrum of total colour-blindness leads to the assumption that in this condition visual purple is the only substance present, and that the totally colour-blind individual is dependent for his vision wholly on this substance. The features of total colour-blindness, which have led to its being regarded as a pathological condition, namely, photophobia and diminished visual acuity at ordinary illumination, become quite natural if vision depends only on visual purple. Further, there should be an absolute central scotoma corresponding to the fovea, and this has been in several cases recorded, and may exist in all, probably varying in size in different cases. The nystagmus which is a frequent symptom may be consequently explained by absence of a place of most distinct vision, and therefore of steady fixation. It is in relation to this anomaly that this theory of the action of visual purple may be capable of objective verification; for, if true, the retina of a totally colour-blind eye might show absent or ill-developed cones. There is at present no record of the anatomical condition in this defect.

The departure from the law of colour mixture with adaptation to low intensities would also be ascribed to the influence of visual purple, a new factor coming into play as the intensity is reduced. In order that these deviations may be explained on this hypothesis of the function of visual purple, it is necessary that that side of a colour equation which becomes the brighter at low intensities should have the greater action on visual purple (the greater rod-value); and, according to v. Kries,¹ this is the case. To give one instance: in a match of a mixture of spectral red and green with homogeneous yellow, the mixed field becomes relatively brighter on diminution of intensity, owing to the especially high rod-value of the green, both red and yellow having relatively very low rod-values.

Another phenomenon, which is referred by v. Kries to visual purple, is the recurrent image. He ascribes it to the greater inertia of visual purple, so that this substance reacts to light appreciably later than the other photochromatic substance or substances, the latent period becoming, however, shorter as the intensity is increased. The fact observed by both Bidwell and v. Kries, that there is no recurrent image with red light, is very much in favour of this view, and so is the influence of adaptation on the phenomenon. In a case of night-blindness, v. Kries found that no recurrent image was perceived, although other equally

¹ *Ztschr. f. Psychol. u. Physiol. d. Sinnesorg.*, Hamburg u. Leipzig, 1896, Bd. ix. S. 81; and Bd. xii. S. 1.

unpractised individuals perceived it easily. According to v. Kries, there is no recurrent image in total colour-blindness (again only one case examined); but this is denied by Hering and Hess. Hamaker's observations (p. 1074) seem to show that the phenomenon is complicated by other processes going on at the same time.

The slow rate of dark-adaptation upon which night-blindness depends would be due to slow formation of visual purple. The two chief causes of this condition, namely, disease of the retinal pigment layer, and action of too strong light, would naturally affect the formation of the substance, while its occurrence in jaundice and in diseases of the liver would be explained by the solvent action of bile salts on visual purple. Pilocarpine is said to have a beneficial effect on night-blindness,¹ and Kühne found that this drug hastens regeneration of visual purple (p. 1045). Schirmer² has observed slowness of adaptation in cases of detached retina, and compares this condition with the slowness of the auto-regeneration described by Kühne.

Certain other facts are consistent with the theory. Exposure of one eye to light has no effect on the dark-adaptation of the other eye, while Engelmann found that exposure of one eye led to no change in the visual purple of the other eye. G. E. Müller has found that the sensations arising from electrical stimulation of the eyeballs are unaffected by the condition of adaptation, and Kühne found that visual purple was not influenced by electrical stimuli. The fact that Dor (p. 1050) found a difference in the staining of rods and cones, after the action of red light, none after blue light, is explicable if the former acts only on the cones, the latter on both rods and cones. The observations of Koester and König on visual acuity (pp. 1055 and 1086) are explicable, if the acuity of dark-adaptation depends on the rods, that of bright adaptation on the cones.

Foveal vision and absent visual purple.—The absence of rods and visual purple from the fovea gives a means of verifying the truth of the hypothesis. The difficulties of studying foveal vision have been already mentioned. Another difficulty is the uncertainty as to the anatomical limits of the area of the retina which contains no visual purple. Most observers give the foveal depression a diameter of .2 to .4 mm., while others assign it larger values. For the present purpose, however, the importance of the fovea lies in the exclusive presence of cones. Comparatively few measurements have been made of the area free from rods. Koster³ has recently examined four cases, and found the area in which rods were entirely absent varied from .44 to .901 mm., while rods were comparatively scanty in a still larger area. Koster has suggested .5 mm. as the probable average diameter of the rod-free area, and .8 mm. as that of the area in which cones predominate. There is still greater uncertainty as to the area from which visual purple is absent, for Kühne's observations seemed to show considerable individual differences, while, if his observation is correct, that the rods in the macula are devoid of purple, still larger values than those of Koster must be assigned to the area which has no visual purple.

One feature of foveal vision about which there is no doubt, is the high threshold for light. This low degree of sensitiveness to light, which is especially marked in the dark-adapted eye, would be a natural

¹ Kuschbert, *Deutsche med. Wchschr.*, Leipzig, 1884, S. 324.

² *Verhandl. d. X. internat. med. Congress*, Berlin, 1890, Bd. iv. Abth. 10, S. 63.

³ *Arch. f. Ophth.*, 1895, Bd. xli. Abth. 4, S. 1.

deduction from the theory. A second feature is the absence of the photochromatic interval for coloured light of low intensity. According to some observers, the interval is only diminished, and v. Kries supposes it possible that the colour of a light may not be perceived at very feeble luminosities when it acts on the chromatic apparatus proper, although the interval in this case is very much less than that which exists where visual purple is present. A third feature in accordance with the theory, is the absence of Purkinje's phenomenon. This rests not only on the observations of v. Kries and other advocates of the theory, but also on the independent observation of Hering, that the phenomenon may be produced by going from the centre to a more peripheral part of the visual field. According to Tschermak, both Purkinje's phenomenon and the deviations of matches occur in central vision, but to a less marked degree than elsewhere.¹ Nagel and Stark (colour-blind) have found that the deviations from Newton's law do not occur for the fovea, and they have been able to measure the area of the visual field within which colour equations hold good at all intensities, and find that it corresponds closely with the measurements of the rod-free area made by Koster. The existence of an absolute scotoma in total colour-blindness has already been mentioned. Lastly, according to v. Kries, the recurrent image cannot be seen in an area of the visual field corresponding to the fovea.

This theory of the function of visual purple has been criticised by Hering and Hess,² who have objected to the theory mainly in regard to its proposed explanation of total colour-blindness. In two cases of total colour-blindness examined by themselves, and in one examined by Pfüger, no central scotoma was found. In view of the considerable individual differences which exist in the distribution of rods and cones within the macular area, of the difficulty of detecting a small central scotoma, and of the possibility that in such abnormal individuals the absent or defective cones may be replaced by rods, the failure to detect a central scotoma in some cases does not tell seriously against the theory. Hering and Hess also found in one case of total colour-blindness that, when dark-adapted, the sensitiveness increased from the centre to the periphery of the fovea, as in the normal eye. This fact is, however, not inconsistent with the theory. Hering and Hess also found that one of their cases, a good observer, saw a recurrent image. Uthoff³ has since given a full description of a case in which there was a definite central scotoma, and other features which were all in harmony with the hypothesis that vision depended on visual purple.

Some of the peculiarities have been referred to the influence of the pigment of the macula, which probably extends throughout the fovea. Its absorptive power might explain the diminished sensitiveness to light, though, according to Breuer, the diminution is too great to be accounted for in this way.

The accumulation of evidence in favour of this theory of the function of visual purple is further supplemented by the comparative evidence which first led Schultze in this direction. Krause⁴ has found that Schultze was wrong in supposing that rods were exclusively present in nocturnal animals, cones being

¹ *Arch. f. d. ges. Physiol.*, Bonn, 1898, Bd. lxx. S. 297.

² *Ibid.*, 1898, Bd. lxxi. S. 105.

³ *Ztschr. f. Psychol. u. Physiol. d. Sinnesorg.*, Hamburg u. Leipzig, 1899, Bd. xx. S. 326.

⁴ *Internat. Monatschr. f. Anat. u. Physiol.*, Leipzig, 1886-1895.

also present in all the instances examined. Krause, however, finds that nocturnal animals are characterised by the length of the outer limbs of the rods. Krause did not pay especial attention to the presence or absence of visual purple; but there is no doubt that it is present in fishes, in nocturnal animals, and in those who live mainly underground. It is very abundant in the owl, and absent or scanty in birds whose habits are wholly diurnal. The greater length of the outer limbs of the rods found by Krause in nocturnal animals would give greater thickness in the layer of visual purple. The only known instance of a nocturnal animal whose retina is devoid of visual purple is the bat. Its minute rods show, according to Kühne, only a trace of a purple colour, but the experiments of Spallanzani and others have shown that the bat is dependent to a very slight extent upon vision, and the imperfect condition of the rods in this animal may well be the result of disuse.

If dark-adaptation depends primarily on visual purple, the question remains, whether the changes in the pigment and cones have a similar function. Their rate of occurrence is much the same as that of the bleaching and regeneration of visual purple, but the fact that the changes of cones and pigment are not limited to the eye acted on, is against their connection with adaptation being so close as is that of visual purple. There is no doubt that one function of the pigment is to supply material for regeneration of visual purple, and it can probably do this quite as efficiently when situated round the outer part of the outer limb of the rods, as in the dark position. In the light position also, it probably acts by absorbing light and preventing too violent action on the sensitive structures, and its absence will explain the photophobia of albino vision, and also the photophobia which often accompanies night-blindness in abnormal conditions of the retina.

Cerebral centres for light and colour-vision.—This is a subject on which our knowledge is very scanty. It has been supposed¹ that recorded cases in which there has been hemianopia for colours with retained light sense, are in favour of a separate cerebral centre for colour, and similar cases in which red-green blindness occurs as a hemianopic defect may similarly be held to point to separate cerebral representation of different colours. The facts known are, however, far too few to justify any definite conclusion.

THEORIES OF COLOUR-VISION.

Introductory.—If the theory of the function of visual purple considered in the preceding section is correct, it still leaves the question of colour-vision almost untouched. But certain anomalous features of colour-vision are explained by it; and if accepted, it will necessitate some modification of, at least, one of the prevailing theories of colour-vision.

There are two important assumptions common to these theories. It is assumed that the manifold colour sensations that we experience are derived from a limited number of components, these components being known as primary, fundamental, or elementary colour sensations. Any given colour sensation is to be regarded as arising by a process of fusion of two or more primary sensations. The idea appears to have had its origin in the facts of colour mixture, and it derives its strongest support from colour-blindness, which seems to be most naturally explained by the absence of one or more of the components. Although the idea is earlier than that of specific nervous energy, the two are closely connected, and the former is a necessary consequence of the latter.

The second assumption is, that the visual process is primarily photo-

¹ Schneller, *Arch. f. Ophth.*, 1882, Bd. xxviii. Abth. 3, S. 73.

chemical; that light acts primarily on certain visual substances; and that, further, these substances are limited in number corresponding to the components of sensation. The behaviour of visual purple and the analogy of photography have probably largely contributed to the general acceptance of this view, and certain of the facts of colour-vision, and especially those of persistence and induction, naturally suggest a process of this kind.

The two chief theories of colour-vision are component theories,¹ and assume the existence of a limited number of visual substances. There is no direct evidence of the existence of such substances. They are purely hypothetical factors, which enable the facts of light and colour-vision to be expressed simply and consistently.

The chief theory at present advocated which rejects the idea of components is that of Wundt, who holds that the series of colour sensations which pass into one another by insensible gradations have their basis in a series of changes in one complex substance, which similarly pass gradually into one another.

Young-Helmholtz theory.—The theory of Thomas Young, adopted by Helmholtz and Maxwell, is a component theory, and is closely

FIG. 396.—König and Dieterici.

connected with the doctrine of specific nervous energy. In its earlier form it was supposed that there were three kinds of nerve fibre in the retina corresponding to three primary colours. In its modern form these have been replaced by three photochemical substances, with three corresponding fundamental sensations. Each of the three substances is acted on by light of all wave-lengths, but on one the action of the long-wave end of the spectrum greatly predominates, on another the middle, and on the third the short-wave end. The action of the spectrum on each of the three substances is usually represented by curves such as those in Fig. 396.

¹ G. E. Müller has recently used the term "component theory" in another sense. A component theory is, according to him, one in which the sensation white is regarded as a mixture of component chromatic sensations. Used in this sense, the Young-Helmholtz is a component theory, while Hering's theory is not.

With predominant decomposition of one substance the sensation red is experienced, of the others green and violet or blue. The colours intermediate between these, and the purple series connecting the two ends of the spectrum, depend on the relative amounts of decomposition of the three substances. According to this theory, the white-black series of sensations has no separate physiological basis, but arises when all three chromatic substances are excited in an equal degree. Black is the sensation which accompanies absent or subliminal decomposition of the substances.

The primary colours.—There has been much difference of opinion as to the choice of the three primary colours. Those most commonly adopted have been red, green, and violet. In addition to evidence derived from colour mixture, their adoption has been supported by the fact that, when the intensity of the spectrum is lowered, these three colours remain visible after yellow and blue have disappeared. Donders and König have attached importance to the existence at each end

FIG. 397.—The curve *c* is the elementary curve of the sensation of the short-wave end of the spectrum, and was approximately the same in both groups of red-green blindness. The curve *b* is that of the sensation from the long-wave end in the scoterythrous group, while the curve *a* is that of the photerythrous group.—König and Dieterici.

of the spectrum of a region showing only change in saturation and no change of colour-tone, and they suppose that at each end only one fundamental sensation is present, namely, red and violet. Maxwell adopted blue as the third primary, and Exner¹ came to the same conclusion, on the ground that red, green, and blue were the colours least changed in tone by fatigue.² More recently Helmholtz and König have arrived at more exact conclusions as to the nature of the fundamental sensations.

König and Dieterici³ distinguish between elementary and fundamental sensations. By the former König means the smallest number of elements to which it is possible to reduce the manifold colour sensations we experience,

¹ *Arch. f. d. ges. Physiol.*, Bonn, 1868, Bd. i. S. 373.

² On the ground of his fatigue experiments, described on p. 1059, Burch regards red, green, blue, and violet as primary colour sensations.

³ *Ztschr. f. Psychol. u. Physiol. d. Sinnesorg.*, Hamburg u. Leipzig, 1893, Bd. iv. S. 241.

and he regards this reduction as an experimental procedure which does not necessarily carry with it any physiological significance. By fundamental sensations, on the other hand, he means the colours which correspond to simple physiological peripheral processes. In order to arrive at the elementary sensations, he constructs elementary sensory curves in the following way. He assumes the division of the spectrum into five regions: two end regions (red end to 655λ and 430λ to violet end), in each of which only one elementary sensation is present; two intermediate regions (655λ to 630λ and 475λ to 430λ), in each of which two of the elements are present; and a middle region (630λ to 475λ), in which all three elementary sensations are present together. The intermediate regions are characterised by the fact that every colour-tone in each of them can be matched by mixing the light at the point where it joins the middle region with light from the corresponding end region. In dichromatic vision there will be only three regions, namely, the two end regions, and a middle region in which the two elementary sensations of the dichromatic eye occur together.

Starting from these assumptions, König has calculated from a series of equations the curves of excitability of the three elementary sensations of the normal eye (Fig. 396), and the two of the dichromatic eye (Fig. 397). The short

FIG. 398.—The curve represents the colours of the spectrum, while points at the three angles represent the fundamental colours.

wave or cold curve of the latter was the same in all cases, and corresponded with the blue or violet curve of the normal eye. The warm curve of the colour-blind differed in the two groups, and the two curves corresponded fairly closely with the red and green curves of the normal eye. On the basis of these results, König deduced the three fundamental colours by means of the colour triangle, and concluded that they were a red lying outside the spectrum, being rather more purple than the red of the end region, a green at 505λ , and a blue at 470λ . The green is much more saturated than spectral green, as is seen by the figure of König's colour triangle (Fig. 398).

Helmholtz¹ calculated the fundamentals mathematically by another method, from the degree of sensibility for differences of colour-tone in each part of the spectrum. He has taken as his data the observations of König and Brodhun,² on the degree of sensitiveness of the eye for changes of colour-tone, and has arrived at the conclusion that the three elementary colours are a

¹ "Handbuch d. physiol. Optik," 2te Aufl., S. 449.

² *Ztschr. f. Psychol. u. Physiol. d. Sinnesorg.*, Hamburg u. Leipzig, 1892, Bd. iii. S. 97.

highly saturated carmine-red, bluer than spectral red ; a green, lying between 540 and 560 in the yellow-green ; and a blue, corresponding to ultramarine ; all three fundamental colours being much more saturated than the colours of the spectrum. Their relation is shown in Fig. 399, in which the curved lines represent the spectrum, x , y , and z the three fundamentals, the distance of the spectral curve from the sides of the triangle representing the difference of saturation. This difference in saturation is held to show that light of any wave-length acts on all three photochemical substances ; the different colours depending simply on the quantitative relations of the three processes.

It will be noticed that the red and blue fundamentals of Helmholtz correspond with those of König deduced by a different method, and also, as will be seen later, with the fundamental red and blue of Hering arrived at in a

FIG. 399.—Helmholtz.

wholly different way. The greens of Helmholtz and König, on the other hand, differ considerably, 505λ (K) and 540 to 560λ (H) ; both, however, lie between the fundamental yellow and green of Hering (see p. 1114).¹

Adaptation and induction.—Of all the facts of light and colour-vision, the most difficult to explain by the Young-Helmholtz theory are adaptation and induction. Adaptation was almost completely neglected by Helmholtz, and he apparently did not regard it as anything requiring special explanation. He explained after-image phenomena by fatigue, supplemented when necessary by psychological explanations. In addition to the arguments already brought against the fatigue explanation in general, there are other special objections to it when combined with the hypothesis that the sensation white is a complex of chromatic sensations. It is a necessary consequence of this hypothesis

¹ For criticism of König's methods by Hering, see *Arch. f. d. ges. Physiol.*, Bonn, 1893, Bd. xlvii. S. 310 ; and 1895, vol. lx. S. 540.

that diminution in the sensibility for white light should involve diminution in sensibility for coloured light, and *vice versa*.¹ It is found, however, that the two kinds of excitability vary independently of one another. If a large coloured (red) surface be observed after prolonged fixation of a black disc on a white ground, the part of the coloured field previously exposed to black appears much less saturated than the rest of the coloured surface. According to this theory, fatigue for white involves fatigue for red, but this experiment would mean that a part of the retina fatigued for red gives a better red sensation than one which has been exposed to black, *i.e.* has not been fatigued at all.

The influence which fatigue of the retina to one colour has on the colour-tone of different parts of the spectrum, has been much discussed in relation to the Helmholtz theory. Hering regards these facts as irreconcilable with the theory. The yellow of the spectrum does not change in colour-tone with fatigue; it only undergoes change in saturation, and the same is the case with blue (v. Kries, Hess, etc.). But since by this theory yellow is due to predominant excitation of the red and green substances, and blue to that of the green and violet substances, blue should change in tone, after fatigue to yellow, and appear violet, *i.e.* of the two processes upon which blue depends only the green has been affected (or affected to any extent) by the fatigue to yellow. Again, to a retina fatigued for spectral blue, violet appears red (Exner, Hess). Violet light by this theory has a slight action on the red substance, and yet here the action of the red substance predominates over and masks the action of the violet substance which has only been partially fatigued by blue light, and is being stimulated by its own special stimulus, namely, violet light.

Helmholtz² held that these and other similar objections only apply if the fundamental colours are to be found in the spectrum, and that they are met by the assumption already mentioned, that light of any wavelength acts on all three substances; the difference between the action of different lights being only quantitative. Hess,³ on the other hand, holds that the changes of colour-tone after fatigue are incompatible with any form of the three-colour theory.

Helmholtz never attempted to explain contrast physiologically, and was content with the psychological explanations already considered. v. Kries has also regarded contrast as chiefly a psychological matter, and as unimportant for a physiological theory of vision.

Colour-blindness.—The facts of colour-blindness, together with the condition of the peripheral retina, may next be considered. At one time the facts of colour blindness seemed to be strongly in favour of the theory, and, according to Maxwell, colour equations, in the common form of the defect, were consistent with the absence of one of the three normal components. In the scoterythrous group the red component was supposed to be absent, while in the photerythrous group the green component was wanting, and the two groups have since been commonly known as red-blind and green-blind respectively. The rare cases of confusion between yellow and blue were held to depend on absence of the violet component.

At an early stage, however, doubts were raised. The correspondence

¹ *Arch. f. d. ges. Physiol.*, Bonn, 1888, Bd. xliii. S. 329.

² "Handbuch d. physiol. Optik," 2te Aufl., S. 517.

³ *Arch. f. Ophth.*, 1893, Bd. xxxix. Abth. 2, S. 45.

between colour-blindness and the peripheral retina was made by Fick¹ the basis of a suggestion that, instead of assuming absence of a component, it would be more in agreement with the correspondence in question, if it were assumed that in these conditions there was an altered condition of excitability of the physiological bases of the components; that in the red-green blind condition the red and green parts of the spectrum might excite two of the processes in an equal degree, so that their curve of excitability might nearly or altogether coincide with one another; while in the extreme periphery of the retina, and in total colour-blindness, light of any wave-length would act equally well on all three substances.

The chief advocates of the three-colour theory (Holmgren, v. Kries, König) have now accepted the position, that the subjective sensations of the red-green blind most probably correspond with the yellow and blue of the normal eye; while nearly all agree that the white of the colour-blind agrees with the white of the normal eye; and the old idea, that colour-blindness depends simply on absence of one or more components, has been almost entirely given up by advocates of the theory.

In the second edition of the "Physiologisches Optik," S. 373, Helmholtz assumed that in the red-blind zone the substance sensitive to red has become similar to that sensitive to green, while at the extreme periphery all three substances have become like one another. As an alternative hypothesis, Helmholtz suggested a psychological explanation,—that, when one of the fundamentals is absent, we interpret the colours which are still perceptible, as the colours of a line which, in the colour triangle, would pass through white parallel to the line joining the two fundamentals still present. According to Helmholtz, these would pass from yellow through white to blue.

König² has advanced the view, that the curves of the three elementary sensations vary with the absolute intensity. These variations are held to be the basis of Purkinje's phenomenon, and of the characteristic spectrum of low intensity. He further supposes that the visual substances of the various forms of colour-blindness behave at ordinary intensities in the same way as those of the normal eye at lower intensities. He gives a series of luminosity curves of the spectrum at different intensities, and shows their correspondence with a number of curves in different individuals, some of whom had dichromatic, others normal trichromatic, others anomalous trichromatic systems.

The correspondence of the spectrum of low intensity with that of total colour-blindness was explained by supposing that in the latter condition the three substances behaved at all intensities in the same way as in the normal eye at low intensities, *i.e.* all three substances were acted on equally by light of any wave-length.

v. Kries has supposed that, in colour-blindness, the three components of the retinal process are present, and that the defect depends upon abnormal action of the nerve paths, or nerve centres.

Retinal basis for the theory.—More recently, König³ has endeavoured to bring the Young-Helmholtz theory into relation with definite retinal substances. König explains Purkinje's phenomenon, and

¹ *Verhandl. d. phys.-med. Gesellsch. in Würzburg*, 1873; see also *Arch. f. d. ges. Physiol.*, Bonn, 1896, Bd. lxiv. S. 318. Helmholtz had, however, previously made a similar suggestion himself, "Handbuch d. physiol. Optik," 1867, S. 848.

² "Beitr. z. Psych. u. Phys. d. Sinn.," 1891, S. 311.

³ *Sitzungsab. d. k. Akad. d. Wissensch.*, Berlin, 1894, S. 577.

the departures from Newton's law, by supposing that visual purple, with feeble decomposition, gives rise to a colourless sensation, but that with stronger decomposition the visual yellow formed is the basis of the blue component of the Young-Helmholtz theory. The former supposition has already been considered, and the latter was based on a correspondence between the curve of absorption of visual yellow with the curve of the elementary blue sensation calculated by König and Dieterici, and on the supposed blue-blindness of the fovea.

König places the red and green substances in the pigment epithelium, and regards the cones as dioptric mechanisms. It would follow from König's hypothesis that in red-green-blindness the fovea should have only monochromatic vision.

In 1884 an attempt was made by Holmgren¹ to prove the truth of the three-colour theory by stimulation of minute retinal points. He found that a minute yellow point of light appeared red at some points of the retina, green at others, and concluded that this depended on the stimulation of elements for red and green respectively. Hering,² however, showed that Holmgren's results were due to his use of impure light, and did not occur with true homogeneous yellow light. Isaachsen³ also, working under König, failed to confirm Holmgren's results. Holmgren,⁴ later, repeated his experiment with homogeneous spectral light, and with a number of observers, some of whom saw the phenomenon, others with difficulty, or not at all. He obtained very indefinite results with blue light.

If the recent theory of the function of visual purple is correct, the Young-Helmholtz theory will not be weakened; in fact, the acceptance of the former will to some extent assist the latter theory, for it relieves the latter from the difficult necessity of explaining total colour-blindness and Purkinje's phenomenon. If these depend upon the visual purple in the rods, which function independently of the chromatic apparatus, the cones may be the basis of the colour vision. But though visual purple may relieve the Young-Helmholtz theory of some of its difficulties, those connected with the explanation of after-images and contrast, and the subjective sensations of the colour-blind, still remain.

Hering's theory.—The starting-point of Hering's theory was the failure of Helmholtz to give a physiological explanation of contrast. Hering also objected to some of the fundamental principles of Young's theory. Any theory of sensation must have a physical, a physiological, and a psychological aspect; and Hering objected to the psychological aspect of the three-colour theory. In 1865, Mach⁵ had pointed out that the black-white series of sensations differed wholly in quality from the chromatic series, and that, to be consistent with psycho-physical parallelism, the two series should have a separate physiological basis. Consciousness is totally unable to analyse the sensation white into any coloured components. He further pointed out that in the series of colour sensations there are four which appear simple and undecomposable, namely, red, yellow, green, and blue,—and that each of these colours should have a separate physiological basis. Hering adopted the same attitude, and pointed out that two of the original three primary colour sensations of Helmholtz were manifestly complex; that

violet is obviously a mixture of red and blue, while spectral red, if isolated so as to exclude contrast from the strong yellow of the spectrum, manifestly contains a yellow component.¹

Hering advanced novel views about the sensation of blackness. He objected to the generally accepted view, that this sensation could be defined as that accompanying absence of external stimulation. He pointed out that with total exclusion of light from the eye, *i.e.* in the dark-adapted eye, the sensation was one of a considerable degree of brightness, and was named by him the sensation of mean grey. Black proper only occurs, according to Hering, under the influence of external stimulation, *i.e.* under the influence of simultaneous or successive contrast. The after-image of a white patch, or a black patch seen on a white ground, give us a special quality of sensation, which we recognise as present in the mean grey, but in a less degree; and it is this special quality of sensation which Hering regards as black proper. Since black is a special quality of sensation, as well-defined and undecomposable as white or red, it is in accordance with psychophysical parallelism that it should have a separate physiological basis.

Hering, then, regards the whole series of our visual sensations as made up of six primary sensations; but the most novel and fundamental feature of his theory is the arrangement of these six sensations in three pairs, the two members of each pair being antagonistic in nature to each other, and depending on physiological processes of an opposite kind. Hering usually speaks of his theory as the theory of antagonistic colours.

Each of the three pairs of sensations depends upon the action of a special substance, the three substances being called the black-white, the red-green, and the blue-yellow respectively. The processes of an opposed nature taking place in these substances are the two kinds of metabolism. In most kinds of stimulation of the retina, all three substances are set in action, and the character of the sensation is determined by the relative amount of action of each. This relative amount determines the "weight" of each primary sensation in the complex sensation. Both the general character of the sensation and the "weight" of each element depend on the condition of excitability of the substances, as well as on the value of the stimulating light. The term "value" (*Valenz*), which has been used in the earlier part of this article to express a fact, has, when used by Hering, a special meaning. The white value of a light expresses its action on the black-white substance, and its colour value on one or both of the chromatic substances. All coloured lights, except those corresponding to the four primary colours, have three values, corresponding to their action on the three substances.

Hering² always distinguishes carefully between the optical value of a light and its physiological value (*Moment*), which depends on the optical value and the condition of excitability of the visual organ.

The exact colours which were originally chosen by Hering were those which appeared simple to psychological analysis, namely, a red in which no trace of either blue or yellow could be perceived, a yellow in which no trace of red or green could be perceived, and similarly pure green and

¹ Wundt has objected that the choice of red, yellow, green, and blue is purely arbitrary; that all sensations are equally simple; and that one has as much right to regard red as a mixture of purple and orange, or blue as a mixture of violet and blue-green, as to regard orange or violet as a mixture of red with yellow or blue. The new fundamentals of Helmholtz and König are not open to Hering's objections.

² *Arch. f. d. ges. Physiol.*, Bonn, 1887, Bd. xli. S. 29.

blue. The colours so adopted on purely psychological grounds were found later to correspond with the colours which were found not to change in colour-tone in different regions of the retina, namely, a red more purple than the extreme red of the spectrum (and obtained by mixing blue light with the latter), a yellow at $574\cdot5\lambda$, a green at 495λ , and a blue at 471λ .

Hering's theory of metabolism.—In order to consider the application of Hering's theory to the conditions of excitability of the visual substances, it will be necessary to enter more fully into his general theory of metabolism.¹ When a substance is protected from external stimulation, it undergoes spontaneous or autonomous katabolism and anabolism, which are equal to each other; the substance is in a condition of autonomous equilibrium. If the substance is affected by a stimulus to katabolism, it undergoes a descending change. Hering now calls the katabolism allonomous; the substance becomes less capable of performing work, and is regarded as at a low potential. With this there is a spontaneous tendency to return to a condition of autonomous equilibrium, or of mean potential, *i.e.* its autonomous anabolism becomes stronger. Allonomous katabolism is therefore accompanied by autonomous anabolism, and the latter becomes the greater, the longer the katabolic stimulation lasts. Sooner or later, with constant stimulation, the autonomous anabolism becomes equal to the allonomous katabolism, and a new condition of equilibrium is set up, which Hering speaks of as allonomous equilibrium at a low potential.

If, on the other hand, the substance is affected by a stimulus to anabolism, it undergoes an ascending change. The substance becomes more capable of work, and is at a high potential. There is a spontaneous tendency to return to a condition of mean potential, and the allonomous anabolism is therefore accompanied by autonomous katabolism, which sooner or later, with constant stimulation, produces allonomous equilibrium at a high potential.

It is the direction of the change, *i.e.* whether ascending or descending, which determines the nature of the sensation; the ascending change in the three substances being the basis of black, blue, and green respectively; the descending, of white, yellow, and red. These general conceptions may now be applied in detail to the hypothetical visual substances of Hering. In the case of the white-black substance, the sensation, corresponding to equilibrium, between katabolism and anabolism, is the neutral grey, *i.e.* a grey of the brightness of that seen after prolonged stay in the dark. A descending change from a condition of higher to one of lower potential determines a sensation brighter than this neutral grey; the degree of brightness depends on the rapidity of the change, or, in other words, on the degree in which katabolism preponderates over anabolism. An ascending change from lower to higher potential determines a sensation darker than the neutral grey, the depth of darkness again depending on the rapidity of the ascending change.

Adaptation and induction.—The conditions of allonomous equilibrium are the basis of adaptation. When the black-white substance is completely adapted to the dark, it is in the condition of mean potential, corresponding to autonomous equilibrium. During the day the eye is always adapted to the surrounding illumination. The exact condition of adaptation must vary to some extent with the continual changes of external illumination to which one is normally exposed, but for practical purposes the condition of adaptation may be regarded as

¹ Cf. vol. i. pp. 868-870.

changing very slowly, and in any definite interval of time as corresponding to the mean illumination during that period. The white-black substance is then in a condition of allonomous equilibrium at a low potential. The brighter the illumination to which the eye is adapted, the lower is the potential at which equilibrium occurs. During the daytime the white-black substance is always to be regarded as in a condition of relatively low potential. The condition of allonomous equilibrium at a high potential is exceptional in the case of the black-white substance, owing to the fact that there is no external stimulus to anabolism. Black proper, according to Hering, only occurs under the influence of simultaneous or successive contrast; and the best example of allonomous equilibrium at relatively high potential, in the case of the black-white substance, occurs in Hering's "simultaneous induction." If a black square on a white ground is fixed, the whole surface after a time is seen as a uniform grey. The black-white substance corresponding to the black square will have undergone an ascending change, that corresponding to the white a descending change, and the condition of uniform grey of the whole surface corresponds to equilibrium, which in the former case is at a high potential, and in the latter at a low potential. The potential of the former will only, however, be higher than that of the eye completely adapted to the dark, if the experiment is carried out with the eye adapted to the dark. In the case of the white-black substance, it would seem as if allonomous equilibrium might in ordinary life take place at very different levels of potential, less than that of the autonomous condition; and that allonomous equilibrium, at a potential higher than that of the dark-adapted eye, only occurs under very exceptional conditions. This might be urged as an objection to the terminology adopted by Hering. It is due, however, to the absence of proper external stimuli to anabolism, and this difficulty does not occur in Hering's treatment of the chromatic substances.

When the red-green and yellow-blue substances undergo the descending change, the corresponding sensations are red and yellow respectively. When they undergo the ascending change, they are green and blue respectively. The rapidity of the change (or the predominance of one process over the other) partly determines the "weight" of the particular element in question in the sensational complex, or, in other words, the purity or saturation of the colour; the other factor determining the purity being the degree of simultaneous stimulation of the other substances.

The conditions of adaptation to coloured light may be readily referred to different conditions of allonomous equilibrium. When the chromatic substances are in a condition of equilibrium, they do not contribute to the quality of the sensational complex. They are equally in a condition of autonomous equilibrium, whether the eye has been wholly unstimulated or whether the stimulation has been exclusively by mixed colourless light. When the eye, after exposure to red light, no longer sees objects red, the red-green substance has become adapted to the light, and is in a condition of allonomous equilibrium, but at a low potential; on the other hand, in adaptation to green light, this substance is in allonomous equilibrium at high potential. With removal of the light to which the eye has become adapted, the complementary after-image colour is due to the autonomous change back to a condition of mean potential. After-images occupying limited portions of the visual field are due to local adaptation, and are explained on the same lines as general adaptation. The after-images seen with complete exclusion of light from

the eye, which formed the great difficulty of the fatigue theory, are here referred to autonomous changes. Hering has formulated the nature of the active opposed change, which Plateau had previously suggested as the basis of after-image in distinction from the passive condition advocated by Fechner and Helmholtz.

The absence of colour in all kinds of light at low intensity is, according to Hering, a function of the dark-adaptation of the eye rather than of the low intensity of the stimulus, and is due to the fact that in the dark the white-black substance rises greatly in potential, while the chromatic substances remain in the condition of autonomous equilibrium. Consequently, the weight of the chromatic is very small compared with that of the colourless elements, and the former remain under the threshold. The altered distribution of brightness of the colourless spectrum will be considered later.

While the ordinary negative or complementary after-image may easily be explained by the adoption of Hering's views of metabolism, the same cannot be said of the prolonged positive image which occurs after looking at the sun or other strong illumination. Hering proposes the following explanation.¹ When looking at the sun there is not only very violent katabolism, but also a considerable increase of anabolism, so that not only is the visual substance used up, but also the material for anabolism. Consequently, in the darkened eye, the sensation depends on very feeble katabolism due to intrinsic stimuli and still feebler anabolism. The substance is at a very low potential, but the sensation is one of brightness. If now the retina is illuminated, the increase of katabolism in the blinded area will be very slight, but its anabolism will be very much increased by the katabolism going on in the rest of the retina (see Explanation of Contrast). Anabolism will be in excess of katabolism, and the image will appear dark. Given the assumption that the material for anabolism is used up, this explanation follows perfectly from the theory; but it is not quite easy to understand how this consumption can take place during the very short exposure necessary for a blinding image. The phenomenon clearly borders on the pathological, and is of essentially the same nature as the persistent scotoma which has in many cases followed direct vision of the sun. Its explanation belongs to the pathology rather than the physiology of metabolism.

The relation of Hering's theory to the question of fatigue is a problem belonging to general physiology, but it may be briefly considered here. Some of the objections which have been most strongly urged against the theory have involved this question. Donders pointed out that during the day the eye is exposed for hours to light which gives a more intense sensation than that of the mean grey, and that the eye should consequently become fatigued. The answer to this is the occurrence of allonomous equilibrium, and from one point of view this may be regarded as fatigue, since the substance is then less capable of work. This condition, however, must be rigorously distinguished from such a condition as that resulting from exhaustion of the material for anabolism and also from accumulation of metabolic products. During the continuous daylight of a northern summer, the visual substance oscillates about a condition of equilibrium at a low potential, but the supply of new and the removal of waste material go on with a regularity suited to the needs of the substance at its comparatively low level of potential.

¹ "Zur Lehre vom Lichtsinn," S. 102.

Simultaneous contrast, and the other phenomena which I have included under spatial induction, are explained physiologically by Hering on the same lines as the phenomena of temporal induction. When a retinal area undergoes katabolism under stimulation, the process of katabolism may be regarded as acting as a stimulus to anabolism in the same area; it is due to this tendency of allonomous katabolism to promote autonomous anabolism that allonomous equilibrium occurs. In the same way, allonomous anabolism in a retinal area may be regarded as acting as a stimulus to autonomous katabolism in that area. Contrast is simply explained by supposing that this tendency to promote the opposite kind of change is not limited to the area stimulated, but extends to adjoining areas, and that this action is most marked at the line of junction of the reacting areas, and diminishes from here outwards. Hering formulates the nature of the physiological reciprocity of retinal areas, advocated by Johannes Müller, by making an assumption which is perfectly consistent with his general theory.

The strong point of Hering's explanation is, that it brings temporal and spatial induction into the closest relations with one another; each of the two processes helps to make the occurrence of the other more intelligible. In both kinds of induction we may see the working of a general law, that the occurrence of destructive metabolism at once determines an increase in constructive metabolism, which hinders the living substance from undergoing too great or too rapid decomposition; and that, on the other hand, constructive metabolism determines an increase in the tendency to spontaneous decomposition, which sets a limit to assimilation, and prevents it from reaching a degree beyond the needs of the organism.

Specific brightness.—Hering's treatment of the subject of brightness may be considered here. It is interesting, as the only feature in which the theory has suffered any important modification since first formulated. In the "*Lehre zum Lichtsinn*" Hering thought it probable that the brightness of a visual sensation was wholly due to its white component, and that if we were able to see the four primary colours in a state of purity they would appear of equal brightness. For this assumption has now been substituted the idea of specific brightness of the colours.¹ The two colours, red and yellow, which are due to katabolism, are supposed to contribute positively to the total brightness, while the contribution of green and blue is negative and diminishes the total brightness of the sensation. This assumption is especially applied to explain the changes in the spectrum with lowered intensity. In the eye adapted to the dark, the black-white substance will have been raised to a condition of high potential, while the chromatic substances will not be appreciably affected; consequently, the "weight" of the colourless component of the sensation will be relatively much increased, and with slight stimulation the coloured components will remain under the threshold. The chromatic substances will also cease to contribute to the brightness of the sensations, and the curve of luminosity of the spectrum will be that of the black-white substance. According to Hering's theory, then, the spectrum of low intensity is the spectrum of the black-white substance. With increase of intensity the specific brightness of the chromatic processes begins to affect the curve of luminosity; red and yellow contribute positively, green and blue negatively, and the consequence is a shifting of the maximum brightness of the spectrum towards the former, until yellow again becomes the brightest part. From this

¹ Hillebrand, *Sitzungsb. d. k. Akad. d. Wissensch.*, Wien, 1889, Bd. xxviii. Abth. 3, S. 70.

it follows that in the long-wave half of the spectrum, the white value of a colour should be less than the brightness as determined by the methods of heterochromatic photometry, while in the short-wave half the reverse should be the case. This was shown to be true by Sachs,¹ who used the method of pupil photometry; and with the flicker method the same relation between brightness and white value is found.

The colourless sensation which occurs when two complementary coloured lights are mixed, depends on the combined action of the coloured lights on the black-white substance; one of the two complementary lights acts as a katabolic, the other as an anabolic, stimulus; and with a suitable intensity of each, these stimuli neutralise each other, and the chromatic substance or substances remain in a condition of equilibrium. Hering has repeatedly verified by experiment the proposition that the white value of the grey produced by mixing two colours is equal to the sum of the white values of those colours, the brightness of the grey depending wholly on the action of the black-white substance. Abney and Rood have also found that the brightness of a grey produced by mixing two colours is equal to the sum of the brightness of those colours as determined by heterochromatic photometry. If both propositions are correct, it would mean that the positive contribution made by the specific brightness of the warm colour is exactly neutralised by the negative contribution of the cold colour.

Peripheral retina and colour-blindness.—According to Hering, the peripheral retina of the normal eye shows the same conditions as are found in colour-blindness. In total colour-blindness, and in the outermost zone of the retina, only the black-white substance is present; the middle zone of the retina is regarded as red-green blind, and the smaller individual differences are of the same nature as those which distinguish macular from extramacular vision. Since the curve of luminosity of the spectrum at a low intensity depends, according to the theory, on the black-white substance, it should correspond with that of total colour-blindness, and Hering found this to be the case. He was able in 1892, on the basis of his theory, to foretell the matches that would be made by the case of total colour-blindness he was about to examine. Hering has also supposed that the white values of coloured light were the same for the extreme periphery of the retina as for total colour-blindness, but according to v. Kries (p. 1084) this is not the case.

Red-green blindness and the vision of the middle zone of the peripheral retina are ascribed by Hering to absence of the red-green substance.² The investigations of Hess on the vision of the peripheral retina and the nature of vision in acquired colour-blindness, and in Hippel's unilateral case, are strong evidence in favour of Hering's view. The chief difficulty in the way of the theory is the existence of two distinct classes of this form of colour-vision. Hering's explanation is, that these differences are of exactly the same order as the individual variations first described by Rayleigh, and depend like them upon differences of pigmentation of the macula and of the lens. A large number of very careful observations were made by Hering³ on Prof. Biedermann and Dr. Singer, who were well-marked examples of individual variation. He regarded the former as relatively yellow-sighted,

¹ *Arch. f. d. ges. Physiol.*, Bonn, 1892, Bd. lii. S. 79.

² More exactly, the condition of the peripheral retina is regarded as one of feeble red-green sense.

³ *Lotos*, Prag, 1885, Bd. vi. S. 142.

and the latter as relatively blue-sighted, these conditions depending on relatively greater and less pigmentation respectively. Hering regards the photerythrous group as relatively yellow-sighted, and corresponding to this he found that Biedermann's matches were good for photerythrous cases. The scoterythrous group, on the other hand, would be relatively blue-sighted, and Singer's matches were found to be good for them, but required alteration for Biedermann. Hering prepared a number of dried human retinæ, and found when Singer looked through the macular region of one of these that Biedermann's matches appeared correct, and by the same means Hering was able to convert a scoterythrous into a photerythrous case. Hering also found that the extramacular region of his own retina gave results which stood in the same relation to those of his central region as the results for the central region of scoterythrous stood to those of central photerythrous vision. Biedermann and Singer carried out a series of observations on their peripheral vision, and Hering expected to find that the differences between them would disappear. They remained present, however, though considerably diminished in amount, and Hering ascribed this to differences in the pigmentation of the lens, which he found to be of a distinct yellow-green colour, not only in adults but in the newly-born child.¹

If this explanation be correct, it might be expected that there would be a gradual transition of one class into the other, corresponding with a graded series of degrees of pigmentation, but the evidence seems to be against this. Hering himself was inclined to think that the cases he examined centred round Biedermann and Singer, rather than round a point between them. It is quite possible, however, that the variations of pigmentation may be discontinuous; and, in the absence of direct investigation of the question, the existence of two distinct groups by no means destroys the validity of the proposed explanation.

From his examination of individual variations, it seemed probable to Hering that there is a relation between macular (and lens) pigmentation and development of the colour sense. Biedermann had a very highly developed colour sense (high degree of discrimination and wide limits of visibility of spectrum), while Singer had a weak red-green sense, and much more limited spectrum; and in cases of red-green blindness it seemed as if the group with more pigmentation (yellow-sighted or photerythrous) had a more highly developed blue-yellow sense, and Hering supposes that the shortening of the spectrum in the scoterythrous group may be due to weakness of the yellow sensation.

v. Kries has recently written strongly against Hering's view. He points out that the most marked distinction between the two groups of red-green blindness is at the long-wave end of the spectrum, while the macular pigment, as Sachs has shown, only begins to show any appreciable absorption in the yellow-green. In order to determine the influence of macular pigmentation in a number of cases of dichromatic vision, he matched blue-green light of 490λ with a mixture of blue (460λ) and green ($510-517\lambda$); the quotient $\frac{\text{blue}}{\text{green}}$ showed no regular difference between the two groups of red-green blindness; in fact, the extremes were both in the scoterythrous class.

According to Hering's theory, there should be in yellow-blue blindness two neutral bands, without shortening of either end of the spectrum. Hering

¹ The greenish yellow colour of the lens in childhood is seen best if observed in water placed in a white porcelain vessel. The greenish yellow colour changes to yellow in adult life.

explains the shortening in the case recorded by Vintschgau and himself, partly by a co-existing weakness of the red-green sense, and partly by a quantitative anomaly. He found evidence that the colourless region at the violet end had a red value, for when violet light was added to a red which was below the chromatic threshold, the mixture became red, while addition of violet light to a green above the chromatic threshold produced a mixture which appeared colourless.

Hering's theory and the retina.—It might be supposed that, according to Hering's theory, the katabolic colours should produce an electrical change in the retina in an opposite direction to the anabolic colours. Red and yellow should cause a variation of one kind, and green and blue of the opposite kind. This is not the case. This supposition, however, neglects the black-white substance which is acted on by all kinds of light, and the variation due to this would mask any difference in the behaviour of the chromatic substances. In order to support the theory, it would only be necessary to show that a green of a definite white value gives a smaller variation than a red of equal white value. Another factor to be taken into account is the influence of spatial induction, which, by causing the opposite kind of change in the non-stimulated area, would still further obscure the direct results of stimulation.

The recent views considered on pp. 1101–1105 must, if correct, modify the theory to some extent, at any rate in the form in which it is usually understood. According to these views, the spectrum of low intensity of total colour-blindness is the spectrum of visual purple, while the effect of dark-adaptation depends on accumulation of this substance. This suggests that Hering's black-white substance and visual purple may be one and the same thing; against this is the undoubted fact that the production of colourless sensation by colour mixture holds for the fovea; the colourless sensation cannot here be due to the combined white values of the coloured lights. It must be remembered, however, in answer to this and other difficulties, that Hering has never regarded his theory as an expression of retinal processes. In one place¹ he expressly states that his theory has nothing to do with the first immediate changes in the peripheral organ. If Hering's substances are regarded as central, these difficulties to a great extent disappear. Under ordinary conditions, the central black-white action could be excited by two kinds of peripheral activity, *i.e.* changes in visual purple, or changes in the chromatic apparatus. As already mentioned, the existence of binocular colour contrast suggests the central origin of contrast in general, and, if spatial induction is central, temporal induction has probably the same seat.

Hering has not only left the actual seat of the psycho-physical processes undecided, but, further, has only adopted the conception of three special substances, in order to assist the exposition of his views. He would prefer² to speak of only one psycho-physical substance, capable of manifold qualitatively different kinds of anabolism and katabolism, each kind being capable of analysis into three components, corresponding to three chief varieties of anabolism and katabolism.

G. E. Müller³ has lately suggested certain modifications of Hering's theory, by means of which he thinks certain difficulties may be removed. He supposes that visual purple acts as a sensitizer to the visual substances proper, and that, in

¹ *Arch. f. d. ges. Physiol.*, Bonn, 1887, Bd. xli. S. 39.

² *Sitzungsb. d. k. Akad. d. Wissensch.*, Wien, 1889, Bd. xxviii. Abth. 3, S. 73.

³ *Ztschr. f. Psychol. u. Physiol. d. Sinnesorg.*, Hamburg u. Leipzig, 1896, Bd. x. S. 1 and 321; and 1897, Bd. xiv. S. 1 and 161.

addition to the three kinds of visual substance with their seat in the periphery, there is a central black-white excitation which is the basis of the intrinsic light, and is capable of being set in action by change in the chromatic substances in the periphery as well as by change in the peripheral black-white substance.

Ebbinghaus¹ attempted to bring the theory into relation with retinal structures. He supposed that visual purple was Hering's blue-yellow substance, that it existed alone in the rods, and together with some other substance which neutralised its colour in the cones. These views were supported by the correspondence of the absorption curves of visual purple and visual yellow with the elementary curves for yellow and blue in the red-green blind.

Other theories of colour-vision.—The theory of Donders² occupies a position intermediate between those of Helmholtz and Hering. Donders recognised the claims of red, yellow, green, and blue to be regarded as primary, or, as he called them, simple colours. On the other hand, he held the facts of colour mixture to show a threefold physiological process. The colours corresponding to these three physiological energies he called fundamental colours, and he adopted as such red, green, and violet. He supposed that these energies had their seat in the periphery, while the processes in the visual centres had a fourfold nature, corresponding to the four simple colours. He further supposed that a single peripheral process might affect more than one central process, so that a fundamental colour, as violet, might correspond to two simple colours, as red and blue. For his central processes Donders adopts a hypothesis in terms of molecules. The sensation white corresponds to complete, colours to partial, dissociation of the molecules; this partial dissociation gives rise to molecules whose secondary dissociation is the basis of the colours complementary to those arising through the primary dissociation. Black corresponds to a condition where dissociation and repair are equal, but both are reduced to a minimum. Donders did not attempt to apply his theory to the whole range of colour phenomena, but used it chiefly in reference to colour-blindness. A somewhat similar molecular hypothesis has been advanced by Ladd Franklin.³

In 1881, Preyer⁴ advanced a theory which, in many respects, resembled that of Hering. In this theory analogies were drawn with the temperature sense of the skin, and assumptions were made as to the seat of the different kinds of sensation, the rods being regarded as photogenous, and the cones as chromatogenous elements.

The theory of Wundt⁵ has been already mentioned. He assumes the existence of separate substances for light and colour sensations, but supposes that the latter depend on different kinds of change in one complex substance. In order to support his theory, attempts have been made to show that colour-blindness may occur in a far greater variety of forms than is commonly supposed (Kirschmann).⁶ Contrast is explained psychologically, while after-images are referred to fatigue assisted by contrast.

A theory of a different nature has been advanced by Charpentier.⁷ He distinguishes between two kinds of retinal elements,—photo-aesthetic elements of a rudimentary nature, which have to do with sensations

⁷ "La lumière et les couleurs," Paris, 1888, p. 265.

of simple luminosity, having little to do with localisation; and more specialised visual elements, the basis of distinct perception. He supposes that colour is due to the simultaneous activity of the two kinds of retinal element; to interference between the two sets of vibrations started by their stimulation. He formerly believed visual purple to be the basis of the photo-æsthetic activity, but since this substance is absent from the fovea, and since the presence of only one kind of element would involve the colour-blindness of this part of the retina, he has lately¹ given up the idea that visual purple is the source, or the only source, of the photo-æsthetic activity. The other kind of vibration he supposes to be set up by thermo-electric action between the cones and the retinal pigment. Charpentier thinks it probable that the retinal oscillations described by him (p. 1074) depend on transverse vibration of the free ends of the rods and cones.

BINOCULAR VISION, MOVEMENTS OF THE EYES, AND SPATIAL PERCEPTION.

Introductory.—The point of especial interest in this part is the physiological basis of visual perception of space. Its consideration involves psychological factors to a much greater extent than the subject of the second part of this article. The physiological factors are of two kinds, namely, movements of the extrinsic and intrinsic ocular muscles with the central motor processes connected with their innervation, and the binocular mechanism by means of which the two eyes are brought into physiological association with each other, and are made to act in many ways as if they were one organ. Certain facts about these two sets of factors must first be considered.

Binocular combination.—In studying binocular vision, it is necessary to have some means of presenting different objects to the two eyes. This may be done without apparatus, by placing the object on the lines of direction of the eyes, either beyond or nearer than the fixation point, when the combined image is seen accompanied by the lateral images. The observation of the combined image may be assisted by screens to hide the lateral images. Some individuals, especially myopes, obtain binocular combination most readily with the lines of vision crossed beyond the objects, and with normal vision this method is usually rendered more easy by wearing weak convex glasses. Probably most individuals, however, obtain more satisfactory results by fixing a point nearer than the objects to be combined. Of the different forms of stereoscopic or haploscopic arrangement, which have been used for the same purpose, the most suitable for physiological experiments is Wheatstone's, especially in the modified form of Hering's haploscope.

Retinal rivalry.—When the fields presented to the two eyes are different, a phenomenon known as "retinal rivalry" occurs. If two glasses differing in brightness are held, one before each eye, the combined field may be observed to become periodically lighter and darker; with glasses of different colour, the field may change periodically in colour. The greater the difference in brightness between the two fields, the more marked is the rivalry. When there is in one field an

¹ *Arch. d'ophth.*, Paris, 1896, tome xvi. p. 337.

object with well-marked contours, this will tend to prevail in the struggle between the two fields, and will not disappear periodically, although the background may continue to do so. If each field contain an object with contours, and these coincide, there will be marked rivalry, especially if the objects differ greatly in form. At times only one of the objects will be seen, while at other times parts of the two objects will be seen together. Rivalry may occur when one eye is closed; if a sheet of white paper is observed close to the eyes while one eye is closed, a periodical darkening of the paper occurs, which is due to the influence of the intrinsic light of the closed eye (Purkinje, Hering). In 1864, Hering¹ pointed out that the behaviour of black in retinal rivalry was evidence in favour of black being a positive sensation.

The explanation given of retinal rivalry has been chiefly psychological. Helmholtz referred the phenomenon to the influence of attention, this being applied at one moment to the field of one eye, and at the next to the field of the other. The variations may take place with considerable regularity, and the periods of variation show some correspondence with those of the variations of after-images. We are at present wholly in the dark as to the physiology of this phenomenon.

Brightness of binocular field.—The apparent brightness of a given illumination is not the same for one and for two eyes; according to old observations, a light seen with two eyes appears about one-tenth brighter than when seen with one eye alone. When the illumination of the two eyes is different, the apparent brightness of the combined field varies with the intensity, and with the difference of illumination of the two eyes. Fechner² found that if a dark glass were held before one eye, the apparent brightness of the field increased when this eye was closed or screened, and diminished again on reopening the eye. In this experiment the brightness of the sensation increases when the amount of light entering the eyes is diminished, and decreases when it is augmented, and it is consequently known as "Fechner's paradoxical experiment." After a time the brightened field may be observed to darken again owing to rivalry. If the glass used lets through much light, this effect does not occur, and the field brightens and darkens with increase and decrease of illumination. For each individual, Fechner found an indifferent point, corresponding to a glass with which the brightness of the combined field remained the same whether the eye was closed or open. Such a glass was found on the average to be one which transmitted two-thirds of the light.

The greatest amount of darkening occurred with a glass which let through about $\frac{1}{2\frac{1}{5}}$ of the light, and on either side of this point glasses could be found with which the combined field was equally bright; thus a glass transmitting $\frac{1}{3}$ of the light gave a combined field of the same brightness as one transmitting $\frac{1}{3\frac{1}{10}}$, and such glasses were said by Fechner to be of conjugate intensity. It has been supposed that the paradoxical experiment is due to the pupil; closing the eye behind the dark glass would lead to a consensual widening of the pupil of the other eye, and might in this way brighten the field. Fechner found, however, that the experiment succeeded with a small artificial pupil, and the phenomenon also occurs as well with atropinised pupils as in the normal condition. No satisfactory physiological explanation has been given. It has been supposed that the brightness of the combined field is the

¹ "Beitr. z. Physiologie," Leipzig, 1864, Heft 5, S. 309.

² *Abhandl. d. k. sächs. Gesellsch. d. Wissensch.*, 1861, Bd. v. S. 416.

mean of that of the two eyes, and the phenomenon has also been referred to the influence of attention, which is supposed to be concentrated on the open eye when the darkened eye is closed. Fechner supposed that it depended on antagonism between the two retinae.

Binocular colour mixture.—When a different colour stimulus is applied to each eye, the mixture-colour may be observed during the transitions from one colour to the other which depend on rivalry. With suitable adjustment of the two stimuli in respect of intensity, the rivalry may be very much lessened or abolished, and the mixture-colour persists. The existence of true binocular colour mixture, however, has been denied by Helmholtz¹ and others, but there can be no doubt of its existence, the mixture-colour being in all respects comparable with the colour produced by mixture on the colour wheel or by the double-image prism. It may be seen with simple binocular combination; with the stereoscope; and by a method devised by Hering,² in which a patch of light is seen in a dark box containing two coloured glasses, arranged in such a way that each eye looks through a different coloured glass. The patch of light is most conveniently produced by covering an aperture in the floor of the box with ground glass, and looking through the box towards a brightly illuminated surface. Binocular colour mixture may also be observed in the combined after-image of the two eyes.³

In experiments showing the rivalry of contours, the parts where the images of the two eyes join have a peculiar lustrous appearance. This is also seen in the binocular combination of black and white fields, the combined image looking like graphite. If a red and blue pattern be observed with a red glass before one eye, and a blue glass before the other, the same lustre is very marked. The natural lustre of certain objects has been referred to the same cause. It is supposed that objects with a certain degree of roughness of surface reflect rays in irregular directions, so that corresponding points of the two eyes are stimulated by light of different degrees of intensity.

Corresponding points.—The physiological basis of single vision with the two eyes is the mechanism of corresponding or identical points. These points may be defined as those parts of the two retinae which receive the two images of the same distant point of light (star). If one retina be placed in front of the other, so that the foveae are in contact, and the temporal half of one retina covers the nasal half of the other, any point in one retina will cover its corresponding point in the other, and such points have therefore also been called covering points. Since the nasal half of each retina has a more extended field than the temporal half, only the central part of the visual field is binocular.

J. Müller⁴ demonstrated the parts of the two retinae which corresponded to one another by means of pressure phosphenes. He found that a phosphene produced by pressure on the outer side of one eye was projected, so that it was localised in the same position in space as one due to pressure on the inner side of the other eye. Hering⁵ showed that an after-image of one eye has exactly the same localisation in the visual field of the other eye as the original of the after-image to the

⁵ "Beitr. z. Physiologie," Leipzig, 1863, Heft 3, S. 182.

first eye. The method most widely used is that of substitution, which depends on identical localisation with the stereoscope or haploscope.

In considering the mechanism of corresponding points, it is necessary to have some definite terminology for different parts of the retina. It is now usual to regard each retina as made up of a number of points arranged in vertical and horizontal sections. One point corresponds with another, when it lies in the same vertical and horizontal sections in the two eyes. Points which do not correspond are termed "disparate" points. If a point lies in the same horizontal section in the two eyes, but in different vertical sections, the points are termed horizontally disparate, or as having horizontal disparation. If they lie in the same vertical but in different horizontal sections, they have vertical disparation.

It has been found that the strictly vertical meridians of the two eyes do not correspond with one another. If the double images of two lines are observed, it is found that these appear to be vertical and parallel to one another, when the lines diverge from one another upwards, so as to form an angle of 2° with one another. This "physiological incongruence" of the two retinæ varies in amount in different individuals; the deviation of apparently vertical lines may reach $2^\circ 30'$, but is much less and may be absent in myopia.

According to Volkmann,¹ there is a similar incongruence between the horizontal meridians, amounting, however, only to half a degree, the meridian of each eye inclining slightly downwards and outwards.

Another kind of incongruence has been described by Kundt,² who found that when he halved a horizontal line seen with one eye, the outer half was made constantly too large, and Hering³ supposes that this is due to difference in the distance between corresponding points on the two sides of the retina.

Single and double vision.—When retinal disparation is marked, two images of an external point are seen. The nature of the disparation and diplopia depends on the position of the point in relation to the fixation point. When nearer, the double images are crossed or homonymous, *i.e.* the image of the right eye appears to the left, and that of the left eye to the right; when the point is beyond the fixation point, the diplopia is uncrossed or heteronymous. The retinal disparation is similarly termed crossed and uncrossed respectively.

When the disparation is slight, fusion of the two images occurs, and single vision results. This was first shown by Wheatstone,⁴ and the amount of disparation with which single vision can occur has been investigated by Volkmann.⁵ He combined vertical lines (Fig.

FIG. 400.

400), in which *a*, *b*, and *c* were fixed, and *d* movable; *a* and *b* being presented in the stereoscope to the left, *c* and *d* to the right eye. He found

¹ "Physiol. Untersuch. im Gebiete d. Optik," Leipzig, 1864, S. 206.

⁴ *Phil. Trans.*, London, 1838, p. 371.

⁵ *Arch. f. Ophth.*, 1859, Bd. v. Abth. 2, S. 1.

that the amount of difference between ab and cd , which still allowed single vision, varied with the distance between a and b , and was also considerably diminished by practice; when ab equals 5.3 mm., observed at a distance of 16 cm., he found the limit when cd was less than ab to be 1.84 mm.; when cd was greater than ab , it was 2.27 mm. With horizontal lines the amount of disparation consistent with single vision was much less, being under similar conditions, only .42 mm. and .75 mm. Fusion into single vision takes place much more readily with horizontal than with vertical disparation, and consistently with this result he found that a circle fused more easily with a smaller ellipse when the shorter axis of the ellipse was horizontal. From experiments on fusion in different meridians, he found that the tendency for disparate lines to fuse diminished with their deviation from the vertical.

Wheatstone supposed that it followed, from the occurrence of single vision with disparate points, that double vision could occur with corresponding points, and in favour of this described the following experiment. In Fig. 401 the image of the thin line would, in binocular combination, fall in the left eye on points corresponding to those of the thick line in the right eye, but Wheatstone found that the two thick lines fused, giving an

FIG. 401.—Wheatstone.

inclined line, seen in relief crossed by the thin vertical line. This experiment has been used by him and by others as evidence against any necessary physiological connection between corresponding points. The experiment has been very fully criticised by Hering,¹ who has found that if the vertical line presented to the right eye be distinguished by a mark, and care be taken that the two vertical lines are seen with corresponding points, and with accurate fixation, the two vertical lines either fuse or can be observed independently of the oblique line. Care has also to be taken to ensure that both eyes are being used. Hering points out that the stereoscopic appearance of the cross exists when it is observed with only one eye, and is especially marked when drawn on glass, there being a natural inclination for two lines crossing each at an acute angle to be seen stereoscopically. Other experiments in favour of double vision with corresponding points, brought forward by Nagel and Wundt, have been similarly shown by Hering to be inconclusive.

It has been supposed that corresponding points are identical in function, and also that the nerve fibres from corresponding points are connected with the same nerve cell. Single vision with disparate points, and double vision with corresponding points, have both been brought forward as facts inconsistent with identity. If the existence of double vision with corresponding points were proved, the doctrine of identity would have to be given up. Single vision with disparate points, on the other hand, only requires a modification of the doctrine, to the effect that, while single vision is necessary with stimulation of corresponding points, it is possible with that of disparate points. In the latter case the single image is not only in many cases capable of analysis into double

¹ "Beitr. z. Physiologie," Leipzig, 1862, Heft 2, S. 81.

images, but there is a further distinction that the single image receives a different localisation, and is seen either nearer to or further from the eye than the single image of corresponding points. This difference of localisation was first observed by Wheatstone,¹ and, as will be seen later, there is a close connection between disparation and spatial localisation.

Panum² proposed a modification of the doctrine of corresponding points, in which it was supposed that to each point in one eye there corresponded a definite sensory region (*Empfindungskreis*) in the other.

The horopter.—The horopter is the name applied to the sum of those points of space which, in a given position of the eyes, fall on

FIG. 402.—Hillebrand.

corresponding points in the two retinae. The form of the horopter has chiefly been determined mathematically, but is also to a certain extent capable of experimental investigation. According to J. Müller, the points forming the horopter lie in a circle passing through the fixation point and the nodal points of the two eyes, and also in a line at right angles to the plane of the circle, passing through the fixation point. In this theoretical construction it is assumed that corresponding points are identical; that no wheel rotation occurs in movements of the eyes; that the retina is a spherical surface; and that the centre of rotation of the eye coincides with the nodal point. None of these assumptions are correct, with the doubtful exception of the first, and consequently the theoretical horopter changes

¹ *Loc. cit.*, p. 374.

² "Physiol. Untersuch. über das Sehen mit zwei Augen," Kiel, 1858, S. 62.

with every change of convergence, and does not exist in asymmetrical positions of the eyes. In the experimental investigation of the horopter, it is not sufficient to determine the points in space which in any given position of the eyes are seen singly, since single vision occurs not only with corresponding but also with slightly disparate points. Hering¹ determines the form of the horopter by finding the points which are seen singly and in the same vertical plane as the point fixed. He distinguishes between the vertical and the horizontal horopter; the vertical horopter being made up of lines which fall on corresponding vertical sections of the retina, and the horizontal on corresponding horizontal sections. The total horopter is the part common to both vertical and horizontal horopters. In the determination of the vertical horopter, Hering uses vertically

FIG. 403.—Hillebrand.

suspended threads, the ends of which are not exposed, seen against a uniform background. He finds that if these threads are viewed with both eyes, and arranged so that they appear to be in a plane parallel to the frontal plane, at a certain distance, less than 2 metres from the eyes, they form a plane; nearer than this they form a curved surface concave to the face, the concavity increasing with approach to the eyes; beyond this distance they form a surface convex to the face. Helmholtz² also found that threads apparently in a plane really formed a concave cylindrical surface near the eyes, and became a plane surface only at a certain distance, which he found to vary in different individuals; and he explained the facts partly by erroneous estimation of degrees of convergence. He also found that if small objects were fixed on the threads, these were arranged in a plane and not a curved surface; but Hillebrand³ has shown that this is not the case if the objects are at irregular distances from one another; Hillebrand also found that the arrangement as described by Hering occurs with any degree of convergence. According to Hering, the curved surfaces are the real form of the horopter at different distances from the eyes, and depend on the special kind of retinal incongruence described by Kundt and himself (see p. 1125).

FIG. 404.—Hillebrand.

Hillebrand illustrates the form of the horopter by Figs. 402, 403, and 404, in which O and O' represent the nodal points of the two eyes. In all three figures the angle α is less than the angle β , corresponding to the incongruence in which a distance on the nasal half of the retina is greater

¹ "Beitr. z. Physiologie," Leipzig, 1864, Heft 5, S. 296.

² "Handbuch d. physiol. Optik," 1867, S. 654.

³ *Ztschr. f. Psychol. u. Physiol. d. Sinnesorg.*, Hamburg u. Leipzig, 1893, Bd. v. S. 1.

than its corresponding distance on the temporal half. There will be a certain distance, at which the point of intersection of the indirect lines of vision will lie in the same vertical plane as the fixation point (Fig. 403); nearer than this they will lie nearer (Fig. 404), beyond this they will be farther (Fig. 402) than the fixation point. The horopter, as experimentally determined, is more extended than the theoretical or mathematical horopter, which Hering speaks of as the skeleton of the real horopter.

MOVEMENTS OF THE EYES.

Methods of measurement.—The centre round which the eyeball rotates has already been dealt with (p. 1029). The plane passing through the two lines of fixation is known as the plane of fixation. In investigating the movements of the eyes, it is important to exclude movements of the head, and this is done most satisfactorily by means of a fixed board with a cast into which the teeth of the observer fit accurately. The head may then be fixed in any position, and the amount of ocular movement measured by means of movable fixation points on graduated scales.

The movement of the eyeballs which presents the greatest difficulty is the wheel or swivel rotation round the optic axis. Numerous methods have been devised for observing it and for measuring its amount. It may be observed directly by watching a marking of the iris, a conjunctival vessel, or a mark placed on the conjunctiva (J. Müller, 1826). It has been doubted whether the conjunctiva follows the movements of the eyeball with sufficient exactness for this purpose, but this seems to be the case. Another method is to make use either of regular or irregular astigmatism. In the latter the movement of the star-like figure may be observed by comparing it with a stationary thread. In regular astigmatism the amount of rotation may be measured by finding the cylindrical glass which corrects the defect in different positions; for satisfactory results, probably a degree of astigmatism of over 1 D is necessary. Another method which has been employed satisfactorily for exact measurements is the degree of rotation of the blind spot. The method, due to Ructe, which has been most widely used, is the observation of the apparent rotation of an after-image. A linear after-image will show the changed direction of any retinal meridian on which a linear image has been formed, and this method is well adapted for quantitative results.

Another method by means of which any difference in the swivel rotation of the two eyes may be detected, is the observation of half-images of a doubled vertical line. This method is very delicate, and gives more exact results than the after-image method, but the error due to retinal incongruence (p. 1125) must be taken into account.

Listing's law.—When the head is fixed, there is, according to Listing, only one position of the lines of fixation from which the eyeball is able to move upwards and downwards and from side to side without any swivel rotation. This position is known as the primary position of the line of fixation. Listing's law states that when the eyeball moves from the primary position to any secondary position, the axis round which the movement of the eyeball takes place is one at right angles to a plane passing through the line of fixation in both its primary and its secondary positions. In other words, the axis round which oblique movements take place lies in the same plane as the axes round which simple horizontal and vertical movements take place.

The law was first formulated by Listing¹ on theoretical grounds, and was shown experimentally by Helmholtz to be true for distant vision.

Helmholtz used the after-image method, in which the observer should be seated opposite a screen at sufficient distance to render the convergence inappreciable. The position of the head must be found from which the after-images of a vertical and a horizontal strip do not deviate from a vertical and a horizontal line respectively on the screen with vertical and lateral movements of the eyes. When this position is found, the line of fixation of each eye is in the primary position, and the correspondence of the after-images with the lines shows that Listing's law is true for simple vertical and horizontal movements of the eyeball. In order to show that the same is true for oblique directions, the screen should be capable of rotation in a vertical plane round its centre, and the after-

FIG. 405.—Hering.

images of oblique strips will be found not to deviate from lines on the screen of corresponding obliquity. If, on the other hand, a fixed screen is used, such as is shown in Fig. 405, the after-images of horizontal and vertical strips will appear distorted, as shown in that figure. This distortion is apparent, and depends on the fact that the lines of the screen, which really cross at right angles, give rise to retinal images in which the lines cross obliquely. Nevertheless the objective lines are seen at right angles, and the obliquity is ascribed to the after-image, as is represented in Fig. 406.

Donders found that it made no difference whether the visual axis was moved from the primary to a secondary position in a straight line or in any other way, and this fact was referred to by Helmholtz as Donders' law. The apparent distortion of the after-image is exactly the same for each eye.

Listing's law only applies to parallel or approximately parallel positions of the visual axes. With convergence there is evidence of a swivel rotation of the eyeballs outwards, *i.e.* an increase of the normal divergence upwards of the median vertical sections of the two retinae.

According to Donders,² the swivel rotation of convergence may be shown by a simple experiment, in which a horizontal line, doubled by convergence for a nearer point, gives two images which form an angle open downwards. The amount varies considerably in different individuals. In seventeen cases Donders found it to vary from 1°·2 to 5°·5.

FIG. 406.—Hering.

¹ See Ruete's "Lehrbuch d. Ophth.," 1857.

² *Arch. f. d. ges. Physiol.*, Bonn, 1876, Bd. xiii. S. 418.

Nagel¹ and Hering² have found that certain small deviations from Listing's law occur, when it is necessary, for the sake of single vision, to keep the images of an external object on corresponding points.

Compensatory eye movements.—The movement of this kind about which there has been most doubt, is the swivel rotation which takes place when the head is inclined to one side. Such a movement in the opposite direction to the inclination of the head was first described by John Hunter. Its existence has been denied, but the results of many investigations show that there is a partial compensation only, the angle of rotation of the eyeball being given by different observers from $\frac{1}{6}$ to $\frac{1}{12}$ of the angle of inclination of the head. The subject has recently been investigated by W. A. Nagel,³ using the blind-spot method. He found that the amount of compensation varied from $\frac{1}{5.2}$ to $\frac{1}{11.8}$, the rotation of the eyeball decreasing relatively as the inclination of the head increased.

The compensatory movements of the eyeballs are influenced by the condition of the labyrinth, and especially of the semicircular canals, and have been much used as a means of investigating the functions of these organs, both in man and other animals. The movements are abolished by destruction of both labyrinths, and either appear not to be affected or are exaggerated with destruction of one side.

Nagel⁴ has investigated the compensatory swivel rotation in a number of animals, and with more extensive rotation of the head than has been studied in man, and has found considerable differences in different animals. The rabbit showed as much as 90° of rotation of the eyeball round its axis; while in birds, with great mobility of the neck, compensatory eye movements may be completely absent.

Associated movements.—Some movements of the eyeballs are more closely associated than others. The parallel movements of the two eyes together are very closely associated, and not only continue when one or both eyes have become blind, but were observed by Donders⁵ in a case of complete congenital blindness. The exact association between the movements of accommodation in the two eyes has already been considered (p. 1038). There is a very close association between convergence, accommodation, and contraction of the pupil on the one hand, and divergence, relaxation of accommodation, and dilatation of the pupil on the other; but these movements are capable of dissociation to a considerable extent. Distinct vision with convex or concave glasses depends on a certain degree of this dissociation, accommodation altering while the convergence remains constant, while, by means of a prism, convergence or divergence may be made to occur without accompanying accommodation. The same dissociation occurs when well-defined double or combined images of objects are seen by diverging or converging the eyes. The ease of dissociation may be greatly increased by practice. The amount of accommodation which can take place with a given convergence of the visual lines is known as the relative range of accommodation. Donders⁶ found that with increasing convergence the relative range at first increased and then decreased, till with maximum convergence it became nil.

⁴ *Loc. cit.*, S. 346.

⁵ *Arch. f. d. ges. Physiol.*, Bonn, 1876, Bd. xiii. S. 283.

⁶ "Anomalies of Accommodation and Refraction," p. 113.

Using the method of binocular combination, Dixon¹ found that the variation in the angle of convergence which he could make without altering his accommodation, decreased with the distance of the objects. At 100 cm. he found that he could vary his convergence to an amount corresponding to 6 D, without alteration of accommodation.

How far the association between convergence and accommodation persists in monocular vision, has not been satisfactorily determined.

The axes of the eyeballs during sleep are usually described, following J. Müller, as directed upwards and inwards. Raehlmann and Witkowski,² however, found that any position might occur, and that inco-ordinated movements of a special character were common during sleep. The movements were very slow, and might lead to any kind of divergence, horizontal or vertical, of the lines of vision. They also found that movement of one eye only, occurred frequently. Henke³ and others have found that while going to sleep crossed and slanting double images may be observed, indicating divergence and swivel rotation of such a kind that the vertical meridians converge upwards.

As already mentioned, co-ordinated movements persist in the blind, even in congenital blindness, although in some cases minor degrees of inco-ordination have been observed after many years.

In newly-born children, most observers have failed to observe co-ordinated eye movements till some time after birth. Raehlmann and Witkowski⁴ found the movements often inco-ordinated and much like those in sleep, but more rapid. They failed to observe movements of fixation in the first ten days. Two such excellent observers as Donders⁵ and Engelmann, however, observed definite binocular fixation with alteration of convergence in a child a few minutes after birth, but Hering has pointed out that this result can only be expected exceptionally, since most children pass the early days of life almost in a condition of sleep.

These various cases have all been discussed in connection with the question whether the association of eye movements is innate or acquired, a question important in connection with theories of the genesis of spatial perception. The observations of Donders are sufficient evidence that the association is not acquired in the life of the individual, but it is also certain that the association is not so fixed as to be incapable of being dissolved under many conditions.

SPATIAL PERCEPTION.

Visual localisation.—This has been referred to factors of three kinds,—to sensations derived from movements of the eyeballs and of accommodation; to sensations, or modifications of sensations, arising from the simultaneous stimulation of the two retinæ; and, thirdly, to a number of factors of a more purely psychological nature. The sensations of movement have been referred to peripheral changes set up by movements of the eyeballs, and also to central changes connected with innervation. The psychological factors are of great importance, and in vision with one eye and at great distances are the chief or only means of localisation. They also, however, influence the process of localisation under all ordinary conditions, and in order to investigate the physiological factors they must be excluded. This is done by using very fine

¹ *Mind*, London and Edinburgh, 1895, vol. iv. p. 205.

lines or points or falling objects, in which the factor of size is reduced to a minimum, or is unknown. Fine suspended threads are better than lines on paper, since in the latter case other markings or inequalities of the paper surface may be of influence.

Two kinds of localisation must be rigorously distinguished from one another, namely, localisation relative to the fixation point, and localisation of the fixation point itself; or, more strictly, of the fixation point relative to the individual. The apparent position of a fixed point does not necessarily correspond with its actual position, and it would be more accurate to follow Hering, and to speak of localisation relative to the nucleus or central point (*Kernpunkt*) of visual space and localisation of the nucleus itself. The surface containing the nucleus which appears parallel to the plane of the face is called by Hering the nuclear plane (*Kernfläche*), and corresponds to the horopter of actual space. Since, however, fixation point and nucleus coincide with one another under ordinary conditions, the former designation may be employed.

Localisation relative to the fixation point.—A point may be localised on either side of, above or below, and nearer or farther than the fixation point. The three dimensions may be termed breadth,

FIG. 407.—Greeff.

height, and depth respectively. It is the third which has been most fully investigated, and about which there is most difference of opinion. It is a familiar experiment that the relative distances of two objects (needle and thread) is estimated much better with two eyes than with one, and the great importance of binocular vision is shown most conclusively by means of Hering's fall experiment.¹ An observer looks through a broad tube at a bead on a vertical thread which acts as the fixation point. The psychological factors are excluded by using falling balls of different colours and unknown size. It is found that, with only one eye open, the observer is unable to distinguish whether the falling ball is nearer or farther than the bead, while with two eyes the accuracy of perception is very considerable, the just perceptible difference of distance being about $\frac{1}{50}$ of the distance of the fixation point. It has been objected, that perception might depend on some other factors, such as the apparent rate of movement of the ball. In order to overcome this and other objections, Greeff² has modified the apparatus, as shown in Fig. 407, so that at all distances the ball is seen to fall through the same distance at the same rate. The ball is always visible for less than .02 sec., which excludes the influence of movement of the eyes. With

¹ *Arch. f. Anat., Physiol. u. wissenschaft. Med.*, Leipzig, 1865, S. 152.

² *Zischr. f. Psychol. u. Physiol. d. Sinnesorg.*, Hamburg u. Leipzig, 1892, Bd. iii. S. 21.

this apparatus Greeff found with monocular vision that the right and wrong answers were approximately equal, while with both eyes the wrong answers formed a very small percentage of the total, varying from 2 to 6 per cent., according to the distance of the fixation point, F , the width of the slit, cc' , and the distance between the falling ball and the fixation point. He found the experiment succeeded at any distance of the fixation point up to 20 metres, at which distance the falling ball had to be not less than 35 cm. from the fixation point. Taking the just perceptible difference at $\frac{1}{100}$, Greeff found that this corresponded to a retinal distance of .002 to .003 mm. Diminished visual acuity diminished the influence of binocular vision. At one time Greeff believed that no cases of squint gave good results with the experiment, but later¹ has found that cases do occur in which it seems that the capacity for performing the fall experiment can be acquired after tenotomy. It seems also that such cases may be able to give correct answers with the fall experiment, though unable to combine stereoscopically (Simon).²

The fall experiment shows conclusively that there is a binocular mechanism of some kind for the perception of relative distance. It also shows that this mechanism is independent of movements of the eyes, the time during which the falling ball is exposed being too short for a movement either of the eyeballs or of accommodation to be completed. That perception of depth is independent of movement, is also shown in other ways. Dove³ found that the appearance of distance in stereoscopic combination occurred with instantaneous illumination. This was doubted by Donders,⁴ but on careful investigation he found that, with a suitable position of the eyes, the stereoscopic effect might occur with a single electric spark. Usually more than one was necessary; the first spark probably only enabled the observer to fix suitably.

As a proof that binocular relief is independent of movement of the eyes, Wheatstone⁵ showed that it may be seen in the after-image. He exposed broad coloured lines on a complementary ground, and found that the binocular after-image showed itself in bold relief in the intervals of the alternation due to rivalry. A similar observation was made by Rogers,⁶ who found that the appearance of relief in the after-image also occurred when the lines had been presented to the eyes successively.

Localisation of fixation point.—It is generally supposed that we localise the fixation point in its real position, namely, at the point of intersection of the lines of fixation, and that this localisation depends on our knowledge of the position of the eyeballs, derived either from muscle sensations of peripheral origin, or from "sensations of innervation." There is no doubt, however, that in the absence of retinal factors our knowledge of the position of the eyeballs is very defective. Very large errors may be made in localising a point of light in complete darkness (Exner).⁷ In cases of blindness due to optic atrophy, after the eyeballs have been directed to one side, they may slowly return to the median position without the knowledge of the owner, who still believes he is looking to one side

(Raehlmann and Witkowski).¹ Under certain conditions, as in stereoscopic combination, we localise quite independently of the degree of convergence.

Accommodation and localisation in depth.—Several investigations have been carried out to determine whether sensations of movement may act as subsidiary factors in localisation. It is impossible to test the influence of convergence experimentally, since the binocular retinal mechanism cannot be excluded when both eyes are used. In experiments with one eye the psychological factors must be absolutely excluded. In order to do this most completely, Hillebrand,² following a suggestion of Hering, has used the dividing line between two surfaces. The observer looks through an aperture at a fixed white screen, one-half of which is hidden by a black screen with sharply cut edge which is capable of being moved towards or away from the eye. It is found that the observer is totally unable to tell the distance of the black screen, or whether it is moving towards or away from him, or even whether it is moving at all. Wundt³ found that he was able to detect the approach of a vertically suspended thread when there was no appreciable change in its apparent size, and supposed that this was due to the influence of accommodation. He was only able to detect recession of the thread from the eye when it had undergone a visible change in size. Arrer⁴ has also obtained results with the the thread experiment, which he thinks can only be explained by the influence of movement factors. Hillebrand found when his screen was exposed at intervals at different distances, that some individuals were able to detect whether the screen had been moved towards or away from the eye during the interval, and this has been confirmed by Dixon⁵ and Arrer. It is not easy to feel quite certain that psychological factors have been absolutely excluded, and the evidence shows that if sensations arising from accommodation are of any influence at all in localisation, this influence is very slight and limited to certain individuals.

Hillebrand argued that, owing to the close association between convergence and accommodation, his experiment disproving the influence of accommodation also disproved the influence of convergence in depth perception, but the association is not close enough to justify this argument, and the possibility still remains that convergence may have some influence, although there is no positive evidence in favour of it.

The cyclopean eye.—Some of the chief investigators of binocular vision (Helmholtz, Hering, and less definitely Donders) have adopted the idea that we localise objects in space in reference to the middle point between the two eyes, and as if seen by an eye in that position. If two parallel lines are drawn at a distance apart, corresponding to the interocular distance, and are observed so that one line lies in the line of vision of each eye, the combined image of the two lines will be seen in the median plane between the two eyes, as if it were coming from a middle eye. The same appearance is produced with converging lines, provided that the lines of vision converge to a corresponding degree.⁶ This tendency is so strong, that, in monocular vision,

⁵ *Mind*, London and Edinburgh, 1895, vol. iv. p. 195.

⁶ For other experiments illustrating the cyclopean eye, see Towne, *Guy's Hosp. Rep.*, London, 1865, vol. xi. p. 144; and Le Conte, "Sight," 1883, p. 213.

the nearer of two objects may be localised in the line passing from the farther object to the root of the nose, and not in the line passing to the open eye. This reference to the cyclopean eye is not constant; and by practice in using one eye, as in shooting, it is probable that localisation in space may take place in reference to the visual direction of that eye.

In connection with the idea of the cyclopean eye, it is interesting that we are unable to tell with which eye we are seeing an object. If a piece of black pasteboard with a pinhole in the middle is moved about till the hole is in front of one eye, it may appear to be midway between the two eyes, and mistakes are frequently made in naming the eye which is exposed to the light (Rogers).¹ An after-image obtained by exposure of one eye may appear to be seen with the other eye. The familiar experiment in which a tube on the right side of an opaque object seems, when the right eye is applied to the tube, to penetrate the object, is another example. On the other hand, Helmholtz² noticed that if one of two stereoscopic photographs had on it a spot, it gave rise to an appearance of dimness in the combined picture, and that he found himself involuntarily rubbing the eye of the same side as the spot. Helmholtz supposed that this indicated that he was sensible of the eye stimulated.

Psychological factors in localisation.—These are often known as the empirical factors, but since this name seems to assume that the other factors are not based on experience, it is perhaps better to avoid this nomenclature.

The psychological factors play a very important part in localisation of the fixation point, but are also of great importance in localisation relative to the fixation point. They are the only factors in question for localisation beyond a certain distance from the eyes, namely, that distance at which the binocular retinal mechanism ceases to be of value, probably about 20 metres. The appearance of distance produced in paintings is due exclusively to the application of devices based on these psychological factors, and it is on this account that the appearance of distance in pictures, as was pointed out by Francis Bacon, is more marked when only one eye is used. Our ideas of distance and size are very closely related; it is probable that in general the idea of distance is primary, and that our idea of the size of an object depends on the estimated distance of the object (p. 1140), but, when the size is known, it may greatly influence depth perception. This is shown in a striking way in Hering's fall experiment. Observers tend to localise the larger balls nearer than the fixation point, the smaller farther than the fixation point, and they may be unconscious of the factor upon which their erroneous localisation has depended. Linear and aerial perspective have great influence on the apparent distance of an object, while the distribution of light and shade is especially important in producing the appearance of relief and solidity. The parallactic movements of objects at different distances on moving the head may also be important factors in depth perception.

Theories of localisation.—Most of the older theories ignored the distinction between relative and absolute localisation. At one time it was generally accepted that the estimation of distance depended on movement; one object was supposed to appear nearer than another,

¹ *Am. Journ. Sc.*, New Haven, 1860, vol. xxx. p. 404.

² "Handbuch d. physiol. Optik," 1867, S. 744.

because movements of convergence and accommodation were necessary in order to see it distinctly. This view is altogether negatived by experiments, and there is at present no evidence to show that movement factors take any part whatever in relative localisation, while they seem to be comparatively unimportant in the process of absolute localisation in adult life.¹ The importance of binocular vision in spatial perception was first shown by Wheatstone, who, however, adopted a psychological view of the binocular mechanism, supposing that the estimation of distance depended on a mental comparison of the two dissimilar images of the two eyes, and this mode of describing the binocular mechanism in psychological terms is still commonly adopted.

Local signs.—This term, which is due to Lotze, is often used in connection with this subject. Lotze supposed that in the skin differences of quality of the sensation arising from stimulation of different parts, were the basis of localisation, the differences of quality being produced by differences of texture and thickness of the skin and of underlying parts, and these differences of quality were spoken of as "local signs." In the case of the retina Lotze supposed that the local signs were movements or rather impulses to movement. He applied the idea, however, only to estimation of height and breadth, and not of depth, referring the latter to more psychological factors. When a definite point of the retina is stimulated, a reflex movement occurs which brings the image of the stimulating object on the place of most distinct vision. Each retinal point will then become associated with a definite movement, and Lotze supposed that the starting of this definite movement was the local sign in the case of the retina, and acted in the same way as the difference of quality in touch as the basis of localisation.

Hering's theory of the binocular mechanism.—The most satisfactory physiological theory of the binocular mechanism is, that relative depth-perception depends on double images, or rather on retinal disparation. This view was first advanced by Panum,² and has been most fully developed by Hering.³ According to this view, it is held that retinal disparation is the physiological basis of the idea of nearer or farther than the fixation point, the difference depending on whether the disparation is crossed or uncrossed. An object is seen nearer than the fixation point when it stimulates points with crossed disparation. The appearance of nearness occurs both when double images are seen and when the disparation is so slight that the double images are fused into one. Further, the greater the disparation, the greater is the apparent distance of the object from the fixation point. In the same way, uncrossed retinal disparation acts as the basis of the idea of farther than the fixation point. It must be clearly understood that our ideas of distance are not held to depend on double images, which, as a matter of fact, few people ever see, or probably ever have seen; but retinal disparation is held to be the physiological basis of our ideas of relative distance in much the same way that certain chemical changes in the retina are held to be the physiological basis of our ideas of colour; in both cases there is, of course,

¹ To what extent they take part in the genesis of spatial perception is another matter which cannot be considered here.

² *Arch. f. Anat., Physiol. u. wissenschaft. Med.*, 1861, S. 63 and 173; and "Physiol. Untersuch. über das Sehen mit zwei Augen.," 1858.

³ "Beitr. z. Physiol.," 1864, Heft 5; and *Arch. f. Anat., Physiol. u. wissenschaft. Med.*, 1865, S. 152.

no direct consciousness of the nature of the retinal mechanism. Localisation above or below, to right or to left of the fixation point, is similarly held to depend directly on the nature of the retinal stimulation. In the exposition of his theory Hering uses the expression "value" ("*Werth*"), and ascribes to each retinal element a certain height, breadth, and depth value. The localisation of a point relative to the fixation point (*Kernpunkt*) is determined by these three values. Two corresponding points have identical height and breadth values and opposed depth values. The opposed values cancel one another, so that the external point appears in the horopter. Points situated on the opposite sides of the median section, but at equal distances from it, have the same depth value and opposed breadth values, so that the external point is seen in the line passing from the cyclopean eye through the fixation point, and at a distance from the latter, depending on the nature and amount of the disparation. Hering's theory has met with much opposition from psychologists, because it has been held to imply innate ideas of distance. As Hering points out, the anatomical mechanism of retinal disparation is certainly innate, and therefore the function of that mechanism must also to some extent be innate.

Hering further supposes that retinal disparation acts as a stimulus to movement, the movement being of a kind adapted to abolish the disparation. Crossed retinal disparation will then act as a stimulus to reflex convergence and accommodation, while uncrossed retinal disparation will act as a stimulus to divergence and relaxation of accommodation. Similarly, breadth and height values will act as stimuli to horizontal and vertical movements respectively. If Hering's values are regarded as "local signs," it will be seen that he would differ from Lotze in regarding the sensory side of the reflex action as the local sign, while Lotze supposed that the motor side was the local sign.

Hering regards retinal rivalry, and the fact that contours prevail in the rivalry, as most important factors in the mechanism of depth perception. In order that contours shall prevail, it is necessary that they should be sharp and well defined, and it is on this account that he believes contrast to be of such fundamental importance in vision (p. 1066).

Hering denies that muscle sensations have anything whatever to do with localisation of the fixation point itself. The idea of nearness which may accompany convergence is regarded by him as rather the cause than the consequence of the movement. The distance of the fixation point is referred by him to the influence of retinal values, acting together with the psychological or experience factors. So far as the position of the head and eyes is of importance, localisation depends, not on their actual position, but on the idea which we have of their position.

Schön's theory of the binocular mechanism.—Another view as to the nature of the binocular mechanism has been advanced by Schön.¹ This view only applies to indirect vision, and is based on the difference in sensibility of the nasal and temporal halves of the retina. According to Schön, the nasal half is much more sensitive, especially to light, than the temporal half of the same or of the other eye. Consequently, corresponding or slightly disparate points of the two retinae will produce sensations of different intensity, when stimu-

¹ *Arch. f. Ophth.*, 1876, Bd. xxii. Abth. 4, S. 31; and 1878, Bd. xxiv. Abth. 1, S. 27.

lated by the same point; and Schön supposes that this difference of intensity, assisted by differences of quality due to differences of sensibility to colour, acts as the basis of the ideas of distance. Schön, in fact, suggests that differences of quality act as local signs in the retina, in much the same way that Lotze supposes them to act in the skin. The objections to this theory are, first, that it is doubtful whether the differences between the nasal and temporal halves described by Schön exist. Other observers have found slight differences, but very much less than those described by Schön; secondly, the sensibility of the retina is continually varying with the condition of adaptation, and varying adaptation should produce variations in our estimation of distance, which is not found to be the case; and lastly, this explanation, as Schön himself acknowledges, only applies to indirect vision, for images of objects in the same line as the fixation point will fall either on the nasal halves or on the temporal halves, which have, according to Schön, equal sensitiveness.

To explain this latter kind of localisation, Schön suggests another explanation, another kind of local sign, which he calls the "rivalry sign." Since images of an object beyond the fixation point fall on the more sensitive nasal halves, and those of objects nearer the fixation point on the less sensitive temporal halves, the former will more easily prevail in the rivalry; and Schön supposes that this difference acts as the basis of estimation in the case of direct vision.

Perception of form.—The physiological basis of localisation in space has now been considered at some length, and especially of localisation in depth. This localisation in space is the chief factor in various kinds of more complex perception, and these, namely, the perception of form and size, can now be more briefly considered.

Certain very simple cases of perception of form were dealt with in the second part of this article, and in such cases the process seems to be comparatively simple. In the case of very small objects, such as letters, it is doubtful how far the form of the retinal image is the sole physiological factor, and how far perception depends on minute movements of the eyes following the outline of the object. In the case of large objects, movements must be of greater influence. The phenomenon of metamorphopsia is evidence of the view that the retinal factor is very important. This occurs in retinitis, especially in the early stages; the forms of simple objects are found to be distorted, a straight line appearing curved or irregular. Its occurrence in the early stages of retinitis points to its dependence on inflammatory exudation, disturbing the relative position of retinal elements, so that a row of such elements which have previously been in a straight line becomes distorted. A linear retinal image will therefore fall on retinal elements which have normally occupied a curved or irregular position, and have been previously stimulated by curved or irregular objects, and a straight line will consequently appear curved or irregular.

The perception of form in three dimensions, *i.e.* of solidity, depends primarily on the physiological binocular mechanism for relative distance, but is very greatly influenced by psychological factors, and especially by the distribution of light and shade, as is shown by Wheatstone's pseudoscope and by other experiments in which reversal of the apparent direction of incidence of light produces illusions of relief.

Perception of size.—The two chief factors on which depends the

perception of the size of an object are the size of the retinal image and the estimated distance of the object. The importance of the latter factor is shown by an after-image experiment. If the after-image of an object is projected on a moving screen, it will be seen to change in size, becoming smaller as the screen approaches the eyes, larger as it recedes. The retinal image upon which the after-image depends remains constant in size, and the changes in apparent magnitude depend on the projection. Emmert¹ measured the after-image at different distances, and found the linear size of the image equal to the linear size of the object, multiplied by the distance at which the image was seen. He found that the changes were the same when accommodation was paralysed, and occurred equally well in monocular and binocular vision. The estimated distance of the after-image is therefore probably dependent on psychological factors. It is known that judgments of size are greatly influenced by these factors; the large size of objects seen indistinctly in a fog is a familiar example of the influence of aerial perspective.

Another instance which has excited much discussion is the apparently greater size of the sun and moon at the horizon than at the zenith. This is usually brought into relation with the apparent flattening of the sky; the horizon appearing farther away than the zenith, the moon appears larger at the former. A favourite explanation of the larger size at the horizon is that in that position it can be compared with intervening objects; while, according to another, the appearance is an instance of the illusion that a space filled with objects appears longer than an unfilled space (see p. 1141). Another explanation for which there is much to be said refers the larger size at the horizon to greater indistinctness, consequently greater estimated distance and greater apparent size. Helmholtz² found that a reflected image of the moon at the zenith, seen so that it appeared near the horizon, was not enlarged. Scharwin and Novizki³ have observed corresponding changes in the size of an after-image, when projected at horizon and zenith. It is probable that the apparently greater size at the horizon is due to more than one factor, greater indistinctness being the most important.

Micropsia and macropsia.—Illusions of size appear in certain conditions which throw some light on the process of perception. The metamorphopsia of retinitis is often accompanied, especially in the early stages, by micropsia. Objects may appear reduced to as much as one-fifth their natural size. This micropsia is referred to the influences of inflammatory exudation separating the retinal elements, so that a group of elements which are normally covered by the retinal image of a small object require a very much larger object in order to be covered, and the latter consequently appears diminished in size. Occasionally macropsia is observed, and this is referred to crowding of retinal elements together; it is, however, much rarer than micropsia, and the increase in size is comparatively slight.

Similar illusions of size may occur under numerous other conditions. An appearance of diminished size of small objects (printed type) may be due to indistinct vision, the outer part of the type being hazy, while the central part is seen distinctly. A more important effect is due to irradiation,⁴ and is

¹ *Klin. Monatsbl. f. Augenh.*, 1881, Bd. xix. S. 443.

² "Handbuch d. physiol. Optik," 1867, S. 631.

³ *Ztschr. f. Psychol. u. Physiol. d. Sinnesorg.*, Hamburg u. Leipzig, 1896, Bd. xi. S. 408.

⁴ *Mind*, London and Edinb., 1896, N.S., vol. v. p. 71.

well marked in black type. Such type appears very much reduced in size with a dilated pupil, and a difference of apparent size to the two eyes may be due to inequality of the pupils. This kind of micropsia disappears with an artificial small pupil, and does not occur for white objects on a dark ground.

One kind of micropsia which has attracted much attention is that which occurs after instillation of atropin. This may be due to the dilated pupil and irradiation, but also occurs when this factor is excluded. It is then probably an instance of a physiological micropsia, which occurs when an object is observed lying beyond the fixation point, and is associated with an appearance of greater distance. Objects nearer than the fixation point, on the other hand, appear enlarged, and with this may be connected the macropsia which occurs after instillation of eserin. Donders¹ and others have supposed that the micropsia of atropin is due to greater effort of accommodation and consequent idea of greater nearness, and that with this idea of greater nearness is associated one of smaller size. This explanation is open to the two objections that the micropsia is usually accompanied by an appearance of greater distance, and that it occurs with complete paralysis of accommodation, and Donders himself gave up this explanation in 1886.² The micropsia which occurs with commencing presbyopia seemed to be in favour of this explanation, but this probably depends on indistinct vision.

Geometrical illusions.—A number of illusions, usually classed together under the above heading, are of considerable interest for

FIG. 408.

the theory of the physiological basis of spatial localisation. A few of the more important are shown. In Fig. 408 the unfilled distance *ab* appears shorter than *bc*. In Fig. 409 the line *ab* is really continuous with *cd*, but appears as if continued to *e*. In Fig. 410 the parallel lines appear to converge at each end.

Figs. 409 and 410 and many similar illusions, including the well-known Zöllner's pattern, may all be referred to the erroneous estimation of angles, namely, to the over-estimation of acute angles and the under-estimation of obtuse angles.

The influence of various conditions on these illusions has been determined. The illusions are present with instantaneous illumination, although, according to Helmholtz, the effect is less marked than when movement of the eye is allowed. They are present in the after-image (Hering). Zöllner found that the maximum apparent deviation of the parallel lines in his pattern occurred when the cross lines were at an angle of 30°. The illusion is marked when his figure is observed with the eye at right angles to the paper; it becomes more marked when looked at obliquely from in front, and disappears when observed obliquely from either end. The illusion is

FIG. 409.

¹ *Nederl. Lancet*, 1851, S. 607.

² *Ber. Ophth. Gesellsch.*, Heidelberg, 1886, S. 82.

very slight close to the eye, becomes more marked as it is removed, and then decreases, till at a certain distance it is no longer visible. Kundt¹ determined the distance at which the illusion of Zöllner's pattern disappeared for different observers, and varied the size of the figure and number and angle of the cross lines. This illusion disappeared at a smaller distance from the eye when the number of cross lines was increased, and at a smaller distance with an angle of 20° than with

FIG. 410.

one of 32° or 45° . There was no illusion with an angle of 70° . The results of different observers differed to some extent, but the variations under the different conditions were the same for all. In Fig. 409, Kundt found the illusion increased by distance.

The illusions described have been referred to retinal factors, to the influence of movement, and to purely psychological factors. The

FIG. 411.—Kundt.

physiological factor to which they have been referred by Hering² and Kundt is the curvature of the retina. Their mode of explanation may be illustrated by the simple illusion in which an empty space appears shorter than an equal space partially filled with intervening points. It is supposed that our estimation of length, when two points of the retina are stimulated, is a function of the chord of the segment of the retina included between the two points. If this is the case, our judgment of the distance (*adeb*) in Fig. 411

will depend on the sum of the component retinal chords (*b'e'*, *e'd'*, and *d'a'*), while that of the uninterrupted distance (*bc*) will depend on *b'e'*, and the interrupted distance will consequently be over-estimated.

The wrong estimation of angles is explained by Hering³ on the

¹ *Ann. d. Phys. u. Chem.*, Leipzig, 1863, Bd. cxx. S. 118.

² "Beitr. z. Physiol.," 1861, Heft 1, S. 65.

³ *Ibid.*, S. 71.

same lines, and his explanation is illustrated by Fig. 412, in which n and n' represent vertical and oblique sections of the same eye, looking at the point s in the triangle. Owing to the curvature factor, ab

FIG. 412.—Hering.

will be relatively less under-estimated than cb , and the angle bca will be seen too large as βca . If this explanation is correct, all triangles will appear in different relations except one in which all three angles are equal, namely, 60° , and consequently this explanation involves the under-estimation of angles under 60° , and the over-estimation of angles over 60° , and, as already mentioned, it is about this angle that the illusion of Zöllner's pattern ceases to be seen.

The illusion of Fig. 408 has also been referred to the influence of movement. It is supposed that the eye in passing from b to c is interrupted, and the movement taking place either with more difficulty or more slowly than in passing from a to b gives rise to an appearance of greater distance. Similarly, the fact that vertical lines are over-estimated relatively to horizontal lines has been referred to greater difficulty of vertical movements. Unsatisfactory attempts have also been made to refer the wrong estimation of angles and the various related illusions to movement factors.

On the other hand, these illusions have been referred exclusively to psychological factors. Lipps¹ has shown that the illusion that a square is longer vertically than horizontally is greatly assisted by the addition shown in Fig. 413, and he endeavours to explain this and all the other illusions by supposing that they suggest certain mechanical activities.

FIG. 413.

Another illusion which has recently excited much discussion is that

¹ "Beitr. z. Psychol. u. Physiol. d. Sinnesorg.," Hamburg u. Leipzig, 1891, S. 219.

shown in Fig. 414. It has been referred to the erroneous estimation of angles, and to psychological factors. The most satisfactory explanation is that our judgment of the length of the line ab is influenced by the idea of other imaginary lines, $a'b'$, $a''b''$. The illusion is diminished by making the base line ab more obvious, and increased by making the end lines more distinct. This illusion has been investigated quantitatively by Heymans, who found the illusion increased with the acuity of the angle. It increased, but not continuously with increase in length of the end lines, but attained its maximum when the end lines were between 20 and 40 mm. (with a base line of 75 mm.). Heymans¹ supposed that this result contradicted the above explanation, but it is to be expected that the distances near the base line would influence

FIG. 414.—Auerbach.

perception to a much greater extent than those more remote, and that when the two lines at each end became longer than the base line, a new kind of figure would be produced and new factors introduced.²

Colour stereoscopy.—In a red and blue pattern on a black background one of the two colours may be observed to stand out in relief. The phenomenon occurs for other colours, but is more marked the farther the two colours lie from one another in the spectrum. The first observers of this appearance saw red (or yellow) stand out in relief, but it has been found that to some individuals blue appears nearer, and that there is little difference in the numbers of those who see red or blue in relief respectively, while to others the phenomenon is very indistinct, or is not observable under ordinary conditions. In marked cases (Donders) the colour may appear to stand out as much as 20 cm. from the background at a distance of 4 metres. The appearance only occurs to a marked extent with binocular vision, but under certain conditions may be observed with one eye, though much less distinctly. It has been found by Einthoven³ to be to a considerable extent dependent on the eccentricity of the pupil; individuals with the pupil situated on the temporal side of the optic axis see red in front of blue, while those with nasal pupils see blue in relief. This comes out much more clearly if the pupils are dilated with atropin, and a small artificial pupil placed before each eye. When the artificial pupils are separated from one another, red is in relief, while, as they are approached to one another, blue starts forward. This may also be observed by separating and approaching to one another lenses held before the eyes. Hess made use of this fact to test the movements of the lens described by him (see p. 1035). With convex lenses, situated temporally, blue is seen in front; when situated nasally, red appears in front. Hess put eserine in one eye, and found, on inclining the head to the same side, thus making

¹ *Ztschr. f. Psychol. u. Physiol. d. Sinnesorg.*, Hamburg u. Leipzig, 1896, Bd. ix. S. 221.

² For reference to the chief papers on this illusion, see *ibid.*, 1896, Bd. ix. S. 16.

³ *Arch. f. Ophth.*, 1885, Bd. xxxi. Abth. 3, S. 211.

the lenses farther apart than normal, that blue stood out, while with the head inclined to the opposite side red was in relief.

The explanation originally given by Donders was based on the supposition that all individuals see red in front of blue. A greater effort of accommodation is necessary to focus red distinctly, and Donders supposed that this greater effort gives rise to the idea of greater nearness. The correct explanation was given by Einthoven, who referred the appearance primarily to chromatic aberration, acting together with the deviation between the optic axis and the line of vision. In an eye accommodated for blue, the red rays will form a diffusion circle round the focus for blue, and owing to the deviation of the optic and visual axes, as in Fig. 415, the focus for blue will not be in the centre, x , of the diffusion circles, but towards its nasal side, *i.e.* with a median pupil. If the pupil is temporal, this eccentricity will be increased; if

FIG. 415.

FIG. 416.

slightly nasal, it will be compensated for; while, with marked nasal pupil, the focus for blue will be on the temporal side of the diffusion circle. In an eye accommodated for red, as shown in Fig. 416, the focus for blue will have the same relation to that for red as in the eye accommodated for blue. Assuming that red is localised in the centre of its diffusion circle, the foci for red and blue in one eye will be on different points, while in binocular vision the red foci will be on disparate points. With median pupils the red focus will be on the temporal side of blue in each eye, and the disparation will be crossed; consequently, red will appear the nearer. With temporal pupils the disparation will be greater, and red will appear in stronger relief. With marked nasal pupils, on the other hand, the red focus will be on the nasal side of the blue focus in each eye; consequently, the disparation will be uncrossed, and red will appear further away than blue, *i.e.* blue will appear in relief.

The less marked appearance of relief which occurs in monocular

vision has been explained by Einthoven¹ differently. If a series of alternate red and blue strips are looked at with one eye and an eccentric pupil, one of the colours will appear in relief. The raised colour depends on the nature of the eccentricity and on the direction from which the strips are observed. Einthoven points out that the red and blue will be displaced laterally on the retina giving rise to dark and light borders which appear to separate the strips, and have the same effect as shadows. The colour relief, depending on the distribution of the light and shade, will consequently vary with the direction from which the colours are regarded.

Another appearance which may be referred to the same factors as colour stereoscopy, is the apparent movement of different parts of a coloured (especially red and blue) pattern. Such a pattern, when moved, especially in peripheral vision, gives a flickering appearance, which in some people produces dizziness and even vomiting. The apparent difference of movement is naturally explained by the difference of focus for different colours, and greater excursion of the more peripheral focus on movement (Schapringner).²

Visual perception of movement.—A moving object must have a certain velocity to be seen as moving. Aubert³ has found this velocity in direct vision to be between 1' and 2' in the second. At about 1', movement is only seen after some seconds; while with slower movement, namely, about 40" per second, the object appears to be at rest. The retinal distance corresponding to 1' being about 4.36 μ , the threshold of movement for the fovea corresponds fairly closely with the limit of visual acuity. It was found difficult to investigate the just perceptible difference of velocity, but for small velocities it was found to be about the same as the threshold, namely, 1'. For peripheral vision, Aubert found that the angular velocity had to be increased for movement to be seen, but the decrease of sensibility for movement from centre to periphery was proportionally very much less than the decrease in visual acuity. On the other hand, there is evidence that the peripheral retina is especially sensitive to movement. It is a familiar experience in perimetric observations that at the extreme periphery of the retina an object is not seen at all till it moves, and that this movement may be seen by an individual who is unable to describe in any way the object which is moving. According to Exner,⁴ there is a tendency to see any kind of change (change of intensity) in the periphery as movement. It is generally supposed that seeing a movement is due to a more or less complicated mental process; that a body is seen at *a* at the moment *t*, at *a'* at the moment *t'*, and at *a''* at the moment *t''*, and that it is inferred that the body has moved from *a* to *a''*. Exner⁵ supposes that there is in addition direct sensibility to movement, immediate sensation of movement. Animals often fail to see an object till it moves, even when it is quite close; and it is to be expected that seeing movement in peripheral vision should be one of the most primitive properties of the visual apparatus.

Certain after-image phenomena, which are consistent with direct

⁵ *Sitzungsb. d. k. Akad. d. Wissensch.*, Wien, 1875, Bd. lxxii. Abth. 3, S. 156.

sensibility of the retina to movement, usually receive a more complicated psychological explanation. Helmholtz¹ explained the well-known railway carriage and waterfall illusions, by supposing that an observer becomes accustomed to regard the voluntary impulses set up when looking at a moving object, as those adapted for the fixation of a resting object. When the eyes are turned to a resting object, the motor impulses continue, and bring about movements of the eyes; and since the observer supposes that his eyes are stationary, objects appear to him to move in the opposite direction to the previously observed objective movement. Helmholtz believed that this illusion did not occur with accurate fixation.

This explanation cannot apply to the modification of the illusions observed with a spiral disc (Fig. 417). When rotated this gives the appearance of circular bands moving inwards and outwards, according to the direction of rotation. When the rotation is stopped, the rings appear to move in the opposite direction, and if any object is observed it will appear to swell or diminish in size. If a grey screen is observed, or if the eyes are closed, the visual field shows a peculiar streaming appearance inwards or outwards, according to the direction of rotation.

FIG. 417.

As a modification of the experiment, Dvořák² laid on a large disc with a spiral a smaller concentric disc with the spiral in the opposite direction, and on this a smaller disc with the spiral in the same direction as the first. The after-image showed, with apparent movement, the opposite directions in the different parts. The appearances occurred with accurate fixation, guaranteed by obtaining a well-defined after-image of a white patch in the centre. According to Helmholtz's explanation, this would involve different ideas of movements simultaneously present for different parts of the retina.

There seems no doubt that these illusions depend on an after-image change of some kind taking place in the retinal (cerebro-retinal) apparatus, and are independent of movements of the eyes. Dvořák has investigated other conditions to find if change of stimulation can produce an after-image, and has found that if the illumination of a room is alternately raised and lowered, that the alternation appears to continue for a time after the illumination is made constant; during the objective alternation he noticed contraction and dilatation of the pupil, which did not continue during the subjective alternation. These subjective alternations may, however, have been of the same nature as the periodical variations of the after-image.

When a figure made up of narrow concentric black and white rings

¹ "Handbuch d. physiol. Optik," 2te Aufl., S. 746.

² *Sitzungsb. d. k. Akad. d. Wissensch.*, Wien, 1870, Bd. lxi. Abth. 2, S. 257.

is moved in the same way, as in rinsing out a basin, the figure appears to rotate round its centre. One of the factors upon which this depends appears to be the unequal distinctness of vision in different meridians, due to astigmatism. If a number of such figures be placed round a ring with teeth projecting inwards, and the whole moved in the same way, the inner toothed ring will appear to rotate in the opposite direction to that of the figures, and more slowly.

A peculiar illusion of movement was first described by Charpentier,¹ and later by Aubert² and Exner;³ by the latter it is referred to "auto-kinetic" sensations. If a small feebly illuminated object be observed in a room, otherwise completely dark, the object will appear to move with a certain rapidity in a definite direction. Charpentier found its angular velocity about 2° to 3° per second, and that the total movement might be through as much as 30°. He found that the appearance was not due to unconscious movement of the eyes, and occurred, though in a less marked degree, when other control points of light were present. Its direction was influenced by the idea of a certain direction; a loud sound caused a movement towards the supposed direction of the sound, and direction of the attention to the floor caused movement downwards, to the roof upwards. If due to movement of the eyes, the apparent movement should have been in the opposite direction. Aubert found also that a real movement of the object might not be seen.

Localisation in animals.—The question of the mechanism of the estimation of space relations in animals below man is one of great difficulty. One can hardly believe that the more psychological motives of localisation, which play so important a part in man, can be of any importance here; on the other hand, the most definite physiological factor, the binocular mechanism, is out of the question in some animals, as birds, and must be of a special nature in other animals. Only man and some primates have the two features, optic axes capable of convergence and a single central fovea. Other animals have structural peculiarities which have been regarded as of a foveal nature, but we know nothing of their function. It is quite possible that binocular mechanisms may exist wholly different from that found in man. Loeb⁴ has suggested that the marked astigmatism found in many animals may play a part in space perception. The astigmatism is so considerable that the form of the retinal image must be appreciably affected by movements of an object nearer to or away from the eye, and it is quite conceivable that these changes in form might act as the basis of localisation.

THE EXTERNAL EAR.

The auricle.—The most natural supposition is that the auricle reflects sound-waves into the external meatus. But cases of absence of the auricle have been recorded without any appreciable diminution in the power of hearing,¹ and persons from whom the external ear has been removed have been found to possess normal hearing power. Experiments upon the auricle, in which the depressions on its surface were filled up, have given contradictory results.² M'Kendrick³ found that covering the external ear with plaster of Paris, leaving the entrance to the canal free, weakened the intensity, and altered the quality of tones. It must be observed that in such experiments the mass of the auricle itself would not be able to vibrate to the same extent as in the normal condition, and hence an apparent diminution of hearing may have been due to a loss of vibrations conducted by the solid structures, and not to the loss of the reflecting action of the auricle.

Long ago, Boerhaave attempted to show mathematically that the concha acts as a parabolic reflector, collecting and throwing vibrations into the meatus. Savart,⁴ however, demonstrated experimentally that this is not the case. Still there is evidence that the concha does in a slight degree affect acuteness of hearing by reflection. Thus⁵ if a small tube, curved like a

⁵ Politzer, "Diseases of the Ear," 1894, p. 710.

hunting-horn, is inserted into the meatus in such a way that its wide opening is directed backwards to the concha, hearing is assisted, the sound-waves which strike the concha being reflected upon the instrument, which then directs them inwards.

A more delicate mode of testing this question is to sound a compound tone, and observe whether it changes in quality, according to its position in relation to the ear. Thus, if the auricle reflects the fundamental tone more strongly than the partials, or the converse, then a change in the quality of the tone should be perceptible when alterations are made in the position of the source of sound. Experiment shows that such a difference in quality is found to occur. Thus S. P. Thompson¹ has pointed out that the ticking of a watch placed in the middle line behind the head appears to have a slightly different quality from that which it possesses when held in the corresponding position in front of the head, the higher tones being relatively more pronounced in the former case. Gray² has found that by putting the hand in front of the ear, with the hollow of the palm directed backwards, while the watch is behind the head, the relative increase in the intensity of the higher tones is annulled, and the sound has the same quality as when held in front of the head.

Mach³ has suggested that the pinnae may act as resonators for the higher partials of compound tones. S. P. Thompson⁴ is of opinion that the cartilaginous rim at the outer margin of the pinna may catch sound-waves that have been reflected from the ground in an upward direction. Politzer⁵ asserts that not only the concha but also the tragus exercises a certain influence upon sound-waves. By placing a small disc behind the tragus, and thus directing its apex outwards, he found that acuteness of hearing was appreciably increased. This increase he attributes to the larger surface which the tragus offers to waves which have been reflected forward from the concha, and which are finally reflected into the meatus. It must be stated, however, that some authorities⁶ hold that the auricle does not act as a reflector of sound at all.

Another function of the auricle, probably quite as important as its acoustic function, is its protective influence. The mouth of the meatus is somewhat twisted, and since the tragus projects backwards over it, the difficulty of foreign bodies obtaining entrance is much increased. The stiff hairs which are present in the lower animals, and frequently also in the human subject, at the entrance to the meatus, no doubt aid in this protective function, by preventing the entrance of dust, insects, etc., into the outer canal.

The external auditory meatus.—The functions of the external auditory meatus are (1) to conduct waves of sound to the membrana tympani, and (2) to afford protection to this membrane and the delicate structures in the middle ear.

As regards its first function, the question of its action upon the reflection of sound again comes into consideration, and authors are not wanting who find in its various curves a means of reflecting the waves of sound to the drum-head. Such curves exist at two places, one at the depression on the posterior wall of the cartilaginous meatus, immediately after its commencement, and the other at the concavity which occupies the anterior and inner wall of the meatus, and which is subtended by the tympanic membrane. Politzer⁷ states that the latter concavity is in the form of a parabolic curve, and will thus reflect sound-waves very powerfully on to the membrane. The

⁷ *Op. cit.*, p. 57.

value of these cavities, however, for thus concentrating and directing sound-waves, is problematical, as obliteration of the external one by displacement of the auricle backwards has no detrimental effect upon hearing (Gray).

The width of the meatus varies much in different individuals; in rare cases the greater part of the drum-head may be seen by looking directly into the meatus, without any displacement of the cartilaginous structures. These anatomical variations have not been found to produce any appreciable effect upon hearing. Further, the lumen of the tube may be considerably narrowed by putting in small pellets of wax without any noticeable diminution in the intensity with which sounds are heard.¹

The protective function of the meatus is more important than any function it may perform of reflecting waves of sound upon the membrane. The tube protects the membrane in two ways—(1) By its varying curvature and by its length, and (2) by the secretion of cerumen. As regards the first, it is obvious that any foreign body entering the meatus will come first into contact with one wall and then with another, and may thus be arrested. Further, as the meatus is of considerable length (averaging 24 mm.) in proportion to its transverse area, the air in its cavity maintains a fairly uniform temperature. This temperature is only slightly affected even when the external air is very cold, or when strong winds or draughts blow upon the ear.

By the secretion of cerumen, the entrance of foreign bodies, especially insects, is prevented. Dust and small particles of foreign matter readily stick to the cerumen, and are thus hindered from passing inwards.

The chemical analysis of cerumen shows water, fats, and a yellow pigment, the nature of which has not yet been determined. Cerumen has a bitter taste and an aromatic odour. Probably those qualities deter insects from entering the meatus. They are rarely found in the cavity.

Cerumen is formed, usually in small quantities, by the tubular glands found in the skin lining the walls of the cartilaginous portion. At the outer part of the meatus the glands are scattered throughout the whole circumference of the tube, but on passing inwards we find that those on the inferior and anterior wall rapidly diminish in number, and cease to exist before the osseous meatus is reached. On the posterior and superior wall they are found further along the tube, and a few even exist in the osseous meatus.

Now, since the cartilaginous portion of the tube slopes downwards, from within outwards, it is obvious that the force of gravity will tend to draw the cerumen

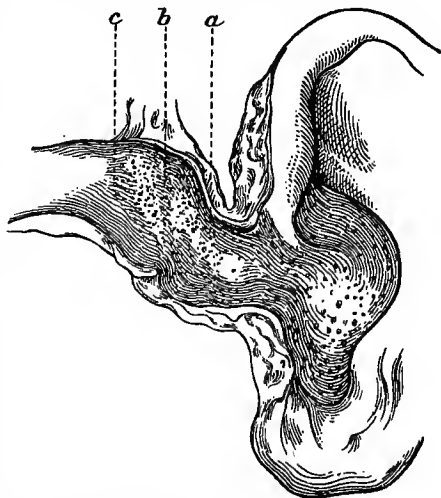

FIG. 418.—Posterior wall of the cartilaginous and osseous meatus. *a*, Orifices of glands on the cartilaginous portion; *b*, boundary between osseous and cartilaginous meatus; *c*, termination of the triangular space occupied by the orifices of the glands.—Politzer.

¹ Politzer, *op. cit.*, p. 57; and *Arch. f. Ohrenh.*, Bd. ix. S. 72.

downwards and outwards. Since the osseous portion of the meatus runs from above downwards and inwards, it is evident that, if glands existed in this portion, the cerumen would collect around the tympanic membrane, with a result disastrous to the transmission of sound.

The outward flow of cerumen is also aided by the continually repeated movements of the cartilaginous meatus which occurs during mastication.

Movements of the auricle.—The movements of the auricle in the human being are for the most part insignificant. They have no effect on hearing. The muscles of the tragus and antitragus tend to contract the orifice of the meatus, while those of the helix produce the opposite effect. Many animals have the power of moving the opening of the auricle in the direction from which the sound comes. Thus the horse pricks its ears when it hears a sound, and no doubt its appreciation of the direction of sounds is thereby assisted.

Though none of the muscles of the pinna are, as a rule, under the control of the will, yet some individuals have the power of moving that structure as a whole. No doubt, by attention and practice, a man may acquire the power of moving the auricle slightly; but at best these movements are small as compared with those of the lower animals. Politzer¹ states that an unconscious movement of the ear occurs in many persons when they listen to a very feeble noise. In some animals a reflex contracture of the muscles of the pinna occurs when the ear is suddenly stimulated by sound.

THE MIDDLE EAR.

The function of the middle ear is to receive sound-waves occurring in the air, and to transmit the effect of these to the labyrinth. The reception of the waves naturally comes first under consideration, and, since the tympanic membrane is the only structure concerned in this part of the process, an accurate knowledge of its anatomical structure, position, and tension in the living being are necessary for a full appreciation of its important function.

The tension of the membrana tympani, and its regulation.—Although, as a matter of fact, the membrana tympani is a stretched membrane, yet, from the acoustic point of view, it does not act like the membrane of a drum. If it did so act, waves of sound would cause it not only to vibrate, but to continue vibrating after the tone had ceased, and thus confusion and indistinctness of the sound would result. The membrane is also perfectly elastic in all its parts, although the amount of movement of various parts is not the same, owing chiefly to the fact that the relative number of radiating and circular fibres varies in different parts. Thus the central portions are composed almost entirely of radial, while the peripheral parts are formed chiefly of circular fibres. If the air in the external meatus be rarefied and condensed alternately by means of a pneumatic speculum, it will be observed that certain parts of the membrane undergo much greater alterations in position than others. Mach and Kessel² first demonstrated that this change in position of the membrane was greatest in the posterior segment.

Some writers have asserted that the membrane has a tone of its own. Thus Politzer³ names the tone as e^4 (m^4), having a vibration frequency

¹ *Op. cit.*, p. 56.

² *Sitzungsab. d. k. Akad. d. Wissensch.*, Wien, 1874, Bd. lxxix. S. 221.

³ *Op. cit.*, p. 58.

per second of 2560, and König places the pitch of the proper tone two octaves higher, namely at mi^6 , the frequency of which is 10,240. But it is very doubtful if the membrane can be said to have any proper tone in the living body; if it has such, the pitch is in all probability nearer that assigned to it by König than by Politzer.

The tension of the drum-head is maintained in the living body by the *tensor tympani*: like other muscles, it possesses a constant tonicity. As the tendon of the muscle is inserted into the handle of the hammer a short distance below the horizontal axis of rotation of the bone, it is obvious that it must exert a constant force tending to draw the membrane inwards.

The cone which is formed by the inwardly drawn membrane has its walls convex outwardly. This is due to the arrangement and relative length and strength of the circular fibres. This mechanism may be illustrated by an experiment upon a spider's web, which is also composed of circular and radiating fibres. If the centre of the web be drawn out at right angles to its plane, it will be found that the sides of the cone thus formed are convex in a direction opposite to that towards which the apex of the cone points (Gray).

Secchi¹ maintains, as the result of experiment, that there exists in the living subject a pressure in the tympanic cavity of 4 mm. above that of the external air. This statement has neither been confirmed nor denied by other investigators, but it is difficult to see how it can be brought into line with well-ascertained facts regarding the tympanum.

Movements of the membrana tympani in response to sound pressures.—If the drum-head had been a uniformly flat stretched membrane, the amplitude of its movements in response to the varying pressures of sound-waves would be greatest in the centre, while it would diminish as the periphery of the membrane was approached. A variety of conditions combine to render the movement much more complex. These are the peculiar curvature of the membrane, the fact that it is weighted by the hammer, and the pull which the tensor tympani exerts upon it through the hammer. Helmholtz² was the first to investigate this problem in a satisfactory manner.

As the outward curvature of the radial fibres is slight, each fibre may be regarded as the long arm of a lever, while the handle of the hammer is the short arm. This mechanism secures that a slight pressure of the air, corresponding to a sound-wave, exerts a considerable force upon the malleus. To aid in understanding the mechanism, it will be easier to consider, first, the effect of pressure upon a single radial fibre. The fibre may be regarded as inextensible and slightly curved outwards; hence variations in pressure on the convexity of the curve will cause the degree of curvature to change, while the length of the arc will remain the same.

FIG. 419.—*a*, Outer margin of meatus; *b*, *c*, tympanic ring with the membrane between, showing its curvatures.—Helmholtz.

¹ *Trans. Internat. Med. Cong.*, Berlin, 1891; Rome, 1894.

² "Ueber die Mechanik der Gehörknöchelchen," "Wissenschaftliche Abhandlungen," Bd. ii. S. 503 and 515; "Die Mechanik der Gehörknöchelchen und des Trommelfells," *Arch. f. d. ges. Physiol.*, Bonn, 1868, Bd. i. S. 1; see also the translation of the latter work by A. H. Buck and N. Smith, New York, 1873. The description is taken from Helmholtz's work.

In other words, the radius of the arc and the chord of the arc will change, while the length of the arc remains constant. But the length of the arc may be regarded as the length of a radial fibre; hence—

$$l = 2r \sin^{-1} \left(\frac{\lambda}{2r} \right)$$

where l = length of fibre, r = radius of the circle of curvature, and λ = chord of the arc l , because $\frac{\lambda}{2r}$ is the sine of half the angle at the centre belonging to

FIG. 420.

the arc l . This equation may also be written—

$$\lambda = 2r \sin \left(\frac{l}{2r} \right).$$

Now, if we subtract the one equation from the other, we have—

$$l - \lambda = 2r \left\{ \frac{l}{2r} - \sin \left(\frac{l}{2r} \right) \right\}$$

which gives the difference between the chord of the arc and the curve.

But as the curve is very slight, r is large in comparison with l , and the divisions becoming rapidly very small as the sine in the formula is developed by the involution of its arc. Hence—

$$\sin \frac{l}{2r} = \frac{l}{2r} - \frac{1}{6} \left(\frac{l}{2r} \right)^3$$

and from this the preceding equation becomes—

$$l - \lambda = \frac{1}{24} \frac{l^3}{r^2} \dots \dots \dots (1).$$

Again, let s be the distance of the centre of the arc from the centre of the chord, then the degree of curvature is found by the equation—

$$\frac{r - s}{r} = \cos \frac{l}{2r}.$$

So that

$$\begin{aligned} s &= r - r \cos \frac{l}{2r} \\ &= r \left(1 - \cos \left(\frac{l}{2r} \right) \right). \end{aligned}$$

By evolution of the cosine—

$$s = \frac{1}{8} \frac{l^2}{r} \dots \dots \dots (2).$$

Now eliminate r from equations 1 and 2, and we obtain

$$l - \lambda = \frac{8}{3} \frac{s^2}{l}$$

This equation gives the amount of shortening of the chord which occurs when the curve of the arc is increased; that is to say, it gives the extent to which the two ends of the fibre are drawn together. Now, if s , the displacement of the middle of the fibre, be very small in comparison with l , then $l - \lambda$ obviously becomes very small in comparison with s . Conversely, the very small increase in the magnitude $l - \lambda$ must cause a relatively great increase of

s; that is to say, it must cause a relatively great displacement of the centre of the fibre.

Again, if t = the tension of the fibre, p = the pressure on each unit of its length, and r = the radius of curvature, then—

$$t = pr$$

and the forces which act upon both ends of the fibre must be equal to the pressure which acts upon the diameter of the semicircle through a width equal to that of the fibre.¹ Therefore

$$2t = 2pr.$$

Hence the greater the radius of curvature, the greater will be the alterations in tension of the fibre, caused by changes in the pressure of the air. Further, as the radial fibres are those which are attached to the malleus, it is evident that the variations in the tension of the fibres cause movements of the bones when sound-waves strike the drum-head. Thus a very small change of pressure in the air causes a considerable change in the tension of the fibres; and further, in accordance with the laws regulating the action of the lever, as the force which the fibres exert upon the handle of the malleus increases, the amplitude of movement of that bone diminishes. In this way the special form of the drum-head secures a maximum of efficiency for tones of the feeblest intensity.

The movements of the malleus.—The movements of the malleus are of two, possibly of three kinds. An accurate knowledge of the anatomy of the ligaments and articulations is necessary for their comprehension.

In the first place, as the malleus is firmly attached to the membrana tympani along the manubrium, it is obvious that the movements of the membrane would tend to carry the bone inwards as a whole. This movement, however, is to a great extent prevented by the ligaments attached to the head and neck of the malleus, and in the living subject it is exceedingly minute. A second and also comparatively unimportant movement of the malleus is that of rotation on the axis passing through the length of the bone from above downwards. This movement is produced by the tensor tympani, the tendon of which is not inserted into the bone straight, but somewhat at an acute angle or on one side. Hence, when the muscle contracts, it not only pulls the handle of the malleus inwards, but also rotates it round an axis passing from the head of the bone downwards to the tip of the manubrium. This movement, however, is very insignificant.

By far the most important movement of the malleus is one of rotation round a horizontal axis, which passes through the anterior ligament and head of the malleus, the body of the incus, and the short process of the incus (see Fig. 421 p. 1158). When the manubrium is pushed inwards, the part of the malleus above this axis must move outwards. The ligaments, especially the external and superior, prevent extensive movements of the malleus.

The movements of the incus.—This bone is attached to neighbouring structures at three places. Two of these attachments are true joints, namely, the malleo-incudal and the stapedial; the third is where the short process of the incus is connected with the posterior wall of the tympanic cavity. The malleo-incudal joint is peculiar both as to

¹ Helmholtz, *op. cit.*

structure and mode of action. The posterior surface of the rounded head of the hammer fits into the somewhat saddle-shaped concavity of the anterior surface of the anvil. At the lower margin of the joint the prominent edge of the malleus fits on the lower edge of the articular surface of the incus in such a way, that with every movement of the edge of the malleus inwards the incus is carried inwards at the same time; whereas, when the malleus moves outwards, the incus behind is not compelled to follow the malleus to the full extent of its movements.

The short process of the incus fits into a slight depression on the posterior wall of the tympanic cavity, close to the entrance to the mastoid cells, where it is fixed by a ligament. The tip of the short process is covered with cartilage, and a certain degree of movement is possible at the point of contact with the temporal bone.

The remaining connection of the incus is that of its long process with the stapes. This presents the usual features of a joint. Its capsule contains a considerable amount of elastic fibre, and it is somewhat firmer and stronger on its inferior aspect. The movements of the incus, under the influence of sound-waves, are similar to those of the malleus, but less in extent. The bone rotates round an axis, which passes from the tip of the short process through its body, and which, if continued, would pass through the neck of the malleus, and just above the cog-like edge of the articular surface. Thus, as has already been pointed out, when the handle of the malleus moves inwards, the greater part of the body of the incus and of the head of the malleus move outwards together, and the long process of the incus moves inwards. The result of this lever-like mechanism is that, when the *membrana tympani* and the handle of the malleus move inwards, the base of the stapes is pushed into the oval window.

The movements of the stapes.—This bone is fixed in the *fenestra ovalis* by the annular ligament. It is placed almost at a right angle to the long process of the incus, and one would at first sight imagine that it must slightly follow the to-and-fro movements of that process. It does not, however, move exactly in this way, because the fibres of the annular ligament are more tense below than above the foot-plate of the bone, and hence movement is more free along the upper edge of the foot-plate than along the lower edge.

Before we discuss the movements of the ossicles, as constituting a chain or lever passing from the *membrana tympani* to the *fenestra ovalis*, it is necessary to describe the action of the intrinsic muscles of the ear.

The tensor tympani.—When this muscle contracts, the *membrana tympani* becomes more tense. A careful consideration of the exact position of its insertion into the bone shows that the tendon is attached to the anterior surface of the inner edge of the manubrium, and not to its posterior surface; contraction of the muscle must tend to rotate the malleus on its vertical axis. Further, the point of insertion is much nearer the axis of rotation than the attachment of the radial fibres of the tympanic membrane. Thus the mechanical arrangement is that of a lever of the third order, in which the power (contracting force of the muscle) is placed at a short distance from the fulcrum, while the weight (resistance or tension of the fibres of the membrane) is at a considerable distance. Hence the force with which the muscle renders

the membrane tense will be much less than its actual power, while, on the other hand, the amplitude of movement at the point of resistance will be considerable.

Again, when the muscle is in a state of contraction, it renders all the ligaments of the ossicles tense, with the exception of the superior ligament of the malleus. This effect may be seen in the human subject, if the tympanum be opened during rigor mortis.

The normal stimulus which causes the tensor tympani to contract is the pressure of sound-waves on the membrana tympani. Although the innervation of the membrana has not been conclusively established, there is little doubt it is supplied with sensory nerves by the fifth, and also by the tympanic plexus, formed by fibres derived from the otic ganglion, from the petrosal ganglion of the glosso-pharyngeal, and from the carotid plexus.¹ When pressure is made on the membrana, there is irritation of these sensory nerves, followed by a reflex contraction of the tensor tympani, supplied by a motor filament from the motor division of the fifth nerve.² This response to sound was first discovered by Hensen and Bockendahl.³ They attached a light signal to the tendon of the muscle in the dog, and observed a movement when a note was sounded. Pollak⁴ found that when one ear was stimulated by sound-waves, the tensor tympani on the opposite side was also thrown into contraction. He also found that the reflex contraction was most marked when a tone of high pitch was sounded, deep tones causing only very slight contractions. The tensor tympani also contracts during yawning. In a few rare cases, the muscle appears to be under control of the will.⁵

The stapedius.—Henle⁶ was of opinion that the stapedius, when it contracted, held the plate of the stapes firmly in its place, and prevented it being forced into the fenestra ovalis, when strong pressures were communicated to it from the membrana tympani. On the other hand, Politzer⁷ endeavoured to demonstrate that contraction of the muscle draws the plate of the stapes out of the fenestra ovalis, and, by releasing the tension of the chain of bones, produces relaxation of the membrana tympani. According to this view, the stapedius is the antagonist of the tensor tympani. The stapedius is supplied by a branch of the facial nerve. We have no direct evidence of any reflex excitation of the stapedius, but one would expect it to respond in a manner analogous to the response of the tensor tympani. Lucae⁸ suggests that it may respond to tones of high pitch, and he also mentions that contraction of certain muscles of the face, especially of the orbicularis palpebrarum, causes a simultaneous contraction of the stapedius.

The movements of the ossicles as a whole under the influence of sound-waves.—When a sound-wave strikes the membrana tympani, that structure will be driven inwards during the positive phase; that is to say, during the time when the pressure is greater than

atmospheric pressure. As the handle of the malleus is attached to the membrana tympani, it must also move inwards; but as this bone rotates round its axis, the head of the malleus is carried outwards, and it carries the upper part of the body of the incus along with it. The incus also rotates round an axis passing through the lower part of the body, so that the long process passes inwards, driving the stapes before it. During the negative phase of the sound-wave—that is to say, when the pressure is less than atmospheric pressure—the reverse action takes place, with this difference, that the malleus can unlock itself from the incus and swing some distance outwards without carrying the incus along with it.

In the transmission of the effect of a sound-wave from the membrana tympani to the labyrinth, there is a change in the amount of force, and a corresponding change in the amplitude of the movement. We may regard the mechanism of transmission as serving the purpose of conveying periodical variations of

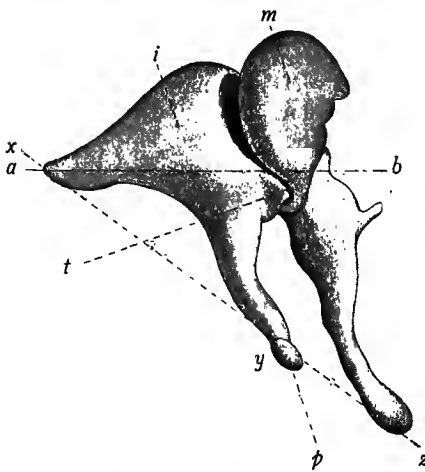

FIG. 421.—To show the relations of the malleus and incus to one another.—Helmholtz. *m*, Malleus; *i*, incus; *p*, its long process; *t*, tooth of incus fitting against ridge of malleus; *a-b*, axis of rotation of the bones; *x, y, z*, line joining short process of incus with end of handle of malleus.

pressure, occurring in the air, into a minute cavity or space full of fluid, in which the terminal organ of hearing exists. It is extremely difficult to transmit sound-waves from air into a fluid, especially if the cavity containing the latter be of very small dimensions. This result is attained with a minimum loss of energy by the chain of bones. The chain may be regarded as a lever, in which the manubrium of the malleus forms the long arm, the axis of rotation passing through the malleus and incus forms the fulcrum, and the long process of the incus, carrying the stapes, forms the short arm. The pressure of the sound-wave, applied by the membrana tympani to the manubrium of the malleus, may be regarded as the force, while

the resistance is at the base of the stapes, by which the pressures are communicated to the labyrinth. The mechanism is therefore a lever of the second order. Careful measurements have shown that the length of the long arm is to the length of the short arm as 1.5:1. The resulting force at the stapes is therefore correspondingly increased, while the amplitude of the movement at the stapes is correspondingly less than at the tip of the manubrium. Thus the pressures are conveyed with great efficiency from the membrana tympani to the labyrinth, and the amplitude of the oscillation is diminished so as to be adapted to the small capacity of the labyrinth. Further, it is to be observed that as the drum-head is nearly twenty times larger than the fenestra ovalis, the energy of the movements of the membrana tympani is concentrated on an area twenty times smaller; hence the pressure of a sound-wave, acting on the membrana,

is increased thirty-fold (1.5×20), when it acts on the plate of the stapes.

Before leaving the subject of the transmission of pressures corresponding to sound-waves, from the air to the labyrinth, we may consider the effect which the dimensions of the conducting apparatus have on the transmission. The first who drew attention to this subject was Weber,¹ and it has been further investigated by von Helmholtz.² By dividing the velocity of sound in air by the number of vibrations per second, we obtain the wave-length. It is thus ascertained that the wave-length of sounds of the lowest pitch recognised by the human ear is about 40 ft., that the lowest tone of the organ has a wave-length of about 37 ft., that the wave-length of the middle *c* of the piano is above 4 ft., that the highest tone of the piccolo stop of the organ has a wave-length of 3.5 in., while the wave-length of the highest tone audible to the ear is at least .5 in. Thus it is evident that the total length of the solid and fluid masses of the ear is only a small fraction of the wave-length of ordinary perceptible sounds. Hence we must regard the ossicles and the intra-labyrinthine fluid, not as forming an independent vibrating mass, but as one body which has practically no proper vibration period. If, for example, it were possible to throw the ossicles into periodic vibrations, the tone resulting thereby would be so high in pitch as to be beyond the limits of hearing. The movement of the chain of ossicles, therefore, forms only a small part of a sound-wave.

The magnitude of the movements of the ossicles.—The movements of the bones of the ear may be studied experimentally in the dead animal by various methods. Politzer³ opened the cavity of the tympanum, and fixed bits of fine glass thread to the various ossicles; the free ends of the threads were then adjusted to a surface of a recording drum. When a sound was allowed to fall on the membrana tympani, the glass threads oscillated and traced curves on the smoked paper covering the drum. The movement of greatest amplitude was found to be at the tip of the manubrium, 0.76 mm.; the movement at the tip of the long process of the incus was 0.21 mm.; while the greatest amplitude at the stapes was .0714 mm. A similar series of measurements were made by Mach and Kessel⁴ and by Buck⁵ in 1870. In the following year the matter was re-investigated by Burnett.⁶ He opened the tympanum, illuminated the interior by a strong beam of light, sprinkled the ossicles with powdered starch, so as to secure brightly luminous points, fixed a tube into the external auditory meatus so as to convey vibrations from an organ-pipe to the outer surface of the membrana tympani, and then observed the excursions of the shining particles when the organ-pipe was sounded. The chain of bones vibrated in excursions bearing a fixed relationship to each other. Particles on the fenestra rotunda were seen to vibrate synchronously with oscillating particles on the stapes. Further, the excursions at the fenestra rotunda were equal to those of the stapes, and sometimes they were equal to those at the point of the manubrium. The amplitude of movement at the base of the stapes and round window varied from 0.001 to 0.032 mm., considerably less than the measurement made by Politzer. Burnett also made the interesting observation that variations in the labyrinthine pressure modified the amplitude of movement at the stapes, an increase of

pressure diminishing, while a diminution of pressure increased the amplitude. It is more than probable that in all of these experiments the amplitude has been over-estimated, as the restraining influence of the tensor tympani and stapedius does not come into play after death. Very feeble sounds no doubt cause a movement of the stapes so small as to be invisible to the microscopic powers that can be employed in such observations. The greatest movements occur with tones of medium pitch.

An interesting experiment may also be performed, in which the cat's tympanum is used as a manometric capsule, after the well-known method of König. Two small glass tubes are fixed with sealing-wax into holes trephined in the tympanic bulla, and a tube carrying a conical mouthpiece is also inserted into the external meatus. Gas is led into the cavity by one of the small tubes, and it issues from the cavity by the other tube to a small gas jet. When sound-waves, such as those of organ-pipes, tuning-forks, or of the human voice, are conveyed by the mouthpiece to the membrana tympani, flame pictures, similar to the well-known flame pictures of König, may be seen on rotating a rectangular mirror in front of the flame.¹

Transmission of sound to the labyrinth otherwise than by the ossicles.—The earlier physiologists, and in particular Scarpa, were of opinion that sound passed from the tympanic membrane into the air in the tympanum, and was transmitted to the labyrinth by the fenestra rotunda, which was termed a secondary tympanum. Experiments made by Weber-Liel,² by a method very similar to that of Burnett, already described, supported this view, but on the whole it was not accepted by the majority of physiologists. In 1894, Secchi³ advocated the same view, on the ground that, as the tympanum is a closed cavity, changes in the position of the membrana tympani must be accompanied by changes in the pressure of the air within the cavity. These variations of pressure in the cavity are distributed over its walls, and as these are rigid everywhere except at the fenestra rotunda, the variations of pressure could be transmitted to the fluid in the labyrinth by the fenestra rotunda. It must be remembered, however, that, from the mechanical arrangements already described, almost all the energy of the membrana tympani is conveyed to the fenestra ovalis by the chain of bones. And if we suppose that pressures are communicated simultaneously to the fenestra ovalis and to the fenestra rotunda, to the first by a chain of bones, and to the second by the air in the tympanum, any inward pressure on the fenestra rotunda will be more than annulled by the inward pressure on the fenestra ovalis, and that therefore there must be an outward movement at the fenestra rotunda, when there is an inward movement at the fenestra ovalis, a result which is confirmed by experimental observation (M'Kendrick). Finally, interference with the movements of the chain of bones has a marked effect upon the perception of sound, which could not be the case if they did not play the more important part in the conduction of sound. At the same time, it may be admitted that in exceptional cases, in which the chain may be absent, hearing may still exist, in consequence of aerial pressures being communicated to the membrane covering the fenestra rotunda.

¹ M'Kendrick, "Text-Book of Physiology," vol. ii. p. 687.

² *Centralbl. f. d. med. Wissensch.*, Berlin, 1876, Bd. xiv. S. 17.

³ *Loc. cit.*

Secchi's views have, up to a certain point, received confirmation from the recent careful observations of Bezold.¹ The latter has found that, in disease causing rigidity or loss of the ossicles, the hearing is seriously affected as regards the lower and middle notes, while the upper notes are heard perfectly well. Thus the sufferers may not hear loud thunder, but the whistling of a canary may be clearly heard at a considerable distance. Hence Bezold holds that the ossicles are indispensable for the transmission of the lower notes, but take no part in the conduction of the upper ones.

There is still another route by which sound pressures may be transmitted from the external air to the labyrinth, namely, by the bones of the head. This is the case not only when the sounding body is applied to the cranium, but also when the sounds are transmitted through the air. Politzer² found that when the external auditory meatus on both sides was filled with glycerine, and the nose and mouth firmly closed, conversation could be understood at a distance of 0·5 metre. It is also known that tones are perceptible even in cases where the stapes is ankylosed to the edges of the fenestra ovalis, if the tones are of sufficient intensity. As sound-waves are conducted through the solid and fluid parts of the body, they must directly reach the labyrinth without passing through the external or middle ears. Therefore, if the structures in the labyrinth are normal, it is impossible to exclude completely sound-waves from being perceived when transmitted by the bones of the head.

Regulation of atmospheric pressure in the tympanum.—As the membrana tympani is very thin and fibrous, the pressure of the air on each side of it must affect its capability of vibrating when subjected to periodic sound pressures. On one side it is freely exposed to the air, while on the other it is in contact with a confined mass of air in the tympanic cavity. As the air in the latter might be to some extent absorbed, and consequently have its pressure reduced, and as, on the other hand, the pressure of the air on the outer surface is liable to considerable variations, there must be some arrangement for establishing from time to time an equilibrium of pressure on the two sides of the membrane. This is accomplished by the Eustachian tube, passing from the tympanic cavity to the posterior part of the pharynx. This tube occasionally opens so as to allow the air of the pharynx, which communicates by the oral and nasal openings, to pass into the tympanum, and to exert its pressure on the inner surface of the membrana tympani. It is usually held that the Eustachian tube is closed during ordinary breathing, and that it is opened only at the moment of deglutition. Cleland³ and others,⁴ however, maintain that the tube is open during rest, and closed during deglutition.

An experiment performed by Politzer⁵ throws some light upon the matter now under consideration. He constructed a small glass manometer, the short limb of which passed through an indiarubber cork. A few drops of a coloured fluid were introduced into the manometer. The cork was pressed

⁵ "Diseases of the Ear," p. 64.

tightly into the external auditory meatus. It was then found that, after closing the nostrils, the first stage of deglutition caused the fluid to rise slightly in the manometer. The rise was quickly followed by a considerable fall during the second portion of the act, and the fluid remained at the level to which it had fallen until deglutition with the nostrils opened was again performed. This would appear to indicate that, when the nostrils were closed, the air in the pharyngeal cavity communicated with that in the tympanic cavity at the beginning of swallowing, thus causing a rise of pressure. Further, that in the later portion of the time of swallowing, the tube still seemed to be open, so as to allow of some of the air being sucked out of the tympanic cavity, causing a fall of pressure. The tube then was closed and remained closed until the next process of deglutition.

FIG. 422.—Ear manometer.—Politzer.

With the same instrument, Politzer found that in many individuals slight fluctuations occurred, synchronous with expiration and inspiration, even when these acts were quietly performed, showing that the tube, in some persons, may be slightly open, even when the muscles of deglutition are not in action. He also states that air passes more readily from the tympanum to the pharyngeal cavity than in the reverse direction, probably owing to the suction-like action of the larger cavity.

It has also been observed that in a case of paralysis of all the muscles attached to the cartilaginous portion of the tube, a falling inwards of the membrana tympani occurred, from absorption of air in the tympanic cavity and consequent diminished pressure, thus showing that the muscles are necessary for the passage of air into the tympanum (Gray).

We may conclude that, during rest, the condition of the Eustachian tube varies from a position of slight opening to gentle closure. When swallowing occurs there is a firm closure of the tube, caused by the upward pressure of the levator palati. This is quickly followed by the tube becoming widely opened, chiefly by the action of the tensor palati.

AUDITORY REFLEXES.

As has already been noticed (p. 1157), Pollak¹ has observed the peculiar fact, that when a sound is led to one ear, a reflex contraction of the tensor tympani of the opposite ear occurs; high notes produce this reflex better than low ones.

Lucae² maintains that a reflex contraction of the stapedius occurs simultaneously with voluntary contraction of the facial muscles, particularly the orbicularis palpebrarum. This produces a deep humming noise in the ear, and a relaxation of the tympanic membrane. According to Politzer,³ during this contraction the perception of the middle and the deeper notes of the tuning-fork is destroyed. The present writers, however, cannot corroborate this latter statement.

Politzer⁴ and Helmholtz⁵ have observed that during yawning a reflex contraction of the tensor tympani occurs, causing slight temporary deafness.

A peculiar aural reflex has been described by Gray.⁶ If a watch or

⁶ *Proc. Roy. Soc. Edin.*, 1897, vol. xxi. p. 443.

tuning-fork of fairly high pitch be held a few inches from one ear, while the chain of ossicles of the other ear is pushed gently inwards by a probe or by pressing the finger into the meatus, thus condensing the air within, the tuning-fork or watch will be better heard. This is probably due to increased labyrinthine pressure in one ear, causing a reflex contraction of the intra-tympanic muscles of the opposite ear.

Urbantschitsch¹ has stated that the stimulation of one ear by sound causes increased sound perception in the other ear. This may be true under some circumstances, but certainly not under all, for, as Politzer² says, a loud sounding tuning-fork held opposite one ear destroys the perception for a weak sounding fork held opposite the other ear.

Various writers have recorded cases of subjective colour sensations accompanying audition, and these cannot be considered pathological, for they have occurred in perfectly healthy individuals.³

BINAURAL AUDITION.

Binaural audition, in the ordinary sense of the term, does not affect the quality of sounds, but there is little doubt that it does affect the intensity with which sounds are perceived. With the exception described above (p. 1163), we hear a sound louder with two ears than with one. Urbantschitsch⁴ attributes this to the passing of subjective irritation from the auditory centre of one side to that of the other. Politzer,⁵ however, maintains that this explanation is superfluous, and considers that the superiority of binaural over monaural audition is due to the well-known physiological law of "summation of sense."

But the greatest difference between binaural and monaural audition is, that by the former we are enabled to judge of the direction of sound with considerable accuracy, whereas in hearing with one ear we are almost completely deprived of this faculty. Our judgments as to the direction of sounds are formed, for the most part, from the different degrees of intensity with which they are heard by the two ears.

In 1874, Mach⁶ put forward the theory that the pinnae of the ears act as resonators for the higher notes, and that their resonating capacity varies according to their position relative to the waves of sound.

Lord Rayleigh⁷ holds that diffraction of the sound-waves will occur as they pass round the head to the ear remote from the source of sound; thus the partial tones will reach the two ears with different degrees of intensity, and consequently there will be a difference in the quality of the sound as heard by the two ears. From this difference in quality we draw our inference as to the direction of the sound.

S. P. Thompson⁸ has advanced a theory somewhat similar to that of Lord Rayleigh. His view of the matter is, that we estimate the direction of a sound by the difference of intensity with which those partials are heard which have the greatest effect in producing the difference of quality with which the sound is heard by the two ears. This hypothesis is in keeping with the fact that the direction of a compound sound can be much more accurately estimated than the direction of a simple note, particularly if it be of low pitch.

It is possible, as suggested by Gray,¹ that when a sound-wave falls on the membrana while the intrinsic muscles are in a state of tension, a slight change may be produced in this tension. This change will be often different in the two ears, and thus we may judge of the direction of a sound by the muscular sense. If this be so, then our powers for estimating the direction of sound are ultimately referable to the muscular sense.

THE INTERNAL EAR.

By JOHN G. M'KENDRICK.

The internal ear consists of a complicated series of sacs and tubes filled with fluid. In certain situations the walls of the sacs contain highly differentiated epithelial structures, which are intimately related to the terminal filaments of the auditory nerve. The problem is to explain how the pressures transmitted by the foot of the stapes affect these terminal structures in such a way as to excite sensations corresponding to the pitch, intensity and quality of tones. It is evident that the subject may be approached from the physical or from the physiological side. The physical phenomena of sound fall within the scope of the principles of mechanics; but when we attempt to apply those principles to an explanation of the functions of the internal ear, we find the task surrounded with difficulties.

We shall in this article discuss the question purely as regards its physiological aspects, presuming an acquaintance with the anatomical structure of the internal ear,² and also with the general principles of acoustics.³

General mechanism of internal ear.—As the base of the stapes is opposite the vestibule in which lie the utricle and saccule, it is evident that these latter structures are the first to receive the mechanical impulses communicated by the chain of bones. The utricle (communicating with the semicircular canals) and saccule (communicating by the canalis reuniens with the ductus cochlearis) are surrounded by the perilymph. It must also be noted that the cavity of the vestibule containing perilymph opens on the one hand into the scala vestibuli, while on the other it is in free communication with the perilymphatic space around the ampullæ and the tubes of the semicircular canals. These perilymphatic spaces in the vestibule, around the canals, and in the scalæ of the cochlea, are contained in corresponding cavities in the bone, the walls of which are, except at the fenestra rotunda, perfectly rigid. The fenestra rotunda, however, is covered by a membrane. Suppose no fenestra rotunda had existed, any pressure of the base of the stapes inwards would have produced no effect on the membranous structures, as the fluid would be practically incompressible; in other words, the base of the stapes, in such conditions, would have been immovable. As a portion of the wall of the bony cavity is yielding, namely, the fenestra rotunda, it is clear that an inward movement of the base of the stapes becomes possible, and this inward movement will always be accompanied by an outward movement of the membrane covering the round window. In this manner, pressures or impulses can be communicated

¹ *Proc. Roy. Soc. Edin.*, 1897, vol. xxi. p. 443.

³ Rayleigh, "The Theory of Sound," 2 vols. London, 1896.

to the membranous sacs which contain the endolymph, and in which we find the nerve-endings.

It is also of importance to observe that, as already pointed out (p. 1159), the dimensions of the internal ear are so small as to form only a small part of the wave-lengths even of tones of high pitch. The whole of the membranous labyrinth may be regarded as part of any wave acting on the ear, and the waves are not arrested by the labyrinth as waves of light are arrested by the retina, but they sweep onwards through the bones of the head. The fact of the labyrinth being so small relatively to the size of the wave, makes no difference to the result, so that the labyrinth is acted on in the same way whether a wave of 30 feet in length, such as is produced by the longest pipe in a modern organ, or a wave of two-thirds of an inch, produced by the highest note of a piccolo flute, falls upon the ear. The nerve-endings are still smaller, but they also act as minute portions of any wave, and any reasoning as to the effect of such waves is quite irrespective of the small dimensions of the receiving organs in the internal ear.

If, now, we consider a wave of sound as a series of states of condensation and states of rarefaction, travelling on continually in one direction; and, further, if we remember that the motion of each individual particle forming the wave is very small, and is alternately backwards and forwards, in the same line as that in which the wave travels,—we see that the movements, inwards and outwards, of the base of the stapes correspond to these oscillations, or, in other words, to increase and diminution of pressure with each wave. Further, the length of time occupied by each excursion inwards and outwards of the base of the stapes will correspond to the frequency of the waves, the amplitude of the movement of the stapes to the amplitude of the wave, while the way in which the base of the stapes moves out and in will correspond to the form or character of the wave communicated to it. We also know, from physical experiments, that the frequency of the movements determines pitch, the amplitude intensity or loudness, and the form quality of tone. No doubt it is difficult to appreciate what is termed form of wave when applied to waves of sound, because our ideas of form of wave are derived from our knowledge of waves in which particles move in a direction more or less at right angles to the direction in which the wave travels, as in waves on the surface of water; and it is difficult to conceive of vibrations of particles in the same direction as that in which the wave progresses, as in a wave of sound.¹ Consequently all writers assist the mind in forming ideas of waves by the use of curves representing waves in which the particles vibrate transversely; but it must never be forgotten that the movements so represented are totally unlike those occurring in waves of sound.

Suppose the base of the stapes to be at rest, and that any movement inward is called a *positive* movement, and any movement outward a *negative* movement, the positive movement would correspond to a positive pressure or condensation, and the negative movement to a negative pressure or rarefaction. Suppose the bone is now moved inwards and outwards through a certain distance, at the same rate, from the two extreme points of its excursion, positive and negative. This is what we may term a simple pendular movement or vibration. But it is easy to conceive that, in moving inwards from its position of rest, it might not move to the extreme point of its positive excursion, but only a short distance, say half the distance, when it might move, for an instant, in the opposite direction; then again reverse its movement, and proceed to the limit of its positive excursion; then swing back to the position of rest; then move in the negative direction to the extreme point of excursion; and then, finally, return to the position of rest. This would

¹ Sir G. B. Airy, "On Sound," 2nd edition, London, 1871, p. 22; also plate i. figs. 6, 7, and 8.

not be a pendular, but a compound vibration; and one can readily understand that, while each such compound movement always was executed in a given time and through a given amplitude, it might be varied in character; or, in other words, while the time and the amplitude of the movement were constant, the form of the movement might be varied to almost an infinite degree, corresponding to the number and intensity of the components that produce the compound movement.

THE UTRICLE AND SACCULE.

The movements of the base of the stapes, as we have seen, may vary in number, in amplitude, and in character or form, and these correspond to the pitch, intensity, and quality of any tone. These movements are communicated to the perilymph, and by it to the sacs of the membranous labyrinth. As already mentioned, the utricle and saccule are the first to receive the impacts, and from them the impulse is transferred to the ampullæ on the one hand, and to the ductus cochlearis on the other. The base of the stapes is chiefly opposite to the utricle, although it partly abuts against the saccule. On the wall of the utricle, immediately in front, there are no nerve-endings or modified epithelium, but on the back wall we find the crista acustica with its characteristic bristle cells, the points of which are directed towards the base of the stapes. In front of these bristle cells lie a well-known mass of otoliths. The pressures must be communicated, in the first instance, to the otoliths, and by them to the bristle cells. As the bristle cells are fixed, while the otoliths are capable of moving backwards and forwards in a fluid, it is clear that an impulse from the base of the stapes may cause the otolith-mass to oscillate, and, by thus making a series of impacts on the points of the bristle cells, the excitation of the latter may be intensified by summation.¹ Further, the thin membrane bearing the bristle cells will readily move to the impacts of the stapes, and the heavy otolithic mass, by virtue of its inertia, will move more slowly at first, but it will continue to oscillate, and thus keep up stimulation. The long and extremely light hairs or bristles also appear to be well adapted for sympathetic resonance.² Helmholtz points out that the bristles in the crista, being of such minute mass, cannot long continue in independent motion.³ The ampullæ, being relatively wide cavities with narrow exits, are suitable for producing a central current, which partly passes into eddies, and these would deflect the bristles, causing them to oscillate. A movement of the whole mass of the bristles, floating in the fluid, would not serve the same purpose. Discontinuous streams of different strengths and in different directions would do so effectively.⁴ Others have suggested that the otoliths act as dampers;⁵ but when we consider that a damping mechanism is only specially necessary for the perception of tones in music, and that otoliths are found in the ears of animals so low in the scale as to make it improbable that they appreciate such tones, this function appears to be unlikely.

Considerable doubt still exists as to the specific functions of the

utricle and saccule. The most primitive form of internal ear is undoubtedly a sac containing fluid in which an otolithic mass is immersed, and having on the wall hair-like processes related to the terminations of a nerve (*Aurelia aurita*, *Unio*, *Phialidium*, *Pterotrachea*). Such an arrangement is adapted to receive impulses from the surrounding water.¹ In the lower vertebrates we find a single sac, into which open the semicircular canals; still higher we find the beginning of the ductus cochlearis; and, lastly, a division of the single sac into two, with a great development of the ductus cochlearis. These facts point to the sacs being organs for the reception of waves giving rise to sensations of sound as sound, and without reference to pitch or quality. Animals furnished with internal ears in which the cochlea is absent or only developed to a slight extent, no doubt have sensations that correspond to tones and noises, but these would differ only as regards intensity. Such sensations would be similar to visual sensations of luminosity, without reference to colour. To analyse auditory sensations, a more complicated mechanism is necessary, and hence we find the gradual evolution of a cochlea.

In man and the higher animals there can be no appreciation of sound irrespective of pitch and quality, because the movements of the stapes will not only call into action the nerve-endings in the utricle and saccule, but also those in the cochlea. One cannot conceive the vestibular portion of the internal ear acting alone. As, however, the two sacs are each supplied by a special nerve, it is not improbable that movements of the base of the stapes acting on both may give rise to two distinct effects, but there is no experimental evidence bearing upon this point.

When we take into account the minute size of the parts, and their situation in the temporal bone, the results of direct experiments on the ear of a living animal must be received with caution. Still the evidence, meagre as it is, is in favour of the view above set forth. Thus, Flourens destroyed all the nervous filaments to the labyrinth except those supplying the saccule and utricle, without observing deafness. Others have observed disease of the cochlea causing its destruction, but without complete loss of hearing.² Destruction of the semicircular canals does not cause deafness. Gellé states that after he destroyed the cochlea in guinea-pigs, deafness came on only after inflammatory changes had invaded the structures in the vestibule.³

Recently Lee⁴ has argued that as fishes have no papilla acustica basilaris, and as, with few exceptions, they are dumb, it is highly probable they have no sense of hearing. Actual experiment appears to support this contention. The papilla acustica basilaris appears first in amphibia in an offshoot from the lagena, and, in the higher animals, it becomes part of the organ of Corti. If this view be correct, then the cristæ and maculæ acusticæ have nothing to do with hearing, but serve for the perception of movements, such as those of rotation and translation through space, which are infinitely coarser than those which are the physical basis of sound. Lee has also endeavoured to show that the organs in the lateral line of fishes and the maculæ and cristæ acusticæ

¹ For an excellent account of the comparative anatomy of the internal ear, see article "Audition," by Gellé, in Richet's "Dict. de physiol.," tome i. pp. 914-919. Figures showing the internal ears of these animals are given in this article.

⁴ *Am. Journ. Physiol.*, Boston, 1898, vol. i. p. 128.

have a common function, namely, the appreciation of mass-movement. Beard¹ had already argued in favour of the parts of the internal ear and the organs of the lateral line being phylogenetically related. According to these somewhat speculative views, when animals became air-breathers, a part of the ear, the papilla acustica basilaris, was gradually evolved for the perception of the delicate vibrations of sound, while even in the higher vertebrates the nerve-endings in the sacculæ and utricle may still have to do with only the perception of mass movements. While it may be that fishes are deaf, it is difficult to believe that hearing is associated in the higher animals solely with the cochlea. In certain fishes there are connections in the form of ossicles between the air-bladder and the acoustic labyrinth,² and in these it is possible the air-bladder may act as a resonator, as Johannes Müller thought.³ In the higher forms of vertebrates the intricate relations between the membrana tympani and the sacculæ and utricle by the chain of ossicles indicates that these sacs, while they may retain their primitive function of appreciating mass movements, are also the recipients of those more delicate movements caused by sound-waves impinging on the membrane.

THE COCHLEA.

It is remarkable that some of the older anatomists conjectured, long before the discovery of the organ of Corti, that this part of the internal ear was in some way analogous to a musical instrument, having wires of varying lengths tuned to tones of different pitch.⁴ Helmholtz, however, was the first to put forth a theory as to its mode of action, and whether this theory be accepted or not, all discussions of the subject must take the work of Helmholtz as a starting point.⁵ Let us inquire, in the first place, what the ear is capable of doing. We can hear musical tones and noises, we have a peculiar auditory sensation to which we give the name of beats, and we have the power of analysing a musical tone into its components. These are sensations capable of being tested by direct experiment.

For this purpose, the inquirer should be furnished with—(1) A set of forks ranging in pitch from 128 to 1024 vibs. per second, say *ut*₂, *ut*₃, *sol*₃, *ut*₄, *mi*₄, *sol*₄, *ti*₄, *ut*₅; (2) forks corresponding to *re*₃, *mi*₃, *mi*₃[♯], *fa*₃, *la*₃, *la*₃[♯]; (3) a set of resonators, as devised by Helmholtz, corresponding to those forks; (4) the manometric analyser, for the series of forks enumerated in (1); (5) a double syren; (6) a set of steel cylindrical bars, for tones of very high pitch; and (7) a few rectangular brass clips, capable of sliding freely on any of the forks, with a tightening screw.⁶

Pitch.—As determined by the syren, a sensation of musical tone begins with about 30 vibs. per second. It is, however, difficult to appreciate the pitch of musical intervals in the lower ranges, and it is only with about 40 vibs. per second that pitches are clearly

¹ *Zool. Anz.*, Leipzig, 1884, Bd. vii. S. 140.

⁶ The best acoustical apparatus is supplied by Dr. Rudolf König, Quai d'Anjou, Paris. An excellent set of apparatus, consisting of bellows, overtone apparatus, difference tone apparatus, apparatus for beats, and fine rich reed tones, is made by Appunn of Hannau, near Frankfort. Appunn's apparatus consists almost entirely of reeds, with appropriate resonators. It is described in "Sprache und Ohr," by Oskar Wolf, Braunschweig, 1871, S. 15. See also M'Kendrick, *Proc. Roy. Soc. Edin.*, 1873-74.

distinguishable. When a tone of lower pitch than 30 is sounded, the ear instinctively picks up the octave, probably because the octave is faintly produced by the instrument.¹ From these tones of low pitch, as we listen to sounds rising in pitch to the upper limits, there is no break in our sensations, but a gradual passage through tones of ever-increasing pitch. This experience is similar to that of running the eye along a pure spectrum. When we get above 4000 vibs. per second, there is again much difficulty in detecting musical intervals, but we observe the gradual rise of pitch, till we reach, with cylindrical steel bars, tones corresponding to 20,000 to 30,000 vibs. per second. Sensitive flames give out even higher perceptible tones.²

In these experiments, the sounds are heard in succession, but an interesting question arises as to the smallest difference in pitch that can be appreciated by the ear when beats are produced by two tones sounding at the same moment.

Beats.—If we simultaneously sound two forks that are in unison, say two forks *ut*, the waves coincide and one sound is heard. Let us then place on one of the forks, near the end of one of its prongs, a brass clip (see above), and sound the fork by bowing. It will be found to be considerably flattened as regards pitch. If we then sound the two forks simultaneously, a rapid, rattling, beating sound is heard, peculiar in its character, unlike a tone, but conveying no idea of two sounds. Let us then slip the clip farther down the prong. On again sounding the two forks, a slow soft throb is heard, and the number of throbs can be readily counted. If we know the pitch of the higher note, the pitch of the lower is at once determined by subtracting the number of beats per second from the number representing the pitch of the higher note. Thus, if one fork makes 100 vibs. while the other makes 101 vibs., then 100 waves from one source are superposed on 101 equal waves from another source. When the two waves are in the same phase, one wave increases the amplitude of the other. But after 50 waves from the first fork have passed, $50\frac{1}{2}$ waves will have passed from the second fork. The two waves will then be in opposite phases; that is to say, the onward movement of the particles of the first wave will be neutralised by the backward movement of those of the second wave, and the particles will be at rest. This rest may last through several waves, and then the waves again change gradually, until they again coincide after 100 waves have passed from the first fork. The same phenomenon will occur with every 100 waves. There will thus be a waxing and waning of the auditory sensation.³ The number of beats per second is equal to the difference of the frequency of the tones. As an interval depends on the ratio of frequencies, it is evident that the number of beats given by two tones nearly in unison will be doubled if the two tones are sounded an octave higher. It is thus possible, by means of beats, to ascertain the sensitiveness of the ear, even to fractions of a vibration per second, and it appears that in no part of the scale can 0.2 vib. per second be distinguished with certainty. The sensitiveness varies with pitch. Thus, at 120 vibs. per second, 0.4 vib. per second; at 500, about 0.3 vib. per second; and at 1000, 0.5 vib. per sec. can be distin-

¹ Preyer, "Physiol. Abhandl.," Jena, 1876; van Schalk, quoted by Rayleigh (*op. cit.*), fixes the lower limit at 26 vibs., *Arch. néerl. d. sc. exactes*, tome xxix. p. 87.

² Rayleigh, *op. cit.*, vol. ii. p. 433.

³ Airy, *op. cit.*, p. 215; Rayleigh, *op. cit.*, vol. i. p. 22.

guished.¹ These results are a remarkable testimony to the sensitiveness of the ear.

König has investigated the phenomena of beats by large tuning-forks specially devised to produce the purest tones by simple pendular movements, and he has found that with such it is possible to obtain primary and secondary sets or orders of beats, and even beats of high orders. When two simple tones interfere, the primary beats belong to either an inferior or superior set, corresponding in number to the two remainders, positive and negative, found by dividing the frequency of the higher tone by that of the lower.² Thus, suppose two tones having frequencies of 40 and 74. Then $74 \div 40 = 1 +$ a positive remainder of 34; or $74 \div 40 = 2 - 6$, a negative remainder of 6. König finds that if two such forks are sounded there are two sets of beats, one at 34 per second and the other at 6 per second. The inferior beat is heard distinctly when its number is *less* than half the frequency of the lower primary, but if its number is *greater*, the superior beat comes out the stronger.

Beat tones.—Much discussion has taken place as to what occurs when very rapid beats fall on the ear. Lagrange and Thomas Young held that they blend into a tone, but Helmholtz and others maintain that this is not the case. It is possible to experience a double sensation at the same time, both of a beat tone and of individual beats; just, as in listening to a syren, we may, as it were, *feel* the puffs and *hear* the beginning of a musical tone. König has undoubtedly given strong evidence in favour of the existence of true beat tones. He uses *pure* tones, instead of the mixed tones of the syren and of reeds. These beat tones are best heard when large forks of high pitch are struck. Thus, take $ut_6 = 2048$ and $re_6 = 2304$. Then $2304 - 2048 = 256 = ut_3$. Strike ut_6 , then re_6 , and ut_3 sounds. This is an example of the grave or inferior beat. Again, take $ut_6 = 2048$ and $si_6 = 3840$. Then $(2048)_2 - 3840 = 256$, a negative remainder $= ut_3$, as before. Sound both forks and ut_3 will be heard. Again, take $ut_6 = 2048$ and $sol_6 = 3072$. Then $3072 - 2048 = 1024 = ut_6$. Sound ut_6 separately, so that the sound may catch the ear. Then sound ut_6 and sol_6 , and we hear ut_6 ringing out.

Strong as this evidence appears to be, it does not satisfy some observers. Lord Rayleigh,³ in particular, declares that the question "must still be regarded as an open one," and he states that no evidence has been adduced that the intensity of the beat tone is proportional to that of the generators.

Audibility as affected by intensity.—In considering the action of sound on the minute mechanisms in the cochlea, it is important to take into account the degree of sensitiveness of the ear, both as to amplitude and as to energy of vibration. When an open organ-pipe is sounded, there is a condensation and rarefaction of the air, and there is a position of maximum condensation, data regarding which can be determined experimentally. From these data, Töpler and Boltzmann⁴ concluded that "plane waves, of pitch 181, of which the maximum condensation is 6.5×10^{-8} , are just audible." These observers also stated the matter thus: The ear is affected by vibrations of molecules of the air

not more in amplitude than $\cdot 0004$ mm. at the ear, or $0\cdot 1$ of the wave length of green light, and the energy of such a vibration on the drum-head is not more than $\frac{1}{543}$ billionth kilo., or $\frac{1}{17}$ of that produced upon the same surface of the retina by a single candle at the same distance.

Lord Rayleigh has investigated the question by two methods.¹ By the first, he estimated that the amplitude of the movement of the aerial particles, with a sound just audible, "was less than the ten-millionth of a centimetre," and that under favourable conditions "an amplitude of 10^{-8} cm. would still have been audible."² By the second method, he not only determined the amplitude, but he estimated the energy emitted when the sound was just becoming inaudible, at $42\cdot 1$ ergs per second. Further, in considering the amplitude or condensation in the progressive aerial waves, at a distance of $27\cdot 4$ metres from the fork, in the second experiment, he states that s , the maximum condensation, $= 6\cdot 0 \times 10^{-9}$, a result showing "that the ear is able to recognise the addition and subtraction of densities far less than those to be found in our highest vacua." Lastly, Lord Rayleigh contrasts the energy-emission of a source of light with that of the fork in the second experiment, and arrives at a conclusion similar to that of Töpler and Boltzmann, namely, "that the streams of energy required to influence the eye and ear are of the same order of magnitude."³

The analytic properties of the ear.—When we listen to musical sounds, even the untrained ear perceives that they may differ much in *character* although they may be of the same pitch. Thus the note *c* as produced on a violin, a harp, a tuning-fork, a clarinet, an oboe, or by the human voice, gives rise to a peculiar sensation, characteristic of the instrument. No doubt this may be partly due to certain noises often produced by the particular instrument; but these noises quickly fade away and disappear as we move away from the source of sound, while the character of the sound still remains. It is well known that physically the waves of such sounds are not simple pendular vibrations, but are more or less complex vibrations, produced by certain tones of shorter wave-length being combined with the first or fundamental wave. When we listen to certain sounds having a character or quality, even the inexperienced ear can detect the fact that the sensation is not that of listening to one sound but to a mixture of sounds, higher in pitch than the tone that seems to give pitch to the sound. For example, if we bow *ut*,² somewhat roughly, we hear, in addition to the tone of the fork, certain high ringing tones which rapidly die away. These tones are peculiar, and do not belong to the harmonic scale of the fork. The forks examined by Helmholtz showed a frequency of the first partial from $5\cdot 8$ to $6\cdot 6$ times that of the proper tone.⁴ When we listen to the syren, we are also often conscious of tones much higher in pitch than those accounted for by the stop we happen to be using and the speed of the syren disc. If we sound strongly a reed having a frequency of 64 vibs. per second, as in Appunn's apparatus, and place a large zinc cone over the reed, we hear a vast number of tones, all of a pitch above 64 vibs. per second, and if we sing a note or series of notes while the reed is sounding, we have the curious sensation of always being in harmony with

¹ *Proc. Roy. Soc. London*, 1877, vol. xxvi. p. 248; *London, Edinburgh, and Dublin Phil. Mag.*, London, 1894, vol. xxxviii. p. 366.

² Rayleigh, *op. cit.*, vol. ii. p. 435.

³ *Ibid.*; footnote, p. 438.

⁴ *Ibid.*, vol. i. p. 59.

the tones of the reed. These experiments show—(1) That many sounds which an unobservant person might consider simple are in reality complex; and (2) that the ear (and by this term we mean, at present, ear, nerve, and brain) has a power of analysis, or of resolving a compound tone into its constituents.

Physically, such a compound tone is built up of a fundamental or prime tone, and of other tones known as over-tones, over-partial tones or harmonics. Taking the tuning-fork (ut_2) in the series as the prime tone, the partials are the following:—

Number	1	2	3	4	5	6	7	8	etc.
Name	Ut_2	Ut_3	Sol_3	Ut_4	Mi_4	Sol_4	7^*	Ut_5	etc.
Note	c	c'	g'	c''	e''	g''	$b''b$	$c'''f$	etc.
Interval ratio		$\frac{2}{1}$	$\frac{3}{2}$	$\frac{4}{3}$	$\frac{5}{4}$	$\frac{6}{5}$	$\frac{7}{6}$	$\frac{8}{7}$	
		Octave	Fifth	Fourth	Major Third	Minor Third	Minor Third	Minor Second	
No. of vibs.	256	512	768	1024	1280	1536	1792	2048	etc.

The upper partials become more and more faint, and pass on to tones making 9, 10, 11, etc., times the number of vibrations of the prime tone.

FIG. 423.—Various forms of wave-curves.

If we sound all these forks together, the motion is periodic but is compounded of the motions represented by the waves of each of the partials; as, when two or more sources of sound move the air simultaneously, the resulting disturbance must be the sum of what would be caused by each source acting separately. The *sensation* is that of a compound musical tone having a period (and therefore pitch) of the lowest or prime tone. The sensation, however, is not simple, but it is capable of analysis, when, by an effort at attention, we sift out its constituents. This process of resolution is easier for certain persons than for others, but even those who are not musical soon develop the power. As well put by Helmholtz, the power of analysis largely depends on attention. In ordinary life it is not necessary thus to analyse compound tones, and indeed it would be a distraction to do so, as our pleasure from musical sounds does not spring from this analysis but from a general recognition of their character, pitch, sequence, and harmony.

Thus we find two classes of tones—(1) Those incapable of further

analysis, and therefore termed pure or simple tones; and (2) those that may be resolved into partials or compound tones. As first shown by Ohm, the only form of vibration incapable of being resolved into simpler constituents is that of a pendulum or tuning-fork, and the curve so obtained is the curve of sines.¹ Such a curve is seen in Fig. 423, A. It represents the pendular motion of the air in the external meatus excited by a tuning-fork in motion. The horizontal line represents time, while the ordinates (d_1 , d_2) show the amount of displacement of the air. Suppose now another tone, represented by curve B, an octave above the first, is sounded, there will then be two vibrations of B for one of A. It will be seen that by superposing B on A, so that d_1 a_1 in A is added to b_1 in B, the ordinate c_1 in C is obtained, and by subtracting b_2 in B from d_3 a_2 in A, c_2 in C is obtained; and so on with reference to other points, until the curve (C) represents the combination of A and B. It will be seen that (C) is periodic, and that its periods are those of A; or, in other words, the motion of the air produced by two tones (A and B) is also periodic, because one of the simple tones makes twice as many vibrations as the other in the same time. Now suppose that e in B were moved to the right so that e was below d_1 in A, then the compound curve would be that shown in D. Thus, by combining A and B in various ways, many curve forms might be obtained, but these could always be resolved into A and B, in which the frequency of B is always double that of A.² These curves represent the motions of the air when two tuning-forks, say ut_3 and ut_4 are sounded, or when a flute is gently blown so as to give a note of that pitch. But the ear can readily hear the tones of the

FIG. 424.—Form of wave produced by combining two simple waves.

two forks. It is more difficult to analyse the sound as produced by the flute, but if we assist the ear by using two resonators, one tuned to ut_3 and the other to ut_4 , all difficulty disappears, and we can analyse the sound. The adjoining figure (Fig. 424) shows (the thick line) the resultant wave—produced by superposing a tone and its octave. Now, just as the ear can pick out different musical tones when several instruments are sounded, so in favourable conditions it can resolve a musical tone into a series of partials. This power is succinctly expressed in Ohm's law as follows: Every motion of the air which corresponds to a composite mass of musical tones is capable of being analysed into a sum of simple pendular vibrations, and to each such single vibration corresponds a simple tone, sensible to the ear, and having a pitch determined by the periodic time of the corresponding motion of the air.³ But we have seen

¹ Helmholtz, *op. cit.*, p. 35; Rayleigh, *op. cit.*, vol. i. p. 17.

² Helmholtz, *op. cit.*, p. 46.

³ *Ibid.*, p. 51.

that, by combining tones that differ in phase and in amplitude, we can produce a great variety of wave-forms. These wave-forms, however, can always, according to Fourier's mathematical law, be resolved into the constituents. This law is expressed as follows: Any given regular periodic form of vibration can always be produced by the addition of simple vibrations having vibrational numbers, which are once, twice, thrice, four times, etc., as great as the vibrational number of the given motion. Applying this to the motion of the air close to the ear, we find that any such motion, corresponding to a musical tone, may be always, *but for each case only in a single way*, shown to be the sum of simple motions, corresponding to the partial tones of this musical tone.¹

The interesting question now arises whether the ear, having to deal with waves varying almost infinitely in form, is differently affected by such waves, according as their form represents various modes of pressure (pushes and pulls) on the drum-head and conducting mechanism. Suppose we sound the harmonic series of forks from u_2 to ut_6 , we hear a rich harmonious sound, and we can analyse the sensation, and pick out the tone of any particular partial, more especially if it is slightly strengthened by a touch of the bow. By varying the order and the intensity of the partials, we can produce a very large number of wave-forms, but the general character of the harmonious sound, so far as we can judge, remains the same. This would appear to indicate, with an experiment comparatively so rough, that the ear takes no cognisance of phase. Helmholtz investigated the question in a similar way, by means of his vowel tone apparatus.² This apparatus consists of a harmonic series of forks, electrically driven, and so arranged that they can be sounded in any order and with various intensities, according to changes produced in the size of the orifices of their appropriate resonators.³ The resonators are thus put slightly out of tune, their resonance is weakened, and thus the phase is altered. Helmholtz stated the result as follows:—Differences in musical quality of tone depend solely on the presence and strength of partial tones, and in no respect on the differences in phase under which these partial tones enter into composition.

It must be admitted that this mode of investigation is not satisfactory, inasmuch as when, in successive experiments produced by pressing on the keys of the instrument, we apparently have the same tonal result, we cannot be sure that there is no difference in sensation, as we have no criterion by which to judge. We apparently hear the same compound tone, but it *may* be slightly different from the one we just heard an instant before. Accordingly, it is better to investigate this question by experiments with intervals slightly inharmonious. This has been done by Lord Kelvin.⁴ Suppose we take the two forks, $ut_2 = 256$ and $ut_3 = 512$, and sound these together, we have a sound composed of a tone and its octave. If, then, we slightly flatten ut_3 , so that its vibration number is 510, we hear, not a roughness corresponding to 254 beats, but a slow beat of only 2 per second. The sensation is

¹ As to Fourier's theorem, see Donkin's "Acoustics," pp. 60-66; O'Kinealy, *London, Edinburgh, and Dublin Phil. Mag.*, London, vol. xlviii. p. 95; Ohm's "System der Mathematik," Bd. ix. S. 286; Airy, *op. cit.*, p. 160; Rayleigh, *op. cit.*, vol. i. pp. 118, 202.

that of an interval with a certain relation of phases, but after a short period the phase relationship will change and will pass through every possible value. The cycle is audible; there are beats on the imperfect harmony. Now it might be said that these beats were produced between 510 and the first partial of ut_2 , namely, $u_3=512$, but as the beats are always most distinct when ut_2 is sounded very feebly, this appears to be out of the question. In like manner, beats may be heard on the approximate harmonies, 2:3, 3:4, 4:5, 5:6, 6:7, 7:8, 1:3, 3:5, and they all "fulfil the condition of having the whole period of the imperfection, and not any submultiple of it, for their period." It is also easy to produce beats on a major chord in which one of the forks is slightly flattened. For example, sound ut_3 , mi_3 , and $sol_3=4:5:6$; then slightly flatten sol_3 or mi_3 , and a peculiar beat will be heard as if a wheel were being turned against a surface, one small part of which was rougher than the rest; the effect is always loudest when the tone of the forks is allowed to almost die away, and one of the forks is then gently touched with the bow.

From the point of view of these investigations, the question under discussion assumes an aspect different from that present to the mind of Helmholtz. A harmony (by which we mean an octave, fifth, major chord, etc.) is a sound which, without being a simple tone, has the variations of air pressure strictly periodic, and, according to Fourier's harmonic analysis (analysis of periodic variations), any periodically varying quantity may be looked on as the sum of quantities, varying separately according to the simple harmonic law, in periods respectively equal to the main period, half the main period, a third of the main period, a fourth of the main period, and so on. Thus, the variation of the air pressure of a harmony is the sum of the variations of simple tones, one having a period equal to the period of the harmony, a second one-half, a third one-third, and so on. A harmony is therefore composed of simple tones, if produced by such instruments as well-bowed tuning-forks. On listening to such a complex tone or sound, a tone may predominate in the sensory impression, and the pitch of the sound is referred to the main period of this tone, the other tones merely giving a special character to the sound. In musical harmony, however, one tone does not thus predominate, and a sound of two, three, or four, or more tones, having commensurable periods, is heard, *and the period of the harmony is the least multiple of the period of its constituent tones.* The harmonic number of a tone in a harmony is denoted by the number of times that the period of the harmony contains this particular tone. Again, the quality or character of a harmony depends on the amplitudes of the tones forming it, the frequency period of these tones, and the relation of their phases. It is most important to observe the effect of *phase*. Thus the instants of maximum pressure or of minimum pressure may coincide, or there may be a coincidence of the maximum pressure of one tone with the minimum pressure of the other. If, now, the tone of a perfect binary harmony be very slightly sharpened or flattened, and if the two tones are sustained so as to secure perfect uniformity as to pitch and intensity, the effect is an imperfect harmony, *with a slow change of phase relation through a cycle*, and there is a variation of the quality of the tone recurring periodically on the imperfect harmony. This is the beat in the imperfect harmony, and it indicates that the ear does distinguish between an increase of pressure on the drum-head and

diminution of pressure, or between a push and a pull; or, in other words, it is affected by phase.¹ The fact, however, that it is affected by phase, does not greatly interfere with the analytic power already discussed, because when one listens to such an imperfect harmony with appropriate resonators, one can still resolve the harmony into its constituents.

S. P. Thompson² has discussed experimentally certain points regarding phase. By leading the sound of a tuning-fork through a tube to each ear separately, so that the phases could not mix in the air, and in such a way that the sound waves struck each tympanic membrane in exactly opposite phase simultaneously, the sound seemed to be localised at the middle of the back of the head. If, on the other hand, the sound-waves struck each tympanic membrane in the same phase simultaneously, the sound appeared to be localised in the ears.

Again, if the sounds of two tuning-forks, which, when sounded together, gave beats, were led to the two ears separately, in such a way that they could not mix in the air, beats of great intensity were still perceived and appeared to be localised in the middle of the back of the head. In this experiment the peculiar fact was noticed, that the silences were not true ones, but rather that the sound appeared to be going on all the time. Interference must therefore have occurred within the ear, or in the nerve-paths, and thus it is obvious that the ears can appreciate difference of phase.

During recent years some experimenters³ have attributed these "subjective beats" to interference occurring, not in the ear itself or nerve-paths, but in the bones of the head. If the latter view is correct, then the experiments described above cannot be considered as proving that the ear or ears are able to appreciate difference of phase.

The question of the influence of phase has also been investigated by König,⁴ by means of an instrument termed a wave-siren, an invention of his own; and there can be no doubt that his observations are not only of great interest, but that they present the greatest difficulties in the way of the theory of Helmholtz. He first drew to scale the curves obtained by compounding partials up to the tenth member of the series; and he modified the curves so that they were compounded first with zero difference of phase, then with all the upper members moved one quarter, then with a difference of half a wave, and lastly with a difference of three-quarters. The sounds of all these curves, according to Helmholtz, should be exactly alike, although they differed in form and position. These curves were cut out on the circumference of metallic cylindrical hoops, which were then mounted on an axis and rotated rapidly. Against these toothed edges (or edges showing sinusoidal curves) air was blown under pressure through narrow slits, as the curves passed in front of the slits; and thus sounds varying in phase from a quarter to three-fourths of the wave-length were obtained. It was found that they *varied in quality*; with a phase of a $\frac{1}{4}$, the sound was loud of a peculiar shrill quality; those of $\frac{3}{4}$ difference were gentle and soft; while the curves of 0 and $\frac{1}{2}$ had a quality intermediate in character. These were no doubt minor differences, and, according to Lord Rayleigh, "the results are in harmony with the view that would ascribe the departure from Ohm's law involved in any recognition of phase relations to secondary causes."⁵ It is clear, however, that the influence of phase is not so absolutely negative as Helmholtz supposed.

The phonograph, better than any other instrument, illustrates many of these phenomena. The marks on the wave-cylinder correspond to the pitch,

¹ Kelvin, *op. cit.*; see also, at the end of the paper, curves showing the variations of pressure with imperfect harmonies.

intensity, and character of the sounds given to the phonograph, and which are reproduced with remarkable fidelity. The *number* of marks in a given time determines pitch; the *depth* of the marks, amplitude or loudness; and the character or *form* of the mark, to the character or quality of tone. These marks can now be carefully traced and analysed.¹

Resonance.—The principle of resonance is of great importance, both as explaining the mode of working of resonators employed in the analysis of compound tones, and as suggesting the probable mode of action of the cochlea. The material systems with which we have to do in this question may be subjected to various modes of vibration, all or any of which may coexist at any particular moment. Thus a system may show free or forced vibrations. The period of a free vibration depends on the constitution of the system itself; the vibration is that made by the system when disturbed from the position of equilibrium and left to itself. A forced vibration, on the other hand, has a period determined solely by the external force acting on the system. So long as the external force acts, the forced vibration continues, but a free vibration quickly dies away. Further, a vibrating system of one degree of freedom may have the amplitude of its movements reduced by damping. Damping will soon extinguish a free vibration, and its influence is felt on a forced vibration, when there is an approach to isochronism. Now, when a forced vibration is excited in any one part of a system, all the other parts are also influenced, and a vibration of the same period is excited, whose amplitude depends on the constitution of the system as a whole.² If a part of the system is specially affected within a certain limit of amplitude, it is in the position of a system having one degree of freedom acted on by a given force and independent of the natural period. Resonance usually occurs when there is an approximate equality of periods between the vibrating body and the resonator. In some cases, the amplitude within which resonance is possible may be considerable; in others, very small; and much depends, as regards delicacy of resonance, on the degree of damping that may be called into play. The best example of resonance may be given by taking two forks in perfect unison, say two forks, *ut*₄; then, when one fork is bowed, the other, placed in any part of the room, will respond; while a slight change of pitch (produced by fixing a slider on the limb of one of the forks) will prevent response, even although the deviation from unison may cause only one beat per second. Tuning-forks are susceptible of sympathetic vibration to a remarkable degree, notwithstanding the difficulty of setting their mass in motion, because they admit of a long accumulation of minute impulses; but for this reason there must be precise agreement between the pitches of the two forks. It is also observed that, if a fork is thus set agoing, it continues sounding for a considerable time. On the other hand, stretched membranes or strings give forth tones that rapidly diminish in intensity, and they are readily set into sympathetic vibration, which, however, is not limited to a particular pitch. Consequently, such bodies may be influenced by several tones. If a body has a vibration that dies away quickly, say after 8 or 10 vibrations, it is not necessary that the next impulses acting upon it should be of exactly the same period as those producing the first movement.

¹ See "Voice Production" in the following article of this volume, also the references therein given.

² Rayleigh, *op. cit.*, vol. i. p. 70.

Helmholtz has shown in a table the difference in pitch in terms of an equally tempered tone ($\frac{1}{8}$ of an octave) necessary to reduce the intensity of sympathetic vibration to $\frac{1}{10}$ of that produced by perfect unison (*A*), and the number of vibrations after which the intensity of tone, in a body whose sound is allowed to die out, diminishes to $\frac{1}{10}$ of its original amount (*B*).¹ The table is as follows:—

A.		B.
1.	$\frac{1}{8}$ tone	38·00
2.	$\frac{1}{4}$ „	19·00
3.	$\frac{1}{3}$ „	9·50
4.	„	6·33
5.	1 „	4·75
6.	$1\frac{1}{8}$ „	3·80
7.	$1\frac{1}{4}$ „ (tempered minor third)	3·17
8.	$1\frac{1}{3}$ „	2·71
9.	2 „ (major third)	2·37

That is to say, suppose a body were started into vibration by an exact unison, and that the resonance was reduced to $\frac{1}{10}$ of its original amount, 38 vibs. would be executed before the intensity of the free vibration was reduced to $\frac{1}{10}$ in the case of $\frac{1}{8}$ tone, and so on. Now, if the ear required 38 vibs. before the sympathetic resonance was reduced $\frac{1}{10}$, as the time occupied for these vibrations for *A* would be $\frac{1}{3}$ second, for *a* $\frac{1}{6}$ second, for *a'* $\frac{1}{2}$ second, it is evident that such a state of things would disturb musical effect, because the first note would not have died away before the end of the second note. This would certainly occur if we executed a shake on a piano of eight or ten notes a second, so that each note would be sounded four or five times. But it is well known that below *A* the sensation excited by such shakes is rough and unpleasant, indicating, in the opinion of Helmholtz, “that the vibrating parts of the ear are not damped with sufficient force and rapidity to allow of successfully effecting such a rapid alternation of tone.” Now, if a body is thrown into vibrations by sympathetic resonance, it has the vibration frequency of the exciting tone, but when the exciting tone ceases, it goes on moving at the rate of its own proper tone. If, then, the ear vibrated as a single system, and continued its movements for a sensible time, it would move at its own rate, which, as has been shown, is independent of the rate of the exciting tone. Thus two tones of a shake, either in high or low tones, would not mix, but they might blend with that of a third tone, that of the ear itself, said by Helmholtz to be between *e'''* and *g'''*, or, say, *f'''*.

To set this aspect of the question in a clear light, we cannot do better than quote from Helmholtz.² “Now, if a shake of 10 notes in a second be made on *A*, of which the vibrational number is 110, this tone would be struck every $\frac{1}{10}$ of a second. We may justly assume that the shake would not be clear, if the intensity of the expiring sound were not reduced to $\frac{1}{10}$ of its original amount in this $\frac{1}{10}$ of a second. In this case, after at least 22 vibs., the parts of the ear which vibrate sympathetically with *A* must descend to at least $\frac{1}{10}$ of their intensity of vibration as their tone expires, so that their power of sympathetic vibration cannot be of the first degree in the table, but may belong to the second, third, or some other higher degree. That the degree cannot be very much higher, is shown, in the first place, by the fact that shakes and runs begin to be difficult, even in tones which do not lie very low. . . . We may, on the whole, assume that the parts of the ear which vibrate sympathetically have an amount of damping power corresponding to the third degree of our table, where the intensity of sympathetic vibration with a semitone difference of pitch is only $\frac{1}{10}$ of what it is for a complete unison.”

¹ Helmholtz, *op. cit.*, p. 213; also Rayleigh, *op. cit.*, vol. i. p. 52; where the mathematical theory of damping is fully explained.

² Helmholtz, *op. cit.*, p. 215.

Probable action of the cochlea.—We have already seen that the impact of sound-waves must produce a variable pressure in the fluids in the internal ear. Each movement inwards of the base of the stapes, acting like a piston, must cause a pressure in the perilymph, which must pass up the scala vestibuli. This pressure must act on the ductus cochlearis, pressing it from the membrane of Reissner down on the membrana basilaris to the fluid in the scala tympani; and, finally, it must cause a movement outwards of the membrane covering the fenestra rotunda. It is not necessary to consider that a wave will pass through the helicotrema from one scala to the other, as it is clear that any pressure in the scala vestibuli must act in the manner indicated. In all probability, the helicotrema serves the office of equalising pressures between the two scalæ, just as the aqueductus vestibuli does for the fluids in the saccule and utricle, and the canalis reuniens for the fluids in the saccule and the ductus cochlearis. These variations of pressure will be made with each movement of the stapes corresponding to a vibration, and it is evident that the pressures may vary in number, in intensity, and in character in a way exactly corresponding to the pitch, intensity, and quality or character of tones. Such being the case, there are only three ways in which the ductus cochlearis, which contains the nerve-endings, may be affected. Either (1) small vibratile bodies may exist between the pressures sent into the organ and the filaments of the auditory nerve, each vibratile body having a frequency period of its own; or (2) individual nerve fibres may be directly excited by waves of a definite period; that is to say, there may be differences in the nerve fibres, so that they have a selective action; or (3) the organ may be affected as a whole, all the nerve fibres being affected by any variations of pressure, and thus the power of analysis, which is admitted, is relegated from the peripheral to the cerebral organs.

The first hypothesis seems *a priori* to be probable, for the following reasons:—(1) The existence of such bodies would give a natural explanation of many if not all of the phenomena; (2) the evidence of comparative physiology points to a gradually increasing complexity in the structure of all the terminal organs of special sense, as if there arose a necessity for differentiation and discrimination in the effects of various kinds of stimuli; and (3) investigations into the action of all the sense organs, such as those of touch and temperature in the skin, of light and colour in the retina, of taste in the tongue, and of smell in the olfactory region—all indicate specialisation of function in the peripheral apparatus. It is not necessary to enlarge on the general evidence indicated under (2) and (3).

The theory that vibrators exist in the cochlea is associated with the name of Helmholtz, because, although it was a conception that flitted before the minds of Thomas Young, Johannes Müller, and others, it was first clearly enunciated and discussed by him.¹ It may be shortly stated as follows:—(1) In the cochlea there are vibrators, tuned to frequencies within the limits of hearing, say from 30 to 40,000 or 50,000 vibs. per second. (2) Each vibrator is capable of exciting its appropriate nerve filament or filaments, so that a nervous impulse corresponding to the frequency of the vibrator is transmitted to the brain, not corresponding, necessarily, as regards the number of nervous impulses, but in such a way that when the impulses along a particular nerve fibre reach the brain, a

¹ Helmholtz, *op. cit.*, pp. 217-226.

state of consciousness is aroused which does correspond with the number of the physical stimuli and with the period of the auditory vibrator. (3) The mass of each vibrator is such that it will be easily set in motion, and after the stimulus has ceased it will readily come to rest. (4) Damping arrangements exist in the ear, so as to quickly extinguish movements of the vibrators. (5) If a simple tone falls on the ear, there is a pendular movement of the base of the stapes, which will affect all the parts, causing them to move; but any part whose natural period is nearly the same as that of the sound will respond on the principle of sympathetic resonance, a particular nerve filament or nerve filaments will be affected, and a sensation of a tone of a definite pitch will be experienced, thus accounting for the discrimination of pitch. (6) Intensity or loudness will of course depend on the amplitude of movement of the vibrating body, and consequently on the intensity of nerve stimulation. (7) If a compound wave of pressure be communicated by the base of the stapes, it will be resolved into its constituents by the vibrators corresponding to tones existing in it, each picking out its appropriate portion of the wave, and thus irritating corresponding nerve filaments, so that nervous impulses are transmitted to the brain, where they are fused in such a way as to give rise to a sensation of a particular quality or character, but still so imperfectly fused that each constituent, by a strong effort of attention, may be specially recognised. The last statement gives an explanation of the analytic powers of the ear.

The structure of the ductus cochlearis meets the demands of this theory. It is highly differentiated, and its parts appear suitable for executing independent vibrations. The minute size of the structures does not present any difficulty; because, however minute the vibrators might be, if they had different periods, they must act in obedience to the same principles of resonance as larger bodies do outside the ear. In 1863, Helmholtz was of opinion that the different degrees of tension in the arches of Corti indicated capacity for vibrating at different periods. Soon afterwards it was shown by Hasse¹ that these rods do not exist in birds, animals presumably capable of appreciating tones; and Hensen² pointed out that the membrana basilaris consists of transverse fibres, which vary in length from 0.04125 mm. at the base of the cochlea to 0.495 mm. at the hamulus. This led Helmholtz to state that "it is probably the breadth of the membrana basilaris in the cochlea which determines the tuning."³ He pointed out that the membrane was in a state of considerable tension transversely, while it had only little tension in the longitudinal direction, and that such a membrane had very different properties from that of a membrane which had the same tension in all directions. The membrana, from its structure, behaves like a system of stretched strings, bound together by a semifluid substance. Each string or fibre would act independently of the others, and would be set into vibration by an impulse to the fluid in the scala vestibuli, corresponding to its period. Consequently, if a part of the membrana were called into action, one of its radial fibres, corresponding to the exciting tone, would vibrate, and the vibrations would extend with diminishing strength on the adjacent portions of the membrane. Possibly some of the structures on the surface of the membrane might act as dampers. In this way the parts of the membrane near the

¹ "De cochlea avium," Kiel, 1866.

² *Ztschr. f. wissenschaft. Zool.*, Leipzig, Bd. xiii, S. 492.

³ *Op. cit.*, p. 218.

fenestra rotunda would be adapted for the higher, while those near the vertex of the cochlea would be suitable for deep tones. Corti's arches are therefore of secondary importance, serving either as supporting structures, or for transmitting vibrations of parts of the basilar membrane to the rows of hair cells placed on their backs. When we take into account the fact that the filaments of the cochlear nerve do not terminate in the rods, nor in the fibres of the basilar membrane, nor even in the hair cells, but, as shown by Retzius,¹ in fine filaments lying against the hair cells, we must consider how vibrations of the fibres of the basilar membrane could affect these filaments.

The short hairs of the hair cells project through apertures in the membrana reticularis, as if it were necessary to cause any oscillation communicated to the hair cells to be always in the same direction. Resting upon the upper surface of the membrana reticularis is the membrana tectoria; in sections the latter appears often to be separated from the former by a considerable interval; but this is not always the case, and in some sections the two may be seen to be almost in apposition. The question whether the two are in actual contact at any time has not been settled by histologists. Suppose that, in accordance with the view of Helmholtz, a segment of the basilar membrane were thrown into sympathetic vibration, it would move in a direction at right angles to the direction of its fibres. These movements would be communicated to the structures lying on its upper surface; and if we suppose the arches of Corti to be elastic, such movements would be transmitted to the hair cells. These would move in the line of their long axis,—in other words, their hairs would move up and down in the meshes of the membrana reticularis, and strike against the under surface of the membrana tectoria. A reaction would take place from the latter, and thus the delicate nerve-endings between the hair cells would receive pressures corresponding in frequency to the oscillations of the membrana basilaris. In the cochlea of birds and amphibia, the mechanism is practically the same, but in consequence of the membrana basilaris not being highly differentiated, there cannot be the nice appreciation of pitch of tone which exists in the higher animals. There is every reason to suppose that a bird has a power of discriminating pitch only through a narrow range. The number of notes birds use in song is very limited, and even those which can be taught to whistle tunes, like piping bullfinches, can only use a very few tones. Parrots, mocking-birds, and minas no doubt can imitate many tones, and it would be interesting to examine the structure of the cochlea in these birds, an investigation not yet carried out.

The theory of the action of the cochlea above described is supported by the results of certain experiments and by clinical observations; but the parts involved are so minute as to make it difficult to be accurate as to the portion actually destroyed or modified. All such results, therefore, must be received with great caution. The experiments of Baginsky,² on dogs show that, when the upper parts of the cochlea are destroyed, deafness for low tones results, while destruction of the basal portions causes deafness for high tones. Stepanoff,³ however, could not

³ *Monatschr. f. Ohrenh.*, Berlin, 1888, S. 85.

find any loss of perception for low tones, when in guinea-pigs the upper parts of the cochlea were destroyed. He tested hearing by the doubtful expedient of observing a reflex movement of the auricle when a sound was heard, and he found that the animals reacted even after the perilymph and endolymph were flowing out of the broken cochlear apex. This was too rough an experiment, and does not appear to have much value.

Hensen¹ has demonstrated that in the supposed auditory organ of arthropods certain hairs vibrate in sympathy with certain tones, and not with others. In certain crustacea these hairs number about 468; the largest is about .72 mm. long, and the shortest .14 mm. The hairs vibrated within a range of three octaves. In *Mysis*, one of the hairs answered strongly to $d\sharp$ and $d''\sharp$, more weakly to g , and very weakly to G . Its pitch was between d'' and $d''\sharp$, or the second partial of d' to $d''\sharp$, the third of g to $g\sharp$, the fourth of d to $d\sharp$, and the sixth of G to $G\sharp$. Another hair answered strongly to $a\sharp$, more weakly to $d\sharp$ and $A\sharp$. Its tone, therefore, was about $a\sharp$.²

There is a certain amount of clinical evidence on this question. One case is on record where an individual showed during life a total want of perception of high tones, while tones low in pitch were audible. The necropsy showed that there was atrophy of the fibres of the nerve furnishing the lowest whorl of the cochlea.³ In boilermaker's deafness the hearing power for high tones is particularly affected. In one such case, a necropsy showed that the lowest whorl was diseased.⁴ It is the general opinion of aurists that in cases of partial deafness from diseases of the inner ear, the loss of audibility is for the higher tones, and, as a rule, post-mortem examination shows changes in the basal portion of the cochlea. A case is recorded of a man, æt. 52 , suffering from locomotor ataxia, who was deaf to the ticks of a watch and to ordinary speech. The fork (c) was heard by bone conduction, while c'' was inaudible. After death the left ear showed the cochlear division of the nerve to be degenerated, and the corresponding organ of Corti also much altered. On the right, however, there still existed a large bundle of nerve fibres at the apex of the cochlea, and the corresponding part of Corti's organ was intact. The rest of the nerve and cochlea were degenerated, as on the left side.⁵

On the other hand, cases have been cited in which the whole cochlea of one side has been exfoliated, and yet the individual was able to distinguish tones with that ear. These are extremely doubtful, and the observation is open to the objection that the patient probably heard, by bone conduction, with the sound ear. There can be no doubt that exfoliation of both cochleæ causes complete deafness for tones, although there may still be something like a sensation of sound.⁶

I have constructed a model of the cochlea, consisting of a rectangular box, with glass sides and top, which is completely filled with water. It is divided horizontally by a glass partition, to represent the basilar membrane (it is not necessary to imitate the membrane of Reissner); the upper

compartment will then represent *scala vestibuli* and the lower *scala tympani*. A hole is then cut in the end opposite each *scala*, and over this hole a thin elastic membrane is stretched. The upper hole is the *fenestra ovalis*, and the lower the *fenestra rotunda*. A hole is also cut in the horizontal glass plate, and covered by membrane. This will represent a segment of the basilar membrane. On this membrane a small weight rests, connected with a fine watch-spring, which has its own period of vibration. Then, by means of a horizontal piston, representing the base of the stapes, moved by a wheel, a series of pressures are given to the membrane covering the oval window. With each inward pressure there is a movement downwards of the membrane in the horizontal glass plate, and a movement outwards of the membrane covering the round window. When the piston moves outwards there is a reversal of the movements of the membranes. If now the wheel moving the piston be rotated rapidly, to imitate simple pendular vibrations the steel spring, resting on the membrane, representing a segment of the *membrana basilaris*, at once begins to oscillate *at its own period* when the number of movements of the piston reach that period. If they go faster, then the spring soon ceases to oscillate. Suppose the period of the spring to be 12 per second, and another hole to be cut in the horizontal plate, and covered with membrane, on which rests a weight, with a spring tuned to the octave of the first, that is 24 per second. By means of a wheel having an eccentric motion, the piston may be caused to execute a compound movement, produced by two movements in the ratio of 2 : 1 to imitate the movements of the base of the stapes when a sound and its octave act upon it. If, now, the wheel be rotated, when it moves at a rate equal to that of the first spring (12 per second), it is seen that *both* springs are oscillating; that is to say, the compound harmonic motion of 2 : 1 is analysed by the springs, each taking its own period. It would only be a matter of trouble and expense to construct a more complete analyser to imitate the cochlea.¹

Beauregard and Dupuy² find that when the cochlea is stimulated by sound, a current of action occurs in the auditory nerve. Non-polarisable electrodes are placed on the *membrana tympani* and the cut surface of the peripheral portion of the auditory nerve. In guinea-pigs the current was much less marked when low tones were used than with high ones. The authors maintain that their experiments prove that sound is analysed in the ear.³

An obvious question in discussing the Helmholtz theory of the cochlea is as to whether the histological evidence as to the number of possible vibratile structures is such as will satisfy the demands of theory. Helmholtz attempts to answer this question on the basis of E. H. Weber's statement, that practised musicians can "perceive even a difference of pitch for which the vibrational numbers are as 1000 to 1001," or the $\frac{1}{1000}$ of a semitone, a smaller interval than that between two of Corti's arches, on the assumption that there are about $33\frac{1}{3}$ for each semitone in each cochlea; and he accounts for the apparent deficiency by the explanation that if a tone came between the pitch of two of the arches "it would set them both in sympathetic vibration, and that arch would vibrate the more strongly which was nearest in pitch to the proper tone." This would also explain how it is that when we listen

¹ No description of the apparatus has been hitherto published; in its construction I have been much indebted to suggestions made by Professor Crum Brown.

² *Arch. internat. de laryngol. etc.*, Paris, July and August 1896.

³ These observations require repetition. I have myself often searched for such an action current, but without success.

to the syren, as its disc revolves faster and faster, our sensations go on not by leaps and bounds but continuously. Since the time when Helmholtz wrote the "Tonempfindungen," histological evidence has accumulated, and now we can give more ample data on which to form an opinion on this question.¹

Suppose we take the lower limit of perception of tone to be that corresponding to nearly 16, and the upper limit nearly 50,000 vibs. per second, sensible discrimination of pitch diminishes towards each end of the range, more especially towards the upper limits. By noticing the smallest changes in different determinations, and by the method of computing right and wrong cases, in observations on the comparison of differences, experiments have shown that between 64 and 1024 vibs. per second the least noticeable difference is so small as 0.2 vibs. Külpe gives 0.4 at 32 and 0.3 at 2048 vibs. per second. It is a striking testimony to the delicacy of the ear that between 32 and 2048 vibs. per second we can observe a difference of less than 1 vib. per second. Even the most skilled ear cannot observe large differences between 12,288 and 16,384, and it may be safely stated that only about 23 tones can be distinguished beyond a vibration frequency of 4096.² From these data we can compute the number of tones the human ear can distinguish. Thus, within the range of human audition, we can hear about 97 tones between 16 and 64 vibs. per sec., 4800 between 65 and 1024, 6144 between 1025 and 4096, and 23 on the upper side of 4097. This gives a total of 11,064 tones heard by the human ear. It is interesting to notice in this connection that the pitch of the highest tone of the piccolo stop of the organ is 4096 vibs. per sec., while the deepest tone of the contra-bassoon is 27. These are the highest and the lowest tones used in music.

The dimensions of the ductus cochlearis, the number of the rods of Corti, and the number of hair cells have been determined by competent observers. At my request, Dr. William Snodgrass made transverse sections of the cochlear division of the auditory nerve of an adult who was not deaf and who did not die of a disease affecting the ear, and he carefully counted the number of nerve filaments.³ These were found to be about 14,000. It is obvious that all such estimations must be approximate.

The following shows the general result of computations relating to this question:—

1. AUDIBLE SOUNDS, THE PITCH OF WHICH CAN BE DISCRIMINATED	11,064
Less those below 64 and above 4096	110
	10,954
Leaving	10,954
Say	11,000

2. DISTRIBUTION OF SOUNDS IN SIX OCTAVES USED IN MUSIC—

$$\frac{11,000}{6} = 1833 \text{ for each octave; } \frac{1833}{12} = 153 \text{ for each semitone.}$$

3. MUSICIAN'S EAR CAN DETECT DIFFERENCE OF $\frac{1}{12}$ SEMITONE—

$$\frac{153}{64} = 2.4 \text{ for each } \frac{1}{12} \text{ semitone.}$$

¹ M'Kendrick, *Trans. Roy. Soc. Edinburgh*, 1896, vol. xxxviii. p. 780.

² Külpe, "Outlines of Psychology," translated by Titohener, 1895, p. 106.

³ Result not hitherto published.

4. NERVE FIBRES IN COCHLEAR DIVISION OF AUDITORY NERVE, 14,000.

Range of audition, 11 octaves.

$$\frac{14,000}{11} = 1273 \text{ nerve fibres for each octave.}$$

Assuming that the number of auditory filaments is the same for each of the eleven octaves —

$$1273 \times 6 = 7638 \text{ for 6 octaves used in music.}$$

$$\frac{1273}{12} = 106 \text{ nerve fibres for each semitone.}$$

$$\frac{106}{64} = \text{less than 2 nerve fibres for } \frac{1}{64} \text{ of a semitone.}$$

5. FIBRES IN MEMBRANA BASILARIS (RETZIUS)—

$$\frac{24,000}{11} = 2182 \text{ basilar fibres for each octave.}$$

$$2182 \times 6 = 13,092 \text{ for 6 octaves used in music.}$$

$$\frac{2182}{12} = 180 \text{ basilar fibres for each semitone.}$$

$$\frac{180}{64} = \text{less than 3 basilar fibres for each } \frac{1}{64} \text{ semitone.}$$

6. HAIR CELLS—INNER, 3487 ; OUTER, 11,700 = 15,237—

$$\frac{15,237}{11} = 1385 \text{ cells for each octave.}$$

$$1385 \times 6 = 8310 \text{ hair cells for 6 octaves used in music.}$$

$$\frac{1385}{12} = 115 \text{ cells for each semitone.}$$

$$\frac{115}{64} = \text{less than 2 for each } \frac{1}{64} \text{ semitone.}$$

7. CORTI'S RODS. INNER, 5590 ; OUTER, 3848 = 9438.

$$\frac{9438}{11} = 858 \text{ rods for each octave.}$$

$$858 \times 6 = 5148 \text{ rods for 6 octaves.}$$

$$\frac{858}{12} = 71 \text{ for each semitone.}$$

$$\frac{71}{61} = \text{at least one rod for each } \frac{1}{61} \text{ semitone. As each rod forms half of a Corti's arch, there will be nearly one arch for each } \frac{1}{61}.$$

There are thus in the cochlea a sufficient number of possible vibratile masses to satisfy theory.

Careful measurements of parts of the cochlea have also shown remarkable differentiation, indicating that we have an organ which cannot be supposed to act only as a whole. These measurements show, for example, that the breadth of the basilar membrane increases towards the apex ; that the osseous lamina spiralis diminishes in breadth as the basilar membrane increases ; that from base to apex, both the

pillars of Corti lengthen; that from base to apex both inner and outer hair cells increase in size; that from base to apex the hairs increase in length, while the increase is greater in the hairs of the outer cells; and that the membrana tectoria increases in breadth from base to apex.¹ Further, if we take man, the cat, and the rabbit, all of which presumably hear tones, but probably have very different powers of discrimination of tones, we find remarkable differences in detail, as given in the following table by Retzius: ²—

	Man.	Cat.	Rabbit.
Ear teeth	2,490	2,430	1,550
Holes in habenula for nerves	3,985	2,780	1,650
Inner rods	5,590	4,700	2,800
Outer rods	3,848	3,300	1,940
Inner hair cells (one row)	3,487	2,600	1,600
Outer hair cells (several rows)	11,750	9,900	6,100
Fibres in basilar membrane	23,750	15,700	10,500

Upper partial tones and the theory of dissonance.—We have seen that a compound tone is built up of a number of partial tones, the frequency numbers of which are multiples of that of the first or fundamental tone. It has also been shown that when two tones sufficiently near in pitch are simultaneously sounded, beats are produced. If such beats are few in number, so as to be readily counted, the sensation of waxing and waning is not disagreeable; but if they are sufficiently numerous it may be impossible to count them, and the sensation is disagreeable. Such a sensation is dissonance. The sensation is most disagreeable when the ear is affected by about 33 beats per second; if they are more numerous, the sensation is rough and unpleasant. Further, even when the frequency of beats is much greater than the number of vibrations required to produce the sensation of a tone, the sensation is never uniform, but is of a rough intermittent character. In other words, the sensation of a tone cannot be produced by the intermittent impulses on the drum-head, due to beats. If now we sound an interval on an instrument giving forth compound tones, such, for example, as an octave, each tone will have its corresponding partials; and as these come closer and closer together the higher they are in the series, it is clear that they may come within beating distance, and thus give a certain harshness to the sound. The beating distance may, for tones of medium pitch, be roughly fixed at a minor third; this interval, of course, will expand for intervals on low tones, and contract for intervals on high ones. Thus the same interval in the lower part of the scale may give slow beats that are not disagreeable, while in the higher part it may cause harsh and unpleasant dissonance. As a rule, the partials up to the seventh are beyond beating distance, but above this they soon come close together. In the neighbourhood of the tenth, the interval may be about a tone, of the sixteenth a semitone, and still higher they come so close together as to cause dissonance. This fact explains the harsh but brilliant quality of some of the tones of a trumpet. Suppose that one of the tones of the interval is slightly out of tune, then all the partials will be correspondingly affected, and the

¹ M'Kendrick, *op. cit.*, p. 782.

² Retzius, "Das Gehörorgan der Wirbelthiere," Bd. ii. S. 356.

dissonance will be most disagreeable, even with compound tones having few partials, such as those of the flute, still more with those having numerous partials, like the tones of reeds, as in a harmonium.¹ Helmholtz has applied this view to an explanation of the satisfying character of certain musical intervals, as contrasted with the discordant character of others. Thus, unison $\frac{1}{1}$, minor third $\frac{6}{9}$, major third $\frac{5}{4}$, fourth $\frac{4}{3}$, fifth $\frac{3}{2}$, minor sixth $\frac{8}{5}$, major sixth $\frac{5}{3}$, and octave $\frac{2}{1}$, are all concords; while a second $\frac{2}{1}$, minor seventh $\frac{10}{7}$, and major seventh $\frac{15}{8}$, are discords. The smoothest interval is the octave, next the fifth, then the fourth, major third, and so on.

There can be no doubt that this explanation satisfies the case, with intervals sounded on instruments giving forth compound tones, but it does not appear to do so when an interval is composed of sounds produced by instruments like large stopped organ pipes, in which there are no over-tones. By careful bowing, few partials may be produced by well-constructed tuning-forks, and these soon die away, leaving the pure proper tone of the fork. In such cases the interval of a minor seventh should be as concordant as that of a fifth, but it is not so. On the theory of the cochlea already described, there is no difficulty in explaining these facts, because, if it possesses analytic powers by sympathetic resonance, it must respond to the prime tones and partials of both of the notes forming the interval. The only thing unexplained is, why the sensation should be disagreeable when two portions of the membrana basilaris sufficiently near are thrown into vibration. The sensation of a beat is not due to the stimulation of one part of the membrana, but the peculiar wave of pressure of two tones, causing a beat, is analysed. While a beat is sounding, listen with an appropriate resonator to one of the constituent tones of the beat, and it will be at once heard. For some unexplained reason, however, if two nerves sufficiently near are simultaneously stimulated, or if they are stimulated in the intermittent manner peculiar to beats, the sensation is disagreeable. Helmholtz compares it with that caused by a flickering light on the eye. Something similar I have found to be produced by simultaneously stimulating the skin, or margin of the lip, by bristles attached to tuning-forks giving both beats. If the frequency of the forks is great, the sensation is that of a most disagreeable tickling. It may be that the instinctive effort at analysis of tones close in pitch causes the disagreeable sensation.

Combination tones.—The law that the oscillations of elastic bodies, and of the air, produced by several sources of sound, are the sum of the individual motions from each source, only holds good when the bodies are of infinitely small dimensions, and when the vibrations themselves are also infinitely small. If vibratile bodies are not infinitely small, then other phenomena may be observed. Helmholtz² considered these phenomena with reference to the theory of dissonance and the action of the ear. If two tuning-forks, representing a fifth, are properly bowed, sounding the fork of lower pitch first and that of higher pitch afterwards, we may hear a weak lower tone, the pitch of which is an octave below that of the first fork. This is known as a combination tone. Such tones are divided into two classes—*differential* tones, in which the frequency is the difference of the frequencies of the generating tones; and *summational* tones, having a frequency which is the sum of those of the tones producing them.

¹ For numerous examples, see Sedley Taylor, "Sound and Music," London, 1873, p. 166, *et seq.*; also, Helmholtz, *op. cit.*, p. 272.

² *Op. cit.*, p. 229.

The following table shows the pitch of several differential tones of the usual intervals:¹—

Interval.	Ratio of Frequency.	Difference.	Combinational Tone is deeper than the deeper generating Tone by
Octave	1 : 2	1	A unison.
Fifth	2 : 3	1	An octave.
Fourth	3 : 4	1	A twelfth.
Major third	4 : 5	1	Two octaves.
Minor third	5 : 6	1	Two octaves and a major third.
Major sixth	3 : 5	2	A fifth.
Minor sixth	5 : 8	3	A major sixth.

Differential tones, first noticed by Sorge about 1740, are usually associated with the name of Tartini.² Summational tones were discovered by Helmholtz.³ It is clear that there must be differential tones of several orders, according as they are produced between the generating tones themselves, between the differential tone and each of the generators, and so on.⁴ It is not difficult to detect differential tones, but this is not the case with summational tones. Helmholtz heard them first with the syren and harmonium, and afterwards with organ pipes and tuning-forks. On the other hand, Hermann and many others assert that they have not been able to hear these tones.⁵ With Appunn's apparatus, which includes a large series of reeds, which can be sounded with great force, I can hear them with the use of the appropriate resonator. Without the resonator, they are almost inaudible, sometimes quite inaudible, because, probably, they are lost in the loud-sounding generators. It is clear that a resonator can have no effect on a tone sensation that is purely subjective. This proves that they have an objective existence, and that they are not produced in the ear itself. Some have contended that, as regards differential tones, these may be produced by a blending of beats. This is open to the objections—(1) That it is doubtful if any number of beats can produce a sensation of tone—although it is held by Hermann and other critics that “the ear is capable of recognising as a tone any periodicity within certain limits of frequency”;⁶ (2) that the explanation does not include the existence of summational tones; and (3) that, by using appropriate sympathetic membranes, Helmholtz was able to demonstrate the existence *outside of, and quite independently of, the ear*, of both kinds of combination tones. Further, Helmholtz states that “whenever the vibrations of the air or of other elastic bodies, which are set in motion at the same time by two generating simple tones, are so powerful that they can no longer be considered infinitely small, mathematical theory shows that vibrations of the air must arise which have the same vibrational numbers as the combination tones.”⁷

By other experiments, however, it may be shown that, in certain circumstances, combination tones may be produced by the mechanism of the ear itself. If two tones are sounded from sources very close together, the combination tone is strong; but if the sources are wide apart, it is weak or inaudible. Helmholtz held that the unsymmetrical form of the membrana

⁷ Helmholtz, *op. cit.*, p. 235. Forsyth and Sowter have recently furnished evidence of the objective reality of combination tones, *Proc. Roy. Soc. London*, vol. lxiii. p. 396. See also Rücker and Edser, *London, Edinburgh, and Dublin Phil. Mag.*, London, 1895, vol. xxxix. p. 341.

tympani favours the production of minute vibrations superposed on those of the membrane proper, and thus gives rise to weak combination tones. The loose formation of the malleo-incudal joint might have a similar effect; that is to say, if acted on by two very powerful tones, minute motions might be produced (corresponding to the pitch of the combinational tones) which would be added to the combined motion of the two generators. This explanation can only be admitted when the generators are loud; but, as Hermann urges, differential tones may be heard when the generators are very weak. Lord Rayleigh supports Helmholtz in the statement that "loud generators are necessary." This is consistent with the results of experiments made with Appunn's apparatus. It is a reasonable objection, however, to experiments with reeds, that the tone supposed to be a combination tone may really be a loud partial of one or other of the reeds. A combinational tone is well brought out, according to Helmholtz, "when two clear and powerful soprano voices execute passages in thirds."

The importance of these combinational tones in the theory of hearing is obvious. If the ear can only analyse compound waves into simple pendular vibrations, of a certain order, how can it detect combinational tones, which no doubt can be heard, and yet do not belong to that order? Or, the question may be put, Can combinational tones explain consonance and dissonance, produced by tones that are simple, and are destitute of partials? Take the octave, and sharpen the upper note, so that the octave is slightly untrue. Suppose the lower tone has a frequency of 100, and the upper 201 vibs. per second, a combinational tone of 101 is produced, and this, with the lower generator, will produce one beat per second. The beats cannot be avoided, unless the octave is pure. Thus the octave, produced by simple tones, is a concord bounded by discords. Again, investigate a fifth slightly out of tune. Here we have, say, the generators produced by 200 and 301. The combinational tone of the first order is 101; it will produce a combinational tone of the second order by the differential tone of the first order, 101, beating with 200; the lowest generator thus giving a differential tone of the second order, having a frequency of 99, and there will also be two beats between the differential tone of the second order, 99, and the differential tone of the first order, 101. Thus a fifth is a consonance less sharply cut off than the octave, owing to the febleness of the combinational tone of the second order.¹ Thus we see that combinational tones are produced when the notes of intervals are sounded strongly on instruments *free from partials*; and that these combinational tones may produce beats with either of the generators, or among themselves; and these beats, feeble as they may be, produce that feeling of less and less consonance, until we come to intervals that are truly dissonant. One might suppose in the case of tones that abound in partials, that combinational tones might be produced by the partials, and that thus a new source of beats might lead to confusion and discord; but theory shows that dissonance due to combinational tones produced between partials never occurs except when it has already taken place by the action of the partials among themselves.

According to this view, combinational tones are not produced by beats, but are true sounds superadded to that of the generators. The ear, therefore, in dealing with them, vibrates in some part of its mechanism with each generator, according to Ohm's law, while it is also

¹ For other examples, see Sedley Taylor, *op. cit.*, p. 181.

affected by the combinational tone itself, according to its frequency. This view will satisfy the theory both as regards differential and summational tones.

Objections to the theory of Helmholtz.—In addition to those already considered, the following may be mentioned. Rutherford¹ points out that a compound tone is heard as one sound; and he argues that if Helmholtz were correct, the note is first analysed by the cochlea into its constituents, and is then reconstructed in the brain, a process apparently unnecessary. The obvious reply is that, as a matter of fact, any compound tone may be analysed by the aid of resonators, and if of sufficient intensity, it does not appear to give rise to a simple sensation; but by a strong effort of attention the apparently simple sensation can always be more or less fully resolved into sensations corresponding to the partials. Waller² adduces the result of an experiment of Hermann³ as a strong objection. Hermann observed that a beat tone might be heard which did not excite a resonator or fork tuned to its pitch. If such be the case, Waller maintains that it is improbable it could act on the fibres of the basilar membrane, if these were supposed to respond as resonators. No doubt if a differential tone really exists in the air, and is not generated in the ear, and yet is unable to set an appropriate resonator in vibration, the theory of hearing founded on sympathetic resonance would receive a severe blow. It does not follow, however, that in Hermann's observation the resonator was unaffected. It did not respond to such an extent as to enable a tone to be heard, although the ear could hear the true differential tone, if sufficiently near the sources of the sounds. This only proves that, with the means at our disposal, the ear is more sensitive than the resonator. Further, as has already been pointed out, it is possible to tune resonators in such a way as to enable them to respond to differential tones, irrespective of the ear. It has also been shown that combinational tones may be generated in the middle ear, in which case it is obvious they would not act on a resonator. Thus, either on the supposition that such tones are generated in the air, or, on the converse, that they are produced in the middle ear, the experiment does not invalidate the sympathetic theory of hearing.⁴

Other theories.—As opposed to the theory of Helmholtz is the one known as the telephone theory, advocated by Rutherford. Rinne⁵ had already, in 1865, offered cogent objections to the analysis theory, and had suggested that the cochlea acted as a whole. This view was supported twenty years later by Voltolini,⁶ and, in 1886, Rutherford⁷ stated it with greater fulness, illustrating the function of the cochlea by the analogy of a telephone, and, in particular, attempting to show experimentally that nervous impulses of different rates of frequency can be transmitted along the auditory nerve.

According to Rutherford, all the hairs of the auditory cells vibrate

³ *Arch. f. d. ges. Physiol.*, Bonn, Bd. xlix. S. 499.

⁴ Gray suggests that the intratympanic muscles may act in such a way as to produce differential tones.

⁵ *Ztschr. f. rat. Med.*, Dritte Reihe, Bd. xxiv. S. 12-64. An excellent analysis is given in "Die Lehren von den Funktionen der einzelnen Theile des Ohrlabyrinths," by Stanislaus von Stein, trans. from Russian by C. von Krzywicki, Jena, 1894, S. 141.

⁶ *Virchow's Archiv*, Bd. c. S. 27-41; see also von Stein, *op. cit.*, S. 153.

⁷ *Rep. Brit. Ass. Adv. Sc.*, London, 1886; also *Journ. Anat. and Physiol.*, London, vol. xxi. p. 166; see also address on "Tone Sensation," *Brit. Med. Journ.*, London, 1898, vol. ii. p. 353.

equally to every note, and the hair cells transform sound vibrations into nerve vibrations, or impulses, similar in frequency, amplitude, and character to the sound vibrations. There is thus no analysis of sound in the peripheral organ. Now, there can be no doubt that a wire connecting two telephones, or connecting a microphone transmitter with a telephone receiver, will carry a series of electric impulses, or waves, corresponding in number, form, and character to the waves of musical tones falling on the microphone or first telephone. Thus the tones corresponding to the vibrations of the disc of a phonograph may be transmitted to a telephone, and be there reproduced with remarkable fidelity. The analogy, therefore, between the fibres of the auditory nerve and such a wire is admissible. But the analogy breaks down when we consider the fact of *analysis*. The distal telephone does not analyse the waves reaching it, and if its movements could be graphically recorded, a matter merely of experimental difficulty, they would reproduce exactly the waves falling on the proximal telephone or the microphone transmitter. When we listen to the distal telephone, we hear all the sounds corresponding to these waves, and we can at once analyse these, sifting the one from the other; that is to say, in the experiment, the ear is, after all, the ultimate analyser. Further, one can conceive a device by which the waves of sound given forth by the second telephone might be analysed, but such a device could only be constructed on the principles of sympathetic resonance.

Waller¹ proposes to explain the mechanism of the cochlea as follows: The basilar membrane, as a whole, vibrates to every tone, thus repeating the vibrations of the membrana tympani; and since the hair cells move with the basilar membrane, they produce what may be called pressure patterns against the tectorial membrane, and filaments of the auditory nerve are stimulated by these pressures. With the exception of the use of the phrase "pressure patterns," this is much the same as the view of the mechanism of the cochlea already described, except that I hold that, in conformity with Ohm's law, there is an analysis by the cochlea, whereas, according to Rutherford, the tones are not analysed by the cochlea, but by the brain; while Waller's view admits of a certain degree of peripheral analysis (pressure patterns), but also relegates ultimate analysis to the brain.

Judging from the effect of rapid stimuli sent along a nerve to a muscle, it might be supposed that a number of nervous impulses, corresponding to a tone of high pitch, could not call forth a response from the terminal apparatus in the nerve centre at the same rate. For when more than about thirty stimuli are sent to a muscle, it passes into a state of complete tetanus, and no matter how many more stimuli per second are sent along the nerve, the muscle remains in the same state. As Rutherford,² however, has pointed out, although the effect upon the muscle, so far as contraction goes, is the same no matter how rapid the stimuli sent to it may be, provided there are more than 30 per second, yet on listening over the muscle while the nerve is being stimulated, a sound is heard, the pitch of which varies according to the number of stimuli per second sent into the nerve. This had been already pointed out by Lovén, who regarded the notes produced as being due to electrotonic variations in the nerve. Thus, when forty stimuli per second are used, a tone

¹ *Proc. Physiol. Soc.*, Jan. 20, 1891.

² *Loc. cit.*

is heard having a pitch equivalent to 40 vib. per second. Rutherford, indeed, found it possible to employ as many as 352 stimuli per second; and, on listening over the muscle, to hear a tone of a pitch of that number of vibrations per second. More than 352 stimuli per second did not produce a tone but only a noise. This, however, does not, according to Rutherford, invalidate his theory, for, as he points out, a muscular fibre is a very different thing from a nerve fibre or a nerve cell, and he is of opinion that stimuli of far greater frequency than that recorded might be transmitted along a nerve. Rutherford further instances the case of the insect's wing, such as that of the honey-bee, in which 460 impulses per second pass along the motor nerves to the muscles of the wing.

The most obvious objection to any theory¹ which dispenses with peripheral analysis, is that it leaves the exceedingly elaborate structure of the organ of Corti, and indeed of the cochlea as a whole, out of account; or, to put the matter in another light, it assigns to that organ a comparatively simple function (like that of a vibrating membrane), and one which could be performed by a more simple structure. Further, the holder of such a theory, while recognising the analytic powers we undoubtedly possess, must refer these powers to the cortex cerebri, and practically admit that the problem cannot be solved. Ohm's law may be subject to limitations, but at present there is no substitute for it. Moreover, the cochlea becomes more elaborate in all its parts as we ascend the animal scale, until in man, who doubtless possesses greater powers of analysis than any other animal, the number of hair cells, fibres of the basilar membrane, and arches of Corti, are all much increased. Finally, it has been shown that on purely physical grounds the organ of Corti may be considered to be an analytic apparatus, a view consistent with physical theory, and with all we know of the mode of action of the other peripheral sense organs.

A further question, however, arises, namely, as to whether it is possible for the cochlea to analyse a compound tone on any other principle than that of sympathetic resonance. Various attempts have been made to explain its mode of action in another way. Hurst² has suggested that with each movement inwards and outwards of the stapes, a peculiar wave is generated which travels up the scala vestibuli, through the helicotrema into the scala tympani, and down the basilar membrane to the fenestra rotunda. This wave is not a mere undulation of the basilar membrane, but it causes movements of fluid to and fro in each scala, and these produce a peculiar wave of pressure. As the one wave ascends while the other descends, a movement (or pressure) of the basilar membrane occurs at the point where they meet, and the movement is chiefly in the direction of the tectorial membrane, so that this membrane strikes suddenly on the hair cells and thus irritates the nerves. The point at which the waves meet will depend upon the pitch of the note, or, in other words, upon the time interval between the two waves. In this way, and without sympathetic resonance, the cochlea would, within limits, respond to tones of different pitch. The intensity of the movement of the tectorial membrane against the hair cells would, of course, correspond to intensity of tone. The mode of action of the cochlea as an analyser is not, I think, sufficiently explained by this theory. Thus, if c' and g' be sounded, we have a fifth, with a vibration ratio of $\frac{3}{2}$. A compound wave-movement is transmitted, and this

¹ A full statement of all the speculations of physiologists as to the cochlea will be found in von Stein's book, *op. cit.*, S. 138-155.

² "A New Theory of Hearing," *Trans. Liverpool Biol. Soc.*, 1895, vol. ix. pp. 321-353.

compound movement must affect the membrana basilaris. Even supposing Hurst's theory is correct, this movement, or its effects, must pass up the membrane of Reissner and down the basilar membrane, but how does this explain the fact of analysis? Further, as Hurst himself observes, according to his theory, the "region of the cochlea where the stimulation of high tones occurs is near the apex; low ones producing a stimulation, near the base." This is contrary to the generally accepted view, founded mainly on pathological evidence, that the seat of stimulation by high tones is in the basal region, while that of low tones is in the apical, and Hurst's explanation appears to me insufficient.

More recently an ingenious view has been set forth by Max Mayer,¹ in which the principle of sympathetic vibration is also discarded. Mayer supposes a wave to travel up the scala vestibuli, and to press the basilar membrane downwards. As it meets with resistance in passing upwards, its amplitude diminishes, and thus the distance up the scala through which the wave progresses will be determined by its amplitude. Further, the wave during its progress will irritate a certain number of nerve terminations; consequently, a tone of feeble intensity (amplitude) will irritate only the fibres lying near the fenestra ovalis a certain number of times per second, while, if the same note be sounded loudly, the wave will travel further up the scala and irritate a large number of nerve fibres the same number of times per second. Thus the pitch will be the same, but the intensity or loudness will be greater. Pitch, according to this view, will depend on the number of stimuli per second, while loudness will depend on the number of nerve fibres irritated. How can such a

FIG. 425.—Compound wave form according to Max Mayer.

mechanism act as an analyser? Suppose a compound wave (such as shown in Fig. 425) to travel up the scala vestibuli, the two tones producing such a curve have a vibration frequency of the ratio 2:3, and it will be observed that there are three maxima and three minima. Now, as the wave passes up the scala, the parts shaded horizontally will die away first, and there will be left two maxima and minima. Let the wave travel still further up, and the part shaded vertically will disappear, leaving only one maximum and minimum. Finally, as the wave travels further, this also will disappear. Thus the nerve fibres in these different portions of the basilar membrane will be affected, and each will be affected a different number of times per second. The compound tone will therefore be resolved into three tones having vibration frequencies in the ratio of 3:2:1. According to Mayer, when two tones of the relationship 3:1 are sounded, we actually hear these tones of the relationship 3:2:1,—the tone indicated by 1 being the so-called differential or beat tone. Similarly, if two tones of the ratio 9:4 be sounded, we resolve into tones of the ratio 9:4:1 (the 1 being obtained by $4 \times 2 = 8$, and $9 - 8 = 1$); and if we construct a curve in the same way as shown in Fig. 425, and cut off successive maxima and minima, we have the same ratio of maxima and minima, namely, 9:4:1. Finally, Mayer, as the result of experimental inquiry, denies the existence of combination tones, the vibration frequencies of which are the sum or the difference

¹ *Ztschr. f. Psychol. u. Physiol. d. Sinnesorg.*, Leipzig, Bd. xvi. and xvii.; also *Verhandl. d. physiol. Gesellsch. zu Berlin*, February 18, 1898, S. 49 (in *Arch. f. Physiol.*).

of the two generating tones. Such tones are, according to him, entirely subjective. On the other hand, when two notes are sounded, a new series of tones appear, as was previously pointed out by König. Thus, suppose two tones of 5:8 are sounded, then there are heard (α) $8 - 5 = 3$ (tone corresponding to 3); also (β) $5 \times 2 - 8 = 2$ (tone corresponding to 2); and also (γ) $5 \times 3 - 8 \times 2 = 1$ (tone corresponding to 1), and so on. Such occurs even when the generators have no overtones, and their intensities depend on the varying strengths of the two primary tones.

Thus Max Mayer agrees with Hurst in imagining a series of waves being transmitted along the scalæ, instead of the scalæ forming part of one wave. The two differ in respect that Max Mayer supposes, on physical grounds, that the amplitude must diminish from base to apex of the cochlea, while Hurst argues, also from the physical point of view, that the amplitude must increase. Mayer's theory wholly rests on the supposition of diminished amplitude. I would urge two objections to both theories: (1) it is impossible to conceive of minute waves following each other in rapid succession in the minute tubes forming the scalæ; and (2) neither theory takes into account the remarkable differentiation of structure found in the epithelium of the organ of Corti. Further, each push out and in of the base of the stapes must cause a movement of the fluid in the scalæ *as a whole*. It appears to me, therefore, that the theory of sympathetic resonance gives a more satisfactory explanation of the facts.

THE SEMICIRCULAR CANALS.

These organs, regarding the functions of which there are still differences of opinion, are anatomically in close connection with the internal ear, and indeed form an integral part of it. The membranous tubes, with their ampullæ, communicate freely with the cavity of the utricle, just as the saccule opens into the ductus cochlearis. In the ampullæ the adherent portion of the membranous structure projects into the cavity of the ampulla as a transverse septum or sharp ridge, which partially divides the ampulla into two. On the summit of this ridge we find a highly specialised epithelium, forming the crista acustica ampullæ, and which presents characters similar to those shown by the maculæ in the utricle and saccule. These general anatomical facts support the supposition that the canals and ampullæ are connected with the sense of hearing.

On the other hand, there is a suggestion that they and the structures lying in the vestibule have functions different from that of the cochlea, in the fact that the cochlear and vestibular nerves pursue a somewhat different course when they reach the brain, and apparently have different centres.¹ Too much weight, however, must not be given to this statement, as the nerve to the posterior semicircular canal passes along the cochlear branch, while those to the two remaining canals accompany the vestibular branch. Further, while one can understand that the structures in the utricle, on receiving impulses from the base of the stapes, may act as peripheral organs for the perception of sounds, without reference to pitch or character, it has as yet been found impossible to suggest any rational view as to the action of the canals and ampullæ with regard to auditory impressions. Helmholtz² thought that in the ampullæ eddies of fluid pressure might follow the pushes inwards and outwards of the base of the stapes, thus causing currents or pressures to pass transversely across the bristles on the hair cells in the

¹ Flatau, "Atlas of the Human Brain," 1894, p. 17, plate i. fig. 13.

² *Op. cit.*, p. 217.

crista in the utricle; but while we admit this ingenious suggestion, it does not appear to account for the presence of such bristles in the cristæ of the ampullæ themselves, nor does it account in any way for the remarkable form of the canals.

Let us consider the base of the stapes moving inwards and outwards with the varying pressures caused by waves of sound. We have already seen how impulses must thus be communicated to the cochlea and the saccule. They must also be communicated to the utricle, into which we find the five openings of the ampullæ of the canals. It is evident that the pressures must act equally on all the ampullæ, and we can conceive the pressure tending to compress or push back the fluid at the mouth of each ampulla. If the pressure were less at the mouth of one ampulla than at the mouth of the other, there would be a flow of fluid in the canal. But as the pressure at the mouth of each canal must be the same, and as the fluid is incompressible, no movement of the fluid can take place, but there will be an increase of pressure on the walls of the ampullæ, and the effect of this will be to cause the ampulla and the other end of one canal to separate slightly, and to press the wall bearing the nerve-endings against the osseous wall. If the tube were slightly elastic, such a movement would undoubtedly take place. Thus, with a positive pressure the ampulla and the other end of the canal would tend to move away from each other, thus, $\leftarrow \rightarrow$, and, with a negative pressure towards each other, thus, $\rightarrow \leftarrow$. In this way one can conceive of sound-waves acting on the ampullæ.¹

Again, as the three canals lie in the three directions of space, it has sometimes been held that they may have to do with the appreciation of the direction of sound. An obvious objection to this view is, that as a matter of fact our perception of the direction of sound, or, in other words, of the position in space of the sounding body, is by no means accurate, and that we look with the eyes for the source of the sound, and instinctively direct the ears or the head, or both, in the direction from which the sound appears to proceed. We usually judge of the direction of a sound by making two or more simultaneous or successive observations. If the sound be heard more loudly in the right ear than in the left, we turn the head to the right, and by repeated observations judge of the direction; if the sound be produced at any point equidistant from both ears, we cannot tell its position unless we see what produces it. It is conceivable that we might have been furnished with an organ by which the source of sound might have been at once located, without moving the head, but we do not possess this faculty.²

The relation of the canals in the two ears is remarkable, and must have some physiological significance. This has been carefully investigated in the human subject by Crum Brown,³ who devised a strict method by which the angles formed by the planes of corresponding canals were measured. The results were as follows:—(1) The horizontal (external) canal has its plane sensibly at right angles to the mesial plane, and therefore the two (right and left) horizontal canals are sensibly in the same plane. (2) The planes of the superior (vertical) and posterior (vertical) canals of the same side make nearly the same angle with the

¹ Suggestion by Dr. M'Kendrick. Not previously published.

³ *Nature*, London, 1878, vol. xviii. p. 663; also M'Kendrick's "Physiology," vol. ii. pp. 694-702.

mesial plane, but the right superior and the left posterior canals are not quite parallel—the posterior making with the mesial plane a somewhat greater angle than the superior—as much as 8° more in one instance. Thus the $\frac{\text{right}}{\text{left}}$ superior canal is nearly parallel to the $\frac{\text{left}}{\text{right}}$ posterior, and in each pair of approximately parallel canals the ampulla of one canal is at the one end, and that of the other at the other end. To sum up—(1) The six canals are sensibly parallel, two and two; and (2) the two horizontal canals are on the same plane, while the superior canal on one side is nearly parallel with the posterior canal of the other. These facts point to the two sets of canals and ampullæ acting as one organ, in a manner analogous to the action of two retinae for single vision.

For many years the view has been developing that the semicircular canals communicate nervous impulses, which give a consciousness of the position of the head in space, and thus bring into play the muscular mechanisms necessary for equilibrium. Suppose that the canals and ampullæ were free to move in the perilymph surrounding them, a very slight movement of the head in space might cause a small pull or pressure on the nerve-endings in the ampullæ, and thus a nervous impulse would be aroused in the nerve fibres distributed to these structures. Such a mechanism would be equivalent to a variation of pressure; but, as we have seen that sound-waves also correspond to variations of pressure, it is evident that such variations might be produced by movements of the stapes or by movements of the head as a whole. Thus the ultimate mechanism of hearing, and that assumed to be the function of the semicircular canals, is essentially the same in kind, only, according to this view, the pressures communicated by the base of the stapes give rise to sensations of hearing, while those brought about by the varying tensions of the ampullæ originate those vague sensations which preside over and regulate the muscular movements required to maintain equilibrium.

These views may be traced to two important researches, the one by Purkinje¹ in 1820, and the other by Flourens² in 1828. Purkinje directed attention to the well-known vertigo that follows rapid rotation of the body in the erect position in a vertical axis. The vertigo is felt, often with nausea, on suddenly stopping the rotatory motion. During rotation, if the eyes are open, objects appear to be moving in an opposite direction to that of the real movement; and when the movement of the body is arrested, a sensation of movement in the same direction continues for a few instants, and external objects still appear to be moving in the opposite direction. This may be termed visual vertigo. It has its counterpart in tactile sensations, when there is a tactile vertigo, on touching bodies during the rotation. In these experiments we may suppose external objects to be rotating round an imaginary axis, and, as we have seen, the rotation may be in the same direction as, or in the opposite direction to, that round the vertical axis of the body. Purkinje made the important observation, that the position of the imaginary axis of rotation for external objects depends on the axis of rotation executed at the head; and that if we change the position of the head, *after* having arrested the movement of the body, we find that the axis of imaginary rotation

¹ *Med. Jahrb.*, Wien, 1820, Bd. vi.; also *Bull. der schlesischen Gesellsch.*, 1825-1826.

² *Mém. Acad. d. sc. de l'Inst. de France*, Paris, 1828, tome ix. p. 5; also "Recherches expérimentales sur les propriétés du système nerveux," Paris, 1842, p. 438.

remains unaltered. It was also noted that the sensation of movement was experienced even when the eyes were closed, and when no tactile sensations were possible; nor could Purkinje avoid observing the disturbance of equilibrium all have experienced, and the involuntary tendency to steady one's-self by seizing hold of external objects. Purkinje explained the phenomena by supposing that when rotation takes place, the brain, of soft consistence, and surrounded by a thin layer of fluid, has a tendency to drag behind the movements of the walls of the cranium, and that the dragging might, without tearing the brain substance, exercise tension on the cerebellum and cerebral peduncles. He did not associate the phenomena with the semicircular canals; but he supposed that, as during rotation the images of external objects flash across the retinae, the objects appear to be in movement, and the ocular muscles contract spasmodically or intermittently to secure fixation. A struggle takes place between the sensations excited by retinal stimulation and the nervous impulses connected with the muscles. This struggle, in the language of Purkinje, along with the tension on the brain itself, and especially on its peduncles, gives rise to vertigo and the peculiar sensations of movement.

As bearing on this subject, the following interesting experiments, first studied by Purkinje, may be readily performed. Stand erect and rotate round a vertical axis for some minutes, and then stop. Surrounding objects appear still to move round, and there may be vertigo. The direction of the apparent motion depends on the direction of the preceding real motion, and is always opposite to it, and the axis about which the apparent motion takes place is always that line in the head which was the axis of the preceding real rotation. Bend the head forwards, rotate, and then stop. In this case the apparent motion is round a vertical axis. Again, bend the head forwards, rotate, stop, and then raise the head so as to look forwards, and the apparent motion will take place round a horizontal axis, the horizontal axis having been vertical when the real rotation took place, and the floor will seem to rise on one side and to fall on the other. Again, certain relations of these movements to visual phenomena are of interest. During real rotation round a vertical axis, at first the eyes move by a series of jerks; that is to say, they remain fixed for an instant, then follow the head, again they remain fixed, again move with a jerk, and so on. After a little time, however, if the rotation is continued, the eye does not continue fixed for even an instant, but moves more slowly than the head, then quickly makes up to it in speed, then falls behind. At last both head and eye move together. If, then, the rotation stops, the movements of the eyeballs are renewed, and gradually become less and less until they cease. The oscillatory movements of the eyeballs are the effect of the visual vertigo. When the real rotation ceases, the person has still a sensation that his head is turning round, but he feels also that his body is at rest relatively to his head; he sees that objects are at rest relatively to his head, and he concludes that as his head is turning round, his body, and external objects, must be rotating also, and his eyes oscillate exactly as they would do if these movements were real. That these oscillations of the eyeball may be related to irritations of the semicircular canals, is rendered probable by the observation of Cyon, that irritation of the canals excites oscillatory spasms of the ocular muscles at the rate of from 20 to 150 per minute. The eyeballs oscillate about an axis perpendicular to the plane of the irritated canal. Oscillatory movements of the eyeballs of a similar kind may be observed in rapid railway travelling when the person looks at near objects, and probably they form no inconsiderable part of the cause of the fatigue in such circumstances.¹

¹ M 'Kendrick's "Physiology," vol. ii. p. 701.

Flourens, in 1828, announced that injury to the semicircular canals causes motor inco-ordination and disturbance of equilibrium, and that section of the canals produces a rotatory movement of a kind corresponding to the canal that had been divided; in other words, that division of a membranous canal causes rotatory movements round an axis at right angles to the plane of the divided canal; that is to say, the body of the animal always moves in the direction of the cut canal. Further, he was led to suggest that, as section of the canals produces disturbances of the same kind as those following injury of the cerebellum, they also have to do with co-ordination of movement.

These observations of Flourens have been corroborated by many other observers. Vulpian¹ thought that the phenomena are due to an auditive vertigo, which acts on all the organs. Brown-Séguard stated that the same phenomena are caused by irritation of the auditory nerve, but this was denied by Schiff.² In 1869, Löwenberg,³ after numerous experiments, more especially on the horizontal and vertical canals, in which they were not only divided but subjected to mechanical and chemical excitation, concluded that the difficulties of co-ordination of movement are due, not to paralysis, but to excitation, that these movements are reflex and unconscious, and that the centres for the reflex excitations are in the optic lobes (bird).

An important contribution was made to the subject by Goltz,⁴ who, although he devised no new experiments of importance, and relied mainly on the observations of Flourens, was the first to clearly formulate the conditions necessary for co-ordination, namely—(1) A central co-ordinating organ, (2) centripetal fibres with their peripheral terminations, and (3) centrifugal fibres with their terminal organs. A lesion of any one of these portions of the mechanism produces inco-ordination. Goltz admitted the contention of Flourens, that the canals are necessary for the equilibration of the body, but he went farther, and contended that they have mainly to do with the equilibrium of the head. The mechanism was stated to be as follows:—The endolymph exercises a stronger pressure on the walls of the ampullæ when the movements of the head bring these to a low level; this pressure irritates the nerves of the ampullæ and excites centripetal impulses, which reflexly cause movements resulting in the equilibration of the head. If, then, the canals are divided or injured, disordered movements ensue from the head losing equilibrium. This theory is often termed the hydrostatic theory of Goltz, and it assumes that the movements of the body are regulated entirely by the more or less conscious appreciation we have of the position of the head in space.

The subject was next investigated by Cyon,⁵ who found the general loss of co-ordination of movement after section of a canal to be due to the disordered movements of the head. Thus, when the head of a pigeon was fixed so that the beak was directed upwards and the

occiput downwards, the bird showed irregularity of movement and a loss of equilibrium, as if one of its canals had been divided. If the apparent position of surrounding objects is determined by the position of the head, any sudden change in position might cause for a moment disturbance of motion, and the same result might be expected to follow a strabismus, at all events for the first few minutes. Cyon adjusted glass prisms before the eyes of birds, so as to cause a squint, and the result was loss, for a short time, of co-ordinating power. He also found that after the disturbance of motion following section of the horizontal canal on one side, consisting of oscillations in a horizontal plane and round the vertical axis of the head, and of loss of equilibrium, supporting the head, by placing the finger below the beak, at once caused the movements to disappear, and the bird became calm. Flight after such an injury was almost impossible. At the end of eight or ten days, all the symptoms described disappeared, except that there was still some awkwardness in flying, but eventually this also disappeared, and the movements of the bird were normal. The phenomena following section of the vertical canals were of the same nature, the only difference being as regards direction of movements. The movements of the head were now from below upwards or from above downwards in a vertical plane and around a horizontal axis, and the movements of the body, instead of being *mouvements de manège*, or round a vertical axis, as after division of a horizontal canal, were now backwards and forwards, as if around a horizontal axis passing through the body. As Cyon held that the perception of the position of bodies in space depends on the position of the head, his general conclusions rest largely on this view. Thus (1) to maintain equilibrium, we must have an accurate notion of the position of the head in space; (2) the function of the semicircular canals is to communicate impressions that give an accurate representation of this position—each canal having a relation to one of the dimensions of space; (3) disturbance of equilibrium follows section; (4) involuntary movements following section are due to abnormal excitations; (5) abnormal movements occurring a few days after the operation, are caused by irritation of the cerebellum.

It might be argued, as indeed was done by Böttcher,¹ that the phenomena of Flourens were secondary, and that they were caused by irritation of neighbouring parts of the brain, more especially of the cerebellum. This view, however, is disproved by the fact that the phenomena of Flourens appear immediately after section, whereas similar phenomena, caused by irritation of the cerebellum, do not appear until several days after the irritation. It is contradicted also by the observation that if we divide, not two symmetrical canals, but on the one side a horizontal and on the other a vertical canal, or if we cut two canals on the same side, the phenomena of Flourens do not appear. It is clear, therefore, that secondary lesions of the brain have nothing to do with the phenomena.

Hitherto we have considered the results obtained by experimental physiologists. The functions of the canals have, however, been investigated in another way, by physical experiment and by the application of purely theoretical considerations. This has been done more especially

¹ *Arch. f. Ohrenh.*, Bd. ix.; see also Baginsky, *Biol. Centralbl.*, Bd. i. S. 438; Jacobson, *Arch. f. Ohrenh.*, 1881-2, Bd. i.; 1894, Bd. xxii.; Högyes, *Arch. f. d. ges. Physiol.*, Bonn, 1881, Bd. xxvi. S. 558.

by Mach,¹ Crum Brown,² and Breuer,³ and they have been led to emit theories similar to each other, and all based on the notion of the canals being organs for sensations of acceleration of movement or for the sense of rotation. Mach was the first to point out that the phenomena of Purkinje, already described, were in all probability related to the semi-circular canals. He showed that when the body is moved in space, in a straight line, we are not conscious of the velocity of motion, but of variations in this velocity. Similarly, if the body is rotated round a vertical axis, we perceive only angular acceleration, and not angular velocity. The sensations produced by angular acceleration last longer than the acceleration itself, and the position of the head during the movements enables us to determine direction. By a special apparatus, consisting of a chamber rotating round a vertical axis and surrounded by a scale, Mach investigated the nature of vertigo. He examined critically all the organs that might be supposed to be the seat of the sensations of vertigo, or rather its cause, such as the nerves, skin, connective tissues, bones and muscles, and the displacement of the mass of blood caused by rotation, and found it impossible thus to account for the phenomena. It will be remembered that Purkinje attached great importance to the movements of the eyeballs, and he supposed that vertigo consists in a displacement of the visual field, produced by the movements of the eyeballs, and which we refer to external objects that appear to be moving, just as we judge of the changes in position of external objects by the sensations excited by contractions of the ocular muscles, as we follow objects with the eye. This explanation did not satisfy Mach, and he inclined to the explanation offered by Breuer, namely, that the movements of the eyeballs are of a reflex character, and that the reflexes are excited by irritation of the nerves distributed to the ampullæ. The movements are, in a sense, compensatory, and they are in the opposite direction to the rotation of the head. When the movement of the head stops, then the eyeballs return to their normal position; but, during this movement backwards, external objects will appear to move in the visual field in a direction opposite to the direction of the rotation of the eye. A sensation is then excited of objects moving in a direction opposite to that of the body, and vertigo is the result. Mach found, however, that this did not fully explain the phenomena, as in certain experiments there was, after rotation, an apparent movement of external objects, even when the retina was stationary, and he finally put forward the following theory:—Suppose in a body, B, there is a cavity on the walls of which there are nerve-endings, and that this cavity contains a solid or liquid, A. By its weight, A will exercise a greater pressure on one part of the walls of the cavity than on the others, and it will thus determine the position of the body, B, relative to the vertical. With each acceleration of B, A will press in the opposite direction, and this contrapressure will be added to the acceleration due to weight, so that the direction of the pressure as well as its intensity will change in the cavity. In like manner, with each angular acceleration communicated to B, A will oppose a rotation in the opposite direction. Thus, B will obtain knowledge both of its

¹ *Sitzungsb. d. k. Akad. d. Wissensch.*, Wien, 1874; also "Grundlinien der Lehre von den Bewegungsempfindungen," Leipzig, 1875.

³ *Med. Jahrb.*, Wien, 1874, 1875, S. 72, 87.

position and of its progressive acceleration in a straight line, and, in the case of rotation, angular acceleration will also be indicated. The vestibule and semicircular canals in Mach's scheme constitute B; the vestibule possibly having to do with the sense of acceleration of movement in a straight line, while the semicircular canals serve for angular acceleration. During each angular acceleration around an axis passing through the plane of the canal, there will be a traction or pull in the opposite direction on the nerves of the ampullæ, and this will give rise to the sense of angular acceleration. Each excitation produced in this manner, or, as regards the nerves of the ampullæ, in accordance with the law of the "specific energies" of nerves, in any other way, will give rise to a sense of rotation. Thus Mach, like Goltz, attaches importance to the fluid in the canals, and by varying pressures of this fluid, produced by angular rotation, and always in a direction opposite to the rotation of the body, sensations of movement are excited, which in turn cause the vertigo of Purkinje and the phenomena of Flourens.

The hydrodynamical theories advanced by Breuer and Crum Brown differ only in detail from that of Mach. All three observers uphold a dynamical theory, as opposed to the statical theory of Goltz. Suppose the three canals to be full of fluid, a rotation of the head in one direction will cause currents of fluid in the canals in the opposite direction, and the amount of flow in each canal will depend on the plane in which the head is turned and on the rate of rotation. As the auditory hairs exist in the crista of the ampullæ, we can conceive that they will be affected by the currents, and produce a sensation of rotation of the head in the plane of the canal in which the flow takes place, and in a direction opposite to it. If the rotation of the head continue, the flow of the endolymph backwards will be arrested by friction, and if the head then suddenly stop, the endolymph will continue to flow in the direction in which the head was previously rotated, and a sensation will be felt of a rotation of the head and body in a direction opposite to that of the first rotation. Crum Brown¹ sums up the matter thus—

"We have two ways in which a relative motion can occur between the endolymph and the walls of the cavity containing it—(1) When the head begins to move, here the walls leave the fluid behind; (2) when the head stops, here the fluid flows on. In both cases the sensation of rotation is felt. In the first this sensation corresponds to a real rotation, in the second it does not; but in both it corresponds to a real acceleration (positive or negative) of rotation, using the word acceleration in its technical kinematical sense."

Mach attributes the effects to variations of pressure in the canals rather than to an actual flow of fluids, while Crum Brown differs from both Mach and Breuer on the following points:—(1) In attributing movement or variations of pressure, not merely to the endolymph, but also to the walls of the membranous canals and to the surrounding perilymph; and (2) in regarding the two labyrinths as one organ, all the six canals being required to form a true conception of the rotatory motion of the head. As already pointed out, the six canals are sensibly parallel, two and two. The two horizontal canals are on the same plane, while the superior canal on one side is nearly parallel with

¹ *Nature*, London, 1878, vol. xviii. p. 633; review of Cyon's work, *loc. cit.*

the posterior canal of the other. Crum Brown states the matter thus:—

“Further, in each of these three pairs (right and left horizontal, right superior and left posterior, right posterior and left superior), the two canals are so placed that when rotation takes place about the axes to which they are perpendicular, one of the two canals moves, with its ampulla preceding the canal, so that the flow or tendency to flow [or pressure] is from ampulla to canal, while in the other the ampulla follows the canal, and the flow or tendency to flow [or pressure] is from canal to ampulla. If, then, we suppose that flow from ampulla to canal—or, adopting Mach’s view, *increase* of pressure in the ampulla—alone stimulates the hair cells, while no effect is produced by flow in the opposite direction—or by *diminution* of pressure in the ampulla—we have in the six canals a mechanical system capable of giving us an accurate notion of the axis about which rotation of the head takes place, and of the sense of rotation.”

Cyon,¹ in later researches, has performed certain experiments which, it must be confessed, throw doubt on both the statical and dynamical theories already described. He has punctured the canals and drawn off the endolymph, injected the canals with gelatin, and plugged them with slender filaments of laminaria, which soon became swollen. Yet by these severe proceedings, by which great variations of pressure must be produced, none of the phenomena of Flourens were observed. The obvious objection to these experiments is, that they were so rough as to entirely destroy the mechanism they were intended to examine. Again, Cyon has repeatedly observed, after making a minute puncture in a canal, that there was a minute pulsation, caused either by a small artery supplying the canal, or by the pulsations of the brain itself through the fluid in the arachnoid with which the membranous canals communicate; and he suggests that, if Mach’s view be correct, we ought in this way to have rhythmic excitations of the nerve-endings in the ampulla. As it is not likely, however, that such pulsations would have any effect, unless the canal were punctured, the observation is of no great importance; at all events, it is not a valid objection to Mach’s theory.

It is well known that a rabbit may show the phenomena of Purkinje after having been rotated on a turn-table. Cyon took advantage of this fact and performed the experiment on animals in which the auditory nerves had been divided, and he states that the results were the same as in normal animals. This observation would at first sight appear to seriously compromise the statical and dynamical theories, but what it really does is to show that some of the phenomena of Purkinje may, as he himself supposed, be due to the action of rotation on the brain itself. If so, one would expect to see these phenomena after the division of the auditory nerves, and the fact does not invalidate the reasoning on theoretical and experimental data regarding the function of the canals already described.

Cyon contends that the semicircular canals only indirectly assist in giving a knowledge of spatial relations. He holds that knowledge of the position of bodies in space depends on nervous impulses coming from the contracting ocular muscles; that the oculomotor centres are in intimate physiological relationship with the centres receiving impulses from the nerves of the semicircular canals; and that the oculomotor centres, thus excited, produce the movements of the eyeballs,

¹ *Thèse, op. cit.*, pp. 41, 42, 43.

which then determine our notions of spatial relations. The canals are thus the peripheric organs of the sense of space, and the sensations caused by excitation of the nervous terminations in the ampullæ assist in forming our notions of the three dimensions, the sensations excited by each canal corresponding to one dimension. Cyon, however, does not show *how* the ampullæ are excited in the first instance. Further, the mechanism assumed to exist is much more complicated than that required for the static or dynamic theories. The latter explain in a satisfactory manner the cause of the sensation of rotation, without touching the much larger question of the origin of our notions of space; and whether one adopts, with regard to this problem, the intuitional or empiric theories, there remains the fact that a comparatively simple function has been suggested for the canals. The interpretation of spatial relations does not, in all probability, depend on one organ alone, but on the combined effect of nervous impulses coming from many organs—eye, ear, skin, tendons, and muscles; and to say that the canals are the only organs having to do with our knowledge of spatial relations is to present a fragment of the truth.

The view of Cyon as to the influence of the canals on the movements of the eyes, is supported by some recent experiments carried out by Lee.¹ By passive rotation of a dog-fish round different axes, compensating movements of the eyes and fins (especially the pectoral fins) were produced. It was observed that if the fish were rotated in the plane of one of the canals, exactly the same movements of the eyes and fins occurred as were produced by experimental operation and stimulation of the ampulla of that canal. Lee is of opinion that each ampulla has a principal and a subordinate function, which produce opposite effects on the eye movements. Thus, if the chief function of one ampulla is to move the eyeball upwards, the subordinate effect is to rotate it downwards. By pressing with a blunt needle upon the ampulla, either of those functions may be called forth. For example, gentle pressure upon the anterior ampulla causes the eyeball of the same side to roll slightly downwards, and that of the opposite side slightly upwards. This is the subordinate function. A stronger pressure upon the same ampulla causes the eyeball of the same side to roll strongly upwards, and that of the opposite side to roll strongly downwards—this is the principal function. It would appear that the compensatory movements of the eyes and fins, when the fish is rotated, are produced by the principal function of a pair of canals, while the reactions following the compensatory movements are produced by the subordinate functions of a pair of canals. On electrically stimulating different parts of the cut surface of the auditory nerves, results were obtained the same as when the stimulus was applied to the corresponding ampulla, and the reverse of the results obtained by mere section of the same nerve. Further, when rotation occurs in a plane different from that of any of the canals, two pairs of canals are stimulated to varying degrees by the pressure of the endolymph, and the result corresponds to the algebraic sum of the stimuli to the various ampullæ. These striking results strongly support the dynamic theory.

The researches of Ewald² merit attention, as he has been led to extend the influence of the canals. He divides the labyrinth function-

¹ *Journ. Physiol.*, Cambridge and London, vol. xvii. p. 192.

² "Untersuch. ü. das Endorgan des Nervus octavus," Wiesbaden, 1892.

ally into two portions, the "hearing labyrinth" and the "muscular-tone labyrinth," the former consisting of the cochlea, and the latter of the semicircular canals, and the structures in the vestibule. After many experiments, he concluded that all the muscles of the body are kept in a state of tone by means of the labyrinth, and that injury to it most affects those muscles whose movements are most delicate, such as those of the eye and larynx. After plugging the canals, abnormal flaccidity of all the muscles ensued. He further states that if the labyrinth of an animal be injured, and the animal be then killed, the usual rigor mortis does not, in most cases, occur. In some cases, however, it appeared to come on earlier. While Ewald thus relates the labyrinth to muscular tonicity, he does not deny that sound-waves stimulate the nerve-endings, and he suggests that in this way rhythmic movements of the muscles, as in dancing to music, may be facilitated.

In 1883, Sewall¹ carried out instructive experiments on cartilaginous fishes. The animals selected were young sharks and skates. He found that merely cutting through all the canals on one side produces no disturbance of equilibrium. The same negative result follows section of the vertical canals on both sides. On injuring the utricle and removing the otoliths, there was occasionally no disturbance of equilibrium; but in the majority of instances it was observed that the fishes dived and swam downwards in circles towards the injured side. The surest way, however, of producing disturbance of equilibrium was to injure the saccule, when the fish kept swimming round in a circle in the vertical plane. Operations on the ampullæ gave somewhat ambiguous, though generally positive, results. Thus, injury to the anterior vertical ampulla tended to produce rotation in the long axis of the body, while similar injury to the longitudinal ampulla tended to produce somersault movements. When the nerve supplying a horizontal ampulla was cut, there was no disturbance of equilibrium.

In the larger sharks serious injuries to the labyrinth often produced little or no disturbance of equilibrium; but the most common results were nystagmus and vomiting. Sewall cautiously concludes that the results of experiments are not sufficient to justify the opinion that the labyrinth is the peripheral organ of equilibrium.

It is remarkable that Steiner² came to the conclusion that in the dog-fish the canals had nothing to do with equilibrium, while we have seen that Lee obtained remarkable positive results (p. 1203). In another research, Lee³ found that, after cutting the auditory nerve in dog-fish on one side, rolling movements round the longitudinal axis towards the injured side occurred. Somersault movements were absent. On cutting the auditory nerves on both sides, the sense of statical equilibrium was lost, and the animal lay on its back, belly, or side indifferently, and swam in these positions. On stimulating the ampulla of the anterior canal, an upward rotation of the eye on the same side, and a downward rotation on the opposite side, were noticed. On dividing the nerve to this ampulla, the opposite effect was produced on the eyes, and if both nerves were cut the fish dived downwards. On cutting the nerves to the posterior ampulla on both sides, the fish swam upwards near the surface, sometimes even putting its head out of the water.

¹ *Journ. Physiol.*, Cambridge and London, vol. iv. p. 339.

² *Deutsche med. Wchnschr.*, Leipzig, 1889, No. 47.

³ *Journ. Physiol.*, Cambridge and London, 1894, vol. xv.

These experiments undoubtedly prove that the ampullæ contain sense organs connected with the sense of equilibrium. Lee is of opinion that the otoliths and maculæ form the organ for statical equilibrium.

The light thrown upon the subject by pathological evidence is scanty. There is no doubt that any disease or injury of these structures, occurring rapidly, produces giddiness, staggering, nystagmus, vomiting, noises in the ears, and more or less deafness, though sometimes some of the symptoms may be absent. But all these, with the exception of the deafness, may merely be reflex symptoms, and even the deafness is probably due to coincident affection of the cochlea.

On the other hand, a slowly progressive affection of the labyrinth may ultimately leave the canals and vestibule transformed into a bony mass, in which no trace of the original soft structures remains. In such cases there may be no perceptible disturbance of equilibrium, no nystagmus or giddiness, nor any other symptom of that nature.¹ If, therefore, we look upon the canals and vestibule as organs whose function is the maintenance of equilibrium, then we must admit that they are not indispensable for that purpose, but that some other organ is able to carry on the function.

From the foregoing, it will be seen that the subject is involved in obscurity. Certain symptoms follow injury to the canals, such as loss of equilibrium, giddiness, nystagmus, and often vomiting; and we may assume that these symptoms are not due to coincident injury of the brain. Injury to the cochlea produces no such symptoms. Are we to conclude, therefore, that the function of the former structures is to make us conscious of the position of the head in space, or the maintenance of equilibrium, or the maintenance of muscular tone, etc.? One difficulty lies in the fact that all the symptoms may be merely reflexes caused by injury, and may not be due to loss of function. The vestibular nerve is in much closer connection than the cochlear portion with those regions of the central nervous system (such as the cerebellum) which, when injured, cause such symptoms.

Whether the canals are concerned in the act of hearing is not known. Injury to these structures in animals does not appear to cause deafness, but we cannot definitely say that hearing is unaffected. In the human subject, on the other hand, it is extremely doubtful whether the canals and vestibule are ever affected without causing deafness; but it must be remembered that these structures are rarely affected without the cochlea suffering coincidentally, so that the deafness may be caused by disease of the latter structure.²

VOICE PRODUCTION.

VOICE is produced by the vibrations of the vocal cords, and developed by the resonance of the upper cavities. It is to be distinguished from speech, which is the production of sounds intended to express ideas. Many of the lower animals have voice, but none have the power of speech in the sense in which man possesses that faculty, or, at all events, the range of animal speech is very limited. There may be speech without voice, as in whispering, or voice without speech, as in singing notes without words.

The singing voice.—One of the functions of the larynx is the production of the singing voice, and hence it is to be looked upon as a musical instrument; but when an attempt is made to compare it with the various instruments used by musicians, we find that it is quite different from any of these. It is most nearly allied to reed instruments, the essential factor in both being that the air is made to pass through a narrow chink, and in doing so it is cut up into a series of successive puffs. The similarity, however, ends here; for in reed instruments changes in pitch are obtained by alterations in the dimensions of the resonator which is attached to them; while in the case of the larynx the pitch is regulated primarily by changes in the length, tension, and thickness of the membranous tongues themselves. The action of the vocal cords, however, may be compared with that of the performer's lips in playing a brass instrument, and his lips may further be likened to membranous tongues. It is to the membranous yielding nature of the vocal cords that the peculiar softness of the human voice is to be attributed; we find that in reed instruments in which the tongues are made of brass or metal, the tone is apt to be cutting, on account of the presence of large numbers of high upper partials.¹

The larynx, therefore, may be compared roughly to a reed instrument, in which changes in pitch are produced by alterations in the tension, length, thickness, and breadth of the cords themselves, and possibly,

¹ Helmholtz, "Sensations of Tone," translated by Ellis, 3rd ed., p. 151.

also, by variations in the strength of the current of air, and not at all, or only in the slightest degree, by changes in the size or shape of the adjacent cavities.

Tone intensity.—The intensity or loudness of tone will be determined by the amplitude of the vibrations of the margins of the membranes (vocal cords), and its pitch will be influenced by arrangements which cause an increase or decrease of the tension of the margins of the membranes. The pitch may also be raised by increasing the force of the blast of the air, since this will also increase the mean tension of the margins of the elastic membranes.

With tones of medium pitch, the pressure in the trachea has been found to be about 160 mm. of water; with tones of high pitch, 920 mm.; and with tones of very high pitch, 945 mm.; while in whispering it may fall to a pressure of only 30 mm.

Tone pitch.—Pitch, so far as the vocal cords are concerned, depends on the number of vibrations per second, or, to put it in another way, on the length of time occupied by each vibration. This again will be determined by the length, thickness, elasticity, and degree of tension of the cords, and on the strength of the blast of air. Other conditions remaining constant, the greater the length of the cords the lower will be the pitch.

The range of the voice.—The *range* of the human voice is about three octaves, from fa_1 (87 vibs. per second) to sol_4 (768 vibs.). In men the vocal cords are more elongated than in women, in the ratio of 3 : 2, so that the male voice is of lower pitch, and is usually stronger. At the age of puberty, the larynx grows rapidly, and the voice of the boy "breaks" in consequence of the lengthening of the cords, generally falling an octave. A similar change, but less in amount, occurs at the same period in the female. At puberty in the female there is an increase of about one-third in the length of the glottis, but it is nearly doubled in the male.

Some of these changes have been carefully studied by Paulsen.¹ In girls, in the sixth year, the pitch ranges from a to $f''\sharp$. From this period there is a slow increase of range in the lower voice tones, while a more rapid extension occurs in the range of the upper tones. The lowest limit of pitch occurs about the age of 12 in the girl's voice, and the highest is reached in the eleventh year. In the boy's voice the range about the age of 6 years is more limited, lying between b and f'' . At first the upper range is extended rapidly, reaching the highest point about the twelfth year, and the lower range increases more rapidly than in girls, reaching the lowest pitch in the thirteenth year. The shrieking voice of a child may, according to Stevens,² rise as high as g''' (3072 v. s. per second), and sometimes screams may even reach from 5000 to 6000 v. s. per second (v. s. = single vibrations).

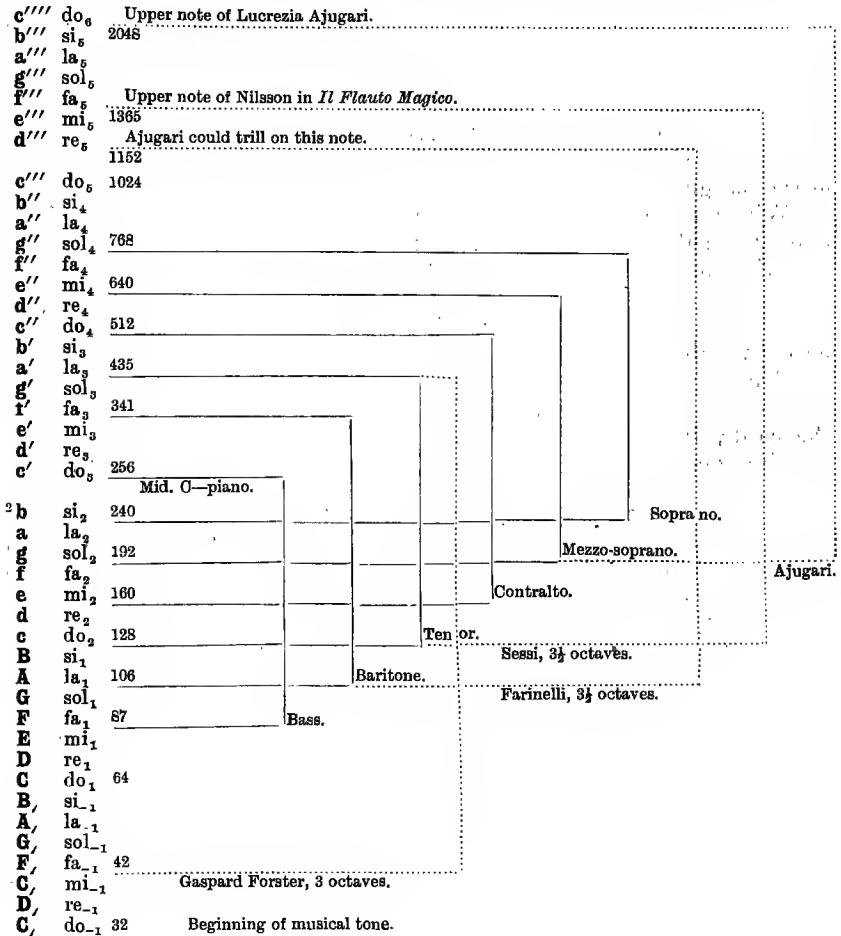

In advanced life the upper tones gradually weaken, and ultimately disappear, while the character of the voice also changes, owing to loss of elasticity caused by calcification (or ossification), which first begins about middle life in the thyroid cartilage, then appears in the cricoid, and much later in the arytenoids. Eunuchs, as a rule, retain the voice of childhood; and by careful training in normal persons it is sometimes possible to so modify the development of the larynx that an adult male can still sing the soprano parts used in cathedral choirs.

The ranges of the different varieties of the human voice are shown in the

¹ *Arch. f. d. ges. Physiol.*, Bonn, Bd. lxi. S. 407.

² *Phys. Rev.*, N. Y., 1895, vol. iii. p. 230.

following diagram, where the dotted lines give the range of certain remarkable voices, and the figures represent the number of vibrations per second.¹

There is thus a range for ordinary voices of nearly two octaves, and certain rare voices may have a range of three and a half octaves. The deepest tone on record is that of Forster, *fa*₋₁ (42 vibs. per second), and the highest, that of Ajugari, on the authority of Mozart, *do*₆ (2048 vibs. per second). The table shows that the lowest note of Forster is not much above the pitch at which the perception of tone begins, and that from this note to the highest of Ajugari is a range of nearly six octaves. From the lowest note of an ordinary bass voice to the highest of an ordinary soprano the range is only about three octaves. In this connection, it is interesting to observe that the range of the human ear is from *do*₋₁ (32 vibs. per second) to *do*₁₀ (33,768 vibs. per second), or eleven octaves.

¹ From article "Voice" in "Encyc. Brit.," 9th edition, vol. xxiv. p. 275, by John G. M'Kendrick. The letters used to designate the tones have been added.

² German writers use *h* instead of *b*, *b* instead of *bb*, *ais* for *a♯*, and *gis* for *g♯*, etc.

THE MUSCULAR MECHANISMS WHICH AFFECT THE VOCAL CORDS.

There is no doubt that the muscle which produces the greatest effect in tightening the vocal cords, and thus raising the pitch of the voice, is the thyro-cricoid. This muscle, acting from the thyroid cartilage as a fixed point, rotates the cricoid in such a manner that its anterior part is elevated towards the thyroid, and the posterior part, which bears the arytenoid cartilages, is depressed and further removed from the angle of the thyroid cartilage, thus stretching the thyro-arytenoid ligaments, the free edges of which, covered by mucous membrane, form the vocal cords. There is, further, no doubt that the lateral crico-arytenoid muscles must tend to rotate inwards the vocal processes of the arytenoid cartilages, and thus to approximate or adduct the cords, and the posterior crico-arytenoids must antagonise the lateral, rotate the vocal processes outwards, and abduct the cords. The arytenoideus muscle, on the other hand, brings the arytenoid cartilages bodily together, and at the same time may somewhat tend to depress their vocal processes. The action of the thyro-arytenoideus muscle is more complex, and will be immediately considered.

All the muscles except the thyro-cricoid, which receives its nerve from the superior laryngeal, are innervated through the inferior laryngeal branch of the vagus, the fibres being derived from the accessory roots.

The inferior laryngeal contains, therefore, both the adductor and abductor nerves. When profoundly anæsthetised, stimulation causes abduction of the cord, but if the anæsthesia is slight, then the same stimulation will cause adduction.¹

The tonic contraction of the abductors, produced by activity of a centre in the medulla oblongata, is normally stronger than that of the adductors, so that during rest the glottis is slightly open; on section of the inferior laryngeal nerve, the cords come together and the glottis tends to close. The bulbar centre is under the dominance of a centre in the Rolandic region of the cerebral cortex.²

With regard to the action of the thyro-arytenoid muscle, until recently it has usually been held by English writers that the muscle, when contracting as a whole, lowers pitch; whereas German physiologists consider that the pitch of the voice is raised by it.

Wyllie³ found that, in the excised larynx, when the cords were approximated and the arytenoid cartilages pushed forward, the pitch of the artificial voice, produced by blowing up through the trachea into the larynx, was considerably raised. But it is not definitely stated by Wyllie what is meant by pushing the arytenoid cartilages forward. If these cartilages, as a whole, are pushed forward, and thus approximated to the thyroid, the vocal cords cannot be tightened. Wyllie, however, appears to mean that if the upper parts of the arytenoid cartilages be pushed forward, a movement of rotation about a horizontal axis takes place and the vocal processes are depressed, thus giving rise to increased tension of the cords. It is difficult to see how the vocal processes could be depressed during phonation, for the articular surfaces of the cricoid cartilage are so placed that one would expect the vocal processes of the arytenoids to rise during phonation. Neumann,⁴ however, found by experiment that the cord sank during phonation.

¹ Semon, *Brit. Med. Journ.*, London, 1886, vol. ii. pp. 405 and 445.

² See article "Cerebral Cortex."

³ "Disorders of Speech," 1894, p. 482.

⁴ *Monatschr. f. Ohrenh.*, Berlin, October 1894.

We must, however, remember that pressure of the arytenoid cartilages from behind cannot be compared accurately with the action of the thyro-arytenoid muscle acting in front. The external part of the thyro-arytenoid might tend to cause depression of the vocal process; but it is very difficult to see how the internal portion of that muscle can produce such an effect; and the small thyro-arytenoid of Sömmering, when present, will have an opposite effect.

Many writers, while admitting that parts of the thyro-arytenoids relax the cords, consider that other portions will cause increased tension.¹ Jacobson,² who has made a careful examination of the function of this muscle, points out that those fibres which run from the outer edge of the vocal process backwards and outwards will aid in causing abduction of the cord. But we cannot admit the unqualified statement that the thyro-arytenoid causes increased tension of the cords. No doubt such fibres, running outwards from their insertion in the vocal cords, could, by pulling on the edge and making it curved instead of straight, tighten the cord. Indeed, the elliptical shape which the rima glottidis assumes, after passing from the chest into the middle register, may indicate some such action. If the part of the muscle which is in contact with the vocal cord contracts as a whole, it will tend to make the cord more rigid; and if the arytenoids were at the same time fixed, the pitch would rise.

VOICE REGISTERS.

The voice has been divided into three registers, namely, the lower or

FIG. 426.—Diagram showing range of registers of human voice.

chest, the middle, and the small or head register. The average range of pitch within each register is shown in the accompanying diagram (Fig. 426).

Chest register.—The chest register belongs more to the male than

¹ Foster, "Text-Book of Physiology," 1891, part 4, p. 1460.

² *Arch. f. mikr. Anat.*, Bonn, 1887, Bd. xxix.

the female singing voice; but in the contralto of the latter it is also used extensively, and it is the voice used in ordinary conversation. If the larynx be examined while the lowest note of this register is being uttered, it will be seen that the epiglottis is kept far back, and, to a certain extent, hides the larynx. In suitable cases, however, it may be seen that between the vocal cords there is an elliptical opening, which extends from the posterior laryngeal wall right up to the apex of the thyroid cartilage in front. During the sounding of such a note, the larynx is fixed by the sterno-thyroid and the thyro-hyoid muscles, and the arytenoid cartilages are brought into apposition by the arytenoideus. We may assume, then, that the note is produced by the vibration of the vocal cords in their whole length, breadth, and thickness (Fig. 427).

If the singer be directed to proceed singing up the scale, it will be observed that the vocal processes of the arytenoid cartilages become rotated inwards. This is brought about by means of the lateral crico-arytenoid muscles, and it continues until these two prominences are in contact, when an elliptical opening exists, extending from the point where they touch one another to the angle of the thyroid cartilage in front. If the singer continues to ascend the scale, this elliptical opening becomes more and more contracted, until the chink of the glottis is represented by a linear slit. This condition is brought about

FIG. 427.—Aperture of glottis during production of low note of lower register.—Bosworth.

by contraction of the thyro-cricoid muscle, and the notes uttered during this stage are said to belong to the upper thick register; the highest note obtainable by this register has now been reached. It should be added that, as the note rises in pitch, the epiglottis is carried further forward, so that the cords are more easily seen (Fig. 428).

During the utterance of the thick register, the false cords are more widely apart than at any other time.

Having reached the highest tension which it is possible to produce, by the mechanism just described, the singer must now employ a different one in order to pass higher up the scale, and

FIG. 428.—Aperture of glottis during production of high note of lower register.—Bosworth.

this is done by making use of the mechanism of the middle register.

Middle register.—On passing from the highest note of the lower register to the lowest of the middle register, a very sudden change occurs, which not only gives a sense of relief to the singer, but is usually detected by the ear. This change consists in the relaxation of the anterior fibres of the thyro-cricoid muscle, which may be felt by the finger

when it is placed over the thyro-cricoid membrane. This relaxation of the thyro-cricoid muscle is accompanied by contraction of the thyro-arytenoid, with the result that the cord is rendered narrower, and now only those parts lying near the edge vibrate. The tension of the cords is still maintained by the posterior fibres of the thyro-cricoid and by the thyro-hyoid.¹

According to Bosworth, the sense of relief in passing from the lower to the middle register is due for the most part to the fact that less muscular effort is required to throw the narrow portion of the cord into vibration, than was necessary in the lower register to set the cord into vibration in its whole breadth. The natural result of this diminution of the vibrating mass is that the voice loses considerably in volume; at the same time, however, it gains in softness. In this register the larynx appears to become narrower than in the lower, and simultaneously with this narrowing the ventricular bands approach one another. It is quite possible that the diminution in the breadth of the vocal cords themselves may be in large part merely apparent, their outer portion being hidden by the ventricular bands, so that they may be really as broad as in the lower register.

The rise in pitch which occurs during the transition from the lower to the middle register is, however, undoubtedly due in part to a thinning of the vocal cords. This is best seen by using Voltolini's method of illuminating the larynx, that is, by placing a strong light directly in front of the thyroid cartilage, instead of reflecting it through the mouth and pharynx. When the mirror is put into the throat, the cords now appear pink or red in colour, and changes in their thickness can easily be observed. In the middle register they are beautifully transparent, but much less so in the lower.

On ascending in the middle register, the cords gradually become more and more tense as the anterior fibres of the thyro-cricoid muscle again come into play, and the crico-thyroid space becomes obliterated. The pitch can be raised no further by this mechanism. It must be added that, in the whole of the middle register, the vocal processes of the arytenoid cartilages are kept in contact by the action of the lateral crico-arytenoid and the inter-arytenoid muscles.

Head register.—Having reached the highest note which can be

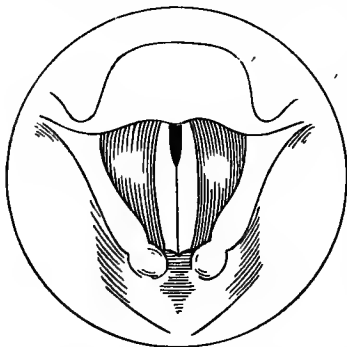

FIG. 429.—Aperture of glottis during production of a note in the head register.—Bosworth.

produced in the middle register, the mechanism must now be changed again, if a series of higher notes is required. This new mechanism is called the head register. By far the most striking change that takes place is, that the vocal cords are now brought closely in contact along their posterior halves, while there remains an oval orifice at the front. Thus the only vibrating portions of the cord are those which bound this opening (Fig. 429).

The tension of the vocal cords in this register is still maintained by the thyro-cricoid and thyro-arytenoid muscles. As the pitch rises the small orifice in front becomes shorter and narrower, until at the highest notes only the anterior third of the cords may be vibrating.

In the preceding description of the registers, that classification has

¹ Bosworth, "Diseases of the Throat and Nose," vol. ii. p. 469.

been followed which is, on the whole, the most generally accepted. As regards the action of the larynx, however, during the different registers, though there is some agreement as to the principal changes which occur, many parts are as obscure as the amount of literature on the subject is large.

Lehfeldt,¹ when experimenting upon larynges removed from the dead body, found, by accident, that when a weak blast of air was driven through the glottis, the pitch of the note produced was higher than when the blast was strong. From this discovery he inferred that the falsetto (thin) register was produced by a weak current of air, while a strong current was necessary for the production of the chest register. He further maintained that the reason why the note produced by the strong blast was deeper than that produced by the weak one, was because in the first case the cords were made to vibrate in their whole extent, while the weak current was unable to effect this.

Johannes Müller² adopted this view, and its truth is still maintained by some authorities. Lehfeldt further supposed that the outer fibres of the thyro-arytenoid muscle might hinder the outer portions of the cords vibrating, while the inner portions were free to vibrate. There is nothing inconsistent in this from an acoustical point of view. Oertel's³ view, promulgated in recent times, is somewhat akin to this; he holds that when the falsetto voice is produced, nodal lines are formed in the vocal cords, parallel to their edges.

Garcia,⁴ from observations with the laryngoscope, which he introduced, held that, in the lower part of the chest register, the whole of the cord, along with the vocal process of the arytenoid cartilage, is thrown into vibration; while, as the voice ascends in pitch, only the ligamentous portion of the cord vibrates, the vocal processes being in contact. Behnke,⁵ on the other hand, maintains that the vocal processes of the arytenoid cartilages do not vibrate at all during phonation. In recent years, however, it has been definitely shown that these cartilaginous structures do partake in the vibration of the cord. Hodgkinson⁶ insufflated finely powdered indigo into the larynx, and, by observing the positions which it assumed on the cord during phonation, he was able to demonstrate the fact that, in the deeper note of the lower register, the vibrating margin extended from the thyroid cartilage in front to a point behind the junction of the ligamentous and cartilaginous portions of the cord. Hodgkinson's experiment further disproved the assertions of some authorities, who maintain that contact of the vocal processes is essential for phonation. In this respect Hodgkinson's view is in agreement with that of Wesley Mills.⁷

As regards the mechanism of the middle register, observers are fairly unanimous upon one point, namely, that the vocal processes of the arytenoid cartilages are in contact throughout. As regards minor points, opinions vary considerably; this may be due to the fact that the mechanism itself differs in individuals.

Martels¹ affirms that, in the chest register, the whole cord vibrates, while in the upper register only the mucous membrane is in motion. Lermoyez² agrees to a certain extent in this view of Martels, and states that the pitch is altered solely by variations in the tension of the cords.

The falsetto register, according to Martels, is a flute sound; the chest register, on the other hand, is comparable to the sound produced by a reed instrument.

Although almost all observers agree that the posterior portion of the glottis is closed during the production of the upper registers, the condition of the anterior part is not so satisfactorily settled. Browne and Behnke³ state that even in the highest register the anterior portion of the glottis is open, while the larger posterior portion is tightly closed. This register, according to these writers, is only used by women and boys. Wesley Mills,⁴ however, states that the anterior as well as the posterior portion of the glottis is closed in the head voice; that is to say, that it is the same mechanism as that which is used by men for the production of their high falsetto voice.

French⁵ has obtained photographs of the larynx, as it appears during the different registers, which should tend to modify very considerably some of the views hitherto prevalent concerning the production of the different registers. He found that, in proceeding from the lowest to the highest notes of the lower register, the vocal cords became lengthened by $\frac{1}{8}$ in.; this was in a contralto singer. When this singer passed to the middle register, the cords became shortened by $\frac{1}{16}$ in., this shortening being followed by another increase in length, as the upper part of the middle register was approached.

From the photographs of the larynx during the production of the lower notes of the head register, French infers, contrary to most authorities, that the edges of the ligamentous cords are not in contact at any portion; so that air passes through the whole length of the ligamentous glottis. During the upper notes of this register, however, it is probable that the cords are closed in their posterior portions.

According to French, it is a general rule, to which, however, there are many exceptions, that in the lower notes of each register the vocal cords are short and wide, and the glottis is open both in its ligamentous and cartilaginous portions. On ascending the scale, the cords increase in length and decrease in width.⁶

THE QUALITY OF THE VOICE AND VOWEL TONES.

The quality of the human voice depends on the same laws as those determining the quality, *klangfarbe*, or timbre of the tones produced by any musical instrument. Tones of a mixed character—that is to say, composed of a fundamental and partials—are produced by the vibrations of the true vocal cords, and certain of these partials are strengthened by the resonance of the air in the air passages and in the pharyngeal and oral cavities. So strongly may certain of these partials be reinforced, as to obscure or hide the fundamental tone, and give a peculiar character to the sound. But there are still many difficulties in the way of a true interpretation of voice tones. Thus we observe that we may sing a scale, using one sound for each note, such as *la, la, la*, etc. Or, by pulling the mouth in a certain position, we can pronounce the vowel sounds, *ah, ā, ē, o, ou* (pronounced as the *u* in *prune*). As we do so, we notice that each sound appears to the ear to have a pitch of its own, different from that of the others. Helmholtz¹ gave the characteristic pitch of the several vowel tones as follows:—

Vowels	OU	O	A	AI	E	I	EU	U
Tone	<i>fa</i> ₂	<i>si</i> ₃	<i>si</i> ₄	<i>sol</i> ₅ or <i>re</i> ₄	<i>si</i> ₆ or <i>fa</i> ₅	<i>re</i> ₆ or <i>fa</i> ₆	<i>do</i> ₆ or <i>fa</i> ₇	<i>sol</i> ₆ or <i>fa</i> ₈
No. of vibs.	170	470	940	1536 or 576	1920 or 341	2304 or 170	1024 or 341	1536 or 170

König¹ has given a different evaluation of the pitch of vowel sounds thus:—

Vowels	OU	O	A	E	I
Tone	$sz\flat_2$	$sz\flat_3$	$sz\flat_4$	$sz\flat_6$	$sz\flat_8$
No. of vibs.	235	470	940	1880	3760

FIG. 431.—Pitch of vowels according to König.

Donders,² who was the first to observe that the cavity of the mouth for different vowels is tuned to different pitches, gave \bar{U} as f_1 , O as d_1 , A as $b\flat$, O (like u in *tugh*) as g^2 , \bar{U} (like u in *lune*, Fr.), as a'' , E , as c''' , and I as f''' .

Again, we may sing a vowel on a scale and still recognise the vowel in each note. Thus, if we sing a , or o , or i , on a scale beginning with c , the ear catches the sound of a , or o , or i , in each note. Such tones as we have described are termed vowels, or we might call them vowel tones.

Other sounds associated with peculiar conditions of the buccal cavity, and which may be strengthened by the laryngeal sound, are those known as consonants. These may be labials, as F , V , or P , linguals, as S , T , D , and gutturals, as J , K , or G , Ger. The physical nature of consonantal sounds has not yet been sufficiently investigated. We shall first proceed to discuss the nature of vowel tones, more especially with the view of determining the cause of quality of vowel tone, and the reason why a vowel tone always appears to have the same quality, whatever may be the pitch of the note on which it is sung.

Theories of vowel tones.—The investigation of vowel tones may be considered to date from the experiments of Willis³ about 1829, who imitated the larynx by means of a reed, above which he placed a resonating cavity, and his conclusions are very similar to those put forward by Hermann at the present day. About 1837, Wheatstone⁴ made certain further observations, and advanced a theory, and in later times the subject has been studied by Donders, Helmholtz, König, Hermann, and many others.

The invention of the tinfoil phonograph by Edison in 1877, and the improvement of the instrument by the labours of Edison, Graham Bell, and others, in more recent years (until we now possess, in the wax-cylinder phonograph, a far better mechanism), have led to the re-investigation of the whole question of vowel tone by Fleeming Jenkin, Ewing, Hermann, Pipping, Boeke, Lloyd, M'Kendrick, and others. The difficulties in the way of accounting for some of the phenomena of vowel tones will be appreciated when we state that these and other competent observers

⁴ *Westminster Review*, Oct. 1837.

are ranged in two camps—those who uphold the theory of relative as opposed to those who contend for the theory of fixed pitch. Assuming that a vowel is always a compound tone, composed of a fundamental and partials, those who uphold the relative pitch theory state that, if the pitch of the fundamental tone is changed, the pitch of the partials must undergo a relative change; while their opponents contend that whatever may be the pitch of the tone produced by the larynx, the pitch of the partial that gives quality or character to a vowel is always the same, or, in other words, vowel-tones have a fixed pitch.

There are many methods of investigating this problem, but these may be grouped in two divisions—first, experimental methods, by which the pitch of the oral cavity, in the position suitable for the production of any given vowel, may be determined; and, second, mathematical methods, by which the curve or wave-form, representing a certain quality of vowel-tone, may be analysed into its components, in accordance with Fourier's theorem.

One of the early experiments of Willis¹ favoured the fixed-pitch theory. A piece of watch-spring was held by forceps against a revolving toothed wheel. A compound tone was produced, which of course retained the same pitch so long as the wheel revolved uniformly. Now, by keeping the wheel revolving at a uniform rate, and at the same time changing the length of the portion of the spring which was allowed to vibrate, Willis found that the qualities of various vowels were obtained with considerable distinctness.

Willis also used reed pipes attached to cylindrical chambers of variable length, and altered the quality of tone by increasing or diminishing the length of the resonant chamber. The shortest tubes gave *I*, then *E*, *A*, *O*, to *U*. In this way he determined the pitch of the vowel as it sounds in words.²

As already stated, Donders³ was the first to show that the cavity of the mouth, as arranged for the giving forth of a vowel, was tuned as a resonator for a tone of a certain pitch, and that different pitches corresponded to the forms of the cavity for the different vowels. This he discovered, not by the use of tuning-forks, but by the peculiar noise produced in the mouth when the different vowels are whispered. The cavity of the mouth is then blown like an organ-pipe, and by its resonance reinforces the corresponding partials in the rushing wind-like noise. The question was then taken up by Helmholtz,⁴ and treated in his usual masterly fashion. To determine the pitch of the cavity of the mouth, considered as a resonance cavity, he struck tuning-forks of different pitches, and held them before the opening of the mouth, say widely opened. Then, the louder the proper tone of the fork was heard, the nearer "it corresponded with one of the proper tones of the included mass of air." As the shape of the mouth could be altered at pleasure, according to the vowel to be emitted, it was easy to

discover the pitch of the included mass of air for each vowel. He came to the conclusion that "the pitch of the strongest resonance of the oral cavity depends solely upon the vowel for pronouncing which the mouth has been arranged." He also found the same resonances for men as for women and children. He then carefully examined the form of the oral cavity for each vowel, and showed how very slight changes would account for the quality being slightly altered for different dialects.

Helmholtz also showed that the tones of the human voice have a peculiar relation to the human ear. Thus the upper partials of *I* are in the neighbourhood of e''' up to g''' , and the human ear itself is tuned to one of these pitches; that is to say, by its resonance it favours the perception of these tones. Powerful male voices produce these partials strongly. Thus, a bass voice singing e' produced the seventh partial d''' , eighth e''' , ninth f''' , and the tenth g''' . Some of these partials, such as e''' and f''' may clash, and by producing dissonance, give harshness to the voice. This illustration will show how Helmholtz, following out the theory applicable to all musical instruments, endeavoured to explain the quality of different voices. His theory as to vowel-tone is summed up in the following sentence—"Vowel qualities of tone consequently are essentially distinguished from the tones of most other musical instruments, by the fact that the loudness of their partial tones *does not depend upon the numerical order, but upon the absolute pitch of those partials*; thus, when I sing the vowel *A* to the note E^b , the reinforced tone b^b is the twelfth partial tone of the compound; and when I sing the same vowel *A* to the note b^b , the reinforced tone is still b^b , but is now the second partial of the compound tone sung."¹

Further, Helmholtz endeavoured to demonstrate the correctness of his view by synthetically combining the tones of certain tuning-forks in his well-known vowel tone apparatus.² He, in early experiments, used eight forks, the first being the fundamental tone si_1^b , and the others the first seven partials. Thus—

$$si_1^b, si_2^b, fa_3, si_3^b, re_4, fa_4, la_4^b, si_4^b,$$

The vowel *O* is well sounded with this apparatus, when we sound si_1^b (characteristic of *O*) strongly; more feebly si_2^b , fa_3 , re_4 , and the fundamental softly. *OU* is good with si_1^b strong, and the partials feeble. Using in another apparatus

$$si_2^b, si_3^b, fa_4, si_4^b, re_5, fa_5, la_5^b, si_5^b,$$

OU was given with si_2^b (the fundamental) alone. *O* was sounded by fundamental si_2^b moderate, si_3^b strong, and fa_4 weak. If we sound si_2^b (fundamental) along with si_3^b and fa_4 moderate, and si_4^b and re_5 strongly, we obtain *A*. This vowel is characterised by si_4^b , along with the partials si_3^b and si_2^b . To obtain *E*, give si_2^b and si_3^b moderate, and fa_4 , la_4^b , and si_5^b as strong as possible. The characteristic partial of this vowel is si_3^b . We have performed many experiments with this apparatus, and find the results obtained by Helmholtz to be consistent with our experience. Much depends, in the appreciation of this experiment, on careful attention, practice, and a good ear.

König investigated the subject with the aid of his manometric

¹ Helmholtz, "Sensations of Tone," p. 172.

² For figure and description of this famous apparatus, see M'Kendrick's "Physiology," vol. ii. p. 691.

flame apparatus. This method is useful, because it shows the different forms of the sound-wave, without change of period, corresponding to a

FIG. 432.—König's apparatus for illustrating the quality of vowel tones by a manometric flame.

tone of determinate pitch, when the vowels are sung upon that tone. The apparatus is shown in Fig. 432.

FIG. 433.—Flame pictures of the vowels *OU*, *O*, and *A*.—König.

The next figure shows the forms taken by the flame when the three notes ut_1 , sol_1 , and ut_2 are sung with the vowels *A*, *O*, and *OU*.

Each of these pictures is composed of two groups of teeth, reproduced again and again, and thus showing a regular periodic vibratory movement. The three pictures of ut_1 contain eight groups of teeth, while those of sol_1 contain twelve, and those of ut_2 sixteen. As the length of all these pictures corresponds to the same duration of a vibratory state, it is evident that the period of the vibratory movement, or the length of the wave characteristic of a tone of determinate pitch, is independent of the vowel upon which the sound is emitted. But the form of the wave characteristic of the tone of given pitch varies much with the vowel upon which it is sung. This alteration of the form of the wave, while the period is constant, must be due to the superposition of a tone developed in the mouth, characteristic of the vowel, upon the tone emitted by the larynx.¹

According to König, OU is always easily emitted with si_2b , and the neighbouring tones la_2 , sol_2 with the lower partials, si_1b , mi_1b . O is emitted with si_3b , the partials la_3 , sol_3 , and the lower partials si_2b , mi_2b , si_1b . A comes with si_4b , with la_4 , with sol_4 , along with the lower partials, si_3b , mi_3b , si_2b . E and I are not easily sounded on low tones, as their characteristic partials are very high. On tones lower than ut_3 , the female voice turns involuntarily to O or OU , which have si_3b and si_2b as their characteristic partials. Above fa_4 it is A , characterised by si_4b , which is most readily given. Above si_4 the voice passes into E and I . These observations of König are harmonious with the conclusions of Helmholtz, and favour the fixed pitch theory.

Hallock² has recently employed a device founded on that of König. Eight resonators in harmonic series were each connected with a manometric capsule, and photographs were taken of the eight bands of flame pictures, reflected in a mirror, when the vowels were sung before the resonators.³ From these photographs, the partials present in any vowel tone within the range of the resonators could be determined. Of course the higher partials, on which, as pointed out by Helmholtz, much depends, were not detected.

Wave-forms of vowel tones.—We must now turn to the evidence adduced by an analysis of the wave-forms of vowel tones. To appreciate this evidence, the following statements must be kept in view:—

1. Pitch depends on the length of time in which each single vibration is executed, or, in other words, on the vibrational number of the tone.

2. Musical tones are higher, the greater their vibrational number; that is to say, the shorter the vibrational period.

3. The sensation excited by a periodic vibration is a musical tone. This tone is usually compound, the constituents being partial tones.

4. Only one form of vibration, like that of a pendulum or the limbs of a tuning-fork, can give rise to a simple tone, destitute of partials. This is a simple pendular vibration, and the sensation is a simple tone.

5. A compound tone is the sensation produced by the simultaneous action of several simple tones, with definite ratio of pitch. Such a compound tone corresponds physically to a wave of more or less complex form.

¹ Gavarret, "Phénomènes physiques de la phonation et de l'audition," Paris, 1877, p. 394.

² *Am. Ann. Photo.*, 1896, p. 21.

³ For a figure of such an analyser, see M'Kendrick's "Physiology," fig. 418, vol. ii. p. 686.

6. Such a compound wave is capable of being analysed into a number of simple pendular vibrations, and each pendular vibration corresponds to a simple tone, having a pitch determined by the periodic time of the corresponding motion of the air (Ohm's law).

7. It is evident that such combinations of simple waves may give rise to an infinite variety of wave-forms, but, according to Fourier's theorem,¹ "any given regular periodic form of vibration can always be produced by the addition of simple vibrations, having vibrational numbers, which are once, twice, thrice, four times, etc., as great as the vibrational number of the given motion."

8. If we know the *amplitudes* of the simple vibrations and the *difference of phase*, then any regularly periodic motion can be shown to be the sum of a certain number of pendular vibrations; in other words, the compound wave may be analysed into its constituents.

The Fourierian analysis of wave-forms.—The method of applying the Fourierian analysis may be shortly stated.² Suppose a single wave (*AA* or *BB*) is taken and referred to rectangular axes (*OX*, *OY*), abscissæ of equal length are measured off along *OX*, ordinates are drawn to meet the curves, and these are very accurately measured. For a simple curve, such as *AA*, few ordinates suffice; but if the curve is complex in form, the number of measurements must be increased until no considerable curvature exists between the summits of any two successive co-ordinates. When a sufficient number of ordinates has been taken, an analysis carried to one-half that number of partials, or even somewhat less, suffices to define the curve. The mathematical process for evaluating the amplitude and phase of a certain number of partials, say the first twelve, is given by Fleeming Jenkin and Ewing in their well-known paper.³ A

FIG. 434. —Diagram showing the first step in analysing wave-forms.

curve may be rebuilt graphically from its analysis, but the process is laborious when the partials are numerous. If we know the pitch of the fundamental tone, then the pitch of any partial is ascertained by multiplying its vibrational number by the figure representing the ratio of its amplitude to that of the fundamental tone. For example, take the analysis of a Swedish *i* (resembling the French), sung by Pipping at a pitch of 293 vibrations per second.

An inspection of this figure shows that two reinforcements are very pronounced, the one on the seventh and eighth, and the other on the fourth partial. Each of these partials has to do with the resonance cavity to which it corresponds, and in which it has been developed to a greater or less extent. In the case of the vowel *i*, one of the reson-

¹ Donkin, "Acoustics," Fourier's theorem proved, pp. 65-71; illustrated, pp. 56-65. See also Everett, "Vibratory Motion and Sound."

² The authors are much indebted to Dr. R. J. Lloyd for aid in the discussion of this difficult subject.

³ *Trans. Roy. Soc. Edin.*, vol. xxviii. p. 750.

ances is obtained in the narrow tube formed between the tongue and the hard palate. This resonance has a very narrow range, for the tube will not respond to any partial having a pitch much different from its own. A rounded cavity, on the other hand, such as is formed when we articulate

FIG. 435.—Diagram showing the amplitude, as indicated by the height of the ordinates, of the partials of the Swedish *i*, sung at pitch of 293 vibs.

aa, will have a much greater range of resonance.¹ The valuation of the pitch of any resonance which only reinforces a single partial, is very simple, and is expressed by the equation—

$$n = Np,$$

where N is the vibrational number of the fundamental tone, p the number of the partial, and n is the vibrational number of the resonance, or, in other words, its pitch. In the above figure, for example, the isolated reinforcement of the tenth partial in the vowel sung at 293 v. d. shows the existence of a resonance of $293 \times 10 = 2930$ vibs. Where two partials are equally reinforced by one cavity, the case is not so simple. Approximately, it is expressed by the equation—

$$n = N \frac{p + p}{2}$$

Thus the resonance which reinforces the seventh and eighth partials is about $293 \times \frac{15}{2} = 2198$ v. d. Even here there are minor considerations involved, which can only be seen clearly after examining one or two more general and more complex cases.

Let us take first an instance of German long *a*, sung and analysed by Hermann.² The pitch is 98 vibs., and the analysis is only carried to ten partials, so that it does not display the higher resonances of this vowel, except slightly on the tenth partial.

¹ Lloyd, "On the Fourierian Analysis of Phonographic Tracings of Vowels," *Proc. Roy. Soc. Edin.*, 1898.

² "Phonophotographisch. Untersuch.," Bd. i.-v.; *Arch. f. d. ges. Physiol.*, Bonn, Bd. xlv. S. 582; Bd. xlvii. S. 44; Bd. xlvii. S. 347; Bd. liii. S. 1; Bd. lviii. S. 255, contain many analyses and much controversy about the Fourierian analysis. No. 2 contains an account of a method of lightening the labour of these analyses; also, "Bemerkungen zur Vocale-frage" (*ibid.*, Bd. xlviii. S. 181); also, "Vocale im Telephon und Microphon" (*ibid.*, Bd. xlviii. S. 543); also, "Weitere Untersuch. ueber das Wesen der Vocale" (*ibid.*, Bd. lx. S. 169) deals chiefly with short (German) vowels.

This analysis displays only one considerable reinforcement, but it extends in varying strength over the sixth, seventh, eighth, and ninth partials. The resonance chamber in this case is the inter-velar or pharyngeal cavity. Call this the α -resonance. How can we value the proper pitch of that resonance? Hermann has employed what he terms a centre-of-gravity calculation; that is to say, he proceeds as if he were finding the centre of gravity of four

FIG. 436.—Diagram showing the amplitude in the partials of the German long a , sung and analysed by Hermann.

heavy points, situated, as above, on the axis of x , and each weighing as many units as there are units in the respective amplitudes. Having thus discovered the “mean partial,” he multiplies the fundamental by it to get the value of the resonance itself. Both operations are combined in the equation—

$$n = N \frac{p' a' + p'' a'' + p''' a''' + \text{etc.}}{a' + a'' + a''' + \text{etc.}}$$

where N and n are again the pitch-numbers of the note and of the desired resonance, respectively; p' , p'' , p''' are successive integers, the numbers of the reinforced partials; and a' , a'' , a''' are the amplitudes found for these partials respectively. For the resonance displayed in the above Fig. 436, the process is as follows:—

$$n = 98 \times \frac{(6 \times 13.9) + (7 \times 44.7) + (8 \times 50.2) + (9 \times 13.6)}{(13.9 + 44.7 + 50.2 + 13.6)} = 737 \text{ vibs.}$$

Pipping¹ objects to the assumption that the partials, as in the above figure, are equidistant from one another. It is true that they are equidistant, when considered as an *arithmetical* progression. Thus, first partial, 98 vibs.; second partial, 196 vibs.; third partial, 294 vibs., etc. But musical distances are not measured in arithmetical, but in geometrical progression, and the equidistant partials are not the first, second, third, fourth, etc., but the first, second, fourth, eighth, etc. The abscissæ in the figure ought not, therefore, to be measured off in proportion to the numbers 1, 2, 3, 4, etc.; but to $\log_2 1$, $\log_2 2$, $\log_2 3$, $\log_2 4$, etc., or simply $\log 1$, $\log 2$, $\log 3$, $\log 4$, etc., seeing the

S. 524–583, containing controversy with Hermann as to real meaning of Fourierian analysis; also, “Ueber die Theorie der Vocale,” *Acta soc. scient. Fennicæ*, Bd. xx. part 11, replies to Lloyd, and gives more analyses.

base does not matter if the right mutual proportion is maintained. The result is shown as follows:—

FIG. 437.—Diagram showing the application of Pipping's method.

If we adopt this view, we get the following equation to find p , the mean partial:—

$$\log p = \frac{a' \log p' + a'' \log p'' + a''' \log p''', \text{ etc.}}{a' + a'' + a''', \text{ etc.}}$$

and then $n = Np$, as before.

This method of Pipping's has been further developed by Lloyd,¹ because he was of opinion that Pipping's method left *frequency* out of account. Look again at the above figures. The amplitudes are 4·2, 8·5, 3·2, etc.; but the first-named amplitude is traversed only once in each period, while the second is traversed twice, the third three times, and so on. The general expression for the whole amplitude traversed in each period is ap , *i.e.*, amplitude multiplied by frequency. It seems a right principle to estimate the strength of the reinforcements of each partial in terms of the whole amplitude traversed, and if so, the multiplied amplitude ($a'p'$, $a''p''$, etc.) will have to be substituted for the single amplitudes (a' , a'' , etc.) in the last equation. Thus—

$$\log p = \frac{a'p' \log p' + a''p'' \log p'' + a'''p''' \log p''' + \text{etc.}}{a'p' + a''p'' + a'''p''' + \text{etc.}}$$

to find the mean partial.

Comparing the three methods of Hermann, Pipping, and Lloyd, it is evident that Pipping's will always give a result somewhat lower, and Lloyd's will give a result somewhat higher, than Hermann's. In the present case, shown in the above figure, the difference between the three calculations is not great. The first (Hermann) gives 737 vibs., the second (Pipping) 732 vibs., while the third (Lloyd) is 741 vibs. With high partials the differences become less and less, but with lower partials the differences are so great as to be, in Lloyd's opinion, "of vital importance," the object of these calculations being to find out what is the true pitch of the resonating cavity that may reinforce several or many partials.

Phonograms.—We are now in a position to examine the methods that have been adopted to obtain graphic tracings of the wave-forms (phonograms) corresponding to vowel tones, so as to submit these to the Fourierian analysis.

Donders,² in 1870, was the first to apply the phonautograph of Leon Scott³ (invented in 1856) to the investigation of the curves produced by the sounds of vowels. In 1878, Fleeming Jenkin and Ewing⁴ succeeded in obtaining tracings of the records of vowel sounds on the tinfoil

⁴ Fleeming Jenkin and Ewing, "On the Harmonic Analysis of certain Vowel Sounds," *Trans. Roy. Soc. Edin.*, vol. xxviii. p. 745.

phonograph, and the curves were submitted to harmonic analysis. This was the beginning of the present discussion. These two observers obtained good curves, even with the imperfect instrument, and the curves were submitted to analysis, so as to determine the amplitude of their constituents up to the sixth partial, and the process of measurement and calculation was applied to more than one hundred curves. The sixth partial was not a high limit to reach, but the phonograph, at that date, did not record the higher partials. For example, it could not reproduce the sound of *I* in machine, nor the French or German *U*. Twelve values for y (the lengths of the co-ordinates for one period chosen) gave the data for calculating the amplitude and phases of the first six partials. Professor Tait supplied the authors with the solutions of the simultaneous equations for twelve values of y , and the results are given in a series of tables, in which the predominance of certain partials is unmistakable. In this way each vowel was examined. The conclusions arrived at were, on the whole, favourable to the constant-pitch theory, and were thus summed up: "It is clear that the quality of a vowel sound does not depend either on the absolute pitch of reinforcement of the constituent tones alone, or on the simple grouping of relative partials independently of pitch. Before the constituents of a vowel can be assigned, the pitch of the prime must be given; and, on the other hand, the pitch of the most strongly reinforced partial is not alone sufficient to allow us to name the vowel. To do this, we must also know the relation of the constituent partials to one another."¹ Again, "The ear is guided by two factors, one depending on the harmony or group of relative partials, and the other on the absolute pitch of the reinforced constituents. The ear recognises, as it were, when it hears a vowel sung, at any pitch, the kind of oral cavity causing the reinforcement. As to the question, "Is the resonance cavity for a vowel sound constant at all pitches?" the authors are cautious; and their opinion appears to be that whilst the resonance cavity for a vowel sound has an absolute pitch, it may have a certain effect in reinforcing other subordinate tones or partials. While experimentally it may be shown that a constant cavity may produce a vowel-like tone, say *O*, over a wide range of pitch, it is probable that the resonant cavities of the human being are slightly adjustable, so as to be, as it were, tuned to the pitch on which the vowel is sung. In other words, Fleeming Jenkin and Ewing hold that both the relative and the absolute factors enter into the composition of a vowel, a conclusion not far from the truth.

The subject was taken up by Hermann² about 1890, and he used the much improved wax-cylinder phonograph. He succeeded in obtaining photographs of the curves on the wax cylinder, a beam of light reflected from a small mirror attached to the vibrating disc of the phonograph being allowed to fall on a sensitive plate while the phonograph was slowly travelling. The curves thus obtained, representing the wave-forms of the vowel tones (Fig. 438),³ were submitted to analysis, with the view of estimating the pitch of the mean partial or the *formant*, as it is called by Hermann, according to the method already described. Hermann also pointed out that the quality of a vowel tone varies considerably, according to the rate at which the cylinder was

¹ Jenkin and Ewing, *op. cit.*, p. 770.

² *Op. cit.*

³ The curves in Figs. 438 and 441 were kindly sent to Dr. M'Kendrick by Professor Hermann. They are here introduced simply as examples.

rotated. This should obviously not be the case, were the relative pitch theory correct. It is curious that even with competent observers there should be such difficulty in deciding this apparently simple question of fact, some asserting that there is no difference in quality, and others as positively stating that there is a difference when the cylinder is caused to move slowly. M^rKendrick, after many experiments, has come to the conclusion that there is a difference, but not so great as to disguise the quality of the vowel. To produce any appreciable change in quality, the cylinder must be driven at an enormous speed. The ear can always distinguish *O* or *A* or *E* at different rates, but the quality is undoubtedly altered. The sound of a vowel never passes into the sound of another vowel.

Hermann presents the fixed-pitch theory in a modified form, and states that there is for each vowel a characteristic tone, a *formant*. Not only does Hermann support the fixed-pitch theory, but he maintains

FIG. 438.—Examples of vowel curves obtained by Hermann.

that the *formant* need not necessarily be a partial of the fundamental. Sometimes it is such a note, but more often not.¹ The pitch of the *formant*, however, may vary considerably; indeed, with the same prime, it may vary as much in certain cases as several semitones. Fig. 439 shows, in musical notation, the pitch of the vowel, according to Hermann.²

Sauberschwartz³ has investigated the subject by an ingenious application of the laws of the interference of sound. Certain vowels were sung into the mouthpiece of a long tube, to which other short tubes of definite length were attached. By closing the outer ends of certain of these tubes, various partials could be extinguished by interference, and the listener at the other end of the tube observed an alteration in the quality of the vowel. Thus, by extinguishing the *formant* of *A*, the sound approximated to that of *O*, and became somewhat nasal. With *E* there are two characteristic *formants*, and

¹ Hermann, *Arch. f. d. ges. Physiol.*, Bonn, 1895, Bd. lxi. S. 178.

² *Ibid.*, Bd. xxxv. S. 42.

³ Hermann, *Ibid.*, 1895, Bd. lxi.

Sauberschwartz found that if one of these was extinguished the quality of the vowel was not much altered, but that when both were shut out the vowel was much changed in quality and approximated to *U* or *O*. Sauberschwartz in general supports Hermann.

FIG. 439.—Pitch of the vowels according to Hermann.

Boeke¹ of Alkmaar has not only devised an ingenious and most accurate method of obtaining curves from the wax cylinder of the phonograph, but he has applied the Fourierian analysis with striking results in general support of the fixed-pitch theory.² The method consists in measuring microscopically the transverse diameter of the impressions on the surface of the phonograph cylinder, on different (generally equidistant) parts of the period, and in inferring from these measurements the depth of the impressions on the same spot, or, in other words, deriving from them the curve of the tone which produced the impression.

Thus the depth (*d*) of the impressions on a certain point may be easily deduced from its breadth (*b*) on the same point. Suppose *EGDF* to be the transverse section of the phonograph marker, and *HK* the longitudinal section of the surface, *ACBD* the transverse section of the groove which the marker ploughs on the wax surface, *AB = b* its breadth, *CD = d* its depth; and *FG = ED = 2r*, being the diameter of the cylinder; if the axis of the recording marker were tangential to the

FIG. 440.—Diagram showing Boeke's theory of measurement of depth of curve.

¹ "Microscopische Phonogramstudien," *Arch. f. d. ges. Physiol.*, Bonn, Bd. 1. S. 297; also *Proc. Roy. Soc. Edin.*, 1898.

² The writers have to thank Dr. Boeke for unpublished notes on the subject, and also for many interesting analyses.

surface of the cylinder, the prolongation of its edge would cut the axis of the cylinder, and we would have the equation—

$$\left(\frac{1}{2}b\right)^2 = d(2r - d).$$

Or $d^2 - 2dr + \frac{1}{4}b^2 = 0 \dots \dots (1).$

From which we deduce—

$$d = r \pm \sqrt{\left(r + \frac{1}{2}b\right)\left(r - \frac{1}{2}b\right)} \dots (2).$$

As the equation (1) is that of an ellipse, the axes of which are $2r$ and r , we see that the breadth and depth of the impression have the same ratio to each other as an abscis to its ordinate in the above-mentioned ellipse. It is true that the supposition as to the axis of the marker does not hold good as regards the phonograph, as it makes an angle (α) with the tangent, but the only difference which this makes is that they should be multiplied by the constant term, $\cos \alpha$, to obtain their real value. As the marker connected with the glass plate of the phonograph is constantly moving up and down, the value of the angle (α) changes at each moment; but seeing the greatest depth of the impressions cut out on the wax surface does not exceed 0.02 mm., these slight variations are of no consequence. By an elaborate and most careful system, the curves, corresponding to the ordinates obtained as above, are plotted out on millimetre paper, and then a magnification of about one hundred is worked out.

Discussion of examples of phonograms.—Examples of curves obtained by Hermann are shown in Figs. 438 and 441. These show

FIG. 441.—Examples of vowel curves obtained by Hermann.

curves of the vowel *A*, sung on the notes *e*, *g*, *c'*; of the vowel *O*, sung on the note *c'*; and of the vowels *Ae* and *Ao*, sung on the notes *c* and *e*.

Curves of vowel tones may also be obtained on a large scale by

M'Kendrick's¹ phonograph recorder. In Fig. 442 we see curves obtained from the tracings on the wave-cylinder representing the tones of various instruments.

FIG. 442.—Examples of tracings obtained by M'Kendrick's phonograph recorder. The dots represent drops of ink from a small syphon. One inch shows the vibrations occurring in the $\cdot 1480$ sec.

The following analyses supplied by Boeke are very instructive. The first is the analysis of the tones of a cornet. Observe how the intensity of the partials gradually diminishes:—

Note	1	2	3	4	5	6	7	8	9	10	Partials.
$f=170$ vibs.	1	1.05	1.22	1.15	1.01	0.80	0.53	0.28	0.13	0.10	„
$c'=256$ „	1	0.92	0.81	0.53	0.39	0.20	0.07	0.04	0.06	0.04	„
$g'=384$ „	1	0.76	0.46	0.14	0.09	0.06	0.07	0.02	0.01	0.01	„
$c''=512$ „	1	0.92?	0.30	0.14	0.15	0.09	0.07	0.06	0.03	0.02	„

Contrast this analysis with that of the vowel $\bar{a}\bar{a}$ sung by Boeke, æt. 50, on the notes f and c' , and the same vowel sung on the notes g' and c'' , sung by his son, æt. 12, both like the vowel in the word "heart," it will be seen from the analytical numbers that the *formant* of the son's vowel $\bar{a}\bar{a}$ was almost the same as that of the father, although the pitch of his voice was exactly an octave higher.

Man, æt. 50, singing $\bar{a}\bar{a}$.

Pitch	1	2	3	4	5	6	7	8	9	10	Partials.
$f 170.6$ vibs.	1	0.86	0.46	1.74	1.90	1.55	0.51	0.54	0.43	0.44	„
$c' 256$ „	1	0.49	1.96	1.25	0.60	0.56	0.23	0.05	0.06	0.10	„

¹ "Observations on the Phonograph," *Trans. Roy. Soc. Edin.*, vol. xxxviii, part. 4; also *Proc. Roy. Soc. Edin.*, 1896-7, opening address; also, "Sound and Speech Waves as revealed by the Phonograph," London, 1897.

Boy, *æt* 12, *singing* *āā*.

Pitch	1	2	3	4	5	6	Partials.
<i>g'</i> 384 vibs.	1	1·22	2·67	0·45	0·17	0·06	„
<i>e''</i> 640 „	1	8·09	1·45	0·53			„

Dr. Lloyd has examined these figures and supplied the writer with the following table:—

MAN'S <i>āā</i> .	PARTIALS REINFORCED.	EVALUATED BY HERMANN'S METHOD.		EVALUATED BY PIPPINO'S METHOD (= LLOYD'S FORMULA).	
		Mean Partial.	V. D. ¹	Mean Partial.	V. D.
<i>f</i> 170·6 v. d.	4-6	4·96	846	4·90	836
<i>e'</i> 256 „	3-4	3·39	868	3·35	859
Boy's <i>āā</i> .					
<i>g'</i> 384 v. d.	2-4	2·82	1084	2·75	1057
<i>e''</i> 640 „	1-3	2·04	1307	1·98	1267

A study of these figures will show (1) that the man's resonance rises slightly (half semitone) in ascending 7 semitones in the middle of his register; (2) that the boy's resonance rises 3 semitones in ascending 9 semitones in the upper half of his register; and in the mid-register the boy's resonance is to the man's as 5 : 4. This indicates that, as we ascend a scale in singing a vowel, the pitch of the oral cavity slightly changes.

Lloyd holds a view differing from those already described. Vowels, according to him, owe their character, not to the resonance of a partial or partials of a certain fixed pitch, but to the relative pitch of two or more partials. This view accounts for a fact which is not explained by the other theories, namely, that the articulation of a vowel seems to be the same for a child as for an adult. Thus, in the vowel *A* as in "fat," sung on a note having a pitch of 134 v. d., Lloyd finds two partials, the lower of which he terms the pharyngeal or α -resonance, and the other the oral or β -resonance. Of these the lower, for *A* in "fat" has a vibrational number of 736, while the upper has 1121. The ratio of these two partials is therefore $\frac{1121}{736} = 1·47$. This is termed by Lloyd the radical ratio, and it determines the nature of the vowel. Again, the radical ratio of the Swedish long *A* is 1·35.

The following curves were sent to the writers by Dr. Boeke. They are the curves, taken by Boeke's method, of the vowel *A* (as in "fat"), sung by M'Kendrick, Pipping, Boeke, and Hermann on a pitch of $ut_2 = 128$ v. d., and $ut_3 = 256$ v. d., and are instructive as showing the same vowel sung on the same pitch by men of different nationalities. The results of harmonic analysis giving, in plotted lines, the amplitude of the partials, are shown graphically in Fig. 444. The numerals at the beginning of each line in Figs. 443 and 444 correspond. In Fig. 444 the dots represent partials, and the height of the dot above the mean represents the amplitude of the corresponding partial. There is a likeness between the *Ac* of M'Kendrick and Pipping, and also between M'Kendrick's *Ac'* and Boeke's *Ac'*, both in form and analysis.

Lloyd, in support of his view of a cleavage in the reinforcement, which is

¹ V. D. = a double vibration, or, as expressed in England, a *complete* vibration.

FIG. 443.—Curves by Boeke. For description, see text.

FIG. 444.—Diagram showing harmonic analyses of the curves in Fig. 443.

the sign of two separate resonances, has reported upon two examples of *O* sung by Hermann, both at 132 v. d. The amplitudes were as follows:—

V. D.	1	2	3	4	5	6	7	8	9	10
132	6·7	10·7	18·4	14·6	18·1	4·7	2·5	1·3	1·0	0·5
132	7·8	23·4	11·2	7·0	17·0	3·6	2·1	1·2	0·6	1·0

To these he adds two other examples of the same vowel, one sung at 148 v. d. by M'Kendrick, and the other at 128 v. d. by Boeke.

V. D.	1	2	3	4	5	6	7	8
148	1	1·12	1·73	0·19	1·90	0·97	0·35	...
128	1	2·32	5·81	2·10	5·48	0·32	0·55	0·76

The fourth partial in each of these four analyses shows a palpable falling off in strength, as compared with its neighbours on either side, and this falling off marks in each case the gap between an α -resonance of 300 to 400 v. d. and a β -resonance of 600 to 800 v. d. The vowel *O*, however low it may be sung, can hardly have more than two partials, intermediate to the two culminations. In three out of the four cases above given it has only one intermediate partial. This common partial must be subject to a strong influence from both resonances at one time. All the other partials are situated so much nearer to the one resonance than to the other, that they may be regarded as being under the sole influence of the former.

The common partial, on the other hand, receives a stimulus from each; and it must be remembered that these stimuli are mutually independent, as the one operates in the oral and the other in the pharyngeal cavity, and that it is a matter of chance whether, in any phonogram analysed, these two stimulations operate to exaggerate or to conceal each other in the tabulated numerical strength of the partial. Thus it comes to be a question of *phase*.

Lloyd has evaluated the α - and β -resonances of the vowel (*O*) as above given, and stated the result in the following table:—

SUNG BY	V. D.	PARTIALS REINFORCED.		MEAN RESONANCE.		RADICAL RATIO.
		α	β	α	β	
Hermann	132	2-4	4-7	421	653	1·553
Hermann	132	1-3	4-7	290	672	2·318
M'Kendrick	148	1-4	4-7	365	812	2·221
Boeke	128	2-4	4-6	391	615	1·573

These four available instances give an average of 368 v. d. for α -resonance, of 688 v. d. for β -resonance, and of 1·916 for the radical ratio. A sounder method would be to take from one voice a sufficient number of *O* analyses to constitute an average, thus eliminating the chances which cause the common partial to vary to such a noticeable degree.

In some vowel tones the intensity of the fundamental or prime tone is weaker than one of the upper partials. Helmholtz lays special emphasis on this observation, and he put the statement conversely, namely, that vowel tones differ from those of ordinary musical instruments in that one of the upper partials is more marked than the prime. Hermann also supports this view, and, in a communication to the writers, Boeke expressly states that his analyses bring out the same fact. On the other hand, Auerbach¹ maintains that the prime tone is always the strongest. Lord Rayleigh² is also of this opinion,

¹ *Ann. d. Phys. u. Chem.*, Leipzig, 1876, Ergänzungsband, Bd. viii. S. 177.

² "Theory of Sound," 1896, vol. ii. p. 477.

while he admits that in the vowel *A*, the fundamental is not heard so loudly as in other vowels. Hermann suggests that when the prime tone is heard of very weak intensity it may exist only in the ear, but Lord Rayleigh shows that even then it does exist in the external air.

General conclusion.—It would appear, on the whole, that the truth does not rest entirely on the side of one theory, but that both are partially true. The view of Donders, that each vowel has a mouth cavity of unchangeable and fixed pitch is too exclusive, and, on the other hand, it cannot be denied (as is virtually done by those who uphold the relative-pitch theory) that each vowel has a predominant partial or predominant partials which give it a definite character, and which must be produced by the mouth cavity as a whole, or by the double resonance of portions of the cavity, as contended by Lloyd. When a vowel is spoken, either separately or as it exists in a word, the complex tone is produced by the vocal cords. The resonance chambers above assume a certain form, and one or more partials peculiar to the vowel are so strengthened as to give such character to the vowel-tone as to enable the ear at once to identify it. As the form of the mouth cavity varies in individuals and in different races, the partials may not be identical in each case, but they will be so near a common pitch as to enable the ear at once to identify the vowel. If, however, men of different nationalities attempt to fix the absolute pitch of the partial, they will not agree, as has been found to be the case. Again, in singing a vowel in a scale, very slight alterations in the form of the resonance cavities take place. In rising from the lower to the higher notes, the larynx rises, and more or less of a muscular strain acts on the walls of the resonance cavities. Thus there must be a slight change in the volume of these cavities, leading to the development of partials different from those formed by the cavity at rest or in speech, but still so sufficiently near as not materially to alter the quality of the tone. Consequently the ear still recognises the tone of the vowel, even when sung at a high pitch, and it may even recognise the special quality of a particular voice. Sometimes, though rarely, the quality may become richer as the voice rises in pitch; usually for each voice there is a register in which the voice has its maximum of good quality. It is not surprising, therefore, that a singer almost instinctively chooses such vowels as best suit the resonating arrangements of his or her voice, and avoids tones, vowels, and words containing vowels that would force the production of notes of inferior quality. On the whole, we are of opinion that Lloyd's theory of double resonance accounts best for the true nature of vowel-tones.¹

THE CONSONANTS.

The classification of the consonants suggested by Wyllie² will be adopted here.

It will be observed that they are arranged from above down, according to the part of the oral cavity in which they are produced. Again, the rows are themselves divided into three vertical columns, the

¹ Another method of examining the marks on the wax cylinder of the phonograph, as regards speech, but without reference to analysis, is given with numerous figures in "La parole d'après le tracé du phonographe," par H. Marichelle, Paris, 1897.

² "Disorders of Speech," 1894, p. 8.

voiceless oral consonants, the voiced oral consonants, the voiced nasal resonants.

	...	(<i>R</i>)	...

The voiceless *W* and the voiceless *L* have been given above within brackets, the former being now almost confined to Scotland, and the latter being peculiar to Wales. The burring or uvular *R* is also given within brackets.

For example, the voiceless labial *p* corresponds with the voiced labial *b* and the voiced nasal resonant *m*. When the consonant is voiceless, it communicates an explosive character to the succeeding syllable, as in "pitch"; but if it comes at the end of a syllable it gives a sharp sudden termination to that syllable, as "stop." If the labial consonant be the voiced *b*, the explosive beginning or sharp sudden termination of the syllable is not so marked as in *Bob*. The difference between these two letters depends in part upon the firmness with which the orbicularis oris closes the mouth. *M* is produced in the same way as *b*, with the difference that in the former the air is allowed to escape through the nose. Voiceless *w* is produced in almost exactly the same manner as *p*, and the voiced *w* in the same way as *b*; the only difference is that, in the two *w*'s the mouth is not completely closed, and a fricative sound accompanies the consonant. The voiceless *w* occurs in "which"; the voiced *w* in such words as "water." *F* and *v*, the former voiceless, the latter voiced, are produced by the passage of the breath between the lower lip and the upper incisor teeth. Similarly, the voiceless and voiced *th*, as in "think" and "thou" respectively, are formed by the breath rushing through between the tip of the tongue and the incisor teeth. *S* and *z* are produced in almost the same way as *th* (voiceless) and *th* (voiced) respectively; in pronouncing the *s* and *z*, however, the tip of the tongue touches the tooth nearer its insertion, and indeed often touches the gum rather than the tooth itself. *Sh* and *zh* (as azure) are respectively the voiceless and voiced oral consonants produced by the tongue and anterior part of the palate; while *t* and *d* are produced by the same structures, but with the stoppage between tongue and palate more complete than when *sh* and *zh* are uttered. *N* is produced in the same way as *d*, but with nasal resonance superadded. *L* and *r* are also produced at this position; in the former case the tip of the tongue is applied to the palate while the breath escapes on each side; *r* is produced by the vibratory movement of the tongue against the palate. The remaining consonants are produced by the posterior portion of the tongue and the palate. *K* and *g* are voiceless and voiced consonants, respectively, while *ng* is *g* with nasal resonance added. It is

interesting to observe that in Greek, when two such consonants as *k* and *g* occur together, nasal resonance is added to one of them, e.g. *συγγαλω*, pronounced *sunkalo*. *H*, *ch*, *y*, and the burring *r* are also produced at this position.

It is only by a proper appreciation of the method of production of the consonants that Grimm's law¹ of the permutations of these letters can be thoroughly understood. Thus *frater* in the Latin is represented by *brother* in the Low-German, and *pruder* in the Old High-German. It is not difficult to see why this should be, since *f*, *b*, and *p* are produced by very similar muscular movements. So also the Greek (*χῆν*) is represented by the Low-German "goose," and the Old High-German "Kans," all three initial consonants being produced by very similar muscular mechanisms.

The acoustic analysis of the consonant sounds has not yet been undertaken, and it is clear that considerable difficulties must be encountered in such an investigation. Tracings representing the consonant sounds have been obtained by Blake,² but for the purposes of analysis these are not satisfactory.

EFFECT OF THE CAVITIES IN CONNECTION WITH THE LARYNX AND PHARYNX UPON THE VOICE.

It needs but little consideration to understand that the various cavities, which are in more or less direct connection with the mouth and larynx, must have at least some effect upon the quality of the voice. It is, however, difficult to say exactly what these effects are.

Moura³ has attempted to show that the trachea has very considerable influence upon the pitch of the voice, but it is clear, from physical considerations, that he attributes too much importance to the phonetic rôle of the trachea. In the first place, its proper tone is far removed from the lower notes of the human voice; and, secondly, although it is a more or less rigid structure, its elasticity must be small when compared with the rigid character of substances used as resonators, especially since its inner surface is covered with mucous secretion. Nevertheless, it is probable that the trachea may resonate to some of the notes of the voice, and thus produce an effect upon their quality; the pitch, on the other hand, is determined by the vocal cords themselves.

It is doubtful if the laryngeal ventricles have any effect upon the voice in the human subject, on account of their small size. In some animals, such as the howling monkey, the orang, and the horse, it is possible that they may act as cavities reinforcing the voice. The loud deep roar of the lion, on the other hand, comes from a larynx in which the ventricles are absent.⁴ In the human subject the laryngeal ventricles probably perform a function unconnected with the voice. Wyllie⁵ has shown, on the dead subject, that if the false cords be partially approximated, and a blast of air be driven up against them from below, the effect upon these structures is to drive them further inwards, and hence close the glottis more completely in a valve-like fashion. The action, indeed, is somewhat similar to that which occurs when the mitral valve

¹ Morris's "Historical English Grammar," 1882, p. 46.

² Blake, *Am. Journ. Otol.*, N. Y., July 1879.

⁴ Wolf, "Diss. Anat.," p. 9.

⁵ *Edin. Med. Journ.*, 1866, vol. xii. p. 214.

of the heart is closed during systole, the valves being distended from below. According to Wyllie, therefore, the principal function of the false cords is to close the glottis tightly against an expiratory blast of air, and thus enable the animal to fix the ribs for effort. This view is borne out by the researches of Brunton and Cash,¹ who not only confirmed Wyllie's statements by new experiments, but carried the investigation into the realms of comparative physiology. They point out that in those animals whose habits required fixation of the thorax, for striking or climbing, the ventricular bands (false cords) are well developed; and, conversely, animals which do not require strong fixation of the thorax, have ventricular bands of insignificant proportions. They further observed, that in animals in which vomiting is easily performed, the ventricular bands are well developed, and thus enable the animal to fix the thorax for the effort in a much more effectual way than in those animals in which the ventricular bands are small or absent.

The oral, pharyngeal, and nasal cavities have considerable influence upon the voice. This has already been discussed. In general, however, it may be said that these cavities, the pharyngeal and nasal in particular, confer a clear ringing character upon the voice; when they are affected by catarrh the voice has a muffled quality.

WHISPERING.

Arnott,² in 1826, defined whispering as articulation without voice, and for a long time it was supposed that during this act the cords were wide apart, allowing the breath to pass freely. Brücke was the first to dispute this statement, maintaining that the vowels are always produced in the larynx even in whispering. This view, at first sight, appears to be supported by an observation made by Czermak. He examined the larynx with the mirror during whispering, and found that an open triangular space is present at the posterior portions of the glottis, while the anterior portions of the vocal cords take up positions very similar to those which they assume during ordinary vocalisation. The air rushing through this triangular area, according to him, produces the fricative noise characteristic of whispering.³

The matter is not, however, by any means settled by this observation, since the open condition of the mouth necessary for laryngoscopic investigation would prevent true whispering, which is invariably performed with an almost closed buccal cavity. Moreover, it has been noticed that, after excision of the larynx, whispering is still possible.⁴ Although it may be questioned whether this is altogether the same as ordinary whispering, nevertheless, to judge by one's own sensations in performing the act, the part played by the vocal cords appears to be insignificant, if not altogether negligible.

THE SENSE OF TASTE.

BY J. B. HAYCRAFT.

CONTENTS:—The Anatomical Mechanisms concerned in the Production of Taste, and the Regions of Mucous Membrane which are involved, p. 1237—Taste Sensations, p. 1240—The Action of Drugs on Taste, p. 1241—Modality and Quality of Taste, p. 1242—The Relationship between Taste Sensations and the Chemico-Physical Properties of the Stimulus, p. 1244—After-Tastes and Successive and Simultaneous Contrast, p. 1244.

Anatomical.—The anatomical mechanism concerned in the production of the sensation of taste consists, in the first place, of certain sensory end-organs within the cavity of the mouth and throat, and, in the second place, of sensory nerves proceeding from these, and entering the base of the brain, where they form connection with fibres from other parts of that organ. The sensory surfaces in which the sensory nerves of taste arise are as follows—the edges, upper surface, and root of the tongue, the palate, the pillars of the fauces, the posterior surface of the epiglottis, and the arytenoid cartilages of the larynx.¹ These sensory surfaces are also connected with nerves that are concerned with the production of the sensations of touch, temperature, and pain.

The gustatory or taste bulbs found in the tongue and posterior surface of the epiglottis are in all probability sensory end-organs; they are distributed as follows:—On the front of the tongue, where they are rare, and lodged in the tops or sides of some of the fungiform papillæ, and at the root of the tongue, where they are more numerous, and are lodged in special gustatory papillæ.

In man there are some eight or ten of these gustatory or circumvallate papillæ; while in the rabbit the bulbs are lodged within foliated portions of the mucous membrane, called the papillæ foliatæ, placed one on each side of the root of the tongue. They are found in a similar situation in the human tongue, but not on special foliate papillæ. Gustatory bulbs are also found upon the posterior surface of the epiglottis, and it was this discovery that induced Nicholson to test the gustatory properties of the epiglottis.

Our belief that the bulbs are end-organs of taste, and not of common sensibility, rests upon the following evidence. They are found solely on the sensory surfaces of taste. Their highly specialised structure, presenting many *homologies* with the end-organs of the special senses, suggests their performance of some special function. We should on this account expect them to be organs of taste, rather than organs of a widely distributed sensory mechanism, like that of general sensibility, which is elsewhere devoid of these structures. More direct evidence is given by the effect of division of the glosso-pharyngeal nerve, which

¹ P. Nicholson, *Virchow's Archiv*, Bd. cxxiii. S. 398-401.

undoubtedly carries nerve fibres of taste from the back of the tongue, where branches of the fifth are concerned in the transmission of ordinary sensory impulses from this situation. M. v. Vintschgau and Hönigschmied¹ found that within a few months subsequent to the division of the glosso-pharyngeal nerve in the rabbit, the bulbs entirely disappeared on the side on which the division was made.

While it is pretty evident that the bulbs are end-organs of taste, and that they are the terminations of the taste fibres which pass up the branches of the glosso-pharyngeal nerve, it is possible, of course, that these fibres have other terminations as well. As regards the front of the tongue where the bulbs are few in number, and where the taste-fibres pass by the lingualis and the chorda tympani, it is probable that here also the bulbs are end-organs of taste, though again they are not necessarily the only end-organs concerned.

FIG. 445.—Horizontal lines indicate distribution of lingual including chorda tympani; oblique lines indicate distribution of glosso-pharyngeal; the larger circles indicate circumvallate papillæ; the smaller circles are placed over the area supplied by the superior laryngeal.

In tracing the course of the nerve fibres concerned with taste, from their origin in the tongue to their terminations in the brain, it will be convenient to commence with those which spring from the anterior portion of the tongue. The paths followed by these fibres are very complicated, and are still to some extent doubtful. The following account will be more readily understood if reference be made to Fig. 445. It is generally admitted that the nerve fibres of taste pass from the front of the tongue in the lingual nerve, since division of that nerve below the point of junction of the chorda tympani produces paralysis of taste on the same side.² The fibres do not pass up in the lingual further than the point where the

chorda tympani joins it, for Erb³ has shown that a lesion of the lingual nerve above the point of junction of the chorda has no effect upon taste. On the other hand, division of the chorda tympani, and disease of the middle ear involving this nerve, lead to loss of taste on the affected side. Hence there is little doubt that the taste fibres pass from the lingual nerve into the chorda tympani on their way to the brain. As regards the further course of the fibres, there is much conflicting evidence. According to some observers, the fibres pass again into the course of the fifth nerve to reach the brain, while others

regard the sensory portion (*pars intermedia*) of the seventh nerve as the path followed by the taste fibres.

The idea that the taste fibres reach the brain by the fifth nerve roots was held so long ago as 1876 by Erb,¹ and has been strongly maintained by Schiff,² and advocated in this country by Gowers and Turner.³ According to these observers, the taste fibres leaving the lingual by the chorda tympani pass into the seventh nerve and so to the geniculate ganglion. Thence they are continued into the great superficial petrosal and Vidian nerves to the spleno-palatine ganglion, through which they pass into the second division of the fifth nerve, and so to the brain. The evidence brought forward is as follows: Intracranial lesion or section of the facial nerve has no effect upon taste. Section of the fifth nerve roots, on the other hand, leads to loss of taste on the anterior part of the tongue (Schiff).⁴ Disease of the root of the fifth nerve also abolishes taste in the front of the tongue, and H. Salomonsohn⁵ found loss of taste subsequent to pressure of a tumour upon the second division of the fifth nerve. Ferguson⁶ has described loss of taste in the front of the tongue, following the pressure of a tumour upon the Vidian nerve.

In favour of the idea that the taste fibres, which leave the lingual nerve by the chorda tympani, reach the brain by the facial nerve (or *pars intermedia*), we have the following observations:—Extirpation of the entire Gasserian ganglion in man, and intracranial section of the second and third divisions of the fifth nerve are often unaccompanied by any loss of taste (MacTiffany, Krause, and Lynn Thomas).⁷ In lower vertebrates the seventh nerve is undoubtedly a nerve of taste (Strong).⁸ Developmentally the sensory fibres of the chorda tympani and of the great superficial petrosal nerves are a portion of the facial nerve in man as in lower vertebrates.⁹

In discussing the contradictory results, as regards taste, which may follow disease or section of the fifth nerve roots, Dixon¹⁰ points out the close proximity of the geniculate ganglion to the Gasserian, and of the facial to the fifth nerve-roots; he views the loss of taste which in some cases follows the extirpation of the Gasserian ganglion or lesion of the fifth nerve roots, as due to an inflammatory or other involvement of the geniculate ganglion or of the root of the facial nerve. He draws attention to the strong developmental and anatomical reasons for looking upon the facial nerve in man as the nerve of taste for the anterior part of the tongue, and contends that by assuming a lesion of the seventh

nerve roots, rather than one of the fifth nerve, many of the pathological cases recorded receive an equally satisfactory explanation.

As the case is one that cannot be determined by experiments on lower animals, the positive evidence of the retention of taste *in man*, after section of the fifth nerve roots, is of great interest.

It is generally admitted that the fibres of taste from the back of the tongue pass up the branches of distribution of the glosso-pharyngeal nerve. It is not certain whether they ascend to the brain by the same nerve, and many believe that they pass by a rather circuitous path to the fifth nerve. It is frequently stated that disease involving the trunk of the glosso-pharyngeal nerve never abolishes taste, though cases have been recorded in which it is maintained that taste was lost under these conditions.¹ It is supposed that the taste fibres ascend in the tympanic branch (nerve of Jacobson), and reach the fifth through the small superficial petrosal, and through branches of the tympanic plexus. In support of this view, it is urged that disease of the fifth nerve is often followed by loss of taste on the back of the tongue, and that disease of the middle ear, which is especially liable to affect Jacobson's nerve, may be followed by a similar result. On the other hand, in direct contradiction to this view, we have the observations of MacTiffany, Krause, and Lynn Thomas above mentioned, as well as the embryological evidence, that the nerve of Jacobson is developed as a branch of the glosso-pharyngeal, and so would not be expected to carry impulses from that nerve into the course of the fifth.²

The tongue may be paralysed as to its nerves of general sensibility, whilst the sense of taste may remain normal, and in other cases it may be paralysed as to taste while its general sensibility remains normal. In the case of smell, on the other hand, paralysis of the nerves of general sensibility, due to injury or diseases of the fifth, produces dryness and certain trophic changes which cause anosmia, although the fibres of the olfactory nerve are not directly affected.

While the lingual and glosso-pharyngeal nerves carry both nerves of taste and of general sensibility, the very root of the tongue is supplied, in part at any rate, by a nervous twig from the superior laryngeal branch of the vagus, about whose function at present but little is known.

Taste sensations.—Many of our so-called tastes are sensations arising from stimulation of the nasal mucous membrane, but a certain residue are quite odourless, and appeal alone to the mucous membrane of the mouth. Salt, sweet, bitter, acid, are true tastes, and so probably are metallic and astringent, though the nerves of tactile sensibility have much to do with the feeling of astringency.

Our power of tasting is much greater on some parts of the gustatory mucous membrane than on others, being generally greater at the root than at the tip of the tongue, and very slight over the middle line of the tongue anteriorly. Our gustatory sensations exhibit, however, great individual differences, more so perhaps than is the case with any other sense organ, and although the above statement is the rule, there are many exceptions; for example, in the case of some persons, the front of the tongue is extremely sensitive, while in others again it is hardly so at all.

¹ F. Pope, *Lancet*, London, 1889, vol. ii. p. 458.

² Dixon, *Trans. Roy. Irish Acad.*, Dublin, 1896.

It is a matter of common experience that bitter substances are tasted best at the back of the tongue, and on that account no one would think of sipping a glass of beer. Sweet substances are tasted best by the tip and sides of the tongue, and so perhaps are salines and acids. All parts of the tongue are, however, sensitive to all four tastes, and bitter if it is strong enough—as quinine powder, for instance—can be tasted on the front of the tongue. The difference appears, therefore, to be one of degree, and suggests that for each taste there are special end-organs present, and that they are unequally distributed over the tongue. We may suppose, for instance, that there are many end-organs for bitter sensations towards the back of the tongue, and very few at the front. In support of this view much evidence is forthcoming. Let us take first the reaction time for the various sensations. M. v. Vintschgau and Hönigschmied¹ give the following reaction times in seconds for the base as compared with the tip of the tongue:—

	Salt.	Sugar.	Quinine.
Tip	·597	·752	·993
Base	·543	·552	·502

The most outstanding fact in the above table is the difference between the reaction time of quinine at the base and tip of the tongue. This corresponds with the observable difference of sensitiveness of these parts, the less sensitive one requiring a longer application of the stimulus to produce an appreciable result in sensation. This result is verified by Öhrwall,² who finds that the reaction time of bitter substances is long at the front of the tongue, while at the base it is the same as for other substances.

Öhrwall, in the same paper, has described the effects of stimuli applied to individual papillæ. He used porous points soaked in sapid substances, and with these he was able to apply stimuli to a single papilla, to the exclusion of the rest. Öhrwall found that the filiform papillæ are insensitive to taste, not so the fungiform papillæ. Of 125 papillæ tested by him, twenty-seven reacted neither to acid, bitter, nor sweet; sixty reacted to all three; and of the remaining thirty-eight, some reacted to acid and sweet but not to bitter, others to bitter and acid and not to sweet, and others to sweet, but not to bitter and acid. On placing an electrode in contact with a papilla, and passing through it a constant electrical current, an acid papilla discharged an acid, and a sweet papilla discharged a sweet taste. These results are again consistent with the separate existence of bitter, sweet, etc., end-organs. Some papillæ are devoid of any end-organs, others possess them all, and others again possess one or two varieties.

Action of drugs.—By the action of drugs we can abolish certain tastes more than others, so as to leave the mouth practically insensible to certain stimuli. This again suggests the presence of different kinds of end-organs, some of which are more affected than others. Cocaine

¹ *Arch. f. d. ges. Physiol.*, Bonn, 1875, Bd. x. S. 1; and v. Vintschgau, *ibid.*, 1879, Bd. xx.

² *Skandin. Arch. f. Physiol.*, Leipzig, 1890, Bd. ii. S. 1.

when applied to the tongue destroys both sensibility to touch and to taste,¹ and it is also said to destroy the sense of temperature.² It appears that this drug destroys the power of tasting bitter substances most readily,³ and does not affect the power of tasting sweet, salt, and sour substances to the same degree. It also abolishes tastes electrically produced. A decoction of the leaves of *Gymnema sylvestre*, according to most observers, paralyses the sense of bitter and of sweet,⁴ while others maintain that all tastes are affected, though bitter and sweet tastes more especially. *Gymnema* abolishes the bitter tastes that can be electrically produced.

Modality and quality.—Some observers maintain with Öhrwall that the difference between the sensations of bitter, sweet, etc., are differences not of quality but of modality. Referring to the definition of the term, as given by Helmholtz, its introducer,⁵ we find that modality is that difference which exists between the sensations of different sense-organs, such as, say, sweetness, warmth, and colour. We can neither compare with each other sensations which differ in modality, nor do they pass into each other by intermediate stages, as do sensations which are associated with the same sense-organ and which differ from each other in quality. We cannot say that a sweet taste is more like blue than red; here is an instance of modality. Orange is, on the other hand, more like yellow than blue, and can pass into yellow by intermediate sensations; here is then an instance of quality. Accepting this definition of Helmholtz, it is difficult to understand how the difference between, say, bitter and salt, can be described as one of modality. A mixture of salt solution and syrup tastes sweetish salt, and one can by graduated mixtures pass from salt to sweet. In the same way we can pass from bitter to salt, or from bitter to sweet. A large number of sapid substances give rise to these intermediate sensations; thus sulphate of magnesia is a saline bitter, a grape is acid sweet, etc. Just as we can say, that the colour orange is more like yellow than blue, so we can institute comparisons between the taste sensations and say that bitter-sweet is more like sweet than it is like acid. It is probable that we have in the tongue special end-organs for bitter, sweet, acid, salt, and perhaps some others. Many sapid substances stimulate but one of these end-organs, while others stimulate more than one, giving rise in sensation to a fairly large number of qualitative differences.

The law of the specific energy of the senses, as taught by Johannes Müller,⁶ is a law which deals with modality and not with quality. As he put it, each sense-organ, however stimulated, gives rise to its own specific sensations; the eye to the sensation of light, but never of hearing and smell; the ear to sensations called sounds, never to sensations of light or taste. This law is also true of taste; and stimuli, whether they are sapid substances, electrical currents, or mechanical

⁶ Johannes Müller was perhaps the first to distinguish between modality and quality. See Müller's "Physiology," English translation, vol. ii. p. 1059.

irritation, if capable of producing sensations, produce those of taste, not those of smell or hearing.¹

Since Müller's time the law of specific energy of the senses has come to mean far more than he intended, and although it is still called Müller's law it is quite contrary to his teaching.² It has become a law regarding quality instead of modality; of nerve fibre rather than of nerve. It is maintained by many recent writers that each nerve fibre with its end-organ has a specific energy, which means that it can, when stimulated, give rise to a certain definite sensation, and no other. If, then, we have more than one kind of sensation, of light, taste, smell, etc., we must have more than one kind of nerve fibre of light, taste, smell, etc., and as many nerve fibres as we have sensations. This law is at the basis of the Young-Helmholtz theory of vision, and Clerk-Maxwell puts it as follows: ³—

“All the evidence we have on the nature of nervous action goes to prove that, whatever be the nature of the agent which excites the nerve, the sensations will differ only in being more or less acute. Now we may perceive with our eyes a faint red light, which may be made stronger and stronger until our eyes are dazzled. We may then perform the same experiment with a green light or a blue light. We shall then see that our sensations of colour may differ in other ways, besides in being stronger and fainter. The sensations of colour cannot be due to one nerve only.”

The facts which we have just reviewed in relation to taste lend support to this neo-Müllerian law of specific energy of the senses, for there appear to be, at any rate in certain cases, special end-organs and nerves associated with the production of each specific taste. Whether this law is really a general law of sensation can only be determined when it is shown to be true in the case of other senses; as to this the evidence is as yet very meagre.

As we have indicated, the end-organs of taste can be stimulated by agencies other than sapid bodies. Mechanical blows and friction act as stimuli; a pencil or glass rod rubbed against the side of the root of the tongue produces a distinctly bitter taste, and acid and sweet tastes are alleged to have been produced by tapping the front of the tongue. Electricity is a very powerful stimulant, for a current too weak to produce an effect upon the skin or the eye will produce a distinct sensation of taste upon the tongue.

It was once thought that the action of the electric current was electrolytic, and that the ions were tasted, but this is negated by the fact that distinct tastes are produced by slight alternating induction shocks, a condition under which there can be little electrolytic change. The electric currents act probably upon the end-organs, and do not directly stimulate the nerves, for cocaine and gymnema abolish the electric taste when applied to the surface of the tongue.

In experimenting with electrical stimulation of the tongue, one electrode, preferably a non-polarisable one, is placed on the dorsum of

¹ Such stimuli generally, of course, stimulate the nerves of tactile sensibility as well, and produce the specific sensations associated with their stimulation.

² Many quotations might be given from Müller's "Physiology," in support of this statement; the following has been selected, as bearing directly upon taste, p. 1066:—"The nerves of taste and smell are capable of being excited to an infinite variety of sensations by external causes; but each taste is due to a determinate condition of the nerve excited by the external cause."

³ "Collected Papers," vol. i. pp. 446-447.

the tongue, and the other electrode, generally flattened, is placed below. The anode upon the dorsum is the stronger stimulus, and its effects are specifically different from the cathode. The action of the anode appears to produce a warm acid feeling at the tip of the tongue, while the cathode is said to produce an alkaline or metallic taste.¹ The results appear to vary, however, with the position of the electrode placed upon the dorsum of the tongue. At the back, bitter and metallic bitter tastes are produced, while in front the effect varies with the nature of the papillæ stimulated. Öhrwall finds the acid papillæ react readily with the anode, while the cathode produces a specific reaction with the bitter and sweet papillæ. The natural stimuli of the organ of taste are certain sapid substances dissolved in the juices of the mouth. Insoluble substances can only affect the tongue by mechanical pressure, for when suspended in water they have no effect.

Chemico-physical characters of sapid substances.—It is frequently stated that there is no relationship between the tastes produced by sapid substances and their chemico-physical characters. This is, however, very questionable, as the following facts indicate.² If we take one of Mendelejeff's groups, containing elements having similar chemico-physical properties, and if we combine these elements each with one other common element to form a series of sapid salts, we shall find the tastes of these salts are the same, or very similar. If, for instance, we select the elements in Group I (L.Na.K.Cu.Rb.Ag.Cs.Au.) and combine them, to form (*a*) chlorides and (*b*) sulphates, we shall find that the soluble chlorides are all salt, and the sulphates are saltish bitter. The chlorides of Group II (Mg.Ca.Zn.Sr.Cd.Ba.Hg.) are saltish bitter, with a warm pungent taste. Sodium and potassium compounds of Group VII (F.Cl.Mn.Br.I.) are salt, passing in the higher members of the group to saltish bitter. Amongst the organic substances which produce an acid taste, such as acetic, oxalic, or tartaric acid, we find the presence of a compound radicle, CO.OH.; and it is probable that just as these substances owe certain of their chemico-physical properties to the presence of this radicle, they also owe to it their acid taste. The alcoholic bodies, like glycerin, glucose, saccharin, contain a radicle, CH₂.OH., and this radicle, the presence of which characterises the group from a chemical point of view, has much to do in all probability with the production of taste, for these bodies when they are sapid are sweet.

It is true that we not infrequently find that similar tastes are produced by sapid bodies of quite dissimilar chemico-physical characters; thus, sugar and acetate of lead are sweet. We cannot therefore affirm that similar tastes prove the existence of similar chemico-physical properties in the stimuli, though in many cases, at any rate, we can say that substances with similar chemico-physical properties have similar tastes. In the case of sight we have an analogous condition. Similar stimuli give rise to similar sensations, but the same sensation may be produced by dissimilar stimuli. A grey or a yellow sensation can be produced in a variety of ways, by very dissimilar stimuli; thus, grey can be produced by red together with blue-green spectral rays, or by orange together with blue spectral rays, and so on.

After-taste and successives and simultaneous contrast.—When a sapid substance acts upon the tongue, the taste may be followed by after-

¹ M. v. Vintschgau, *Arch. f. d. ges. Physiol.*, Bonn, Bd. xx.; L. Hermann, *loc. cit.*

² J. B. Haycraft, *Proc. Roy. Soc. Edin.*, vol. xiii.; and *Brain*, London, vol. x. p. 145.

effects which have been compared with the after-images in the organ of vision. M. v. Vintschgau¹ describes the metallic bitter of the taste which sometimes remains subsequent to the breaking of a current through the tongue, and which, during its passage, produced a metallic acid sensation.

Of greater interest, however, is the after-effect produced by a sapid substance itself. It has long been known that after tasting common salt the tongue is more sensitive to the taste of sugar; so much so, that a very weak solution of sugar, too weak to be distinguished as a sweet liquid, produces a taste, if it is taken after washing out the mouth with salt and water. In the same way, acid stimuli render the tongue more susceptible to sweet substances, and after tasting weak sulphuric acid, even distilled water appears somewhat sweet.² Not only does common salt produce after-susceptibility to sweet, but many other substances act in the same way. Thus, after gargling with chlorate of potash, tap-water tastes sweet with a trace of acid (M. v. Vintschgau). A still more curious case is mentioned by J. Freutzel,³ and one that can be readily verified. If the mouth be rinsed out with a weak solution of sulphate of copper, and if the experimenter then smokes a pipe or cigarette, a well-marked sweet taste is developed.

Simultaneous contrasts also appear to be capable of demonstration in the case of taste, as in the case of vision. If a sapid substance be applied at one region of the tongue, other parts of the organ are rendered more susceptible to other stimuli. Thus, if one border of the tongue be rubbed with salt, the other border will give a reaction with sugar out of all proportion to the strength of the stimulus employed. Salt and acid give likewise simultaneous contrast, but it is questionable whether any facts can be brought forward to show that bitter sensations are affected by other stimuli simultaneously applied.

Taste sensations take some time before they are generated, and the reaction time for taste is comparatively slow. This can readily be understood when we remember that the sapid particles have to diffuse into the somewhat viscous fluids bathing the mouth, before they can gain access to the end-organs of taste. We taste more quickly when we rub the tongue against the roof of the mouth, or when we rub the sapid solution upon the mucous membrane by means of the finger. For the same reason, it is difficult at once to free the mouth from a sapid material which has had free access to it; and a clinging taste is frequently got rid of only after repeated rinsings of the mouth with water or such mechanical expedients as the chewing of bread-crumbs.

Our power of localising the spots at which stimuli are applied is fairly developed in the case of taste, for the sensory surface is also furnished with the nerves of common sensibility, so that sapid stimuli are never applied without at the same time stimulating our nerves of touch. It is on this account that we can learn by everyday experience that bitter substances are best tasted at the root, and sweet substances are best tasted at the tip, of the tongue; for when the bitter sensation develops, we know by our sense of touch that the sapid material has reached the back of the tongue. Sweet sensations, on the other hand, are developed almost as soon as we become conscious of the presence of the sapid substance on the tip of the tongue.

THE SENSE OF SMELL.

By J. B. HAYCRAFT.

CONTENTS :—The Anatomical Data, p. 1246—The Passage of Air through the Nose, p. 1248—Olfactometry, p. 1249—Hyperosmia and Anosmia, p. 1251—The Classification of Odours, p. 1252—The Law of Specific Energy of the Senses, p. 1253—The Relationship between Smell and the Chemico-Physical Properties of Odorous Bodies, p. 1254—The Physical Condition of the Stimulant, p. 1256—The Simultaneous Action of Two Odours, p. 1257—The Psychology of Smell, p. 1258.

Anatomical data.—That sensory surface of the body which is modified in such a manner as to render it impressionable to odorous particles, is found in the upper or olfactory region of the nose. On opening the nasal cavities, the upper region is seen to be lined by a mucous membrane which has a yellow or brown-yellow colour, due to the presence of pigment within it. This yellow membrane is generally believed to be olfactory, and is so termed. It covers the superior and part of the middle turbinated bones, and that portion of the septum which lies at the same level.

FIG. 446.

than 1 cm. across, situated in the upper part of the superior turbinated, together with another area of much the same size upon the septum opposite (see Figs. 446, 447, o).

¹ "Bau der Nasenschleimhaut," Halle, 1862, S. 75.

² *Arch. f. mikr. Anat.*, Bonn, 1892, Bd. xxxix. S. 632.

There are two kinds of epithelial cells to be found in the olfactory mucous membrane, as is also the case in many other sensory epithelia, such as the retina, the auditory, and the gustatory. They are, in the first place, the supporting cells, and between them lie the true olfactory cells. Each of the latter is provided with some seven or eight cilium-like processes,¹ which project from the free surface of the mucous membrane into the serous fluid which moistens it. The olfactory cells are prolonged internally into processes which become the fibres of the olfactory nerve. These fibres, which are non-medullated, arborise within the olfactory bulb, within glomeruli formed by these arborisations and the dendrons of the bulb cells. Central processes of the latter carry the olfactory impulses to their centres within the brain.

FIG. 447.

The fifth is the nerve of common sensibility to the nose, and in the case of disease or section of this nerve, irritants such as pepper, chlorine, and ammonia produce no irritating effect. When loss of smell likewise occurs, this is

FIG. 448.—Diagram of olfactory path (Cajal). *a*, the olfactory cells; *b*, olfactory glomeruli with synapses between their central nerve-processes and the dendrons of the mitral cells (*c*) in the olfactory lobe; *d*, fibres passing from mitral cells to arborise with dendrons of cells of cerebral cortex, *f*; *j*, collaterals from these fibres; *e*, *m*, other cells in the olfactory lobe; *l*, centrifugal fibres derived from cortical cells and terminating in the olfactory lobe.

probably due to dryness of the mucous membrane, and is thus only indirectly dependent upon division or disease of the nerve.

Where the olfactory nerves are themselves divided, diseased, or pressed

¹ von Brunn, *loc. cit.*, S. 638.

upon by a tumour, anosmia may follow. The olfactory nerves are occasionally absent, and in these cases we find congenital anosmia, though this is said not to be invariably the case.¹ In the very exceptional cases in which sensation is present, it has been suggested that fibres of the fifth nerve officiate as nerves of smell.

In the case of man, the monkeys, and some cetacea, the olfactory sense-organ is evidently one which has undergone involution. This is evident, not only from a study of the nose itself, but also from a study of the central nervous system. The olfactory bulbs and tracts are but rudimentary organs, when compared with the olfactory lobes of macrosmatic mammals. In the nose of man, the three turbinals represent the chief remnants of the much more complex organ which must have existed in ancestral forms.² The sensory surface must have greatly diminished in extent, and now occupies, as has already been described, but a small patch of the upper region of the nasal cavity. It is probable, therefore, that the sense of smell was more acute in the ancestral forms, and that it played a relatively great part in the psychology of man's ancestry, a condition which we find to-day among the macrosmatic mammalia.

The passage of air through the nose.—The organ of smell is stimulated by odorous particles which reach the nose, and enter it either by the anterior or by the posterior nares. If a bottle containing a volatile oil be unstoppered in a room, the oil volatilises, and the particles gradually diffuse into the room. The dispersion of these particles by diffusion may be aided by agitating the air, as with a fan, or by a draught, and by displacements of air due to differences of temperature, etc.³

The outside air in the neighbourhood of the face is drawn through the nose, either in the course of ordinary inspiration, or by sniffing. If this air contains a sufficiency of odorous particles, we are sensible of the odour.

The air stream was supposed by the older observers to pass chiefly along the lower region of the nose on the upper surface of the palate, and to take, in fact, an almost straight course from the anterior to the posterior nares. More recent observers have shown that the main air-stream on entering the nostrils at first ascends almost vertically, due probably to the horizontal position of the inlet; it then bends round, and sweeps backwards and downwards at the level of the middle turbinals, and leaves the nose by the posterior nares.

The earliest experiments were made by E. Paulsen.⁴ He divided the head of a cadaver in the mesial plane, and placed tiny squares of red litmus paper upon the mucous membrane of the nasal cavity. The two halves were then replaced in juxtaposition, and air saturated with ammonia vapour was drawn through the nose by means of a pump attached to the trachea. On separating the halves of the head once more, and looking into the exposed nasal cavities, he could see the direction which the main air-current had taken, for this was indicated by the blueness of the litmus paper. H. Zwaardemaker⁵ performed a

⁵ "Die Physiologie des Geruchs," Leipzig, 1895, S. 49.

somewhat similar experiment with the head of a horse, and G. Franke with the human cadaver.¹ They divided the head through the mesial plane, and applied a glass plate, so that it closed one nasal cavity, replacing the septum. On drawing smoke through the nose, they could observe through the glass the direction that it took.

While these observers are not quite agreed as to the exact height that the main stream of air reaches, they are at one in placing it below that portion of the nose in which von Brunn has localised the position of the olfactory epithelium.

This olfactory epithelium is, in fact, placed in a narrow chink above the main stream of air, and the question arises, how do the odorous particles reach it? Diffusion no doubt will account for the entrance of many particles, for this is a rapid process, and will occur during the period of the shortest sniff. The air, however, within the true olfactory region must suffer, at any rate, partial *displacement* towards the posterior nares, and this air will in its turn be *displaced* by fresh air entering the nose and laden with odorous particles. The pressure of air during the commencement of inspiration is less at the posterior nares than the pressure of the outside air, and therefore less than that of the air within the whole cavity of the nose. There will consequently be a displacement of the outside air, and of that of the whole cavity of the nose towards the posterior nares. Braune and Clasen² have indeed experimentally shown what is *a priori* a certainty, namely, that the air even within the antrum of Highmore suffers partial displacement during each act of inspiration. We may conclude, therefore, that although the main stream does not reach the level of the true olfactory mucous membrane, yet over this surface there is nevertheless a definite motion of the air. This motion may be difficult to recognise by the methods of Paulsen and his followers, but it may be quite sufficient to appeal to the exquisitely delicate sense-organs of the olfactory nerve.

Olfactometry.—It is a matter of great theoretical as well as of practical interest to determine how small a quantity of a substance can excite the sense of smell. It will be remembered that Kirchoff and Bunsen were able to distinguish by means of the spectroscope as little as $\frac{1}{1,400,000}$ of a milligramme of sodium. As we shall see, the nose compares most favourably with the eye. A grain of musk will scent a room for a very long time, and the actual quantity drawn into the nose during any given inspiration must therefore be inconceivably small. E. Fischer and Penzoldt³ placed a weighed quantity of an odorous substance, such as mercaptan, in a room. The air was mixed with a fan, and the experimenter entered the room from time to time until he was able to smell the substance. In these investigations it was found that mercaptan, with a dilution of 1 to 50,000,000,000, could be detected. By calculation it was found that the actual weight of mercaptan, in the 50 c.c. of air, inspired by the experimenter, was $\frac{1}{100,000,000}$ of a milligramme.

By methods such as the above, which give the smallest amount of a substance which can produce sensation, we can arrange odorous bodies in the order of their potency. We can also test the sensibility of the

¹ *Arch. f. Laryngol. u. Rhinol.*, Berlin, 1893, Bd. i. S. 236.

² *Ztschr. f. Anat. u. Entwicklungsgesch.*, Leipzig, 1876, Bd. ii. S. 1.

³ *Sitzungsab. d. phys.-med. Soc. zu Erlangen*, 1885-86, Bd. xviii. S. 7.

nose under various physiological conditions, and test the acuteness of the sensations of those supposed to suffer from partial or complete loss of sensation. For the latter purpose we have to determine the quantity of a substance which can just be detected by a normal individual, and then determine in the case of another person with blunted sensations how much the stimulus must be increased.

In this line of research Valentin was a pioneer,¹ and the methods adopted since his time are but modifications and improvements of his methods. Valentin took a weighed quantity of an odorous substance and diffused this into a known quantity of air. Of this air he took a portion, and again and again diluted it until it could just and only just be detected by the person experimented upon. In other experiments water was used to effect this dilution instead of air.

FIG. 449.—Diagram of Zwaardemaker's olfactometer—*a*, external protecting tube of glass; *b*, tube of indiarubber, giving off odorous particles from its inner surface when this is exposed; *c*, inner graduated glass tube through which air is drawn; *d*, profile view of wooden shade; *e*, end of tube placed in the nostril. In 1, the inner tube is pushed home, none of the indiarubber is exposed and nothing is smelt. In 2, the tube is pulled out for three divisions, each being .7 cm. long, so that 2.1 cms. or three olfactics of tube are giving off particles of odorous indiarubber into the inner tube, through which the air is drawn.²

Fröhlich³ placed odorous bodies in a stoppered bottle, and tested the acuteness of smell by determining the distance at which the odour could be detected. The odorous particles diffusing from the bottle would become more and more scattered the greater the distance from the bottle, and would require, therefore, a more acute organ of smell to detect their presence when the bottle was held at some distance from the nose. While this is a good practical method, by means of which we may compare the organ of smell in the case of one individual with that of another individual, it is useless when we wish to compare the

¹ "Grundriss d. Physiologie," S. 515.

³ *Sitzungsb. d. k. Akad. d. Wissensch. math.-naturw. Cl.*, Wien, 1851, Bk. vi.

potency of one odour with that of another, the reason being that no two odours agree in their rate of diffusion. For the latter purpose there is probably no better method than the one already alluded to, namely, that of Fischer and Penzoldt, who caused a weighed quantity of an odorous body to diffuse into the air of a room (which was agitated by means of a fan) until it produced a sensation. The quantity of the body necessary to produce the sensation was a measure of its potency.

Perhaps the most important recent advance has been made by H. Zwaardemaker, who has invented a very useful olfactometer, which can be used for physiological and clinical purposes, and by means of which the sharpness of smell may readily be expressed in smell units or olfacties.

Zwaardemaker's olfactometer may be described as follows, but for a more detailed description the reader should consult his work :¹—

Indiarubber tubing has a distinct odour, and in Zwaardemaker's instrument the air inhaled by the nostrils is drawn over the surface of indiarubber, and the amount of this surface is so adjusted that its odour can only just be perceived. The extent of this surface is measured, and is a quantitative test of the acuteness of the sense-organ in the individual tested. The tubing, two or three inches in length, is fitted inside a wider tube of glass, which prevents any odorous particles from leaving its outer surface. Another longer glass tube, just wide enough to fit within the indiarubber tube, is pushed within it. When this is pushed from one end to the other of the indiarubber tube, both sides of the latter are covered (Fig. 449, 1), and no particles of the indiarubber diffuse into air aspirated by the nostrils. On drawing the inner tube a little way out of the indiarubber tube, a certain portion of the latter is exposed (Fig. 449, 2), and odorous particles are inspired, and produce a sensation if they are in sufficient quantity. With his olfactometer Zwaardemaker found that a normal individual could perceive on the average the odour of the indiarubber when .7 cm. long was exposed. The inner glass rod was therefore graduated, each graduation being .7 cm. An individual who can only detect an odour when the tube is drawn out to the second division, exposing 1.4 cms. of the tube, has half the normal sensitiveness; if he can perceive the odour only when it is, as in the figure, drawn out to the third division, he has but one-third the normal sensitiveness. The physical quantity or stimulus, namely, the number of odorous particles given off into the inspired air by .7 cm. of indiarubber, Zwaardemaker takes, therefore, as a unit of measurement, and this is termed an "olfactie." Ordinary indiarubber has too faint an odour to permit of its use, except in those cases where the deviation from the normal is considerable. In testing cases of partial anosmia, a tube is used made of a substance which is twenty-four times as powerful a stimulus as indiarubber, itself. This is "Kunsthorn" or "Guttapercha ammoniacum," called in English "hoof cement," and used by the veterinary surgeon for strengthening the hoof. By means of two instruments, one containing a tube of indiarubber, the other a tube of hoof cement, we can stimulate the nose from one up to two or three hundred olfacties. Zwaardemaker further found that in many cases of anosmia certain odours might be perceived almost to the normal extent, while others hardly acted as stimuli at all. To investigate these cases, he constructed tubes of odorous substances, some smelling of bees-wax, others of asafetida, etc.²

Hyperosmia and anosmia.—It appears from olfactometric observations that hyperosmia is not of very rare occurrence. Increased sensitiveness is common in hysteria and other nervous affections, and certain

¹ "Die Physiol. des Geruchs," Leipzig, 1895.

² *Arch. f. Laryngol. u. Rhinol.*, Berlin, Bd. iv.

drugs are capable of inducing it. One of the most important of these is strychnine, which may, in a diluted form and locally applied, be given for the treatment of anosmia. Cocaine is said to produce hyperosmia before it causes partial or complete loss of the sensation.

Anosmia is not of infrequent occurrence. It may be complete and congenital, as in cases where the olfactory nerves are absent; and partial anosmia may occur from a variety of causes, such as stenosis of the nasal passages, catarrh and disease of the mucous membrane, and various nervous affections. Habitual smoking produces partial anosmia, morphia and cocaine locally applied rapidly induce it. It is questionable whether the strongest odour, pure and simple, can produce complete anosmia. When this is induced by the vapour of ammonia, we have to deal with an odorous body which is at the same time a powerful irritant; and the complete anosmia which may result is, in all probability, due to inflammation of the olfactory mucous membrane itself.

There are some persons who, while acutely sensitive to most odours, are incapable of recognising others. There are many individuals who are unable to smell methyl-alcohol, hydrocyanic acid, and mignonette. Cloquet¹ mentions the case of an individual who was unable to smell vanilla, although sensitive to the perfume of flowers; while Gründe, quoted by Cloquet, mentions a man insensible to everything but decaying and faecal matter.

The classification of odours.—In judging of the acuteness of smell, we have almost entirely confined our attention to our power of being stimulated by different *quantities* of an odorous material. But almost no two odorous bodies smell exactly alike, and we are able to experience throughout life an almost infinite number of odours differing from each other in *quality*. Thus we can distinguish the odour of almost every kind of flower, fruit, beast, etc. Various attempts have been made to group these sensations together, but without very satisfactory results. Albrecht v. Haller² divided odours into (1) sweet smelling, (2) foul smelling, (3) neither the one nor the other. This, which is a classification on purely physiological lines, gives us very little information, and is rather a classification of the feelings that accompany sensation than of the sensations themselves. Fourcroy and Lorry have each classified odours, but their basis is not physiological, it is purely chemical. Linné, whose work is best known, classifies odours into the following seven classes:—

1. Aromatic odours, such as turpentine, peppermint, and lavender.
2. Fragrant odours, such as those of the lily, jasmine, vanilla.
3. Ambrosial odours, such as musk and ambergris.
4. Alliaceous odours, such as chlorine, sulphuretted hydrogen, asafœtida.
5. Goatly odours (*Odores hircini*), such as those of cheese, cat's urine, rancid oil.
6. Repulsive odours (*Odores tebræ*), such as hyoscyamus, and many of the family of the deadly nightshade.
7. Nauseating odours, such as those of fæces, putrid flesh, etc.

The above classification, which is drawn up upon partly a chemical and partly a physiological basis, would hardly find general acceptance, and indicates most forcibly the fact that any rigid classification is at present quite impossible. In the case of the sense of taste, it is probable that there are only four sensations—those called sweet, sour, bitter, and salt; and these four sensations are universally recognised and have definite and well understood names. Were it

¹ "Osphrégiologie," Paris, 1821, p. 132.

² "Elementa Physiologiæ," 1763, p. 162.

possible in the same way to group bodies that produce similar or allied smells, mankind would long ago have introduced a well-understood smell nomenclature. This has not been done, and odours are called by the names of bodies which give them out, and of these there are an infinite number.

The law of specific energies of the senses.—As far as we know the sense of smell obeys the law of the specific energies of the senses, as taught by Johannes Müller; that is to say, however stimulated the nose may be, an odour is invariably produced. While the usual stimulation is naturally brought about by the action of odorous particles, we can also stimulate the nose electrically and produce the sense of odour. If the cavities of the nose are filled with normal saline, and one electrode from an electric battery be dipped into the solution, while the other is placed upon the forehead, an odour something like that of phosphorus is experienced whenever the intensity of the current is changed.¹ The action of a mechanical stimulation has not yet been investigated. How far the sense of smell obeys the neo-Müllerian law of the specific energy of the senses, is as yet an undecided question. By this law, every sensation which differs from every other sensation, except as regards its quantity or intensity, must have its own nerve fibre and end-organ. Putting it another way, a nerve fibre only transmits impulses producing one kind of effect. It has been assumed that this neo-Müllerian law is true of all the senses, although the evidence is at present certainly inconclusive in the case of almost all of them. It is therefore still upon its trial, and we have to examine the evidence in the case of smell. Were we able, as in the case of the sense of taste, to classify our odours into certain groups, and were we able to find evidence that portions of the olfactory mucous membrane are sensitive, each particular portion to the odours of a particular group, then we should be in a fair way to establish this law in the case of smell. This, as we have seen, we are unable to do. How far cases of partial anosmia have a bearing upon this question, it is difficult to say. We have seen that some persons are unable to smell mignonette, hydrocyanic acid, violets, etc. It may be that in these cases one of the special sets of nerves necessary for the transmission of the impulse set up by the action of this odour is absent. It may be equally possible that the protoplasm of the end-organ of the nerve—on the supposition that there is but one kind of end-organ—may exhibit an individual variation of such a nature as to prevent its reaction to that particular stimulus. This evidence is therefore inconclusive in our present state of ignorance, as to what actually occurs when the end-organ is stimulated.

Aronsohn² found, on fatiguing the nose by the vapour of ammonium sulphide, that sulphuretted hydrogen, and the vapours of chlorine and bromine, produced very diminished effects, while ethereal odours could be perceived as before. Again, in another experiment, when the nose was fatigued by the odour of camphor, he found that ether and eau de Cologne could not be smelt. These experiments are of great interest, and show that various odorous bodies are capable of producing similar fatigue effects upon the olfactory organ. It does not follow, however, that a group of bodies so acting fatigues one kind of end-organ to the exclusion of the others. The fatigue that they produce may be that of all the end-organs to allied kinds of

¹ E. Aronsohn, *Centralbl. f. d. med. Wissensch.*, Berlin, 1888.

² *Arch. f. Physiol.*, Leipzig, 1884.

stimuli. The very uniform appearance of the olfactory end-organs indicates, indeed, that they are all concerned in the reception of all the stimuli which produce olfactory sensations; and we may at any rate conclude that the neo-Müllerian law requires, in the case of smell, additional evidence before its acceptance can be granted.

Relationship between smell and chemico-physical properties of odorous bodies.—From general analogy we should expect that there will be found to exist some sort of resemblance between the sensations produced by stimuli of similar physico-chemical properties. This connection is at first sight by no means apparent, and was only clearly understood after Mendelejeff had classified the elements into natural groups under what is known as the Periodic Law.¹ Taking one of these groups, we find that they consist of elements having similar general chemico-physical properties; thus in the sixth group we have oxygen, sulphur, chromium, selenium, molybdenum, and tellurium. In ascending one of these groups, beginning in the sixth group with oxygen, we find that the molecular weight increases, and that there is a progressive change in the chemico-physical properties of each member of the group. We also find that the odd and even members respectively of the group resemble each other more particularly. Thus in group six we find that, in their chemico-physical properties, sulphur, selenium, and tellurium closely resemble each other. Now what we can say as to the chemico-physical properties of these elements, we can also affirm as to their physiological properties, as regards the sense of smell, and also of taste. Thus in group six, sulphur, selenium, and tellurium, when compounded with hydrogen, with methyl, or with ethyl, etc., have strong and disagreeable odours. They are not the same, although there are points of resemblance, especially as regards their offensiveness. The odours of the selenium compounds are, however, recognisably intermediate between those of sulphur and those of tellurium, just as its molecular weight occupies a position between these two. There are other groups having elements which give rise to smell; thus in group seven we have chlorine, bromine, and iodine. These odours are not unlike each other, the odour of bromine linking the lower chlorine to the higher iodine. Among these compounds may be instanced chloroform, with its fragrant odour; bromoform, with a fragrant odour, mixed with another odour which we recognise as that of the higher iodoform.

Leaving Mendelejeff's groups, and studying groups of organic bodies like the monatomic alcohols or the fatty acids, having similar chemico-physical properties, but showing a progressive change in their characters as we pass from the lower to the higher members of the group, we shall find that there exists in like manner a change in respect of the sensations they are capable of producing.

Ethyl-acetate	.	.	.	Has an acetic and ethereal odour.
Propyl-	„	.	.	Has an acetic odour together with a slight flavour.
Butyl-	„	.	.	Has a slight acetic odour with a pine-apple flavour.
Amyl-	„	.	.	Has no acetic odour, but has a well-marked flavour of pine-apples.

¹ J. B. Haycraft, "The Sense of Smell," *Proc. Roy. Soc. Edin.*, 1887, vol. xiv. p. 207; and *Brain*, London, 1889, vol. xi. p. 166.

This last example will best illustrate how difficult it was to correlate smell with the chemico-physical properties of odorous substances. No one would group the sensation of ethyl-acetate with that of amyl-acetate; they are very unlike, yet they are linked together by the smells of the intermediate members of the group. It is only by studying a whole group of related elements, or compounds, that it is possible to make out any connection at all. We may say then that smell follows the periodic law, and that the power of existing smell, when present, is found to vary in the same way as the chemico-physical properties of substances.

Such a statement is not vitiated by the fact that certain substances, having dissimilar chemico-physical properties, produce the same smell. This only shows that the nose has not a sufficient power of analysis to distinguish in this case the two stimuli from each other. In the case of vision, two very dissimilar stimuli may affect the eye, and produce identically the same sensation. Thus a mixture of red and blue-green spectral rays will produce a sensation called grey, identical with that produced by a mixture of orange and blue. In the case of taste, where there are but a limited number of sensations, we find many instances of a like nature. Our previous conclusions, although they place the power of producing smells on all-fours with the chemico-physical properties of chemical substances, do not commit us to the statement that odorous substances act chemically upon the olfactory end-organs. This is quite another matter, and must be discussed on its own merits. While it is quite possible that the differences in quality of smell may be due to the different chemical decomposition produced upon the protoplasm of the end-organ, it does not necessarily follow that this is the case. Odorous bodies have dynamical properties which might fully account for their action as stimuli. Odorous bodies have no doubt definite vibratory periods, and they absorb in great amount the heat rays. Spectroscopic investigation indicates, although the evidence is as yet somewhat fragmentary, that the elements—or their compounds—in one of Mendelejeff's groups are similar in the character of their molecular vibrations; and Carnelley¹ has shown that a progressive change of vibrational pitch occurs on passing from a lower to a higher member of a group. Much the same is true of the alcohols, and of the fatty acids; the alcohols, for instance, have characteristic absorption-bands which shift towards the red end of the spectrum on ascending the group. William Ramsay² showed that a substance must have at least fifteen times the molecular weight of hydrogen in order that it may be smelt at all. The light gases of the atmosphere are odourless; so is marsh gas (8), ethane (15), olefiant gas (14), hydrocyanic acid (15), methyl-alcohol (16), the latter two of which are smelt by some persons and not by others. Bodies of similar constitution, but with heavier molecules, are frequently odorous; and as a rule the strength of the odour increases with the molecular weight. Thus, while methane and ethane are odourless, propane (22) can be smelt. While hydrocyanic acid is odourless, the higher members or nitriles have characteristic smells. While methyl-alcohol is odourless, the higher members have stronger and stronger odours. Recently J. Passy³ has shown by olfactometric measurements the relative potencies of some of the alcohols, and his results are given in the following table:—

Methyl-alcohol	.	.	.	1
Ethyl-	„	.	.	4
Propyl-	„	.	.	100
Butyl-	„	.	.	1000
Amyl-	„	.	.	10,000

¹ London, Edinburgh, and Dublin Phil. Mag., 1884, ser. 5, vol. xviii.

² Nature, London, 1882, vol. xxvi. p. 187. ³ Compt. rend. Soc. de biol., Paris, 1893.

In both sight and hearing we have this interesting fact, namely, that vibrations, which are either enormously rapid or comparatively slow, are in both cases incapable of acting as stimuli. We have, according to Ramsay, an analogy in the case of smell, for bodies of low molecular weight, and having therefore a high vibrational period are odourless. In the case of smell there are no known bodies of slow vibrational periods incapable of producing a sensation; but in the case of taste there are indications that there exist both a lower as well as an upper margin to our sensation.

The physical condition of the stimulant.—E. H. Weber¹ maintained that if you allow a 10 per cent. watery solution of eau de Cologne to flow into the nose, it fails to produce an effect upon the sense of smell; and he concluded that if we are to smell them, odorous particles must be carried by the air into the cavities of the nose. Recently Aronsohn² found, on repeating these experiments, that such solution is highly irritating to the mucous membrane of the nose, and produces partial anosmia. It is supposed that the olfactory cells swell up, become waterlogged, and are no longer sensitive to stimuli, and on account of this action Aronsohn explains Weber's inability to smell the watery solution of the eau de Cologne. In other experiments Aronsohn replaced the water by normal saline, and states that under these conditions the scent produces its normal effect. In all these experiments we must bear in mind that the true olfactory region of the nose is now known to be situated in quite the upper part of what is really nothing more than a narrow chink. It is therefore a matter of very considerable difficulty to displace the air from this chink and replace it with the scent in a fluid form. But with this successfully accomplished, I myself, and three other persons upon whom I have experimented, have been unable to perceive any odour at all in the case of 5 or 10 per cent. solutions of eau de Cologne. The experiment may best be performed as follows:—The person to be experimented upon lies upon his back on a bench with his head hanging downwards over the end, so that the olfactory region of the nose is lowest. Two glass funnels are connected by tubing with a T-junction, and from the third limb of the T, another tube passes into one nostril. Warm normal saline is allowed to flow from one funnel until both nasal cavities are filled, and the air-free solution falls upon the ground. This is then displaced by warm scented normal saline.

The following experiment indicates that although the nose is filled with odorous particles, yet they are incapable of affecting the olfactory nerves, and only do so when the air containing them is set in motion. The subject of this experiment performs several acts of respiration in rapid succession, so as to render himself apnoeic. Under these conditions he is then able to remain perfectly immovable, without breathing, for from one to three minutes. A bottle containing ammonia is unstoppered under his nose; the vapour diffuses into the nose, is irritative, but cannot be smelt. If, after waiting say two minutes, he then pinches his nose so as to imprison the ammonia vapour already within it, walks into the fresh air, removes his fingers from the nose, and inspires through it, the ammonia is at once smelt. These experiments may be repeated with eau de Cologne, camphor, bergamot, etc., and indicate that odorous particles do not stimulate the end-

¹ *Arch. f. Anat., Physiol. u. wissenschaft. Med.*, 1847, S. 342.

² "Exper. Untersuch. z. Physiol. des Geruches," Inaug. Diss.

organs simply by their presence, even when in the gaseous condition, they must be moved over the olfactory surface.

The simultaneous action of two odours.—When two odours diffuse into a room, we can generally recognise them both, or the odour partakes of the nature of each. If one of them (*A*) is small in amount, and the other (*B*) greatly preponderates, we may only just recognise *A*. On increasing the quantity of *A* the sensation changes, and we may recognise the two odours; and on increasing *A* still further, we may lose the sensation of *B* in the preponderance of that of *A*. But this is not always the case, for certain odours appear to antagonise each other; and if two such antagonistic odours are mixed, either one of them alone is smelt or nothing at all. Thus iodoform may be antagonised by balsam of Peru, the odour of musk by that of the smell of almond. This antagonism may of course be merely a chemical or physical action outside the body of one odour upon the other. Zwaardemaker, however, maintains that there is in some cases a purely physiological antagonism. He has constructed a double olfactometer, consisting of two olfactometers of the form already described. Two odours in any desired quantity can thus be led (without mixing) one into each nostril, so that each odour will stimulate its own portion of olfactory mucous membrane. The best results were obtained when the vapour of a 2 per cent. solution of acetic acid was led into one nostril, and the vapour of a 1 per cent. solution of ammonia into the other. If ammonia was alone smelt, he increased the strength of the acetic acid vapour, until a point was reached at which there was no odour perceptible.

The following is a list of physiologically antagonistic odours:—

Musk and oil of bitter almonds.
Caoutchouc and paraffin.
Volatile oils and iodoform.
Ammonia and acetic acid.

If these statements are true, and we can hardly doubt the results obtained by so experienced an investigator as Zwaardemaker, we have here what appears to be a unique fact in the physiology of the senses. We have to suppose that two stimuli, each one capable by itself of producing an effect on consciousness, when they act together mutually antagonise one another's action. There are other cases, in other sense-organs, in which one stimulus may modify the effect of another; but in no other case that I am aware of do two separate stimuli destroy each other's effect on consciousness. This discovery modifies, too, one definition of modality as used by Helmholtz. Modality is the difference which exists between the sensations of the different sense-organs, and these are distinguished by their inability to pass into each other by intermediate stages. By quality, however, is meant the difference which exists between sensations of the same sense-organ, and these are distinguished by their power of passing into each other by intermediate links. As this is not the case with the smell of ammonia and acetic acid—for, according to Zwaardemaker, you either smell the one or the other, or nothing at all—the differences between them must be one of modality rather than of quality, although they belong to one and the same sense-organ.

The psychology of smell.—We detect the presence of most of

the substances taken into the mouth by the nerves of common sensibility; and our experience leads us therefore to associate taste with the direct application of certain bodies to the surface of the tongue. Most of these bodies are scented, and the odorous particles they give off affect the olfactory mucous membrane at much the same time as the substances reach the mouth. We do not, of course, know that the odorous particles are within the nose, and we associate therefore the sensation, which is really a combined olfactory and gustatory sensation, with the presence of the substance within the mouth, and we conclude that our sensation is one of taste. Thus we say we taste fruit, meat, etc., although the olfactory component of the sensation is really the greater one of the two; we project our olfactory sensation into our mouth. In the case of odorous bodies which are not eaten, like the rose, our experience leads us to associate our sensations with the object itself, generally felt and seen just in front of us. The odorous particles which proceed from the rose do not excite the nerves of common sensibility; and the fact which localises their actions as stimuli to the sensory surface of the nose is the experience that the scent is best felt when air is voluntarily sniffed through it. In most cases, therefore, we project our sensations outside the body, and this is expressed by the saying that "the rose smells." Persons who pay any close attention to their sensations, and are accustomed to detect odours by sniffing with their eyes closed, are conscious of the sensation, as something connected with the interior of the nose; and in their cases they can hardly be said to project their sensations.¹

¹ As works of further reference, the reader is referred to Zwaardemaker's book, "Die Physiol. des Geruchs," Leipzig, 1895; and "Physiol. des Nase und ihrer Nebenhöhlen," by Justus Gaule, Wien, 1896. The older references will be found in v. Vintschgau's article in Hermann's "Handbuch," Bd. iii. Th. 2, S. 225.
