TEXT-BOOK OF PHYSIOLOGY.

NUNQUAM ALIUD NATURA, ALIUD SAPIENTIA DICIT.

TEXT-B O O K

OF

PHYSIOLOGY

EDITED BY

E. A. SCHÄFER, LL.D., F.R.S.,
PROFESSOR OF PHYSIOLOGY, UNIVERSITY OF EDINBURGH.

VOLUME SECOND.

EDINBURGH & LONDON:
YOUNG J. PENTLAND.

1900.

EDINBURGH: PRINTED FOR YOUNG J. PENTLAND, 11 TEVIOT PLACE, AND
38 WEST SMITHFIELD, LONDON, E.C., BY MORRISON AND OIBB LIMITED.

October 1900.

CONTENTS OF VOLUME SECOND.

THE MECHANISM OF THE CIRCULATION OF THE BLOOD.

By LEONARD HILL.

ACTION OF HEART—Form of Heart—Valves and Papillary Muscles—Pressure in Cavities—Heart Sounds—Heart Impulse—Work of Heart—Diastolic Filling of Heart—Systolic Output—Action of Nerves—Cardiac Centres and Reflexes—Depressor Nerve—HÆMODYNAMICS—Torricelli's Law—Poiseuille's Law—General Principles of Circulation—Pressure in Arteries—Velocity of Flow—Circulation Time—Effect of Change of Posture on Circulation—The Pulse—THE CAPILLARY CIRCULATION—Microscopical Examination—Rate of Flow—Capillary Pressure—BLOOD FLOW IN THE VEINS—Pressure in Veins—Effect of Muscular Movements—Rate of Flow—INFLUENCE OF RESPIRATION ON CIRCULATION—VASOMOTOR MECHANISM—Historical—Methods—Action of Vaso-dilators—Local Tone—Traube-Hering Curves—Vasomotors of Veins—CIRCULATION IN SPECIAL PARTS—Cerebral Circulation—Pulmonary Circulation—Blood Flow in Limbs—Renal Circulation—Mesenteric Circulation—Hepatic Circulation—Splenic Circulation—Pancreatic Circulation—Coronary Circulation—Vasomotor Reflexes page 1

THE CONTRACTION OF CARDIAC MUSCLE.

By W. H. GASKELL.

The Meaning of the Heart-Beat—The Sequence of the Contractions of the different Parts of the Heart—The Causation of the Beat of the Heart and of the Sequence of the Contractions of the Separate Cavities is the same in Warm-blooded as in Cold-blooded Animals—The Peculiarities of the Cardiac Muscle by which the Rhythm and Sequence are to be explained—On Fibrillar Contraction—On the Tonicity of the Cardiac Muscle—The Meaning of the Ganglion Cells in the Heart, and their Relation to the Cardiac Nerves—The Nature of the Action of the Cardiac Nerves: (1) The Inhibitory Nerves, (2) the Augmentor Nerves, (3) the After-Action of the Inhibitory and Augmentor Nerves—The Action of Certain Poisons—On the Nutrition of the Heart page 169

ANIMAL MECHANICS.

By J. B. HAYCRAFT.

Introductory—The Movements and Positions of the Body—The Mechanism of Joints—The Muscle as a Machine—The Centre of Gravity of the Body—Methods of Recording Movements of the Body—Detailed Description of Special Movements page 228

THE MUSCULAR AND NERVOUS MECHANISM OF THE RESPIRATORY MOVEMENTS.

By E. H. STARLING.

MECHANICAL CONDITIONS—Inspiration—Diaphragm—Intercostal Muscles—Expiration—Accessory Respiratory Movements—Types of Respiration—Movements of the Lungs—Respiratory Rhythm—Pressure in Lungs—Methods of Registering Movements—NERVOUS MECHANISM—Respiratory Centre—Spinal Centres—Automatism of Centres—Influence of Afferent Nerves—Action of Vagus—Normal Movements and Effects of Division of Vagi—Effects of Distension and Collapse of Lung—Apnoea—Electrical Stimulation of Vagus—Influence of other Sensory Nerves—Influence of Brain—Asphyxia—Modified Respiratory Movements page 274

THE MUSCULAR AND NERVOUS MECHANISMS OF THE DIGESTIVE TRACT.

By E. H. STARLING.

Mastication—Sucking—Deglutition—Movements of the Stomach—Vomiting—Movements of the Intestines—Defæcation page 313

THE MUSCULAR MECHANISMS OF THE URINARY TRACT.

By E. H. STARLING.

MOVEMENTS OF THE URETERS—MOVEMENTS OF THE BLADDER—Muscular Tissue of Bladder and Urethra—Mechanism of Closure of Bladder—Intravesical Tension—Nerve Supply of the Bladder—Mechanism of Micturition—Voluntary Control of Micturition page 338

THE MUSCULAR MECHANISMS OF THE GENERATIVE APPARATUS.

By E. H. STARLING.

Erection—Nervous Mechanism—Retractor Penis—Parturition—Nervous Mechanism page 347

THE MECHANICAL, THERMAL, AND ELECTRICAL PROPERTIES OF STRIPED MUSCLE.

By J. BURDON SANDERSON.

THE MECHANICAL RESPONSE—Response to Successive Excitations—Response to Single Stimulus—Influence of Mechanical Conditions on Excitatory Process—Muscular Tonus—Genesis of Tetanus—Summation of Stimuli—Period of Latency—Rate of Propagation—Conduction of Slow Waves—EXHAUSTION AND DEATH OF MUSCLE—Fatigue—Causes of Exhaustion—Death of Muscle—Rigor Mortis—NATURE OF PROCESS CONCERNED IN MUSCULAR CONTRACTION—PRODUCTION OF HEAT DURING CONTRACTION—ELECTRICAL PROPERTIES OF MUSCLE—In the Unexcited State—Current of Injury—Electromotive Pheno-

mena of Excited Muscle—Electrical Response to a Single Stimulus—Electrical Response to a Series of Stimuli—DIRECT ACTION OF VOLTAIC CURRENT ON MUSCLES—Polarisation of Muscle—Polar Effects during and after Passage of Current—Polar Excitation—Secondary Excitation—Polarising Action of Currents of Brief Duration—CARDIAC MUSCLE—The Mechanical Response—The Electrical Response page 352

NERVE.

By FRANCIS GOTCH.

FUNDAMENTAL CHARACTERISTICS OF NERVE PHENOMENA—General Review of Nerve Functions—Phenomena of the Excitatory State—Metabolism during Activity—Conductivity of Nerve—Transmission in both Directions—THE EXCITATION OF NERVE—Modes of Stimulation—Induced Currents—Undulatory Currents—Condenser Discharges—Galvanic Currents—Unipolar Excitation—Chemical Excitation—Mechanical Excitation—Conditions determining the Efficiency of Stimuli—Law of Excitation—Influence of Direction of Electrical Currents—Nerve Indefatigability—Limits of Excitation by Repeated Stimuli—THE CIRCUMSTANCES AFFECTING NERVE EXCITABILITY AND CONDUCTIVITY—Maintenance of Circulation—Maintenance of Continuity with Nerve Cells—Comparison of Different Nerves and Different Parts of the same Nerve—Alterations of Temperature—Chemical Reagents—Anæsthetics—Polarisation Changes—POLAR EXCITATION OF NERVE BY ELECTRICAL CURRENTS—Pflüger's Law of Contraction—Influence of Duration, etc.—Causation of Polar Excitation—Closing and Opening Tetanus—Polar Excitation in Crayfish Nerves—In Man—In Peripheral Sense Organs—ELECTROMOTIVE CHANGES IN UNEXCITED NERVE—The Nerve Current—Its Production—Influence of Various Conditions on its Amount—ELECTROMOTIVE CHANGES IN EXCITED NERVE—The Negative Variation—Its Discontinuous Character—Electrical Response to One Stimulus—Influence of Various Conditions—After-Effects—ELECTROMOTIVE CHANGES ASSOCIATED WITH PASSAGE OF CURRENTS—External and Internal Polarisation—Electrotonus—Influence of Physiological Changes upon Electrotonus—Excitatory After-Effects—Polarisation and Excitation page 451

THE PHYSIOLOGY OF ELECTRICAL ORGANS.

By FRANCIS GOTCH.

General Description—Minute Structure in *Raja batis*, *Gymnotus*, *Torpedo*, and *Malapterurus*—Functional Activity—The Electrical Changes of Nerve Organ Preparations; Activity Effects—The so-called Current of Rest—The Organ Response—Its Time Relations—Self-Excitation of the Electrical Organs—Effect of Repeated Stimuli—Residual Effect of the Response—Electromotive Force of the Response—Polarisation Phenomena, Secondary Electromotive Effects, Irreciprocal Conductivity—The Reflex Response of the Organ—The Nature of the Activity page 561

THE NERVE CELL.

By E. A. SCHÄFER.

Classification of Nerve Cells—Theory of Isolated Units (Neurone Theory)—Structure of Nerve Cells—Changes in Nerve Cells as the result of Excitation—Changes resulting from Section of the Nerve Fibre Process—Conduction in Nerve Cells—Time lost in Transmission from Cell to Cell—Refractory Period page 592

THE SYMPATHETIC AND OTHER RELATED SYSTEMS OF NERVES.

By J. N. LANGLEY.

GENERAL ACCOUNT OF THE SYMPATHETIC NERVOUS SYSTEM—Sympathetic Nervous Supply of the Head—Of the Skin, except that of the Head and of the Ano-Genital Region—Of the External Generative Organs and of the Skin of the Ano-Genital Region—White and Grey Rami; Some General Features of the Sympathetic Nerve Supply to the Skin—Of the Skeletal Muscles—Of the Thoracic and Abdominal Viscera—Nerve Fibres of the Sympathetic System—Degeneration of Nerve Fibres—Regeneration—Structure of Sympathetic Nerve Cells—Duration of Effects caused by Section of Nerves—Efferent Pre-Ganglionic Fibres in relation to the Anterior and Posterior Roots of the Spinal Nerves—NERVOUS SYSTEMS RELATED TO THE SYMPATHETIC NERVOUS SYSTEM—Distribution and Action of Cranial Autonomic Nerve Fibres—Distribution and Action of Sacral Autonomic Nerve Fibres—The Enteric Nervous System—Possible Autonomic Fibres running direct in the Cerebro-Spinal Nerves—Local Nerve Centres other than the Cranial, Sympathetic, and Sacral Ganglia—QUESTIONS COMMON TO THE SYMPATHETIC AND TO SOME OTHER PARTS OF THE AUTONOMIC SYSTEM—Mode of Action of Inhibitory Fibres—Automatism of Peripheral Ganglia—The Peripheral Ganglia as Centres for Definite Areas—Reflex Action from Autonomic Ganglia—The Number of Nerve Cells on the course of a Pre-Ganglionic Fibre; Commissural Fibres—The Size of Nerve Fibres as a Characteristic of the Autonomic System—Afferent Autonomic Nerve Fibres; Referred Pain in Visceral Disease—Growth of Pre-Ganglionic Cranial Fibres into Sympathetic Ganglia—General Comparison of the Cranial, Sacral, and Sympathetic Autonomic Systems page 616

THE CEREBRAL CORTEX.

By E. A. SCHÄFER.

GENERAL FUNCTIONS—Results of Removal of whole Cortex—Of one Hemisphere—Results of Artificial Excitation—Character of Muscular Contractions resulting from Excitation—Other Phenomena resulting from Excitation—Effects on Respiration—On Circulation—On the Pupil—On the Secretions and on the Muscular Tissue of the Viscera—Heat Centres—Epilepsy—SPECIAL LOCALISATIONS—The Motor Areas and Centres—Sensory (?) Functions of Motor Areas—Results of Stimulation and Removal of Particular Areas—Associated Movements—The Principal Parts of the Motor Cortex of the Monkey—The Head and Eyes Area—Face Area—Arm Area—Leg Area—Trunk Area—The Motor Centres in the Orang—The Motor Centres in Man—The Sensory Areas of the Cortex—The Visual Area—The Auditory Area—The Olfactory and Gustatory Areas—The Localisation of Tactile Sensibility—Latent Regions of the Cortex—Hypothesis of Association Centres of Flechsig—Aphasia—Connections of Cortical Centres with one another and with Lower Centres page 697

THE SPINAL CORD.

By C. S. SHERRINGTON.

Reflex Action—The Way In—Recurrent Sensitivity—The Way Out—Relation of Afferent to Efferent Root Cell—Reflex Tonus—Regeneration of Afferent Roots—Functional Anatomy of Mediate Spinal Cell-Systems—The Spinal Grey Matter—Reflex Capacity of Fragments of the Cord—THE SPINAL ANIMAL—Rules of Spread in "Short" Reflexes—In Long Reflexes—Influence of the

Quality of the Stimulus—Summation of Stimuli—Intensity of the Stimulus—Character of the Muscular Response—Influence of the Locus of the Stimulus—"Local Sign" and Spinal Reflexes—Fatality of Spinal Reflexes—Influence of Condition of the Central Organ itself; Vascular Condition—Drugs—Influence of Associated Parts of the Central Organ; Inhibition and "Bahnung"—Co-ordinate Character of the Movements—Phasic Variation in Reflex Activity—Autotomy—Spinal "Shock"—Difference between Skeletal and Visceral Musculature in regard to Shock—Spinal Visceral Reflexes—Urinary Bladder—Defaecation—Sexual Spinal Reflexes—Other Visceral Reflexes—Reflexes Affecting the Vascular Musculature—Significance of Spinal Reflexes—SPINO-CEREBRAL AND CEREBRO-SPINAL REACTIONS—Conduction in the Cord—Spinal Traumatic Hyperæsthesia—TONIC FUNCTIONS OF THE CORD—Automatism—"Knee-Jerk" and Allied Phenomena—TROPIC FUNCTIONS OF THE CORD—REGENERATION OF THE SPINAL CORD page 783

THE PARTS OF THE BRAIN BELOW CEREBRAL CORTEX, VIZ. MEDULLA OBLONGATA, PONS, CEREBELLUM, COR- PORA QUADRIGEMINA, AND REGION OF THALAMUS.

By C. S. SHERRINGTON.

THE MYELENCEPHALON OR REGION OF THE MEDULLA OBLONGATA—The Root Cell Systems—The Bulbo-spinal Frog—The Bulbo-spinal Mammal—"Centres" in the Bulb—Conduction Paths in the Bulb—THE METENCEPHALON OR REGION OF THE PONS VAROLII AND CEREBELLUM—Reactions in the Frog—And Rabbit—THE PONS—The Root Cell Systems—"Centres"—Conduction Paths—THE CEREBELLUM—Excitation—LESIONS—Unilateral Ablation—Ablation of the whole Cerebellum—Destruction of the Middle Lobe—Longitudinal Bisection—Ablation in the Bird—Ablation in Lower Vertebrates—Phenomena caused by Section of the Cerebellar Peduncles—Section of Anterior Peduncle—Section of Middle Peduncle—Section of Posterior Peduncle—Bilateral Section of the Peduncles—Phenomena of Cerebellar Origin in Human Disease—Inferences drawn from Comparative Anatomy—Functions of the Cerebellum—THE MESENCEPHALON OR REGION OF THE CORPORA QUADRIGEMINA—The Root Cell Systems—Excitation of the Corpora Quadrigemina—Reactions of Animals after Ablation of all the Encephalic Regions in front of the Mesencephalon—Lesions of the Corpora Quadrigemina—Decerebrate Rigidity—Conduction Paths through the Mesencephalon—THE DIENCEPHALON OR REGION OF THE OPTIC THALAMUS—Visual Connections—Excitation—Destructive Lesions page 884

CUTANEOUS SENSATIONS.

By C. S. SHERRINGTON.

THE SENSE OF TOUCH—Touch-Spots—The Adequate Stimulus—Weber's Law in respect to Tactual Sensations—The Spatial Quality of Touch—Theory of "Localising" Power of Touch—Projection of Touch—Illusions in Tactual Judgments—Reaction Time for Touch—THE SENSE OF TEMPERATURE—"Cold" and "Warmth" as Distinct Species of Sense—Distribution of Apparatus for Thermal Sensations in the Skin, etc.—The Adequate Stimulus—Other Stimuli—Paradoxical Sensation of Cold—Some Characters of "Cold" and "Warmth" Sensations—Relation of Thermal Sensation to Pain—Influence of Areal Extent of Stimulus upon Intensity—The Physiological "Zero-temperature" and "Adaptation"—The Degree of Projection of Thermal Sensation—The Thermal Sense in relation to Thermotaxis—The Liminal Difference of Intensity of Stimulus—Reaction Time—Antagonism of Sensations of "Cold" and "Warmth"—Paths of Conduction—COMMON SENSATION—Cutaneous Pains considered in relation to Pain in general—Relation of Pain to Intensity of Reaction—Quality

of Cutaneous Pain—Scope of the term “Common Sensation”—The Viscera and Common Sensation—The Musculo-articular Apparatus and Common Sensation—Nature of “Physical Pain”—Action of Painful Stimuli—Character of the Motor Reactions provoked—The Central Neural Mechanism for Cutaneous Pain—Tickling—Dolorous Reflexes compared with Tactual—The Spinal Path of Pain—Associated (Referred) Pains—Interference of Pain with other Sensations—The Peripheral Path of Pain—“Pain-Spots” in the Skin—Pain and Nerves of Muscular Sense—Pain and Visceral Nerves—Hunger as a Type of Visceral Sensation—Evolution of Visceral Pain—Cutaneous Pain and Adequate Stimuli—Specific End-organs or Undifferentiated Endings—The Forms of “Excess” of Stimulus—Summation in Production of Pain—“Inertia” of the Neural Apparatus of Pain—The Brain and Physical Pain . . . page 920

THE MUSCULAR SENSE.

By C. S. SHERRINGTON.

Definition of “Muscular Sense”—Views regarding the nature of Muscular Sense—Charles Bell’s “Sixth Sense”—The Peripheral Apparatus of the Muscular Sense; Histological Data—Nerves of Muscles and Tendons—End-Bulbs and Pacinian Corpuscles—Hypothesis as to the Mode of Excitation of the Peripheral End-Organs of the Muscular Sense—Muscle-Reflexes—The Performances of Muscular Sense—Perception of Posture—Perception of Passive Movement—Perception of Active Movement—Objective Effects of Loss of Muscular Sense upon “Willed Movement”—Subconscious Character of Reactions of Muscular Sense—Probable Importance of Tonus for Co-ordination—Apæsthesia produces Ataxy of “Willed Movement”—Senso-paralysis—Perception of Resistance—The Liminal Stimulus—The Liminal Difference—“Adaptation”—Interpretation of Results—Fusion of Muscular with other Sensations . . . page 1002

VISION.

By W. H. R. RIVERS.

THE DIOPTRIC SYSTEM—Accommodation—The Pupil—THE RETINA AND VISUAL SENSATIONS—Physiological Retinal Processes—Visual Sensations—Adaptation and Induction—The Duration of Stimulus and Sensation—The Brightness of Colour Sensations—Mixture—Vision of Different Regions of the Retina—Colour-Blindness, etc.—Binocular Phenomena—Functions of the Retinal Structures—Theories of Colour-Vision—BINOCULAR VISION—Movements of the Eyes—Spatial Perception page 1026

THE EAR.

By JOHN GRAY M’KENDRICK AND ALBERT A. GRAY.

THE EXTERNAL EAR—The Auricle—The External Auditory Meatus—Movements of the Auricle—THE MIDDLE EAR—The Tension of the Membrana Tympani, and its Regulation—Movements of the Membrana Tympani in response to Sound Pressures—The Movements of the Malleus—The Movements of the Incus—The Movements of the Stapes—The Tensor Tympani—The Stapedius—The Movements of the Ossicles as a whole under the Influence of Sound-waves—The Magnitude of the Movements of the Ossicles—Transmission of Sound to the Labyrinth otherwise than by the Ossicles—Regulation of Atmospheric Pressure in the Tympanum—Auditory Reflexes—Binaural Audition—THE INTERNAL EAR—General Mechanism of Internal Ear—The Utricle and Sacculæ—The Cochlea—Pitch—Beats—Beat Tones—Audibility as affected by Intensity—The Analytic Properties of the Ear—Resonance—Probable Action of the Cochlea—Upper Partial Tones and the Theory of Dissonance—Combination Tones—Objections to the Theory of Helmholtz—Other Theories—The Semi-circular Canals page 1149

ON VOCAL SOUNDS.

BY JOHN GRAY M'KENDRICK AND ALBERT A. GRAY.

Voice Production—The Singing Voice—Tone Intensity—Tone Pitch—The Range of the Voice—The Muscular Mechanisms which affect the Vocal Cords—Voice Registers—The Quality of the Voice and Vowel Tones—Theories of Vowel Tones—Wave-forms of Vowel Tones—The Fourierian Analysis of Wave-forms—Phonograms—General Conclusion—The Consonants—Effect of the Cavities in connection with the Larynx and Pharynx upon the Voice—Whispering page 1206

THE SENSE OF TASTE.

BY J. B. HAYCRAFT.

The Anatomical Mechanisms concerned in the Production of Taste, and the Regions of Mucous Membrane which are involved—Taste Sensations—The Action of Drugs on Taste—Modality and Quality of Taste—The Relationship between Taste Sensations and the Chemico-Physical Properties of the Stimulus—After-Tastes and Successive and Simultaneous Contrast page 1237

THE SENSE OF SMELL.

BY J. B. HAYCRAFT.

The Anatomical Data—The Passage of Air through the Nose—Olfactometry—Hyperosmia and Anosmia—The Classification of Odours—The Law of Specific Energy of the Senses—The Relationship between Smell and the Chemico-Physical Properties of Odorous Bodies—The Physical Condition of the Stimulant—The Simultaneous Action of Two Odours—The Psychology of Smell. page 1246

INDEX OF SUBJECTS page 1261

INDEX OF AUTHORS page 1336

LIST OF ILLUSTRATIONS.

FIG.	PAGE
1. Sections through the frozen thorax of a dog (Haycraft and Paterson)	5
2. Diagram showing the resultant pull of the papillary muscles (Ludwig)	8
3. Multiconvex upper surface of the closed tricuspid valve (Krehl)	8
4. Mitral valve. Insertion of the chordæ tendineæ (Krehl)	9
5. Diagram of the chordæ tendineæ (Krehl)	9
6. Intracardial pressure curves (Chauveau and Marey)	14
7. Fick's straight spring manometer	15
8. Goltz and Ganle's combined maximal and minimal manometer, as modified by Hürthle	16
9. Fredericq's sphygmoscope	17
10. v. Basch's hollow spring manometer	17
11. Hürthle's differential manometer	17
12. Intraventricular pressure curve (Bayliss and Starling)	19
13. Aortic pressure curve (Bayliss and Starling)	19
14. Aortic and intraventricular pressure curves (Hürthle)	20
15. " " " " (Hürthle)	21
16. Auricular pressure curve (Porter)	22
17. Cardiac and aortic pressure curves (Porter)	24
18. Tracing of the right auricle and carotid pulse (Porter)	27
19. Diagram of Hürthle's experiment	30
20. Tracing of pulse and of first and second sounds of the heart (Einthoven and Geluk)	31
21. Tracing of sounds of heart from a case of aortic regurgitation (Einthoven and Geluk)	32
22. Areas of cardiac impulse, when supine and when lying on the left side (Sequeira)	33
23. Edgren's cardiograph	35
24. Impulse curve and sounds of the heart (Edgren)	36
25. High and low aortic pressure curves (Hürthle)	37
26. Simultaneous records of carotid pulse and heart impulse (Edgren)	38
27. Myocardiograph (Roy and Adami)	39
28. Tracing illustrating effect of compression of the thorax (Hill and Barnard)	45
29. " " " " " "	45
30. Effect on aortic pressure of artificial ventilation of the lungs (Hill and Barnard)	46
31. Pressure in the air passages and carotid pulse (Mosso)	47
32. Cardiometer (Roy and Adami)	49

FIG.	PAGE
152. Pedestrian furnished with special shoes and carrying a chronographic apparatus (Marey)	264
153. Special apparatus for recording the contacts of a horse's feet with the ground (Marey)	265
154. Chronographic apparatus recording the paces of a horse (Marey)	265
155. Rhythm curves obtained from a man running (Marey)	266
156. Chronographic record of the periods of contact of the feet of a man executing various paces (Marey)	266
157. Chronophotographic method of recording bodily progression (Marey)	267
158. Chronophotograph of a man's movements when walking (Marey)	267
159. Chronograph of the movements of a man's leg in running (Marey)	268
160. Illustrates certain mechanical forces operative during progression	270
161. To illustrate the surface of the body exposed to the resistance of air in bicycling, in running, and in walking	271
162. Illustrates the difference between the centre of gravity of the body in the erect posture and in running	272
163. Shows the effect of the thrust of the foot against the ground in progression	272
164. Diagrammatic representation of position of diaphragm during expiration and inspiration	276
165-167. Diagrams illustrating the action of the intercostal muscles upon the ribs	277, 278
168. Normal tracing of diaphragm-slips of rabbit: Head's method	283
169. Diagrammatic section of medulla oblongata below middle of olivary body, to show region of respiratory centre (Bechterew)	285
170. Effect on respiratory movements of closing trachea at height of inspiratory period (Head)	294
171. Effect on respiratory movements of closing the trachea during the expiratory pause (Head)	295
172. Effects on respiratory movements of dividing first one and then the other vagus (Head)	297
173. The right vagus has been divided, and the curve shows the effect produced by complete collapse of the left lung (Head)	298
174. Effects on respiratory movements of positive ventilation with air (Head)	299
175. " " " negative " (Head)	299
176. Diagrammatic representation of effects of different kinds of ventilation (Head)	300
177. Apnœic pause, caused by positive ventilation with hydrogen (Head)	300
178. Respiratory tracing showing negative after-effect of inflation of lungs (Head)	302
179. Tracings of blood pressure and of intratracheal pressure, taken by Einthoven's "differential manometer"	310
180. Diminution of respiratory excursions produced by spasm of bronchial muscle (Einthoven)	311
181-183. Curves obtained during swallowing (Kronecker and Meltzer)	317
184. Curve obtained by placing a balloon in the œsophagus (Kronecker and Meltzer)	318
185. Starling's Enterograph	327
186. Rhythmical contractions of circular coat of small intestine	328
187. Curve to show effects of exciting peripheral end of right vagus	332
188. Curve showing inhibitory effect on contractions of small intestine	333
188a. Diagram of the nerve supply to the bladder and colon in the cat (Langley and Anderson)	343
189. The double adductor preparation	354
190. Cosine lever, combined with writing lever and tension recorder (Fick)	355

FIG.	PAGE
191. Work-diagram (Fick)	357
192. Isotonic curve drawn by a double semi-membranosus preparation (Fick)	358
193. Series of isotonic curves with increasing loads (Fick)	359
193A. Work-diagram for the same muscle (Fick)	359
194. Isotonic and isometric curve of the same muscle, represented as springing from the same base line (Fick)	362
195. Blix's apparatus for recording isometric and isotonic curves synchronically	365
195A. Enlarged view of the same apparatus to show the torsion rod from above	365
196. Series of "after-loading" curves with increasing load (v. Kries).	367
197. v. Kries's apparatus for taking "after-loading" curves and "arrested-contraction" curves	367
198. Series of "arrested-contraction" curves (v. Kries)	368
199. Isotonic curve and arrest curve of the same muscle, as in Fig. 200, cooled to 6° C. (Schenck)	369
200. Isotonic curve and arrest curve of a muscle, warmed to 31°·5 C. (Schenck)	369
201. Isometric and isotonic curves of the same muscle (Schenck)	370
202. Schenck's apparatus for taking "jerk curves"	370
203. Isotonic and jerk curves (Schenck)	371
204. Curves of isotonic and arrested contractions of an unloaded muscle (Kaiser)	373
205. (1) Isotonic curve of unloaded muscle, at temperature 14° C.; (2) the same, at 25° C.; (3) at 0° C.; (4) at 14° C., with load on muscle (Kaiser)	373
206. Isotonic curves of muscle unloaded on the summit (Kaiser)	374
207. " " with same muscle more heavily loaded (Kaiser)	374
208. Series of release curves following arrest, with muscle cooled to 0° C. (Kaiser)	374
209. Isotonic and arrest curves of an unloaded muscle. Modified from Kaiser	375
210. Two isotonic curves of an unloaded muscle (Kaiser)	375
211. Isotonic curve and release curve, after arrest, of an unloaded muscle (Kaiser)	377
212. Muscle curve, showing summation of inadequate stimuli (Richet)	380
213. Method of measuring mechanical latency of muscle	382
214. Facsimile of the photographic record of the beginning of the contraction of the sartorius	382
215. Fatigue curve of muscle (Kronecker)	387
216. Muscle curves showing the effect of fatigue (Waller)	388
217. Showing curves of rigor mortis of white and red muscles of rabbit (Bierfreund)	392
218. Curves of rigor mortis in fresh and exhausted muscle (Nagel)	392
219. Engelmann's apparatus for recording contraction of a violin string on heating	396
220. Blix's apparatus for taking the extension curves of muscle with the load either increasing or decreasing (Fick)	404
221. Two extension curves of the same excited muscle taken continuously with decreasing and increasing loads (modified from Fick)	405
222. Showing the arrangement of the fibres in the gastrocnemius muscle	408
223. Diagram of method for studying the electrical properties of muscle	409
224. Non-polarisable electrode	410
225. Diagram of muscle rhomb	412

FIG.	PAGE
226. Bernstein's differential rheotome	414
227. Progress of the wave of excitation, according to Bernstein	416
228. Curves of electrical response to instantaneous stimulation (Matthias)	417
229. Diagram representing the excitatory variation of muscle	417
230. Burch's projecting electrometer	418
231. Comparison curve for estimating the value of the curves of the capillary electrometer	419
232. Diphasic and monophasic curves of the sartorius	420
233. To illustrate the point of equipotentiality in the curve of the capillary electrometer	420
234. To illustrate the excitatory variation of muscle	421
235. Electrical response to a series of stimulations (du Bois-Reymond)	422
236. Method of leading-off from injured muscle	423
237. Tetanus curve of injured sartorius	424
238. Responses to ten excitations of an uninjured gastrocnemius	424
239. Response to indirect excitation of a cooled muscle	425
240. Veratrine curve (sartorius)	425
241. Strychnine curve of an uninjured gastrocnemius	426
242. Method of showing polarisation of muscle	427
243. Effects on excitability of the passage of a constant current through muscle	430
244. Hering's double myograph	432
245. Contractions of sartorius recorded by the double myograph (Biedermann)	433
246. Contractions of the two ends of the sartorius, as recorded by the double myograph (Biedermann)	433
247. Diagram of Frank's apparatus for recording isometric curve of frog's ventricle	440
248. Isometric and isotonic curves of the ventricle of the heart of the frog (Frank)	442
249. Excitatory variations of cardiac muscle (Einthoven)	446
250. Einthoven's electro-cardiogram of man	448
251. Experiments showing transmission in both directions	456
252. Time relations of induced currents	460
253. Diagram of rheonome	471
254-256. Influence of temperature on nerve excitability	485, 486, 487
257. " " neutral salts " "	489
258. " " vapours " "	491
259. Curves showing polar changes in excitability of nerve	495
260. Influence of increased length of nerve on polar changes	495
261. Tripolar arrangement of electrodes	501
262, 263. Influence of poles on rate of transmission	502
264. Method of multipolar contacts	506
265. Influence of demarcation current on polar excitation	508
266. " " salt on polar excitability	511

ACTION OF THE HEART.

THE FORM OF THE HEART.

THE changes in form of the heart during systole and diastole can be studied in an animal, the heart of which has been exposed by opening the thorax under an anæsthetic, artificial respiration being meanwhile maintained. When the heart is watched beating in full vigour and rapidity, it is an impossible task to unravel, by the eye alone, the sequence of events which form the cardiac cycle.

Harvey felt this difficulty, and writes: "When first I gave my mind to vivisections, as a means of discovering the movements and uses of the heart, and sought to discover these from actual inspection, and

¹ The writer of this article is greatly indebted to Tigerstedt's "Lehrbuch der Physiologie des Kreislaufes," Leipzig, 1893. To this work the reader is referred for an exhaustive analysis of the literature of the circulation.

not from the writings of others, I found the task so truly arduous, so full of difficulties, that I was almost tempted to think (with Fracastorius) that the movement of the heart was only to be comprehended by God. For I could neither rightly perceive at first when the systole and when the diastole took place, nor when and where dilatation and contraction occurred, by reason of the rapidity of the movement, which in many animals is accomplished in the twinkling of an eye, coming and going like a flash of lightning; so that the systole presented itself to me now from this point, now from that—the diastole the same; and then everything was reversed, the movements occurring, as it seemed, variously and confusedly together.¹

“When the heart begins to flag, to move more slowly, and, as it were, to die, the movements then become slower and rarer, the pauses longer, by which it is made much more easy to perceive and unravel what the movements really are, and how they are performed.

“In the pause,” Harvey says, “as in death, the heart is soft, flaccid, exhausted—lying, as it were, at rest. In the movement and interval in which this is accomplished, three principal circumstances are to be noted—

“1. That the heart is erected, and rises upwards to a point, so that at this time it strikes against the breast, and the pulse is felt externally.

“2. That it is everywhere contracted, but more especially towards the sides, so that it looks narrower, relatively longer, and more drawn together.

“3. The heart being grasped in the hand is felt to become harder during its action. Now, this hardness proceeds from tension; precisely as when the forearm is grasped its tendons are perceived to become tense and resilient when the fingers are moved.

“4. It may further be observed in fishes and the colder blooded animals, such as frogs, serpents, etc., that the heart, when it moves, becomes of a paler colour; when quiescent, of a deeper red colour.”²

There is also to be noticed in the heart “a certain obscure undulation and lateral inclination in the direction of the axis of the right ventricle, as if twisting itself slightly in performing its work.”³

Analysing the movements of the chambers of the heart, Harvey determined that “first of all the auricle contracts, and in the course of its contraction forces the blood (which it contains in ample quantity as the head of the veins, the storehouse and cistern of the blood) into the ventricle, which, being filled, the heart raises itself straightway, makes all its fibres tense, contracts the ventricles, and performs a beat, by which beat it immediately sends the blood supplied to it by the auricle into the arteries.”

Little can be added to Harvey’s admirable description. Turning to a nineteenth-century author—Sibson—we find the action of the heart described thus:⁴

“The heart, when in action, presents to the eye the most remarkable contrasts in the size, position, colour, and form of its various cavities and great

¹ Harvey, “An Anatomical Dissertation upon the Movements of the Heart, etc.,” ch. i., Canterbury, 1894.

² *Ibid.*, ch. ii.

³ *Ibid.*, ch. v.

⁴ “Medical Anatomy,” London, 1869, p. 73.

vessels. When the ventricles contract they do so with a twisting movement, their walls become rigid and corrugated, their apex and base approximate, the descent of the base being greater than the ascent of the apex, and the arteries and veins on their surface become prominent and tortuous. The auricles become swollen with blood, and seem to push before them the retreating ventricles at the base. The great arteries are distended and lengthened, being apparently drawn downwards at their origin by the contracting ventricles. When, however, the ventricles expand, the aspect of all the parts is reversed. The ventricles enlarge in every direction, but especially towards the base. Their walls are flaccid and smooth; and the arteries and veins on their surface become straight and small. The auricles shrink, becoming pale and wrinkled, and are in great part replaced by the ventricles, into which they empty their blood. The great arteries lessen in size, and shorten and ascend at their origin, being apparently raised by the upward enlargement of the ventricles.

"The chief movement observable in the auricles is the sudden retraction of the appendices, which almost instantly become refilled with blood as the ventricles contract. There is a slight twisting movement of the whole heart during systole, both on its longitudinal and on its transverse axis. By its rotation on its transverse axis the apex of the heart is tilted forwards; by its rotation on the long axis, the left ventricle, which, during the diastole, looks backward, is turned forwards. The combination of the two movements gives to the apex a twisting movement from left to right and forwards."

Sibson measured the change of form of the heart by placing a millimetre scale across the organ, and noting the systolic and diastolic measurements of its parts. By Ludwig¹ the heart of the cat was likewise measured *in situ*. He observed that in systole the antero-posterior diameter increased, the apex-base diameter shortened, the transverse diameter diminished, while the circumference of the base changed from an ellipse to a circle.

The following measurements are a type of his observations:—

	Diastole.	Systole.
Transverse diameter	28 mm.	22·5 mm.
Antero-posterior diameter	16·5 ,,	20·6 ,,

These measurements were taken with the animal in the horizontal position, lying on its back. Now the position of the heart and the pressure of the surrounding organs considerably affect the form of the heart.

During the period of diastole the heart becomes a flaccid bag, and thus passes entirely under the influence of gravity. When an excised frog heart is so placed on a glass plate that the base rests on the plate, the organ is seen to become smaller in systole while the apex rises forward. If the heart be placed with its posterior surface on the plate, the base becomes rounded in systole, and the apex lifts itself up from the plate. Lastly, if the heart be suspended with the apex hanging vertically downwards, then, while the base becomes round, the apex moves nearer to the base during systole.

Since the pressure of the surrounding organs, and especially of the lungs, influences the form of the heart, it is impossible to arrive at any accurate knowledge of the normal variations, so long as the experimental observations are conducted in abnormal conditions with the thorax opened. To obviate this difficulty, Brücke² implanted needles into the

¹ *Ztschr. f. rat. Med.*, 1849, Bd. vii. S. 205.

² *Sitzungsb. d. k. Akad. d. Wissensch.*, Wien, 1855, Bd. xiv. S. 348; "Vorlesungen," 1874, S. 172.

hearts of rabbits through the walls of the closed thorax, and watched the movements of the needle heads. The needles acted as levers, the thoracic wall formed the fulcrum, the movements of the needle heads gave the reverse of the movements of the needle points within the heart. From the result of these observations Brücke maintained that all parts of the ventricles move downwards in systole with the exception of the apex, the amount of movement increasing from below upwards. The apex of the heart undergoes less change of position than any other part. Its upward movement is neutralised by the descent of the whole heart. This descent is occasioned by the elastic recoil of the great vessels.¹ Haycraft² has likewise passed needles through the closed thorax into the mammal's heart. The needles indicated the contraction of the organ, both in the transverse and antero-posterior diameter. They did not show any sign of that twisting of the heart as a whole, which is seen when the chest is opened. Comparing these results with those of Ludwig, it is clear that by opening the thorax, and allowing the lungs to collapse, a material difference is made in the change of form of the heart. This follows from the removal of those structures which naturally support the heart. Thus Haycraft observed that if an animal be suspended horizontally, with the belly downwards, and the chest be opened, the heart moves downwards towards the sternum in diastole, and springs towards the vertebral column during systole. While, if the animal be placed on one side, the heart sinks towards that side during diastole, and springs towards the other side during systole. In diastole the heart always follows the pull of gravity, in systole the direction of the spring of the apex depends upon the fulcrum, or, in other words, upon that part of the heart which is supported by some neighbouring structure. When the animal lies on its back, the fulcrum to the heart is afforded by the fibrous structure of the pericardium. The base of the left ventricle rests securely upon this strong membrane, upon which it is slung as upon a hammock.

In the closed thorax the falling back of the heart in diastole is largely prevented by the resistance of the expanded lungs. Thus, when a dog is placed symmetrically on its back, and the lungs are allowed to collapse, the heart falls backwards and to the left during diastole, while with each systole it springs upwards and towards the right, and the twisting movement from left to right is observed. If the lungs be now inflated so that the heart is fully supported by the lungs on both sides, then no rotation of the organ as a whole takes place.

Ludwig and Hesse took casts of excised hearts, which had previously been distended with blood at a pressure of 150 mm. Hg, so as to imitate the diastolic form. Other casts were taken of empty hearts in a state of heat contraction produced by the sudden immersion of the organs in a solution of potassium bichromate heated to a temperature of 50° C. From the measurements of these casts they determined that the heart is diminished in heat systole in all its diameters except the vertical, while the areas of the auriculo-ventricular orifices are diminished by one-half.

As the musculature of the heart is, speaking generally, composed of an inner and an outer longitudinal layer, and a middle circular layer, we must suppose that in heat-rigor the contraction of these layers strikes a balance, so that the vertical diameter does not shorten.

¹ Halford, "On the Movements and Sounds of the Heart," London, 1861, p. 12.

² *Journ. Physiol.*, Cambridge and London, 1891, vol. xii. p. 452.

This method of investigation is open to considerable fallacy. The hearts are excised and unsupported by surrounding structures, and while the diastole is artificially produced by a high injection pressure, the systolic contraction is not normally obtained, for, contrary to the natural systole, it takes place against no resistance. Thus it comes about that the great contraction of the auriculo-ventricular orifices, found by Ludwig in the rigored heart, is not confirmed by observations on the living heart. Recently Haycraft and Paterson have cut a series of sections through the frozen thorax of dogs, after the heart has been fixed either in diastole or systole.¹ From these sections the form of the heart has been reconstructed. The great difficulty is to obtain the death of the animal with the heart in either the true diastolic or systolic shape. Death nearly always takes place with the heart in diastole, but, according to the distribution of the blood at the moment of death, the heart may be dilated more or less. To obtain death with the heart in systole is a matter of considerable difficulty. Haycraft and Paterson obtained the best results by the injection of a solution of corrosive sublimate into the jugular vein.

FIG. 1.—Sections through the frozen thorax of a dog. *A*, Heart in diastolic death; *B*, In systolic death.—Haycraft and Paterson.

In the figure are presented the appearances observed in sections from two dogs, and seen from below. In *A* the heart is in diastolic death, and in *B* in systolic death.

In a third figure these authors illustrate the alteration in the position of the heart produced by placing the animal after death on the left side. The heart has fallen over to the left, and has, while compressing the left lung, expanded the right. This illustrates the interaction of the thoracic organs on one another; by merely altering the position of the body, and thus of the heart, air may be driven out of one lung and sucked into the other.

By taking plaster casts of the interior, after fixing the heart in diastole or systole, Ludwig and Hesse studied the form of the ventricular cavity. As to the accuracy of this method, the same reservations must be made as above. In diastole the cavity of the left ventricle forms a short and wide tube, while the auriculo-ventricular opening is separated from the aortic orifice by the pendulous anterior flap of the mitral valve. In heat-rigor, a condition of contraction greater no doubt than that produced by any systole during life, the cavity appears as a narrow slit which is star-shaped in the region of the

¹ Haycraft and Paterson, *Journ. Physiol.*, Cambridge and London, 1896, vol. xix. p. 496.

papillary muscles. Above this region there lies a space, which in the ox's heart forms a very irregular cone pointing downwards.¹ The heart, therefore, never empties itself completely in systole.

The outer muscular layers of the heart take an oblique direction from right to left, the inner layers take an oblique direction from left to right, and the intermediate fibres run more or less transversely. Ludwig has shown that in every piece of the walls of either chamber the fibres on the inner surface take a direction across those on the outer surface, the intermediate fibres taking, in regular order, a corresponding change of direction.

The various fibrous structures of the base are all associated together, forming one common fibrous membrane. This surrounds the aortic, the mitral, and the tricuspid orifices, and, resting upon the base of the ventricles, gives a general insertion to the muscular fibres of both of these cavities, and a general origin to the muscular fibres of both auricles.

In the dog the heart within its pericardium is slung above and below by fibrous cords, which allow considerable displacement of the organ. In man the pericardium is suspended above by the stout cords of the deep cervical fascia; below it is attached to the central tendon of the diaphragm, in such a way as to form a triangular box of considerable strength and rigidity. In this box the heart is slung. Almost all lateral movement of the heart is thereby prevented, and since the central tendon of the diaphragm is a fixed point,² the heart likewise cannot descend. This fixation of the pericardium is a striking characteristic of the human body, and its evolution in man can be traced to the assumption of the erect posture.

By means of a special mechanical contrivance (Fig. 27, p. 39), Roy and Adami³ have measured the approximation of any two given points on the exposed heart during systole. They determined that if two lines be drawn parallel either to the intraventricular furrow or the auriculo-ventricular groove, these lines approximate in systole. Therefore the exposed heart shortens both in its longitudinal and transverse diameters.

It is agreed by nearly all observers that the apex does not move up to the base, but the base moves down towards the apex. The latter remains practically a fixed point. The explanation of this fact is partly to be found in the recoil of the heart. When the blood is shot out into the aorta, the heart "kicks back" like a gun on its discharge. The momentum of recoil equals the momentum of output. Thus the heart is jerked downwards with considerable force, and at the dead point there must be a slight pause before it returns. If the veins which feed the heart be ligatured, this recoil fails to take place, and the base does not move towards the apex.⁴

The recoil is probably not the whole explanation of the descent of the base. The aorta and pulmonary artery as they leave the heart form a spiral figure; the blood thrown into them on systole not only extends these arteries but partly undoes the spiral. This may contribute to the descent of the base.

The middle muscular layers of the heart are called by Krehl⁵ the

driving mechanism. These fibres run in circles and almost transversely round the ventricles, forming, when separated from the rest of the musculature, a cylinder open above and below. The external layer of muscle arises from the auriculo-ventricular groove, runs obliquely down the ventricle, and turns in at the apical whorl; thence the fibres ascend in the internal layer to be inserted once more into the auriculo-ventricular fibrous septum. These hook-shaped fibres shorten the cavity of the ventricle, while the middle circular layers compress it. The papillary muscles and the columnæ carneæ shorten, approximate, and at length come into close contact, pressed together by the contraction of the circular layer. Thus the many-celled structure of the lower part of the ventricular cavity contracts, driving the blood out of its meshes, and finally disappears, being replaced by solidified and thickened walls.

Harvey noticed this point. He writes: "Not only are the ventricles contracted in virtue of the direction and condensation of the walls, but further, that those fibres or bands, styled nerves by Aristotle, which are so conspicuous in the ventricles of the lower animals, and contain all the straight fibres (the parietes of the heart containing only circular ones) when they contract simultaneously by an admirable adjustment, all the internal surfaces are drawn together as if with cords, and so is the charge of blood expelled with force."¹

In consequence of the packing together and thickening of the papillary muscles and fleshy columns during the systole, the extent of the contraction of the muscular walls required to empty the cavity is materially lessened, and their expulsive force is thereby economised. The papillary muscles and columnæ carneæ fill up the whole interior of the ventricle, with the exception of the small conical space situated just behind the septum, and in the direction of the aortic opening. Blood is left in contact with the auriculo-ventricular valves up to the end of systole, and thus their closure is maintained. The contraction of the ventricle proceeds in a twisting manner; the blood is as it were wrung out of the cavity, and with a current that naturally takes the spiral direction of the spring and arch of the aorta.

In the region of the aortic opening, the internal surface is perfectly smooth, and offers a free passage to the exit of the blood. In the right ventricle the conus arteriosus is also free from the presence of muscili pectinati, and a space is left therein which is never completely emptied of blood, although the conus arteriosus is shortened by its longitudinal, and contracted by its transverse fibres. In each systole the diastolic swelling of the conus disappears, and its long axis shortens. In the right ventricle muscular bands cross the cavity, act as stays or "braces,"² and prevent its over-distension. The muscili papillares and chordæ tendineæ also take the part of stays in both cavities. The community of the musculature determines the synchronism of the two ventricles. The researches of Chauveau and Marey³ on the heart of the horse, and of François-Franck⁴ on a case of ectopia cordis in man have yielded records of this synchronism.

THE VALVES OF THE HEART AND THE ACTION OF THE
PAPILLARY MUSCLES.

The auriculo-ventricular valves.—If the auricles be removed from the freshly excised heart of a mammal, and the rest of the organ be gently placed under water, these valves immediately float upwards and almost close the auriculo-ventricular orifices. This is not due to the specific gravity of the valves, for an excised valve placed in water slowly sinks. The closure of the valves is caused by eddies. In its expanded state the thin and light valve offers a large surface to the action of such eddies.

FIG. 2.—Diagram showing the resultant pull of the papillary muscles.—Ludwig.

as well as by the shortness of the chordæ tendineæ. In diastole the papillary muscles are wide apart, and their tips diverge from one another and point towards the base of the ventricle. Consequently the flaps of the valves are drawn by the cords outwards and downwards, so that the tricuspid orifice is thrown widely open. As the blood flows in from the auricle, the eddies cause the valves to float up and their edges to approach each other. At the end of the auricular systole the flaps are in such a position that complete closure immediately follows, so soon as the ventricular pressure rises to the slightest degree above the auricular pressure. Thus, on systole of the ventricles, the thin edges of the valves are already in apposition, and the valves then shut with such rapidity that in all probability no regurgitation takes place.

From the results gained by manometric observations of the auricular pressure, Krehl¹ concluded that there is no regurgitation into the auricle so long as the conditions of the circulation are normal.

FIG. 3.—Multiconvex upper surface of the closed tricuspid valve.—Krehl.

¹ *Arch. f. Physiol.*, Leipzig, 1889, S. 289.

Fredericq¹ and Porter,² by more delicate methods of investigation, have obtained distinct signs of a slight rise in auricular pressure, which occurs synchronously with the upstroke of the ventricular pressure curve, but this is probably not caused by the regurgitation of blood, but by the ballooning out of the auriculo-ventricular valve.

By plugging the pulmonary orifice with wax, and then directing into the ventricle a stream of water from the height of one foot, Baumgarten³ observed that the auriculo-ventricular valves closed firmly immediately after the cessation of the stream. This results from the pressure exerted on the fluid in the cavity by the elastic rebound of the muscular walls. The result of such an experiment cannot be directly applied as an explanation of the closure of the auriculo-ventricular valves in the living heart, for the filling pressure in the auricle is often extremely slight, and can give origin to but little elastic rebound.

FIG. 4.—Mitral valve. Insertion of the chordæ tendineæ.—Krehl.

As the blood presses equally on either side of the margins of the valves when placed in apposition, these need no great strength, and are in fact exceedingly delicate. The remainder of the valve, on the other hand, bears the full strain of the pressure, and, consequently, is much tougher. The chordæ tendineæ are affixed both to the ventricular surfaces and close to the free edges of the valve flaps. Each flap is supplied with cords from two papillary muscles, and these are situated opposite to each other. The resultant pull of the cords is shown by the direction of the arrow in Fig. 2.⁴

FIG. 5.—Diagram of the chordæ tendineæ.—Krehl.

By the insertion of a finger into the heart of a living horse, Chauveau and Faivre⁵ determined that an elevation of the auriculo-ventricular valves can be felt to take place before the flaps come absolutely into apposition. When closed, the valvular diaphragm appears slightly ballooned out towards

⁵ *Gaz. méd. de Paris*, 1856, p. 410.

the auricle. Above, its surface is multiconvex (Fig. 3), while below it is multiconcave. Beneath the concave surface a quantity of blood is perceptible, which is not expelled by the ventricular systole. The chordæ tendineæ which are inserted on the edges of the flaps are shorter than those attached to the under surface.¹

Hesse² measured the base of the heart in both the state of diastole and in the systole produced by heat-rigor. In the latter state he found the diameter of the base of the heart was much diminished.

If this diminution takes place in the systole of the living heart, it must not only aid in the closing of the auriculo-ventricular orifice, but must increase the sacculation of the valvular diaphragm. Chauveau³ was, however, by the insertion of his fingers in the heart of the horse, not able to detect any very great diminution of the basal diameter. Sibson⁴ has likewise denied any marked diminution of the diameter of the auriculo-ventricular orifice.

The condition of heat-rigor produced by Hesse is very different to that which obtains in the normal systole, and the observations on the living heart must be accepted as of far greater worth.

Many views have been held as to the action of the papillary muscles. Among such are the following:—

1. That they approximate the flaps of the valves and aid in their closure;

2. That they open the valves, because they are the last to receive the wave of contraction, and therefore continue to shorten after the rest of the ventricle has passed into diastole;

3. That synchronously with the systole of the ventricle they contract, and, in proportion as the longitudinal axis of the ventricular cavity shortens, pull in the slack chordæ tendineæ, and thus prevent the valves from being forced too far into the auricles.

An attempt has been made by Roy and Adami to record the time of action of the papillary muscles, by passing a wire hook through the auricle, and this they hooked on to a flap of the mitral valve. The hook they connected to their myocardiograph (see p. 39). The contraction of the ventricular wall was simultaneously recorded. From the records thus obtained, these authors concluded that the contraction of the papillary muscles began later and ended earlier than that of the ventricular wall, and in the proportion of 5 to 8.⁵ The movement of the flap of the valve is rapid at first, and afterwards reaches a maximum somewhat slowly; this maximum is maintained for a brief space, and is followed by a sudden relaxation.

Fenwick and Overend,⁶ Haycraft and Paterson,⁷ have directly recorded the contraction of the papillary muscles in the excised heart. In order to effect this, the heart is with the greatest rapidity cut out and laid open, the base of a papillary muscle is then pinned down to the table, while hooks are attached to the apex of the muscle, and to the ventricular wall. These hooks are connected by threads to writing

levers. The first two observers found that the contraction of the papillary muscles occurred very shortly after that of the ventricular wall; by Haycraft and Paterson the contraction in vigorous hearts was found to be synchronous with that of the ventricular wall, while it subsequently became later when the rhythm of the heart began to fail.

Roy and Adami's method is not free from fallacy. The movements of the hook and lever connected with the valve cannot correspond exactly to the contraction and relaxation of the papillary muscles. For until the pull of these muscles on the auriculo-ventricular valve becomes of such a strength that it surpasses the difference in pressure between the auricle and ventricle, the flaps will not move in either direction. Roy and Adami found that the first effect of the contraction of the ventricle is to push the valvular diaphragm towards the auricle. The reverse movement does not necessarily mark the beginning of the contraction of the papillary muscles, but marks the moment when the pull of these muscles becomes greater than the intraventricular pressure. Likewise, the fall of Roy and Adami's curve does not mark the end of the contraction of the papillary muscles, but the time when the intraventricular pressure has become higher than the tension exerted by those muscles. The variations, then, in Roy and Adami's curves must be referred not only to the contraction of the papillary muscles, but also to the changes in intracardiac pressure.

The most reasonable view to hold is that the papillary muscles contract synchronously with the ventricular wall, for the rate of propagation of the contraction wave in the heart is so fast, reaching 5 metres a second or more, that, for all practical purposes, we may say that the contraction of the whole ventricle is synchronous. Thus, in the rabbit's heart, beating 180 times in a minute, each complete cardiac cycle occupies $\frac{1}{3}$ second. The ventricular systole occupies about $\frac{1}{3}$ of that time, that is $\frac{1}{9}$ second. The length of the ventricle is some 20 mm., the rate of propagation of the contraction wave can be taken as 5000 mm. a second. The whole ventricle would therefore have passed into systole in $\frac{1}{250}$ second, while it continues in systole for $\frac{1}{9}$ second. Considering that the papillary muscles are in direct continuity with the general musculature of the heart, it is difficult to conceive how the wave of contractility could be delayed from reaching these muscles, even for so long as $\frac{1}{250}$ second in the rabbit. The records of the action current of the heart, obtained with the capillary electrometer, suggest no such delay as is found by Roy and Adami.

It has been stated that the mitral valve closes much more perfectly than the tricuspid valve, and that, therefore, considerable regurgitation can take place through the latter when the right heart is over-distended.¹

The normal heart must be greatly distended before actual regurgitation takes place past any of the valves. The perfect structure of the valves effectually prevents this. A back effect, causing a congestion of the blood in the venous system, can be brought about quite simply and without the aid of systolic regurgitation. The heart fails to empty its cavities at each systole, and thus the diastolic pressure is increased at a time when the valves are naturally open. The blood does not regurgitate during systole, but at each diastole the veins are unable to empty their full quota of blood into the ventricle, for the ventricular cavity is already partially filled. On asphyxiating a curarised animal, regurgitation from the right ventricle is

¹ Flint, "Physiology," 1866, p. 201.

found to take place only in the final stage, when the arterial pressure is falling to zero.

In pathological conditions of hypertrophy and dilatation of the heart, due to a prolonged continuance of obstruction in the pulmonary circulation or in the orifices of the heart, regurgitation takes place, and the great veins may then pulsate equally with the arteries.

The semilunar valves.—It was maintained by Burdach¹ that the semilunar valves close at the end of systole, in consequence of their own elasticity. This is at once disproved by the fact that these valves do not assume the closed position when the aorta and ventricle are filled with fluid at the normal aortic pressure. By Weber² the closure was attributed simply to the agency of the aortic pressure at the moment when the ventricle passes into diastole. Since by its systole the ventricle never completely empties itself, there would be, if Weber's hypothesis were true, a column of blood extending through the arterial orifice at the termination of systole, and considerable regurgitation would thus take place before the closure was effected.

Now the curves of intraventricular pressure do not give us the slightest evidence of regurgitation. Some other method of closure must therefore exist. Light is thrown upon this problem by the following experiment.³ A long glass syringe is filled with water containing a fine powder such as lycopodium spores. The syringe is held in the vertical position, and the fluid column is set in motion by a slight upward push given to the piston. The velocity of movement in the axis of the column is double as great as the velocity of the whole column. Close to the wall of the syringe, owing to viscosity, the movement of the fluid is so slow that the lycopodium spores are seen to be here overtaken by the piston. When this happens, an eddy drags the spores back into the axis, they thence mount rapidly to the top of the column, and there by an eddy once more reach the wall of the syringe. At the moment when the piston ceases to move, the column of fluid is divided into an inner core which runs upward with the axial velocity, and an outer mantle, in which the movement is in the opposite direction. It is this centripetal eddy which produces the closure of the valves in the aorta and pulmonary artery. The sinuses of Valsalva are dilatations in which eddies are bound to be produced, and there can be no doubt that these eddies cause the valves to approximate more and more, and finally close them at the instant when the ventricular pressure ceases to be higher than that in the aorta.

It has been suggested that the closure of the valves is likewise aided by the contraction of the longitudinal bands of muscle fibres which spring from the margins of the aortic or pulmonary orifices. These muscular bands are assumed to contract the orifices into cleft-like openings, bringing the segments of the valves almost into apposition at the end of systole.⁴ The eddies in the sinuses of Valsalva complete the work of these muscular bands.

Moens⁵ explained the closure of the semilunar valves in a different manner.

⁵ *Arch. f. d. ges. Physiol.*, Bonn, 1879, Bd. xx. S. 524.

He supposed that the intraventricular negative pressure, which is known to exist, was systolic in time. He believed that the blood, aided by its momentum, was shot out with a velocity which the ventricular wall could not follow. To this fact he ascribed the origin of the negative pressure, which, in its turn, produced the closure of the valves, and that before any regurgitation could take place. This theory is entirely unsupported by the curves of intraventricular pressure.

The position of the semilunar valves during the time of systolic output has been a subject of considerable controversy. An old doctrine of Thebesius was revived by Brücke.¹ He maintained that the valves swing back against, and close, the orifices of the coronary arteries during the systolic period. Thus, he taught, the heart is only fed with blood during diastole. While, in systole, the want of blood brings the contraction to a close, the re-entry of blood in diastole leads to the expansion of the heart.

The publication of this doctrine led to a fierce discussion, but Brücke defended his position with such brilliancy and wealth of argumentative resource, that for a time his theory was accepted by most of the schools. Meanwhile, several anatomists chronicled cases in which the valves were not sufficiently large to cover the coronary orifices, and in these no abnormality of the heart had been observed during life. Chauveau and Rebatel² finally overthrew Brücke's theory by simultaneously measuring the velocity and the pressure in the coronary artery. The former was recorded by means of Chauveau's instrument, the hæmodromograph (see "Velocity of Flow," p. 85).

At the beginning of systole the velocity and pressure in the coronary arteries increase; later, the velocity becomes negative, and the pressure rises, or, in other words, the blood begins to flow in the reverse direction back to the aorta. At this stage the ventricular wall is so strongly contracted that the muscular tension rises above that of the aorta; the coronary arteries and their tributaries are therefore compressed, and the blood driven back into the aorta. In the final stage, when the diastole is commencing, the velocity once more increases.

By Newell Martin and Sedgwick³ the pressures in the coronary artery and the aorta were synchronously recorded. They found that the coronary tracing was always a duplicate of that of the aorta.

We may conclude, then, that the coronary arteries are not closed by the valves, but that the cardiac vessels are compressed within the muscle, and emptied back towards the aorta. This is confirmed by experiments of Klug,⁴ who ligatured the base of the heart in the period of systole, and again in the period of diastole. In the systolic heart the vessels within the deeper layers of the musculature were found to be emptied of blood. Injection of the coronary arteries with fluid at the pressure of the aorta having been found to produce a negative pressure in the cavity of the ventricles, we must admit the truth of part of Brücke's hypothesis. Each systole does partially cut off the heart muscle from its blood supply, and at each diastole the injection of the coronary arteries does aid in the dilatation of the heart.

⁴ *Centralbl. f. d. med. Wissensch.*, Berlin, 1876, S. 133.

But both these conditions are brought about by a method entirely different from that supposed by Brücke. The sinuses of Valsalva have been evolved for the attainment of two objects. The first of these is the prevention of the semilunar valves swinging back so as to adhere to the wall of the artery; the second is the provocation of eddies which close the valves at the instant systole ceases. Ceradini¹ has experimentally determined that, when fluid is suddenly driven from the ventricle into the pulmonary orifice, the valves do not swing back against the wall of the sinuses.

THE CHANGES OF PRESSURE IN THE HEART DURING THE CARDIAC CYCLE.

Method.—Dissatisfied with the differences of opinion arising from the mere personal observation of the sequence of events in the cardiac cycle, Chauveau and Marey² explored the intracardiac pressure. For

FIG. 6.—Intracardiac pressure curves.—Chauveau and Marey.

this purpose they invented a special instrument, the cardiac sound or sphygmoscope, by which the variations of pressure in one or other chamber of the heart could be recorded.

The sound consisted of a hollow metal tube, of such a bore that it could be easily passed down the jugular vein or carotid artery of the horse. At one end of the tube was a wire framework, over which was drawn a thin rubber bag. This end was passed into a cavity of the heart, and the other end was put in connection with a recording tambour. The rubber bag transmitted the changes of pressure in the heart to the recording tambour, and was at the same time, by means of the framework, prevented from completely collapsing.

In some experiments, Chauveau and Marey employed a byway sound, consisting of a double tube and two bags. When this was passed down the jugular vein, one bag was so situated as to lie in the right auricle, and the other in the right ventricle. Each tube of the byway sound passed to a recording tambour, and the levers connected with each tambour wrote exactly beneath one another, and thus the auricular and ventricular pressures were simultaneously recorded on a revolving drum. These records can be taken while the horse quietly eats at its manger, oblivious of the instrument within its heart.

These and similar instruments are experimentally calibrated against the readings of a mercury manometer.³

Many investigators have followed in the steps of Chauveau and Marey. Magini and Rolleston passed hollow trocars directly through the thorax into the cavities of the heart, while Fick, Hürthle, Fredericq, v. Frey, Krehl, and others, have passed cannulas down the jugular

¹ *Loc. cit.*, S. 60.

² *Mém. Acad. de méd.*, Paris, 1863, tome xxvi. p. 272.

³ Marey, "Circulation du sang," Fig. 45, p. 111.

vein and carotid artery, or directly through the auricular appendix into the heart. These tubes have, in each case, been connected with manometers of special construction, and all more or less adapted to the recording of rapid changes of pressure. None of these methods materially interfere with the circulation. After the introduction of such tubes, the sounds of the heart remain the same as before.¹ Hürthle has shown that the curve given by the cardiac impulse also remains unaltered.² Even if a semilunar valve be punctured during the passing of a tube down the carotid, no harm results, since the tube fills the hole it has made, the valves remain otherwise competent, and the pressure curves are unaltered.

The truth of the records obtained depends entirely on the perfection of the registering apparatus employed. Chauveau and Marey did not give any proofs of the capabilities of their instrument, and the accuracy of their curves. These authors used air transmission, and thus, no doubt, most rapid variations of pressure could be conducted to the recording tambours. Donders³ has since proved that a sensitive Marey tambour gives readings of considerable accuracy, although the lever has a swing of its own, due to the momentum of its mass, which in rapid variations of pressure tends to make the excursions too great.

It is an extremely difficult problem to contrive a manometer which will answer, without much inertia, to extremely quick changes of intraventricular pressure. A mercury manometer is useless, because of the momentum of its mass. Thus this instrument gives a lower reading of intraventricular pressure than of aortic pressure, simply because it has not time to follow the rise of intraventricular pressure. Such a result is, of course, absurd.

FIG. 7.—Fick's straight spring manometer.

The manometer must, in all its moving parts, be made of the smallest mass, and the object in hand is best attained by the use of some form of elastic counterpoise to resist the moving part of the instrument. Fick's straight spring manometer, in which air is employed as the agent of transmission, satisfies most of the conditions required.⁴

It consists of a tube *a a*, which opens into a very small chamber, the floor of which is formed by a rubber membrane. In the middle of this membrane is fixed an ivory knob, which presses against a strong steel spring *f*. The exceedingly small movements of this spring are greatly magnified by the long lever *h*. This instrument has been proved to be accurate by the following experiment.

¹ Chauveau and Marey, *loc. cit.*, p. 301.

² *Arch. f. d. ges. Physiol.*, Bonn, 1891, Bd. xlix. S. 93.

³ *Onderzoek. ged. in h. physiol. Lab. Utrecht*, Hoogesch., Tweede Reeks, 1867, vol. i. pp. 11-18.

⁴ Fick, *Arch. f. d. ges. Physiol.*, Bonn, 1883, Bd. xxx. S. 597. v. Frey's tonometer is constructed essentially on the same principle, air being used as the medium of transmission.

By means of a cannula a pressure record is taken in the left ventricle, the cannula is then pulled out into the aorta, and another record taken. The two readings thus obtained closely tally. As the intraventricular pressure rises about 160 mm. Hg in one second, this instrument can record a variation of pressure equal to 1600 mm. Hg per second, without either shooting on too far or lagging behind.

Hürthle's¹ spring manometer consists of a small tambour, covered with a rubber membrane only 5.5 mm. in diameter. A button attached to the membrane works against a steel spring, which acts as a counterpoise. The movement of the spring is magnified and recorded by means of a lever provided with a writing-style. Fluid is used as the transmission agent, and the great principle of the instrument is the reduction of this fluid to the smallest amount. The use of a practically incompressible fluid, as a medium of transmission, is open to one objection. Once set in motion, the fluid column, extending from the ventricle to the manometer, after the original force has ceased to act upon it, still continues to move. The degree of this inertia is known to be proportional to the mass and the square of velocity of the fluid. In a properly constructed manometer, the smallest mass of fluid practicable must enter for a given increase of pressure. The practical limit is reached somewhat before this mass becomes so small that its movements are appreciably affected by the friction of the lever, or, above all, by the friction of the writing point against the smoked paper.² The Hürthle tambour is therefore made of the smallest dimensions, and the swing of the instrument is further capable of being damped down by the partial turning of a stopcock, placed between the tambour and the artery, which increases the friction of the fluid, and so diminishes its velocity. This stopcock is turned until a point is experimentally found where the inertia is removed with as little sacrifice as possible of the speed of the instrument in following the changes of pressure. When the stopcock is fully open, and the instrument undamped, the Hürthle manometer is found to record changes of pressure equal to 200 mm. Hg in .02 second. This is equivalent to 10,000 mm. Hg per second.

FIG. 8.—Goltz and Gaule's combined maximal, B, and minimal manometer, A, as modified by Hürthle.⁴

Goltz and Gaule contrived another and valuable instrument, the maximum and minimum manometer, by which can be recorded the highest or lowest pressure occurring during a lengthened period of observation in any chamber of the heart.³ This is effected by placing valves between the intracardial cannula and the mercury manometers, and then, according to the direction of the valves, the manometer becomes a maximal or minimal instrument.

A simple form of valve can be constructed in any laboratory out of a tube formed of thick glass, ground to a slant at one end, and brought to a perfectly smooth surface. The orifice of the tube at this end is 1 mm. in diameter. Over this is affixed a flap of oil-silk, which forms an efficient and

simple valve. An instrument so constructed is shown in Fig. 8. If C be placed in connection with the intracardiac cannula, A acts as a minimal, and B as a maximal manometer.

Using Hürthle's spring manometer in conjunction with maximal and minimal manometers, we can arrive at the true changes of intracardiac pressure, for the first will give us the time, sign, and velocity, and approximately the amount of the pressure variations, while the last will give us the true maximal and minimal pressures.

The sphygmoscope of Chauveau and Marey, as modified by Fredericq, is

FIG. 9.—Diagram of Fredericq's sphygmoscope. *a*, cannula; *b*, rubber finger stall; *c*, cork; *d*, lever of tambour.

FIG. 10.—Diagram of v. Basch's hollow spring manometer. The index records the pressure on a graduated scale. A recording style can be affixed to the end of the hollow C-spring.

probably as perfect an instrument as the Hürthle manometer, and is far simpler in construction.¹

The end of a rubber finger-stall is drawn over the end of a rubber cork, and a glass tube connected with the intracardiac cannula passes through the rubber cork into a very small air space, which is left beneath the apex of the finger-stall at the top of the cork. The cork is inserted into the end of a glass thistle-shaped funnel, and this is in its turn connected with a delicate Marey tambour. Every part of the instrument is reduced to the smallest

FIG. 11.—Hürthle's differential manometer.

dimensions, and the rubber tip of the finger-stall acts as an elastic counterpoise to the variations of pressure.

One of the most convenient forms of manometer for accurate work is that of v. Basch, who has constructed a C-spring manometer on the smallest possible scale. The advantages of this instrument are, that a permanent hollow spring replaces a tambour covered with a perishable rubber membrane,

¹ Fredericq, "Manipulations de physiologie," Paris, 1892, p. 174.

and that the pressure height can be read off directly on a dial, while the pressure curve is simultaneously recorded.¹

For the determination of the relations of the pressure changes in any two cavities, Hürthle has constructed a differential spring manometer. In this instrument two cannulæ are brought into connection with tambours placed on either side of the fulcrum of a lever. This lever works against a spring, which sets in motion a writing-style. When the pressures are equal, the style will remain at rest, and will rise or descend according as the pressure in the one rises above or falls below that of the other.²

The curve of intraventricular pressure.—The tracings of Chauveau and Marey, Fick, Hürthle, Fredericq, all exhibit a curve which is marked by a very steep ascent, followed by a maintained plateau which either rises or falls slightly, or remains horizontal. On this plateau occur two or three small waves; thence follows the steep line of descent.³

The curves obtained by v. Frey and Krehl, Rolleston, Roy and Adami are of a different type: these show either no plateau, or else a kind of rounded plateau which subsides quickly into the descent.

The differences in the curves depend almost entirely on the instruments employed, because all the researches have been carried out on dogs, except those of Chauveau and Marey on the horse. The best instrument, as we have seen, is that with the shortest delay, so long as the inertia of the instrument is not too great.

Contejean has passed a hollow needle into the right ventricle, and allowed the blood to spirt on to a revolving drum covered with white paper; in this way he has obtained a hæmautograph of the intraventricular pressure. A plateau is found on such a tracing.⁴

Lastly, Bayliss and Starling have demonstrated the accuracy of the plateau curves by a new method. They connected the intracardiac cannula with a capillary glass tube, which had been partially filled with $MgSO_4$ solution, and had then been sealed at the top. They photographed on a moving sensitized plate the movements of the meniscus of the fluid in the capillary tube. At the same time the movements of a style affixed to a vibrating tuning-fork were also photographed.

Within the rates of pressure variations which occur in the heart, the inertia of the fluid was found to be nil, while the volume of fluid moved for a rise of 100 mm. Hg pressure was only 0.335 c.mm. In Hürthle's smallest manometer, this volume for the same rise of pressure was 100 c.mm.⁵ This method is therefore by far the most perfect yet invented for arriving at the true curve and time relations of intracardiac pressure. Unfortunately, it is too inconvenient to employ habitually. By its means, however, we are assured that the Hürthle manometer and the sphygmoscope are instruments of precision.⁶

The curves obtained by Bayliss and Starling are no doubt a true representation of the intraventricular pressure changes, and it is

¹ *Centralbl. f. Physiol.*, Leipzig u. Wien, 1896, Bd. x. S. 330.

evident, on comparison, that the original tracings obtained by Chauveau and Marey (Fig. 6) also nearly represent these.

The small waves which are seen on the top of the plateau have been explained in several ways. They have been attributed to the vibrations of the auriculo-ventricular valves. By Marey they were ascribed to

FIG. 12.—Intra-ventricular pressure curve.—Bayliss and Starling.

waves set up in the large arteries during the systolic output. He supposed that these waves passed back into the ventricle, and were reflected from the ventricular wall and auriculo-ventricular valves. It is highly probable that such vibrations would be produced by the sudden tension of such an elastic system as is formed by the heart and large arteries. Tigerstedt¹ and Porter² have attributed the waves to the swing of the instruments employed. Fredericq,³ d'Espine,⁴ and Stefani⁵ have ascribed them to three successive muscular contractions of the

FIG. 13.—Aortic pressure curve.—Bayliss and Starling.

ventricle. This is a far-fetched explanation, and is controverted by the curves of the negative variation of the heart, obtained with the capillary electrometer by Waller, Bayliss and Starling, and others.

The plateau and its wavelets are only obtained when the ventricle is filled with blood, and are not seen on curves of contraction obtained from the empty ventricle.⁶ It is to be concluded that the plateau is the sign of the sustained tension on the blood by the ventricle wall during the systolic output, and that the wavelets are due to vibrations set up in the elastic circulatory system by the sudden systolic increase of tension.

The period of rising tension.—Part of the period of ventricular systole is spent in raising the tension of the blood up to and above that in the aorta.

During this period all the valves in the ventricle remain closed, and the capacity of the ventricular cavity does not vary. The muscle bands

on the outside of the ventricle assume the shortest position which is possible without change of the cavity, and therefore the external form of the ventricle becomes more spherical in shape. As the tension rises higher, the blood in the coronary vessels becomes more and more expelled from the musculature of the heart. Chauveau and Marey took synchronous curves of the intraventricular and aortic pressures. They found the rise of aortic pressure occurred .1 sec. later than the beginning of the systolic curve.¹

This, therefore, was the period of rising tension in the horse. The whole ventricular contraction, up to the point of steep descent at the end of the plateau, covered a period of .4 sec.

With improved apparatus Hürthle found the time of rising tension to be considerably shorter; in the dog it was .02 to .04 sec.²

If the aortic pressure be very low this period becomes even shorter. When the aortic pressure was high, Hürthle found no constant relation between the height of the pressure and the duration of the

FIG. 14.—A, aortic, and V, intraventricular pressure curves; O, abscissa; S, time trace = $\frac{1}{100}$ sec.; 0-5, corresponding ordinates.—Hürthle.

period of rising tension. On taking measurements of the difference between the diastolic pressure in the ventricle and the aortic pressure, Hürthle determined that with a pressure difference of 58 to 60 mm. Hg, the period of rising tension was .017 sec., while it was .03 sec. with a pressure difference of 111 mm. Hg. The variations of the period of rising extension are therefore most insignificant, and remain so even when the rhythm of the heart is altered by section of the vagi or excitation of the accelerator nerves. This is equivalent to saying that the heart can meet great demands on its powers, without any appreciable loss of time.

The period of systolic output.—With what smoothness the cardiac mechanism works is strikingly evidenced by the fact that neither the opening nor closing of the valves produces any peak or point on the curves of intracardiac pressure. Similarly, the ventricle fills from the auricle so smoothly, that the auricular systole is scarcely marked on the intraventricular pressure curve.

The point on the intraventricular pressure curve at which the semilunar valves shut, has been a subject of much discussion. The moment when the second sound of the heart is heard has been marked with a signal on tracings of such curves, and this, after

¹ Chauveau and Marey, *Mém. Acad. de méd.*, Paris, 1863, tome xxvi. p. 305.

² *Arch. f. d. ges. Physiol.*, Bonn, 1891, Bd. xlix. S. 59.

deduction of the observer's reaction time, has been taken as the point of closure.

The second sound, however, is not produced by the closure itself, but by the tension of the valves which follows the closure, some fraction of a second later. The closure takes place at the moment when the ventricular pressure falls to the slightest degree below the aortic pressure.

By Hürthle, the differential manometer¹ was employed to settle the moment. A byway cannula was passed into the aorta and ventricle, and the time marked on the intraventricular pressure curve when the aortic pressure surpassed the ventricular pressure.² The aortic and ventricular pressure curves are taken simultaneously with the differential curve by means of Y tubes. The point found corresponds in time

FIG. 15.—A, aortic; D, differential; V, ventricular pressure.—Hürthle.

with the bottom of the dicrotic notch on the aortic curve, and is at the end of the plateau (Fig. 15, 3). Fredericq, Porter, and Starling and Bayliss agree with this conclusion.

Chauveau and Marey placed the closure much lower down on the descending limb of the curve, at a point where a notch occurs in the descent.³ Chauveau has recently attempted to confirm this conclusion by an ingenious experiment. He passed a byway sound down the carotid of the horse, until one ampulla lay in the aorta, and the other in the ventricle. At the seat of the semilunar valves, an electric contact was fixed to the sound; the contact was made by the closure of the valve, and a signal wrote the moment of contact on the tracing.⁴ It is most probable, however, that the contact would be made, not by the closure, but by the tension of the valves, for a certain amount of pressure would probably be required to effect the contact.

The differential manometer also shows the moment when the intraventricular pressure overtops the aortic pressure, and the semilunar valves open (Fig. 15, 1). This moment is found to be a little below the

¹ See p. 18 and Fig. 11, p. 17.

² *Arch. f. d. ges. Physiol.*, Bonn, Bd. xlix. S. 54.

³ *Mém. Acad. de méd.*, Paris, 1863, tome xxvi. p. 298.

⁴ *Compt. rend. Acad. d. sc.*, Paris, tome cxviii. pp. 686, 690.

middle of the ascending limb of the ventricular curve. The period of systolic output extends from the opening to the closure of the semi-lunar valves, and that is the period during which the ventricular pressure is higher in the differential tracing (Fig. 15, 1 to 3). This time of output, according to Hürthle, is from .178 to .195 sec. in the dog, and is, as already stated, but slightly altered either by variations in aortic pressure or in the frequency of the heart.

The maximal pressure in the ventricles.—By means of their graduated cardiac sounds Chauveau and Marey¹ reckoned the maximal pressure in the right ventricle of the horse to be 24 to 30 mm. Hg; in the left ventricle 95 to 140 mm. Hg. With the maximal manometer, Goltz and Gaule found the pressure in the dog to be—

Right ventricle,	:	:	:	:	35-62 mm. Hg.
Left	"	:	:	:	114-135 "

de Jager² employed a maximal manometer, but lessened the resistance by using large cannulæ. He measured the maximum in the ventricle, and then, after pulling the cannula out into the aorta, immediately measured the aortic maximum. The results recorded were—

Left ventricle,	:	:	:	:	150-234 mm. Hg.
Aorta,	:	:	:	:	156-216 "
Right ventricle,	:	:	:	:	26-72 "

These results were obtained during morphia narcosis, and are perhaps too high. The relation of the right to the left ventricular maximum is therefore from 1:3 to 1:6. This agrees closely with the relation found between the pulmonary arterial and the aortic pressures. Thus by Beutner³ this was found to be 1:3 in dogs, 1:5 in cats, 1:4 in rabbits, and by Colin,⁴ 1:3 or 1:4.

In order that the systole may be efficient, the intraventricular pressure must rise to a higher point than the aortic pressure. In certain conditions of the heart some of the beats may be inefficient, and so produce no sign on the aortic curve.

After considerable loss of blood, the intraventricular pressure at each systole exceeds the aortic pressure by a comparatively greater amount.

The auricular pressure curve.—The systolic pressure in the auricle reaches its maximum in .1 sec. in the horse, while the ventricular contraction up to the end of the plateau lasts .4 sec. This short duration of the auricular systole found by

FIG. 16.—Auricular pressure curve.—Porter.

Chauveau and Marey has not been confirmed by all observers.⁵

The pressure curve of the auricle has been obtained by the same instruments as were employed for ventricular observations. The tracings obtained by Chauveau, Marey, and Fredericq with the sphygmoscope, and

by Porter with the Hürthle manometer, agree fairly closely in the main outlines.

By means of a large cannula placed in the auricular appendix, and connected with a Hürthle tambour, Porter¹ took curves (Fig. 16), in which the following points are to be observed:—

A,	The systolic rise of the auricular pressure =	+ 9	mm. Hg.
A.B,	A first diastolic fall		
B.C,	A first diastolic rise	= + 5	„
C.D,	A second diastolic fall	= - 10	„
E,	A second diastolic rise	= + 5	„
F,	A third diastolic fall	= + 0·5	„
G,	A period of no pressure.		

Upon the second curve given in the figure the following relations are marked:—

1. Beginning of the auricular systole.
2. Beginning of ventricular systole.
3. Opening of semilunar valves.
4. The plateau stage of the ventricular systole.
5. Beginning of ventricular downstroke.
6. End of ventricular downstroke.

A considerable negative pressure appears in the auricle during the height of the ventricular systole (Fig. 16, D, 4), a negative pressure which must materially aid in the filling of the auricle. This is given as follows:—

Chauveau and Marey	- 2 to - 33	mm. Hg.
Goltz and Gaule	. - 7 to - 10·4	„
Porter	. . . - 10	„

By Chauveau and Marey the phenomenon was explained by the supposition that the descent of the base of the ventricle during systole pulls on the auricular wall, and thus dilates the auricular cavity. This is scarcely probable, as the auricle is free to move as a whole, and would therefore follow the ventricle. v. Frey, Krehl, and Fredericq suggest a different explanation. During the ventricular systole, the ventricles, by the expulsion of blood, become smaller; by their diminution the negative pressure in the thorax is increased, and thus the auricles, large veins, and lungs are dilated. So long, therefore, as the thorax is closed, the heart can act in this way, not only as a force pump, but also as a suction pump. Each systole of the ventricles helps to fill the auricles. Porter has further put forward an ingenious theory to explain the second diastolic fall. He supposes that when the papillary muscles contract they pull down like a diaphragm the auriculo-ventricular valves, which are closed and ballooned out towards the ventricular cavity. Thus the cavity of the auricle is increased. The commencement of the second diastolic fall agrees closely with the beginning of the downward movement of the valves, as determined by Roy and Adami in their research on the papillary muscles (see p. 10 and p. 39).

Probably this, the most important fall in the auricular pressure, is produced, not by one only, but by both of these factors combined. With an increasing frequency of heart-beat, Porter has found that the

¹ *Journ. Physiol.*, Cambridge and London, 1892, vol. xiii. p. 518.

period of the second diastolic fall, like the period of ventricular systole, remains almost constant. The second diastolic rise, E (Fig. 16),

 D, Aortic pressure curve.

The corresponding times are marked by ordinates, thus—
 ORDINATE 2. The pressure in the auricle and ventricle is equal. An instant later the pressure is higher in the ventricle, and the auriculo-ventricular valves close.
 " 3. There is marked here the beginning of the aortic rise, that is to say, the moment when the semilunar valves open.
 " 4. This marks the bottom of the dicrotic notch. At this point the semilunar valves close.
 " 5. The auricular and ventricular pressures are again equal, and immediately after the valves open, as the auricular pressure rises above the ventricular.

culo-ventricular valves. Owing to the great capacity of the veins, and the absence of elastic tension of the venous wall, this rise is generally not sufficient to produce a venous pulse.

Observations on the maximal pressure in the auricle has yielded very different results—

Chauveau and Marey	estimated it as 2.5	mm. Hg	in the horse,	right auricle.
Goltz and Gaule	"	20	"	in the dog, "
Magini	"	20-22	"	" "
Porter	"	1-2	"	" left auricle.
v. Frey	"	10	"	" right auricle.

The pressure in the cavities of the heart is undoubtedly subject to great variation. On what conditions these variations depend we have as yet no exact knowledge. There is no reason to doubt the results of the above observers, but further researches into the causes of the variations are obviously needed. The fact of the thorax being opened or closed, the efficiency or inefficiency of the vasomotor tone, the

is no doubt produced by the filling of the auricles from the veins; at the same time, the intraventricular pressure may rise above the tension of the papillary muscles towards the end of the systole, and so again tend to drive the auriculo-ventricular valves out towards the auricular cavity. The third diastolic fall (F) is synchronous with the relaxation of the ventricle, and is due to the flow of blood from the auricle into the ventricle.

The time of the opening and closing of the auriculo-ventricular valves is obtained by taking tracings of the auricular and ventricular pressures, simultaneously with a differential trace recorded by the differential manometer (see Fig. 17).

The first diastolic rise (BC) seen in Porter's auricular curve (Fig. 16) has not been found by all observers. When this rise is obtained, it must be due either to a slight regurgitation or to the ballooning out of the auri-

position of the animal, will all markedly influence the filling pressure of the auricle, and no doubt the maximal auricular pressure depends far more on the filling pressure than on the force of the auricular contraction.

The negative pressure in the heart.—The diastole of the ventricles is apparently performed with considerable energy. It has been maintained, therefore, that the diastole, as well as the systole, results from muscular action. It has been impossible, experimenting upon the frog, to prove the existence of any diastolic force in the excised heart, although Luciani has attempted to do so.¹

Roy and Tunnicliffe found that the intracardiac pressure in the frog must be .5 to 1 cm. H₂O above the extracardiac for diastole to take place.² Tunnicliffe placed the frog-heart in a chamber, in which the extracardiac pressure could be varied. By means of a byway cannula the heart was fed with a nutrient fluid, at a pressure which also could be varied.³ The diastole did not take place unless the pressure in the feeding tube was made positive.

The same conclusion was arrived at by Newell Martin and Donaldson,⁴ with regard to the excised mammalian heart. After placing an inflow tube in the vena cava superior, and an outflow tube in one subclavian artery, Martin ligatured the branches of the arch of the aorta, the thoracic aorta, and the venæ cavæ. All connections of the heart with the general circulation were thus removed. The pulmonary circulation and the coronary circulation still continued, for artificial respiration was maintained in the lungs, while a circulation of defibrinated blood was established through the heart at a constant temperature. Under such conditions the heart continued to beat normally for many hours. These authors concluded that if the aspiration of the thorax be removed, the right auricle will not receive blood, unless it be supplied to it under a decided, if small, positive pressure.

On passing a cannula connected with a manometer into one or other ventricle of the dog, Goltz and Gaule obtained evidence of a considerable negative pressure, which appeared in the ventricular cavities at some period of the cardiac cycle.⁵ In one experiment with the thorax open, these authors obtained a minimal pressure of -23.5 mm. Hg in the left ventricle. In another experiment with the thorax closed, -52 mm. Hg was recorded. The negativity was only marked when the systole was strong, and the heart emptied well. No evidence could be obtained of a negative pressure during the beat of an excised and empty heart. These results were confirmed by de Jager,⁶ who obtained, with the thorax open, the following minimal pressures:—

- 5 to - 38 mm. Hg. in the right ventricle.
- 2 ,, - 6 ,, ,, in the right auricle.

Rolleston⁷ obtained a minimal negative pressure in the left ventricle

equal to -20 mm. Hg. Evidence of negative pressure is found at the end of systole in the intraventricular pressure curves taken by the sphygmoscope and by the Hürthle manometer, or by the method employed by Bayliss and Starling.

The origin of the negative pressure has received many explanations. It has been supposed that by shortening the long diameter of the heart certain longitudinal muscle bands enlarge its cavity, and produce the diastole.¹ It has also been suggested that if the circular fibres continue to contract after the longitudinal fibres have ceased to shorten the ventricle, these fibres will help to extend and dilate the ventricles.² When the output of blood takes place the aortic orifice is distended, and this distension must be shared by the adjacent portions of the ventricle (conus arteriosus).³ Many of the spiral ventricular fibres take origin thence, and it is conceivable that the dilatation of the aorta by the undoing of the spiral of these muscle bands may contribute to the production of diastole.⁴

From the arrangement of the musculature of the heart, it is obvious that a great part of the muscle must be strongly compressed by the contraction of the remainder. The columnæ carneæ will, for example, be driven like so many elastic cushions against one another. So soon as contraction ceases this will lead to an elastic rebound of the walls. Again, in diastole, the walls of the heart become like those of a flaccid bag, and under the influence of gravity fall apart. Thus, if an excised heart be placed in a vessel of water, and be rhythmically squeezed, the fluid can be pumped out from the aorta and pulmonary orifices, for, after each compression, the heart, in consequence of the elastic rebound and the force of gravity, relaxes. Goltz and Gaule obtained, after sudden compression, a negative pressure in the empty heart. This must have been entirely brought about by the elastic rebound, following on the removal of the compressing agent.

The flow of blood in the coronary arteries may be another cause of diastole. Chauveau and Rebatel⁵ have proved that the blood is driven back towards the aorta and out of the coronary system during systole, while the current once more sets into those vessels at the end of systole. It has been demonstrated by Donders⁶ that a high-pressure injection of these arteries in the excised heart produces a negative pressure in the ventricular cavity, and that this pressure by expanding the wall aids in the causation of diastole. In the same way as the distension of a hollow curved and elastic tube opens out the curvature, so the injection of the coronary arteries dilates the heart. If this be the true cause of the negative pressure, some relationship should be found between its amount and the height of the aortic pressure.

Moens urged that the negative pressure is systolic, and not diastolic in time, and endeavoured to explain its origin by the following experiment:⁷—

¹ Spring, *Mém. Acad. roy. de méd. de Belg.*, Bruxelles, 1861, tome xxxiii. p. 78.

⁴ Gaule, *ibid.*, S. 617.

⁵ Rebatel, "Rech. expér. sur la circ. dans les art. coronaires," Thèse de Paris, 1872.

⁶ "Physiol. des Mensch.," 1859, Bd. ii. S. 42.

⁷ *Arch. f. d. ges. Physiol.*, Bonn, 1879, Bd. xx. S. 529.

He attached a rubber bag to a tube and filled it with water. By a second tube the bag was put in connection with a minimum manometer. On strongly compressing the bag, and driving the water out, a negative pressure equal to 80 mm. Hg appeared. This is due to the momentum of the fluid, which escapes more rapidly than the walls of the bag can follow. If this be so in the heart, it is clear that the negative pressure should also be found in the root of the aorta, for the momentum of the blood would carry it on beyond the ventricle. de Jager¹ has controverted this explanation by recording an aortic pressure of 130 mm. Hg occurring at the same instant as a pressure of -36 mm. Hg in the left ventricle. Moreover, in all the curves of intra-ventricular pressure, the negative pressure occurs after the closure of the semilunar valves.

Porter² has investigated this difficult subject by means of his minimum manometer in combination with a Hürthle manometer. The intraventricular cannula was connected by a T-tube to both these instruments. He found that the negative pressure in the left ventricle is sometimes entirely absent; often slight, occasionally great. With the thorax open, in five out of fifteen experiments no negative pressure was observed. In one out of six experiments with the thorax closed there was no sign of a negative pressure. The minimum varied from 0 to -58 mm. Hg. Sometimes, when the heart was beating well and powerfully, no negative pressure was apparent; while, on the other hand, a considerable negative pressure was often present in the left ventricle without any synchronous sign of negative pressure in the left auricle. "So also in the tracing taken by Fredericq of the right auricular pressure, there is no fall below zero synchronous with the period of negative pressure in the right ventricle."³

According to Porter, the negative pressure in the ventricle has no appreciable effect on the filling of the heart. He explains this anomaly on the following grounds:—

The ventricular negative pressure may occur so rapidly and last so short a time that it is almost over before the auriculo-ventricular valves can open. The cavity of the closed and relaxing ventricle need become but a few cubic millimetres larger than its contents, in order to produce a great negative pressure, just as the suction of a very few drops of fluid from the cannula has a great effect on the manometer. If this be so, the entry into the ventricle of the smallest quantity of blood from the auricle, would abolish the negative pressure. As the auricle stands in open connection with the veins, so slight a

O.D. right auricle.

Car. carotid pulse.

In the auricular tracing, *ab* is the auricular systole; *bc* the thrust outwards of the auriculo-ventricular valves, or slight regurgitation of blood at the commencement of ventricular systole; *cd* the negative pressure produced by the contraction of the papillary muscles causing the descent of the floor of the auricle, and by the diminution of the volume of the heart in the systole; *de* the refilling of the auricle from the veins. The coincident points on the carotid tracing are similarly marked. At the point *d*, where the downstroke of intra-ventricular pressure is taking place, the auricular pressure is just beginning to rise.

³ "Trav. du labor. de Liège," 1888, tome ii. p. 116.

suction of blood would have no perceptible effect on the auricular pressure.

There is some evidence of two phases of negative pressure in the ventricle, one very short in duration, appearing very early in diastole, the other pre-systolic in time, and lasting longer. This latter has been ascribed by Chauveau and Marey to the aspiration of the thorax, acting on the heart at a time when the tone of the muscle had decreased. The whole subject of the intraventricular negative pressure is still in obscurity; all that can be said is, that we are certain that a negative pressure usually appears, though we do not know why it is inconstant and variable. We are uncertain whether it has any effect on the filling of the ventricle, and must suppose that its origin is complex, depending, probably, on the elastic rebound of the walls, on the filling of the coronary arteries, and especially on the aspiration of the thorax.

THE HEART SOUNDS.

The existence of these sounds was not concealed from Harvey. He writes: "When there is the delivery of a quantity of blood from the veins to the arteries a pulse takes place, and can be heard within the chest."¹ To Laennec,² the founder of the art of auscultation, is owing the first accurate description of the character of the sounds and their significance in the diagnosis of diseases of the heart. To the ventricular contraction he ascribed the first sound, and the second sound to the auricular contraction. The second sound he aptly compared to the sound produced by a dog lapping water. Laennec's authority remained unquestioned until Turner³ pointed out that the second sound occurred, not at the end but at the beginning of the diastolic pause, and therefore could not derive its origin from the auricular systole. He suggested that the second sound might be caused by the dilatation and suction action of the heart at the end of systole. From then till now the cause of the sounds has been a subject of endless controversy. Dunglison,⁴ in 1856, tabulated the opinions of a large number of authors, showing what an extraordinary amount of discordance has existed upon this matter; nor is there even yet a consensus of opinion on the question. Sandborg, in 1881,⁵ collected as many as forty different theories.

That so many theories should have arisen is not surprising, since so many different phenomena attend each contraction of the heart, any one of which may be capable of producing a sound. The mistake has been that each observer, according to his particular theory, has attributed the sounds to one simple factor, and has failed to recognise that the sounds are in reality not pure tones but are compound in origin. Thus the first sound has been ascribed to the following causes:—

1. The impulse of the heart against the parietes of the thorax.
2. The rush of blood through the narrowed orifice of the aorta and pulmonary artery.
3. The contraction of the muscular wall of the ventricles.

⁴ "Human Physiology," 1856, vol. i. p. 140.

⁵ "Résumé des études sur les bruits du cœur," Christiania, 1881, p. 6.

4. The sudden collision of the ventricular contents with the column of blood in the aorta and pulmonary artery.

5. The sudden tension of the blood caused by a collision of the blood particles in the ventricles.

6. The rub of the heart against the pericardium.

7. The vibration of the chest wall from the sudden rigidity and pressure of the heart.

8. The tension of the auriculo-ventricular valves.

9. The sudden opening and consequent vibration of the semilunar valves.

The first sound.—It was shown by C. J. B. Williams¹ and a committee of the British Association, that the first sound can be heard in the excised heart, and this, even if the auriculo-ventricular valves be held open with the fingers.

Ludwig and Dogiel² listened to the heart, after tying in succession the venæ cavæ, the pulmonary artery and vein, and the aorta. The first sound continued, and seemed to be but slightly altered in character. These experiments entirely overthrow the view that the first sound is of simple valvular origin. The valves can be held back by hooks or by the finger, and neither the papillary muscles, nor any other suggested mechanism, can throw the valves into tension, yet a systolic sound continues.³

Sibson and Broadbent⁴ listened to the exposed heart of the ass and of the dog. They record that the first sound is apparently of equal loudness over the whole ventricle, that it begins and continues with a rumble, and that it ends with an accent or sharp sound, which is coincident with the extreme contraction of the cavity, and with a faint shock felt just then over the ventricle. If the blood be shut off by tying the venæ cavæ, the accent appears to be quite lost and the rumble is materially weakened. The tone of the sound is undoubtedly altered by removing the action of the auricular-ventricular valves, and it has been determined that the sudden throwing into tension of the auriculo-ventricular valves in the dead heart does produce a tone.

The first sound has been by Wintrich⁵ resolved into two tones, one deep and the other high. These are, doubtless, the rumble and the accent described by Sibson. Haycraft⁶ has found that the deeper tone alone persists in the excised heart, while the higher tone can be produced in the dead heart by throwing the auriculo-ventricular valves into tension.

By some authors the first sound has been attributed to the bursting open of the semilunar valves, but any vibration of these valves must be entirely damped down in a fluid which is of almost the same specific gravity as the valve itself. There is no evidence in favour of the view that these valves are suddenly forced open. On the contrary, it is highly probable that they quietly open at

³ Halford has denied the occurrence of any sound in the heart after ligation of the venæ cavæ and pulmonary veins ("The Action and Sounds of the Heart," London, 1860, pp. 25-27).

⁴ Sibson, "Medical Anatomy," 1869, p. 89.

⁵ *Sitzungsb. d. phys.-med. Soc. zu Erlangen*, 1875, Bd. vii. S. 51.

⁶ *Journ. Physiol.*, Cambridge and London, 1890, vol. xi. p. 486.

the moment when the intraventricular tension just rises above the aortic.¹

Although the impulse of the heart is not the principal cause of the first sound, as was maintained by Magendie, yet it may be an auxiliary and occasional cause. The first sound can be heard when the chest wall is removed, and also when, by filling the pericardium with fluid, the heart

FIG. 19.—Diagram of Hürthle's experiment. *M*, microphone; *E*, battery; *In*, induction coil; *S'*, *S''*, keys; *T*, telephone; *g*, frog gastrocnemius; *A'*, cardiograph; *A''*, myograph; *T'*, *T''*, tambours.

is prevented from striking against the stethoscope. If, however, a board be applied to the exposed heart, the first sound is increased in loudness. In quietude and the supine position the impulse is probably of no account, but under the opposite circumstances the first sound may very considerably increase. According to Chauveau and Faivre, the vibrations causing the sounds of the heart can be felt by a finger placed over the region of the valves. Recently the sounds have been successfully recorded by means of the microphone. Hürthle inserted the microphone in the primary circuit of a du Bois Reymond

coil, and placed a frog muscle preparation in connection with the secondary circuit. A lever attached to this muscle marked the moment of excitation, when the sound of the heart reached the microphone, and closed the primary circuit.²

By Einthoven and Geluk³ a similar method was employed, but they registered the effect produced by the sounds on the microphone circuit by means of a capillary electrometer. The movements of the electrometer are photographed on a moving sensitized plate. Holowinski has photographed the sounds by means of the optical telephone invented by Babinet and Fizeau.⁴

That the sounds are compounded of several tones, is shown by the photographs of Einthoven and Geluk. Each sound gives rise to a succession of vibrations of the mercury meniscus. The first sound was found to show itself earlier when the microphone was applied

¹ R. Quain denies either the valvular or muscular origin of the first sound. He ascribes the sound to the impact of the blood against the resistance in the aortic orifices (*Lancet*, London, 1897, vol. i. p. 1672; *Proc. Roy. Soc. London*, 1897, vol. lxi. p. 331), but there are many reasons for regarding this view as an impossible one.

² *Arch. f. d. ges. Physiol.*, Bonn, 1895, Bd. lx. S. 263.

⁴ Holowinski, *Arch. de physiol. norm. et path.*, Paris, 1896, tome xxviii. p. 893.

to the apex, than when it was applied over the region of the arterial orifices.

It is concluded that the first sound is formed of many component tones, and is caused by the sudden tension and vibration of the cardiac muscle, of the auriculo-ventricular valves, and of the blood, and that the sound may be augmented by the stroke of the heart beating against the parietes of the chest. The vibrations which are seen on the plateau of the curve of the intraventricular pressure probably appear as sound vibrations in the curves of the capillary electrometer, such as are obtained by the microphonic method of Einthoven.

The second sound.—Carswell and Rouanet¹ were the first to assert that the second sound of the heart was dependent upon the return shock of the blood against the semilunar valves, when, at the end of systole, the intraventricular pressure falls rapidly below zero and the elastic reaction of the arteries comes into play.

A sound is produced when, in the excised aorta, the semilunar valves are suddenly thrown into tension, and this sound is similar in character to the second sound of the heart. The most satisfactory method of obtaining this result is, after ligaturing all other orifices and placing the

FIG. 20.—Tracing of pulse (P), first (A¹, B¹) and second (A², B²) sounds of the heart.—Einthoven and Geluk.

aorta and valves in a vessel of water, to connect one coronary artery with a pressure bottle. On suddenly opening the tap interposed between the coronary artery and the pressure bottle, the valves are thrown into tension and a sound is heard. A tube connected with the vessel of water is used as a stethoscope.

To C. J. B. Williams² we owe the first and conclusive experiments on the living animal. He noticed that the second sound was suspended on applying pressure over the region of the orifice of the aorta and pulmonary artery, and also when, by laying open the auricles, the heart became emptied of blood. In both cases the first sound continued. Williams further passed an ordinary dissecting-hook into the pulmonary artery, and caught up and hooked back one of the semilunar flaps. The second sound was then changed in character. He next passed a shoemaker's curved awl into the aorta, and hooked back an aortic flap. The sound now gave way to a hissing noise. On withdrawing the hook and awl, the second sound of the heart was again heard, and the hissing ceased. For the purpose of these experiments he used asses, supplied

¹ "Analyse des bruits du cœur," Paris, 1832.

² *Rep. Brit. Ass. Adv. Sc.*, London, 1836, p. 269.

them with artificial respiration, and placed them under curari. The committee of the British Association further record, in their investigations on the causes of the heart sounds, that the second sound disappears when the blood is allowed at each systole to escape—not into the arteries, but through openings made in the ventricles.

The semilunar valves close at that moment when the aortic tension rises the slightest degree higher than the intraventricular pressure; the closure will therefore be effected gently, and will lead to no sound. In the next moment of time the intraventricular pressure rapidly falls below zero, and the valves will be thrown into tension by the back swing of the blood, which is in its turn occasioned by the elastic rebound of the arteries. The question has been raised as to whether it is the vibration of the valves, or the vibration of the column of blood in the arteries, which produces the second sound. Talma¹ experimented with long glass tubes: to the end of each of these he tied the root of the pulmonary artery with its valves. The tubes after being filled with water were held upright. If, now, the valves were pushed upward with the finger, and then suddenly let go, a sound was heard. If, by varying the height of the fluid columns, the tones in any two tubes were made similar, then, on further varying the height of the column of fluid

FIG. 21.—Tracing of sounds of heart from a case of aortic regurgitation.—Einthoven and Geluk.

in one tube, the tone was found to vary relatively to the height. On these grounds, Talma attributed the sound to the vibration of the column of fluid. These experiments were repeated by Webster,² who, in place of the pulmonary valves, employed bladders. He found that if the height of the column of blood were kept constant, the tone varied with the thickness of the bladder. Thus the sound consists of tones produced by the vibration of the membrane, and of others dependent on the vibration of the column of fluid.

The photographic method of Einthoven makes apparent the exact time relations of the second sound (see Fig. 20).

It is highly interesting to note the change in the curve of the second sound, resultant on the valves being rendered incompetent. The vibrations are seen to be much more numerous, and to last over a far longer period. In Fig. 21 we see, for the first time recorded by the graphic method, those vibrations which produce a regurgitant murmur. The conclusion reached in regard to the second sound is therefore that it is not simple in origin, but is a sound compounded of two or more tones. These constituent tones arise from vibrations

¹ *Arch. f. d. ges. Physiol.*, Bonn, 1880, Bd. xxiii. S. 275.

² *Journ. Physiol.*, Cambridge and London, 1882, vol. iii. p. 294.

of the valves, thrown after closure into sudden tension, from the vibrations of the blood columns in the multitudinous branches of the arteries, and from vibrations of the arterial walls. Although both the first and second sounds are double in origin, yet the constituent sounds are normally so far synchronous as not to be separable by the ear.

Hæmic murmurs.—Experimenting on the flow of fluids through tubes of glass, thin rubber, and intestines and arteries of animals, Nicolls found that even with velocities much greater than that of the blood-flow, it is impossible to produce sounds in a moving liquid, so long as it is free from air, no matter what dilatations or contractions occur in the pipes. Hence he concludes that hæmic murmurs, such as are heard over the pulmonary artery in cases of oligocythæmia, are produced like vocal sounds, by the vibrations of elastic substances. Likewise the sounds of the heart are produced in all cases by membranous vibration, and not by fluid friction, as the velocity is too small to produce audible sounds by this means.¹

THE CARDIAC IMPULSE.

Synchronously with the systole of the ventricles, the chest wall receives a blow from the heart, at the point where the mass of the ventricle comes in contact with the parietes.

The position of the impulse varies considerably with the position of the body. Although it is generally stated that the cardiac impulse is normally visible in the fifth left intercostal space, 2 in. below the nipple, and $1\frac{1}{2}$ in. to its sternal side, yet in 67 per cent. of men it is stated to be visible in the fourth intercostal space—that is to say, when the body is in the supine position.² The impulse is felt slightly lower in men than in women, and in the old than in the young. By Ransome³ it was found

FIG. 22.—Areas of cardiac impulse, when supine (black), and when lying on the left side (lightly shaded).—Sequeira.

that the seat of the impulse varied much more when the body was rolled from one side to the other, than when the body was raised from the horizontal to the vertical position. In rising from the supine to

¹ Nicolls, *Journ. Physiol.*, Cambridge and London, 1896, vol. xx. pp. 413 and 426.

² Mariannini and Namias, *Arch. ital. de biol.*, Turin, 1883, vol. iv. p. 143.

³ *Journ. Anat. and Physiol.*, London, 1895, vol. ix. p. 137.

the standing position, the apex beat shifts downwards for about $\frac{1}{4}$ to 1 in., and by the same amount to the left.

When a man rolls over on to his right side, the seat of the impulse moves to the right, and may completely disappear beneath the sternum. It has been observed to shift $3\frac{1}{4}$ in. from left to right. Similarly, when a man rolls over on to his left side, the impulse is found considerably to the left side of the nipple line (see Fig. 22).

This shifting of the impulse is due to the effect of gravity on the heart within the pericardium. On passing needles through a certain given spot in the thoracic wall into the heart, with the body placed in the three positions—supine, on the right, and on the left side—the needles are found to pierce the heart at different places. In each position a different part of the heart, owing to the weight of the organ, is brought into close contact with the chest wall. The heart rotates in the pericardium. This membrane is too strong to allow of much lateral displacement of the whole heart.

If the finger be pressed up against the apex, it is shot down by the systole. If the whole heart be grasped by the hand, the fingers sink into the flaccid walls during diastole, but are driven asunder with great force by systole. Wherever the heart is touched it appears to drive the finger outward, and yet the heart diminishes in two if not in all its diameters.

The origin of the impulse has been attributed to many factors—(1) That the curvature of the aorta is straightened out by the blood shot therein. Since the heart is attached to the aorta, the apex is forced to describe an arc of a circle and impinge against the chest wall. (2) That the diastolic filling of the left auricle, which lies between the spine and the base of the heart, pushes the heart forward.¹ Haller experimentally showed that injection of the left auricle caused the heart to “approach the mamma with vivacity.” (3) That the systolic out-thrust of the auriculo-ventricular valves raises the pressure in the left auricle, and thus drives the heart forward.

A more reasonable suggestion, and one put forward among others by Harvey, is (4) that the heart erects itself from the collapsed position, which it assumes in diastole. A fulcrum for this movement is afforded by the base resting on the pericardium (Ludwig).² In consequence of this erection, the heart strikes the chest wall. This explanation is sufficient for the conditions which exist when the body is supine or vertical, but it is scarcely satisfactory when the body is prone, for then the heart is in apposition with the thoracic wall, and the impulse is most diffuse and intense. (5) The recoil of the heart, due to the expulsion of the blood into the aorta, and the straightening out of the spiral figure formed by the aorta and pulmonary artery, have respectively served their turn as an explanation of the cardiac impulse.³ These suggestions are at once negated by the fact that the output of blood from the ventricle occurs later than the commencement of the impulse. (6) During the period of rising tension within the ventricle, the blood presses upon every point of the internal surface with a force equal to that by which it is itself compressed. The pressure of the blood reacts thus on the wall, for the heart contracts against the

¹ Senac, “*Traité de la structure du cœur*,” Paris, 1749, p. 356.

² Ludwig, “*Lehrbuch d. Phys.*,” Leipzig, 1861, Bd. ii. S. 86.

³ Skoda, “*Abhandl. ueber Percussion und Auscultation*,” Wien, 1842, S. 147; Kornitzer, *Sitzungsab. d. k. Akad. d. Wissensch., math.-naturw. Cl.*, Wien, 1857, Bd. xxiv. S. 120.

fluid, the exit of which is hindered by the aortic pressure. If the blood be shut off from the heart, then a finger placed on the ventricle is forced out on systole to a far less extent than before. An outward thrust is still perceptible, however, and this must be so, for muscle layers compress other muscle layers. Thus the columnæ carneæ and papillary muscles are forced together. In this case, it is the elastic resilience of the compressed muscle which produces the impulse.

The points to be remembered in regard to the origin of the impulse are these—

1. The impulse is synchronous with the commencement of the period of rising intraventricular tension.

2. The impulse occurs where the ventricular wall touches the parietes of the chest.

3. By no locomotion of the whole heart can its origin be entirely explained, for it persists after the suppression of the auricular contraction, and of the recoil due to the output.

4. The primary factor is the hardening of the muscular mass, the secondary factor the erection of the ventricles upon the base of the heart.

5. The impulse is felt at a different spot in each position of the body, owing to the influence of gravity acting on the heart.

Cardiographs.—The impulse of the heart can be recorded by various forms of apparatus. In animals a receiving tambour has been inserted between the chest wall and the heart, and placed in connection with a recording tambour.¹ In obtaining curves from man, the receiving instrument has necessarily to be applied to the external wall of the thorax over the seat of impulse. Probably the best form of cardiograph is that of Edgren, which is a modification of Marey's instrument.²

In this instrument the receiving tambour (c) is placed within an outerrigid chamber (A B), which is fastened to the thorax by elastic bands (f g), which encircle the chest. The pressure of the button (K) of the tambour on the seat of impulse can be varied by a toothed wheel and rod (h), while small spiral springs (i) placed between the roof of the tambour and the rubber membrane give to the latter the requisite amount of tension. The tube (d) passes to the recording instrument, and the tube (e) enables the observer to listen to the sounds of the heart, at the same time that the impulse is recorded. By this apparatus the movements of the chest wall are excluded, for the whole apparatus moves with the thorax. Only the cardiac impulse affects

FIG. 23.—Edgren's cardiograph.

¹ Chauveau and Marey, *Mém. Acad. de méd.*, Paris, 1863, tome xxvi. p. 284.

² *Skandin. Arch. f. Physiol.*, Leipzig, 1889-1891, Bd. i. S. 74.

the tambour, and the instrument, therefore, yields the same form of curve as does a tambour placed between the heart and the chest wall in an animal.

The curve of the impulse, or cardiogram, taken when the heart is beating normally, is entirely different from a cardiogram taken when the vessels are ligatured and the heart bloodless.¹

The cardiogram is not, therefore, a true muscle curve, but is a combined curve of pressure and volume. The form of the curve is, moreover, endlessly varied by the application of the receiving tambour to different parts of the heart, and by alteration of the pressure with which the instrument is applied. Thus the instrument is not by itself a perfectly sure or trustworthy guide, and the main physiological interest which it possesses is that, by its means, certain time relations in the cardiac cycle can be decided in man. By simultaneous record of the impulse curve, the time of the sounds of the heart, and the carotid or radial pulse, interesting results can be arrived at, such, for example, as the period of rising intraventricular tension.

The occurrence of the sounds of the heart can be marked below the impulse curve by means of an electric signal worked by the hand of the observer who is charged with the duty of auscultating the heart. The reaction time of a practised experimenter for the making of signals in answer to sounds is known to be from 0.15 to 0.20 seconds. With practice the reaction time for regular periodic excitations is

FIG. 24.—Impulse curve and sounds of the heart.—Edgren.

found to become very constant, and the error due to variations in this may only be 0.01 sec. As the constancy of the reaction time depends on the regular periodicity of the excitation, this method of marking the time of the heart sounds can only be employed on healthy hearts beating with a regular rhythm. In such cases the constancy of the period of each pulse varies by no more than 0.03 to 0.04 sec. The total error of observation is therefore equal to about 0.04 sec. With the use of Edgren's apparatus the observer can discard the method of signalling, and by watching the tracing of the impulse can see, at the same time as he listens to the heart, the points on the curve at which the sounds are heard. Since the heart sounds have been successfully recorded by the combined use of the microphone and the capillary electrometer, it will be possible in the future to improve on the above method, and simultaneously to obtain curves of the impulse and the sounds of the heart.

Marey,² Edgren,³ and others find that the second sound of the heart corresponds in time with a small nick or elevation at the

¹ v. Frey, "Untersuch. des Pulses," S. 112.

² "La circulation du sang," Paris, 1881, p. 127. Cf. Fredericq, "Trav. du labor. de Liège," 1888, tome ii. p. 84.

³ *Skandin. Arch. f. Physiol.*, Leipzig, 1889-91, Bd. i. S. 88.

bottom of the descending limb of the impulse curve, marked *f* in Edgren's tracing.

By Hilbert¹ the second sound is placed earlier—at the beginning of the descending limb of the curve.

The second sound does not mark the exact moment of closure of the semilunar valves, but the time at which these valves are thrown into tension by the back swing of the blood. Synchronous or differential curves of intraventricular and aortic pressure show that the valves shut earlier than the occurrence of the second sound, and without noise, at the moment when the aortic pressure rises to a point higher than the intraventricular pressure.

Another method of obtaining the moment of closure of the semilunar valves on the impulse curve is as follows:—

The cardiac impulse and carotid or radial pulse curves are simultaneously recorded. The time relation of the bottom of the dicrotic notch is then marked upon the impulse curve. The time lost in the

FIG. 25.—Both high and low aortic pressure curves are shown.—Hürthle.

transmission of the pulse-wave from the heart to the artery where the pulse is recorded must be first deducted. By the observations on intraventricular and aortic pressure, curves it has been abundantly proved that the dicrotic notch occurs immediately on the closure of the valves, and synchronously with the commencement of the downstroke of the intraventricular pressure curve. Fredericq² has thus found that the dicrotic notch corresponds in time with the beginning of the downstroke of the impulse curve, and he believes that the nick, which occurs synchronously with the second sound at the bottom of the descending limb of the cardiogram, is caused by the inflow of blood into the ventricle at the commencement of diastole. The waves on the top of the plateau of the cardiogram have no doubt the same

¹ *Ztschr. f. klin. Med.*, Berlin, 1891, Suppl. Heft, Bd. xix. S. 158. Cf. Bramwell and Murray, *Brit. Med. Journ.*, London, 1888, vol. i. p. 10; Martius, *Ztschr. f. klin. Med.*, Berlin, 1891, Bd. xix. S. 108.

² *Centralbl. f. Physiol.*, Leipzig u. Wien, 1892, Bd. vi. S. 257.

origin as the waves seen on the plateau of the intraventricular pressure curve.

The moment when the semilunar valves open can be marked on the impulse curve by synchronously recording the carotid pulse, and deducting the time spent in the transmission of the pulse wave. The commencement of the upstroke of the pulse curve after the necessary deduction marks the beginning of the systolic output when the valves open (see Fig. 25).¹ By Edgren² and Martius³ this moment is placed at the top of the ascent of the impulse curve, where the plateau commences. By signalling the position of the first sound on the impulse curve, the moment of closure of the auriculo-ventricular valves is obtained with sufficient accuracy. All these points are marked in the accompanying figure—

FIG. 26.—Simultaneous records of carotid pulse and heart impulse.—Edgren.

- i*, the auricular systole.
- a*, the commencement of ventricular systole, the time of occurrence of the first sound.
- b*, the opening of the semilunar valves.
- c*, *d*, waves on the top of the plateau.
- e*, the closure of the semilunar valves and commencement of diastole.
- f*, the tension of the semilunar valves and the occurrence of the second sound.

From these points the following time periods can be arrived at in man :—
a-b, The time of rising tension in the ventricle; *a-e*, the period of ventricular contraction; *b-e*, the period of output of blood; *a-f*, the time between the commencement of the two heart sounds; *e-a*, the period of diastole of the ventricles.

Beyond these data, it must be remembered that the impulse curve tells nothing of value, for the form of the curve bears no accurate relation to the contraction of the heart.

In a man with a pulse frequency of 70, Edgren determined the duration of systole to be 0.379 sec., of diastole 0.483 sec. The relation between the duration of the systole and the frequency is shown in the following table :—

Pulse Frequency.	Duration of Systole.	
74- 94	0.327-0.301 sec.	} Donders. ⁴
63-124	0.382-0.199 "	
55- 65	0.300-0.327 "	} Landois. ⁵
55-113	0.346-0.190 "	
47-128	0.347-0.256 "	Thurston. ⁶

If the pulse frequency vary in the proportion 100 : 270, the duration of systole varies in the proportion 136 : 100. In other words, when the frequency increases, the diastolic period of rest shortens far more than the systolic period.

The following observations on animals confirm this conclusion:—

	Systole.	Diastole.		Systole.	Diastole.
Normal duration,	0·149	: 0·373	sec.	On excitation of vagus,	0·158 : 0·635
„ „	0·253	: 0·299	„	„ „	accelerator, 0·210 : 0·044
					„ „ ²

By Roy and Adami an instrument has been constructed by which the actual contraction of the mammalian heart can be investigated.³

In their myocardiograph, one end of the rod (*a*), as is shown in the figure, can, by means of gimbals, freely oscillate from *b*. The other end is fastened to a chosen spot on the ventricle. On this rod is fixed a small pulley, over which there passes a silk thread. The one end of this thread is attached by a hook to some other part of the heart, while the other end is connected with a writing lever. By the arrangement shown, the shortening between any two points on the external surface of the heart can be recorded; and, further, by passing the hook through an auricle and affixing it to a flap of an auriculo-ventricular valve, the movements of the valve and the pull of the papillary muscles can be studied. For the ventricular end of the rod (*a*), by which the pulley is carried, remains a fixed point, while the hook attached to the thread is in systole approximated to, in diastole driven from, this point. A myographic curve of the ventricle thus obtained can be compared with intra-ventricular pressure curves or aortic curves recorded synchronously.⁴

The cessation of the output is placed by these authors at the moment when the ventricle has reached its maximum of contraction, and according to them the ventricle remains contracted for a certain interval after the cessation of the output. They further consider that the contraction of the papillary muscles pulls down the auriculo-ventricular valves, and, by thus increasing the intraventricular tension, causes a temporary arrest in the myocardiographic curve. They find that the apex of the aortic pulse curve corresponds with this moment, and therefore this apex is by Roy and Adami ascribed to the rise of intraventricular tension, produced by the pull of the papillary muscles. The ventricular wall and the papillary muscles remain in contraction for a period which corresponds to the plateau stage in the curve of intraventricular pressure. Reasons have, however, already been given for regarding many of these deductions as incorrect.

FIG. 27.—Myocardiograph. *a*, connecting rod; *b*, frame with guiding hole for thread; *c*, hooked needle moving with heart muscle; *d*, guide for needle; B, frame viewed from above.—Roy and Adami.

THE PRESSURE AND WORK OF THE HEART.

The average mean arterial tension in the brachial artery of a healthy young man is 11 to 12 cms. Hg, and it is probably not much higher in the aorta. If the intraventricular pressure be taken as equal to 13 cms. Hg, the pressure exerted by every square centimetre of the inner wall of the left ventricle can then be reckoned thus—

$$P = 13 \text{ cms.} \times 13.5 \text{ (sp. gr. of Hg)} = 175.5 \text{ grms. per sq. cm.}$$

It is obvious that, other things remaining equal, the greater the superficial area of the inner wall, the greater will be the total stress on the ventricle.

The positive tension of a membrane enclosing a fluid under any given pressure is not a fixed quantity, but, as the radius of curvature at any part of the membrane is greater, so is the tension greater. On account of the larger size of the filled intraventricular cavity, and necessarily greater radii of the curvature of its walls, the distended heart must make a far greater effort at contraction, in order, by means of the tension of its walls, to raise the contained blood to the pressure of that in the aorta. The thinner the heart wall, the fewer the muscle fibres in a given width of its transverse section, the more will each fibre have to exert itself to bring about a given tension. When the exertion of each individual fibre is taken as constant, the fluid pressure per unit area must vary inversely as the cube of the radius of curvature, or, if the pressure be regarded as constant, the exertion of each fibre must vary as the cube of the radius of curvature. If the cardiac chamber be considered a

sphere with a wall of uniform substance and elasticity,¹ then $P = \frac{2te}{r}$ approximately, where P = the blood pressure sustained by each unit of surface of the cardiac wall; t = the muscular tension per unit of section; e = the thickness of the cardiac wall at any time; and r = the radius of the cardiac chamber at the time. Now e , when the wall is thin, varies as $\frac{1}{r^2}$, therefore P varies as $\frac{1}{r^3}$.

For example, if the auricle contract and reduce its diameter by one-half, it would be able to increase the intra-auricular pressure eightfold, supposing the force of contraction of its constituent muscle fibres remained constant. Samways² suggests that an auricle, towards the latter part of its contraction, might thus have the advantage over a full ventricle, and continue in certain cases to force blood therein, even after the systole of the ventricle had begun.

On the other hand, if the auricle or ventricle be suddenly enlarged to twice its diameter, the muscle fibres must be exerted eight times as much as before, to produce the same pressure. It is perhaps on account of this relation between the radius of curvature, and the work of the muscle, that the thickness of the musculature of the ventricle varies more or less directly as the radius of curvature at any point. The columnæ carneæ and papillary muscles, by acting as stays, also compensate for the disadvantage attending the distension of the cavity at the beginning of systole. At the end of systole, when the radii of

¹ The application of this formula to the heart can be only approximately correct, since this condition is only partially fulfilled.

² "Le rôle de l'oreillette gauche," Paris, 1896, p. 36.

curvature of the ventricle have become less, the action of these muscles is no longer needed.¹

The total stress in a dilated heart will be far greater than in a contracted heart. It is for this reason advantageous that the diastolic pressure of the heart be, by the mechanism of the veins, kept very low and fairly constant. If, during diastole, the heart be too forcibly distended, it may in this distended state be quite unable to contract. This condition is seen in asphyxia and in chloroform poisoning. It can readily be produced by pushing chloroform to excess, and by following this with forcible compression of the abdomen with the hand, so that the abdominal veins empty into the right heart. On relieving the distension by letting blood, the right ventricle will begin to beat once more.

It is found on examination that the heart when dilated does not empty; the residual blood is seen to increase on vagal inhibition, on compression of the aorta, on abdominal compression, or on injection of fluid into the veins.²

The force of the heart is increased by flushing the coronary arteries with blood, and improving the nutrition. If a maximal manometer be placed in the right ventricle, and the pulmonary artery be temporarily occluded, the maximal tension exerted by the wall of the ventricular cavity can then be estimated. If, after making such an observation, the aorta be temporarily occluded so as to increase the blood supply of the coronary arteries, and the maximal pressure in the right ventricle be again estimated, it will be found to be higher. Thus a rise of aortic pressure may increase the force of the heart, and this may even more than counterbalance the increase of work demanded.³

Tension also seems to increase the power of muscle, and thus a physiological advantage may compensate for a physical disadvantage. The effect of tension is seen in the case of the arteries. The arteries react to tension with a force that is greater than the force that distends them. Similarly, the power of the isometric muscle preparation when contracting against the pull of a steel spring is greater than that of a muscle which is after-weighted, and not in a state of tension at the moment of excitation. Likewise, the apex preparation of a frog's heart can be made to beat by raising the intracardiac tension; the inhibitory power of the vagus can be diminished by raising the tension of the blood within the chambers of the heart; the beat of the snail's heart can often be arrested by merely letting the blood escape from within it.

In the case of the skeletal muscles, Maggiore⁴ has shown that there is a definite weight and rate of contraction essential to the execution of the greatest amount of work in a given time. Either increasing the weight or the rate of contraction lessens the total output of work, and hastens fatigue. With a given light weight, the abductor indicis can be made to contract and raise this weight once a second for two and a half hours without any sign of fatigue. On increasing the rate of contraction, or the weight to be lifted, fatigue rapidly super-

¹ Woods, *Journ. Anat. and Physiol.*, London, 1891-2, vol. xxvi. p. 362; Samways, *Brit. Med. Journ.*, London, 1897, vol. 1. p. 703.

² Roy and Adami, *Phil. Trans.*, London, 1892, vol. clxxxiii. B, p. 210.

³ *Ibid.*, p. 269.

⁴ *Arch. f. Physiol.*, Leipzig, 1890, S. 191.

venen. Thus, there is no extraordinary difference between the heart and the skeletal muscle. A skeletal muscle, like the heart, can rhythmically perform work once a second, without fatigue, for a long period of time. The heart, like the skeletal muscle, executes most work with a certain weight and at a certain rate. Increase of either beyond a certain point hastens the fatigue and lessens the power of the heart.

More than 150 years ago, Stephen Hales¹ attempted to measure the pressure and work of the heart. He injected melted beeswax into the left ventricle and obtained a cast of the cavity. This cast he covered over with small pieces of paper, pinning the pieces on, in exact apposition to each other. He then removed the pieces of paper, and, placing them once more in apposition on a flat surface, measured the superficial area of the cavity of the ventricle. From this measurement, he calculated the output of the ventricle, and, having experimentally obtained the height of the normal arterial pressure, he drew conclusions as to the power and work of the heart. Ingenious as this method is, there are many fallacies. It is impossible to obtain from the dead heart the diastolic capacity of the living heart; moreover, the ventricle never completely empties itself in systole.

The energy of the circulation.—The energy of the circulation can be reckoned in the following way by the use of hydrodynamic formulæ.

The work done by a force is proportional to the force, and to the distance through which it moves its point of application. The energy of a body is its capacity for doing work, measured by the work to which it is equivalent.²

1. Let Q be the systolic output of the heart in cubic centimetres, v the mean velocity of the issuing stream, t the time of escape, A the area of the aortic orifice. Let A' be the area of the ascending aorta, u the mean velocity of the blood in it, t' the time of a complete cardiac cycle—

$$\text{Then } Avt = A'ut' = Q.$$

That is to say, the output of the left ventricle can be reckoned, if the mean velocity of the blood-flow in the ascending aorta be found by experiment, and if the area of the ascending aorta and the time of a cardiac cycle be known.

The following example is given by Nicolls.³ Assuming the following data, namely, the time of the cardiac cycle, 0·8 sec.; the time of the systolic output, 0·1 sec.; the diameter of the aortic orifice, $2r = 2\cdot5$ cms.; of the aorta, $2r' = 2\cdot8$ cms.; the mean velocity in the aorta, $u = 32$ cms.—

$$\begin{aligned} Avt &= A'ut' = Q \\ \pi r^2 \times v \times \cdot 1 &= \pi (r')^2 \times u \times 0\cdot8 \\ \pi \frac{1}{2} (2\cdot5)^2 \times v \times \cdot 1 &= (2\cdot8)^2 \times u \times 0\cdot8 \\ 25^2 v &= 28^2 \times 8u \\ 625v &= 6272u \\ v &= 10u = 320 \text{ cms. per sec.} \end{aligned}$$

² CM. GRM. SEC. UNITS.

Dyne.—The force which, acting upon 1 grm., produces per sec. velocity of 1 cm. per sec.

Erg.—The work done by a dyne when it has moved its point of application through 1 cm.

Density.—Grm. per c.c.

Velocity.—Cm. per sec.

Acceleration.—Cm. per sec. per sec.

Pressure.—Dyne per sq. cm.

³ *Journ. Physiol.*, Cambridge and London, 1896, vol. xx.

the result arrived at being that the velocity of output is ten times the mean velocity in the aorta. To obtain the output of the left ventricle—

$$\begin{aligned} Q &= Avt \\ &= \pi r^2 \times 320 \times 0.1 \\ &= 5 \times 320 \times 0.1 \\ &= 160 \text{ c.c.}^1 \end{aligned}$$

The diameter of the pulmonary orifice being reckoned as 3 cms., and the output of the right ventricle being the same as the left, the velocity of output at the pulmonary orifice will be in inverse proportion to its sectional area as compared with that of the aortic orifice.

$(3)^2 : (2.5)^2 :: 320 : 222$ cms. per sec. (velocity of output at pulmonary orifice).

The kinetic energy of the velocity of output is largely changed into potential energy in the aorta and pulmonary artery. During diastole the potential energy stored up by the distension of the elastic arterial walls becomes again kinetic. It is spent in maintaining the velocity of flow, and in overcoming the viscosity of the blood in the arterioles and capillaries.

To estimate the work of the heart, the mean pressure and velocity in the aorta, and the volume of the systolic output must be obtained.

If W be the work done during systole of the left ventricle in gramme centimetres; Q , the volume of the output in cubic centimetres; M , the mass of the output in grammes; P , the specific gravity of blood ($\therefore M = PQ$); V , the mean velocity in the aorta; H , the mean aortic pressure in grammes per centimetre; g , the acceleration due to gravity = 981 cms. per second;

$$\begin{aligned} \text{Then, } W &= QH + \frac{MV^2}{2g} \\ \therefore W &= QH + \frac{PQV^2}{2g} \end{aligned}$$

Now, the mean aortic pressure may be taken to be 12 cms. of mercury (sp. gr. of mercury = 13.5). The volume of the systolic output has been reckoned above as 160 c.c.; but experimental determinations of the output in animals lead to the conclusion that the output in man does not much exceed 100 c.c. (see p. 49). For the purposes of this calculation a mean value of 110 c.c. may be taken as the output. Substituting these data in the above equation, one obtains—

$$W = 110 \times 12 \times 13.5 + \frac{1.05 \times 110 \times 32^2}{2 \times 981} = 17,880 \text{ gramme-centimetres.}$$

It is obvious that the work spent in maintaining the aortic velocity is almost negligible (1 : 300 nearly) compared with that spent in overcoming resistance.

If in the case of the right ventricle the mean pressure in the pulmonary artery be taken to be 4 cms. of mercury, the work of that ventricle will be one-third of that of the left ventricle.

Thus the total work of each systole of the heart will be—

$$17,880 \times \frac{4}{3} = 23,640 \text{ gramme-centimetres,}$$

and the total work of the heart per diem about 24,000 kilogramme-

¹ This is, however, undoubtedly too high an estimate (see p. 49).

metres (or 1000 kilogramme-metres per hour).¹ The day's work of the heart is therefore equivalent to 56·6 kilo-calories, or about one-fiftieth of the total amount of heat produced in the body, in addition to which, it must be remembered that there is a constant production of energy in the form of heat in the heart muscle, as in other muscle, as a result of its metabolic changes, and this heat is also taken up by the blood. Thus the heart is an important mechanism for the production as well as for the distribution of heat in the body.

THE DIASTOLIC FILLING OF THE HEART.

In the excised heart no evidence of any suction power has been observed; indeed, the heart will only fill when supplied with blood under a positive pressure. Similarly, when the thorax is opened, the heart cannot fill itself by its own power of suction; this force must be aided by a positive pressure in the thoracic veins.

If the pressure in the *venæ cavæ* be not positive, then *any negative pressure which occurs in the heart cavities leads to a collapse of the thin-walled venæ cavæ, and not to suction of blood from the veins.* In hydraulic engineering the efforts of engineers are directed towards making the water enter without shock. If the negative pressure had any decided action, the blood would enter the heart with considerable shock, and consequent loss of energy. This is contrary to what we should expect in nature. The driving force of the heart is sufficient by itself to complete the circulation and return the blood to the heart, when the action of the respiratory pump is abolished by injection of curari, and the thorax is opened.

Normally, the filling of the heart is largely under the control of the respiratory pump. In the closed thorax the pressure is less than that of the atmosphere by the amount of tension which is required to overcome the pulmonary elasticity, and expand the lungs to the size of the thoracic cavity. In ordinary inspiration this tension is equivalent to 9 mm. Hg; in the position of deepest inspiration it may be 30 mm. Hg. On the one hand, the extrathoracic veins are under a pressure which is nearly that of the capillaries, and is thus somewhat above the atmospheric pressure; on the other hand, the intrathoracic veins and the heart are under a slight but constant negative pressure, which in inspiration may be - 9 to - 30 mm. Hg. The venous blood is by these alterations in thoracic pressure aspirated into the heart. If, in sequence to, or synchronously with, the inspiratory movements of the thorax, the abdominal muscles be thrown into contraction, then the abdominal veins are compressed, and the respiratory muscles act on the venous circulation, not only as a suction- but also as a force-pump. If the pressure in the thorax be made sufficiently great, the efficiency of the heart as a pump ceases, for the heart is unable to fill. Thus the diastole of the heart can be prevented by raising the intrapericardial pressure.

To carry out this experiment, a pressure bottle filled with oil is connected by a T-piece with an oil manometer, and a tube tied into the pericardial sac. So soon as the pressure of the oil rises to 60-70 mm. oil, the arterial pressure falls by 20-30 mm. Hg, while the vena cava pressure

¹ Estimates of more than double this amount are frequently given, but they have been based upon a far larger output and a higher aortic pressure than (for reasons subsequently to be given) have here been adopted.

rises to about 60 mm. soda solution. By a pressure of at most 240–300 mm. oil, the arterial pressure is driven to zero.¹ By no possible means can the vena cava pressure rise beyond this pressure, and thus the heart is unable to fill. “The quantity of blood thrown into the aorta by each contraction of the left ventricle, should accurately correspond to that issuing from the arteries into the capillaries during the period which elapses from the commencement of the systole to the end of the following diastole. It is the maintenance of this proportion that is the source of the constant mean tension of the arteries.”²

In the dog either the vena cava superior or the vena cava inferior below the liver may be completely occluded, and yet no change of pressure is indicated by the arterial manometer. On compressing the vena cava inferior between the liver and the heart, on the other hand, there is an immediate and marked descent of the arterial tension. Thus, too, a rabbit, in which the portal vein has been ligatured, perishes within a few minutes, owing to the rapid accumulation of the blood in the portal tributaries. The capacity of these is so great that they are sufficient to hold all the blood at a low tension. The filling of the heart is thus enormously diminished while the aorta continues to empty itself, by its elastic reaction, into the portal system.

FIG. 29.—A, vertical feet-down position; B–C, effect of compressing the thorax.—Hill and Barnard.

effect depends greatly on the rigidity of the thorax and resisting power of the animal.⁴ In man, compression of the chest produces the same result, and Weber thereby induced in himself loss of consciousness and

FIG. 28.—Compression of the thorax (A–B). Compensatory effect of powerful inspirations, alternating with forced expiratory efforts (glottis closed).—Hill and Barnard.

Stefani³ found that the intrapericardial pressure must, in order to stop the diastole of the heart, be raised to a higher point if the vagi are intact than if the vagi are divided. This need not prove, as Stefani believes, that the vagus actively influences the diastole of the heart muscle. The result can be explained by the alteration in the action of the respiratory pump which follows division of these nerves. By dividing both vagi the rate of respiration is greatly slowed, and thus the action of the respiratory pump, so far as regards the filling of the heart, is lessened.

On compression of the thorax of a dog, the arterial pressure falls towards zero, owing to the increased intrathoracic pressure, while the vena cava pressure rises. The gravity of the

slight convulsive spasms, owing to the production of acute cerebral anæmia.

In the vertical feet-down posture, when the full hydrostatic effect of gravity opposes the return of blood from the parts below the heart, the efficiency of the respiratory pump becomes of vital importance. Thus the establishment of forcible artificial respiration by raising the intra-thoracic pressure, while the animal is in the feet-down position, forces the arterial pressure to zero. In the horizontal posture the fall of arterial pressure is considerable, but not so dangerous. Compression of the abdomen immediately restores the circulation. This compensates for the positive pressure in the thorax, and fills the heart with blood.¹

FIG. 30.—A, effect on aortic pressure of artificial ventilation of the lungs in the vertical feet-down posture; B, compensatory effect of abdominal compression. —Hill and Barnard.

When the larynx is blocked by some hard impacted mass of food, too hastily swallowed, death is hastened by the violent expiratory spasms, which raise the intra-thoracic pressure, and lead to deficient filling of the heart.

So, in the fatal crushes of panic-stricken crowds, death is produced by compression of the thorax and circulatory failure. The women and children with collapsible chests are the first to die, while the men with rigid chests escape.

The case of Colonel Townsend, as reported by Cheyne,² has always aroused considerable interest. Colonel Townsend was in the last stage of some form of nephritic disease, and life was at its lowest ebb. Cheyne reports the experiment he witnessed together with two other

medical men. "The man could die or expire when he pleased, and yet, by an effort or somehow, he could come to life again. He composed himself on his back, and lay in a still posture some time. While I held his right hand, Dr. Baynard laid his hand on his heart, and Mr. Skrine held a clear looking-glass to his mouth. I found his pulse sink gradually, till at last I could not feel any, by the most exact and nice touch. Dr. Baynard could not feel the least motion in his heart, nor Mr. Skrine the least soil of breath on the bright mirror he held to his mouth; then each of us by turns examined his arm, heart, and breath, but could not by the nicest scrutiny discover the least symptom of life in him. We began to conclude that he had indeed carried the experiment too far, and at last were satisfied he was actually dead, and were just ready to leave him. As we were going away, we observed some motion about the body, and upon examination found his pulse and the motion of his heart gradually returning; he began to breathe gently and speak softly." He died the same evening.

The explanation of this case, which appeared so full of mystery to Cheyne, is probably to be found in the following facts. The circulation was failing, the blood pressure very low, and the vascular tone probably almost entirely lost; such was evidenced by his thready and feeble pulse. The heart-beat was so feeble, that the *vis-a-tergo* was insufficient, even in the recumbent posture, to return the blood to the auricle without the aid of respiration. When, therefore, Colonel Townsend held his breath, the circulation ceased, while the empty heart continued to beat, but so feebly as to be imperceptible. If anæmia of the bulbar centres is slow in origin, spasm is never provoked by the total cessation of the circulation. On asphyxiating a curarised animal, the heart frequently is found to continue to beat for fifteen or even twenty

¹ Hill and Barnard, *Journ. Physiol.*, Cambridge and London, 1897, vol. xxi. p. 333.

² Cheyne, "English Malady," London, 1733, p. 307.

minutes, for the supply of oxygen is not exhausted, owing to the absence of asphyxial spasms. Remembering these experimental facts, it is possible to conceive that the heart of Colonel Townsend continued to beat imperceptibly for some time after the cessation of respiration, and that at the end of that time the respiratory centre discharged a group of respirations, which re-established the circulation. The man, in fact, had sunk into the condition of a hibernating animal, where the metabolic processes are at the lowest ebb.

It must be borne in mind that the heart, during its systole, by diminishing its own volume, increases the negative pressure in the thorax. In proportion as the ventricles become smaller, the lungs, the thoracic veins and auricles must become larger. On passing a tube down the jugular vein of a horse or dog, there can be observed, besides the respiratory oscillations, short undulations, synchronous with the heart-beat. The fall of pressure in these is synchronous with the systole.¹ On removing the front of the chest wall from a rabbit, without injury to the pleura, a to-and-fro movement of the lung can be seen to take place synchronously with the beat of the heart. Similarly, the chest wall sinks in, outside the area of the cardiac impulse during systole,² and if the breath be held, a negative pressure appears at the same time in the air passages. This last phenomenon can be recorded³ by means of a tube placed in one nostril, while the mouth and the other nostril are held closed. The tube is connected with a delicate tambour. The larynx must be kept open during the observation.

FIG. 31.—A, Pressure in the air passage; B, carotid pulse.—Mosso.

In Fig. 31, a curve of the carotid pulse is simultaneously shown with that of the pressure in the air passages. During the rise of the former, the latter is seen to fall. The fall is found to begin earlier than the rise of the carotid pulse, because it is dependent on two factors. The first of these is the contraction of the ventricle, which drives outwards the wall of the thorax; the second factor is the expulsion of the blood from the thoracic cavity. The first factor produces its effect on the nasal tracing earlier than the second, while the rise of pressure in the carotid artery is produced only by the latter. Part of the difference in time is due to the fact that the rate of transmission in the air-tubes is far greater than that of the pulse wave along the arteries. If, in the course of this experiment, the larynx be closed, the pressure is found to rise in the nose with each systole, owing to the expansion of the arteries in the mouth, nose, and pharynx.

THE SYSTOLIC OUTPUT OF THE HEART AND THE ARTERIAL PRESSURE.

The determination of the exact output of the heart has been a matter of considerable difficulty. In the calculation of the energy of the circulation, it is shown that the output can be arrived at approximately by hydrodynamic formulæ, if certain data are obtained experimentally. To arrive at one of these data, namely, the velocity of flow in the ascending aorta, has always been a formidable matter.

Volkman¹ and Vierordt² estimated the velocity of the blood-flow in the carotid artery, and, by comparing the sectional area of this with that of the aorta, reckoned the velocity of flow in the aorta, and thus the output of the heart per second. Now, *the flow in such a tube as the carotid depends at any moment on the proportionate relation which obtains between the resistances in the carotid vascular area and in the remainder of the arterial system.* It is therefore impossible, from the velocity of flow in the carotid artery, to accurately reckon the velocity of flow in the aorta. It is equally impossible to determine the diastolic capacity of the ventricle in the dead animal—not only because of the fallacies which arise from the inadequacy of any method to imitate the conditions of the living heart, but from the fact that the ventricle does not completely empty itself during systole.

Stolnikow³ attempted to measure the output in a different manner. He tied all the aortic branches except the axillary, and the outflow from that artery he drew off into a graduated vessel. From thence the blood was sent back to the heart by way of the external jugular vein. Under these conditions, with a low resistance to flow, with the arterial pressure rising to 30 or 40 mm. Hg only, and with ample filling of the heart in diastole, the systolic output was probably maximal. He found it from .00032 to .0016 of the body weight. Tigerstedt⁴ attacked the problem directly, and, by means of an improved form of stromuhr, measured the flow in the aorta of the rabbit. In fourteen experiments, wherein the blood pressure averaged 88.5 to 176 mm. Hg, and the heart frequency 193, the mean outflow was .00027 of the body weight, and the output per sec. .00085 of the body weight. Other observers have availed themselves of indirect methods of arriving at the same result. Thus Zuntz⁵ estimated the blood-gases in arterial and venous blood, and the gases of the expired air. He found that a resting horse consumed 2733 c.c. of oxygen per minute, while the arterial blood contained 10.33 per cent. more oxygen than venous blood. It follows from these data that every 100 c.c. of blood which traversed the lungs took up 10.33 per cent. of oxygen; but, as in one minute 2733 c.c. of oxygen was carried away by the blood passing through the lungs, therefore $\frac{100 \times 2733}{10.33} = 26,457$ c.c. of blood must have passed in the given time. This, then, was the output per minute of the right ventricle. The output per second was .00122 of the body weight (this was about 360 kilos.). By a similar investigation, the output per

¹ "Die Hämodynamik," Leipzig, 1850, S. 204.

² "Die Erscheinungen und Gesetze der Stromgeschwindigkeiten des Blutes," Frankfurt, 1858, S. 104.

second in a dog was found to be .00157 of the body weight (25 kilos.).

Obtained by such different methods, Zuntz and Tigerstedt's results roughly agree. Thus the output per second was—

.00085 of body weight (maximal .00132)	Rabbit	Tigerstedt.
.00122	Horse	Zuntz.
.00157	Dog	Zuntz.

Stewart has recently estimated the output by a new method.¹ A definite amount of 1.5 per cent. solution of NaCl is injected into the right auricle through the jugular vein at a uniform rate. From the femoral artery samples of blood are collected (1) just before, (2) during the injection. The quantity of 1.5 per cent. NaCl solution necessary to add to sample 1, to make its NaCl content equal to that of sample 2, is determined. This determination yields the amount by which the injection is diluted with blood in the heart. If the quantity of the injection in a given time be known, and the extent of its dilution, it is obvious that the output of the heart can be calculated for that time. Stewart's results agree closely with those of Zuntz.

From these data the systolic output in man can be calculated to be a little more than 100 c.c. By the use of hydrodynamical formulæ the output was reckoned to be 160 c.c. (see p. 43), but this, as already stated, is probably much too high.

Such methods of investigation as the above are unsuitable for prolonged researches on the output of the heart under the varying conditions of experiment. An attempt has therefore been made to use the pericardial sac as the chamber of a plethysmograph, and thus obtain records of the changes of cardiac volume. The pericardial wall is not, however, sufficiently rigid for the purpose; moreover, the diastole of the heart is impeded whenever this sac is distended with fluid. The experimental difficulties in the way of inquiry have been recently solved by Roy and Adami's invention of the cardiometer.²

FIG. 32.—Cardiometer.—Roy and Adami.

The cardiometer consists of a metal box, constructed in two parts, these are united by a hinge joint. After the thorax has been opened, and the pericardium slit open, the heart is slipped within the opened cardiometer, and this is then closed. The vessels issue from the heart through an orifice in the cardiometer, and to the edge of this opening the parietal layer of the peri-

¹ *Journ. Physiol.*, Cambridge and London, 1897, vol. xxii. p. 159.

² *Phil. Trans.*, London, 1892, vol. clxxxiii. B, p. 202.

cardium is securely fastened. By this means all leakage from the chamber of the instrument is prevented. Finally, the cardiometer is filled with oil, and connected by a tube to a piston recorder. The instrument is experimentally calibrated, so that a certain extent of stroke is known to signify a certain change in volume, and an automatic counter has been devised by Roy and Adami, which records a notch on the tracing at every period when the sum of the upstrokes of the lever corresponds to an output of 100 c.c. of blood from the heart. A simple and adequate form of cardiometer can be made out of a tennis ball. A tube is fixed into the ball and connected with a piston recorder. On the opposite side to this tube a hole is cut large enough to admit the heart. The pericardium is tied round the ball, and the junction made air-tight by the application of thick vaselin.¹

The efficiency of the systole can be estimated in yet another way. This is by the simultaneous record of the left auricular and aortic pressures. If the ventricle fail to empty itself, and the residual blood increase, then both the diastolic volume and pressure rise. While the cardiometer records the increase of volume, a manometer in connection with the left auricle registers the increase in diastolic pressure.

By one or other of these methods, interesting and important results have been obtained. It is known that, under high pressure, the elastic coefficient of the aorta increases; the energy of the systole must correspondingly increase, in order that the output when the pressure is high may be maintained at the same volume as when the pressure is low. From his researches on the output of the heart, Tigerstedt concludes—

1. That within certain limits the systolic output is independent of the resistance.
2. That under favourable conditions a rise of resistance may increase the systolic output.
3. That with increasing peripheral resistance the systolic output as a rule decreases.
4. That as the arterial pressure generally increases in spite of the diminished systolic output, the diminution in output per second must be proportionately smaller than the increase in resistance.²

The diminution of the output per second is usually shown most strikingly during the rise of arterial tension which is occasioned by asphyxia. In the asphyxial condition the heart muscle rapidly fails and passes into paralytic dilatation; while the output from the ventricles is opposed, the venous input is enormously assisted by the action of the respiratory spasms.

A large area of arterioles, mainly the splanchnic, is thrown into constriction, and the blood in the first stage is propelled from the constricting vessels into the veins,³ while the velocity of flow through the locomotor organs is accelerated owing to a compensatory dilatation of the vessels in these organs, and thus the diastolic filling of the heart is increased. At the same time, under favourable conditions, the heart is accelerated, the systolic output increases, the left auricular pressure falls, and the arterial pressure rises. In the second stage, the vagal centre in the spinal bulb is excited by the high arterial tension, the heart frequency is lessened, and the output diminished. Further, so soon as the arterial pressure reaches a certain point, the heart becomes unequal to the strain of emptying itself against the resistance, the

¹ Hill and Barnard, *Brit. Med. Journ.*, London, 1897.

³ Mall, *Arch. f. Physiol.*, Leipzig, 1892, S. 418.

output then becomes imperfect, the residual blood increases, the left auricular pressure rises, and the blood is congested back upon the venous system.

A greater rise of arterial pressure can be produced by excitation of the splanchnic nerves than by closure of the thoracic aorta with a clip.¹ This difference in result is to be explained by the following facts:—

1. On closing the aorta with a clip, the driving power of the heart is cut off from the lower parts of the vascular system, the blood stagnates therein, and thus the return of the venous blood to the heart is impeded. This is not so in the case of splanchnic constriction.

FIG. 33.—Curves illustrating the effect of a rise of aortic pressure (a') upon the pressure in the right (a'') auricles; to be read from right to left.—Kauders.

2. The power of the heart to empty itself in systole is greatly lessened by the closure of the aorta, for the elastic reservoir formed by the arteries into which the blood

FIG. 34.—Aortic pressure. A, vertical feet-down position; BC, is thrown in systolic effect of abdominal compression; D, horizontal position.—Hill.

Whenever the left ventricle fails to maintain its output, the pressure rises in the left auricle. Subsequently, in consequence of the back effect through the lungs, it rises in the right auricle.² Figure 33 illustrates the effect on auricular pressures of a rise in aortic pressure. The points marked a , a' , a'' , give the corresponding moments in time on the three curves.

The dependence of the arterial pressure and the systolic output on the diastolic filling of the heart is shown by the experimental results obtained on compressing the abdomen or thorax.

FIG. 35.—Aortic pressure. A, horizontal position; BC, abdomen compressed; D, vertical feet-up position; EF, abdomen compressed; G, horizontal.—Hill.

¹ v. Basch, *Ber. d. k. sächs. Gesellsch. d. Wissensch. math.-phys. Cl.*, Leipzig, 1875, S. 383; S. Mayer, *Sitzungsb. d. k. Akad. d. Wissensch. math.-naturw. Cl.*, Wien, 1879, Bd. lxxix. Abth. 3, S. 19.

² Kauders, *Ztschr. f. klin. Med.*, Berlin, 1892, Bd. xxi. S. 68.

If the thorax be compressed, the pulmonary circulation is obstructed, and the filling of the left heart opposed. If the abdomen be compressed, the filling of the right heart is aided, and the output per second may be doubled or trebled. In the one case the arterial pressure falls, in the

other case it rises. Compression of the abdomen, however, only increases the systolic output up to a certain limit.

Thus, in Figs. 34, 35, is shown the comparative effect of compression when the animal is placed in the vertical feet-down, horizontal, and vertical feet-up positions. In the feet-down position the rise of arterial tension is great, in the horizontal position it is slight, and in the vertical feet-up position almost nothing. In the last case the heart has already enough and more than enough blood at its disposal. Beyond a certain point the increased filling of the heart works unfavourably; that is, when the arterial pressure has risen to such a height that the ventricle is unable to rise to the strain of maintaining the output. In such conditions a vicious circle is established, for the greater the input the less the output, since it has been shown (p. 40) that if the ventricle be suddenly enlarged to twice its diameter the muscle fibres must be exerted eight times as much as before to produce the same pressure.

Thus, very powerful compression of the abdomen not only dilates the right heart, but opposes the emptying of the left ventricle. And, as Stephen Hales graphically says, "The heart being in this case like a water-mill, that is, surcharged with a flood both before and behind, its force must needs abate and grow languid." When the heart muscle is weakened by inhalation of chloroform, or by asphyxia, forcible compression of the abdomen may throw the right ven-

tricle into a condition of paralytic dilatation.¹

Besides chloroform, alcohol may be mentioned as another drug which, while it renders the systolic output incomplete, increases the diastolic pressure and the dilatation of the heart. If the heart be

¹ Hill, *Journ. Physiol.*, Cambridge and London, 1895, vol. xviii, p. 51; *Brit. Med Journ.*, London, 1897.

confined in the pericardium, and these drugs be pushed to excess, the heart ceases to have room for diastole when the distension reaches a certain point; cutting the pericardium relieves the heart for a time, but final cessation in diastole takes place eventually. The circulation of calves' blood through dogs' hearts has the same effect.¹ The diastolic distension of the heart can be immediately relieved by placing the body in the vertical feet-down position; the right heart is thus emptied into the splanchnic area.²

The action of the inhibitory and accelerator nerves on the output of the heart is of considerable interest.

The effect of excitation of the peripheral end of the vagus nerve has been recorded by the cardiometer.³ The output per second is lessened, the residual blood is increased, the expansion of the heart in diastole is made more evident. The excitation of this nerve weakens or arrests the auricular contractions, and, while it slows the ventricles, the venous pressure rises because the output is lessened. A considerable rise of pressure in the left auricle accompanies the great fall of aortic pressure.⁴

By moderate stimulation of the vagus, the output per second may be diminished 20 to 30 per cent. The ventricles are more expanded both in diastole and in systole, owing to the increase of the diastolic filling pressure. Excitation of the accelerator nerves, on the other hand, increases the output per second by augmenting the force of the heart, and especially that of the auricular contraction. The venous pressure falls in consequence, the arterial pressure rises, and less residual blood remains behind within the ventricle. As a rule, the output *per systole* is, owing to the increase of diastolic filling, greater when the heart beats slowly, less when the heart is accelerated. The opposite is true for the output *per second*.

So long as the output per second remains unchanged, the arterial pressure will not vary, other factors remaining constant; but if the output decreases the pressure will fall, and if the output increases the pressure will rise. Changes in cardiac frequency, however, affect the mean arterial pressure only when the peripheral resistance is sufficiently great, but not otherwise.

Thus, if the arterioles are in a state of tone and the peripheral resistance is considerable, then acceleration of the heart raises the mean arterial pressure. Such, for example, is markedly the case when both vagi are divided in a morphinised dog. The blood is then pumped into the arteries faster than it can escape through the arterioles. On the other hand, when the peripheral resistance is greatly diminished by section of the spinal cord in the cervical region, then, on dividing both vagi, or exciting the accelerator nerves, only an insignificant change of mean arterial pressure is to be observed.⁵ In this case the blood escapes with great rapidity into the veins. This is a fact of the utmost importance, for it is evident that unless the arterioles are closed down to a certain extent, the heart cannot, between its contractions, maintain the arteries in a condition of distension.

THE CENTRES OF THE CARDIAC NERVES AND CARDIAC REFLEXES.

After placing one electrode within the nostril of a frog, and the other on a cross-section of the spinal cord at the level of the fourth or sixth vertebra, the astounding observation was made by the brothers Weber that tetanic excitation caused standstill of the heart. This experiment led to the discovery of the function of inhibition. By further experiments the Webers localised the seat of the inhibitory power to the spinal bulb, in the region which lies between the optic lobes and the lower end of the calamus scriptorius.¹ By using the prick of a needle as a method of excitation, Eckhard² more minutely localised the inhibitory centre in the frog to be between the cerebellum and the tip of the calamus scriptorius. In rabbits, after dividing the spinal cord immediately below the medulla oblongata, excitation of the

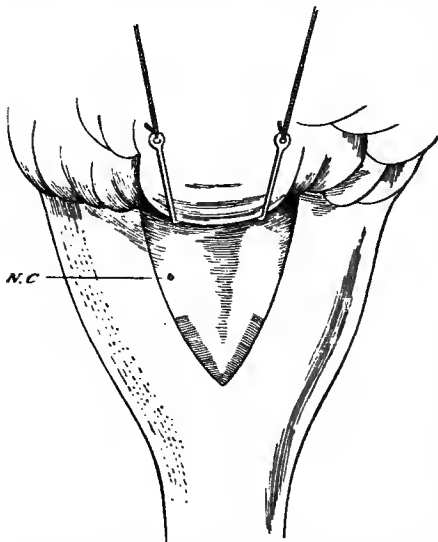

FIG. 37.—Posterior view of medulla oblongata of the cat, showing *N.C.*, position of vagus centre; semi-diagrammatic.—Laborde.

fifth nerve reflexly slows the heart.³ By the needle method of excitation, Laborde⁴ localised the vagus centre in the cat to a point in the middle of the spinal bulb lying in the lateral part of the floor of the fourth ventricle. At this spot there is situated a mass of grey matter, which forms the accessory nuclei of the hypoglossal, spinal accessory, and glosso-pharyngeal nerves.

The vagal centre can not only be excited by the stimulation of afferent nerves, but it can also be influenced by the direct action of blood on the centre, and from the cerebrum. The frequency of the pulse can be altered by psychical and emotional conditions. In many men the pulse may be slowed by directing the attention to the contemplation of painful subjects. It is constantly accelerated in emotional patients by mere physical examination on the part of a physician. In the case of an individual counting his own pulse, the frequency often becomes diminished.

Tarchanoff observed a medical student who could alter his pulse rate at will.⁵ He found that men with this faculty had generally a remarkable power over their muscles; for example, they could bend the third joint of a finger independently of the other joints, or contract the platysma muscle.

In conditions of hypnotism, the pulse rate has been observed to

change markedly under the influence of suggestion. Inquiry for cerebral cardiac centres has been made by the methods of cortical excitation. If, by the use of suitable strengths of current, the excitation of epileptic fits be avoided, François-Franck finds that stimulation of any part of the motor area accelerates the heart when a weak current is employed. On the other hand, a strong current slows the heart. From other parts of the cerebrum the heart can also be influenced. All these cerebral effects are similar to those excited reflexly by stimulation of afferent nerves. The vagus centre maintains over the heart a tonic bridle action, and the question arises as to whether this tonus is kept up reflexly by the constant in-streaming of afferent impulses, or whether the centre possesses automatism.

According to Soltmann and others, vagal tone is not to be found in the new-born animal.¹ On the other hand, pressure on the head of the new-born child slows the pulse,² and thus the centre can be reflexly excited. In support of the hypothesis that the tone depends on afferent impulses, the following experiments may be quoted:—

1. After dividing the cervical spinal cord, the heart is said not to be accelerated by a subsequent division of the vagi.

2. After section of the splanchnic nerves, and thus diminishing the sensory field from which reflexes are excited, the pulse frequency is increased.

Neither of these experiments, however, proves that the tone depends on afferent nerves, for the arterial tension is greatly lessened by both operations. In consequence of any great fall of arterial tension, the heart is accelerated. This acceleration may be so great that the frequency is not increased to any further degree by section of the vagi. There can be no doubt that the arterial pressure is one of the most important agencies by which the vagus centre is constantly influenced, and since it is quite impossible to cut off all afferent impulses from this centre, and at the same time remove the influence of the arterial pressure, the automatism of the centre can neither be proved or disproved. The theoretical assumption of such a power is not required.

After section of both vagi, excitation of the medulla oblongata causes cardiac acceleration. This acceleration takes place after section of the splanchnic nerves, and thus is independent of vaso-constriction and the rise of arterial tension, which normally follows such excitation. A centre for the accelerator nerves is localised in the spinal bulb, and is said to maintain a tonic influence over the heart. Tschirjew,³ and also Stricker and Wagner,⁴ have witnessed, after section of the vagi, a decrease of the pulse rate to take place on excision of the inferior cervical and first thoracic ganglia. It is also affirmed that, after section of the accelerator fibres, inhibition by excitation of the vagus can be induced with greater ease than before. The inhibitory effect is likewise obtained more easily after section of the cervical spinal cord.⁵

Since, by the operative procedures of exposing the accelerator nerve,

or dividing the spinal cord, the action of the respiratory pump is greatly diminished, the above experiments cannot be accepted as convincing proof of the tonic action of the accelerator nerves. The best proof of such tonicity is the fact that Timofeew¹ has kept animals for some time after section of these nerves, and has observed in them a persistent decrease in pulse frequency. The tonicity of the accelerator centre is normally held in check by the stronger tonicity of the vagus centre.

The influence of the blood pressure on the frequency of the heart has been studied both on the isolated heart and on the heart *in situ* in the normal conditions of life. The results obtained have been contradictory and confusing, because the effects of the two factors of most importance, namely, the venous filling pressure and the arterial or systolic output pressure, have not been in all the researches carefully and separately analysed. If the inflow or venous pressure be kept constant in the excised heart of the frog or tortoise, in which an artificial circulation has been established, then it is said a variation of the arterial pressure, by increasing the resistance to outflow, produces no effect on the frequency. On the other hand, an increase of venous pressure accelerates the heart.² Newell Martin drew the same conclusion from observations made on the excised heart of the dog maintained in functional activity by a circulation of defibrinated blood at a constant temperature.

When the normal circulation is maintained with the heart *in situ*, and all the cardiac nerves are divided, then by compression of the abdominal aorta or excitation of the peripheral end of the spinal cord or of the splanchnic nerves, the arterial tension is raised, and acceleration of the heart is caused, and the more so in proportion to the suddenness of the change of pressure. This result has been obtained by several observers, and, since all the nerves have been divided, the acceleration must be provoked by the direct action of the pressure on the heart itself.³ By all these methods of raising aortic pressure, not only the filling pressure of the heart, but the temperature of the blood may be changed. The variation in frequency cannot therefore be ascribed with certainty to the rise of arterial tension. Since a high intracardiac pressure has been found by all authors to render vagus inhibition more difficult, we must suppose that either the intracardiac centre of this nerve is hindered from action by the rise of diastolic pressure, or that the part of the cardiac musculature at which the contractions originate is rendered thereby hyper-excitable.⁴ If all the cardiac nerves be intact, a rise of arterial pressure always slows the heart, and a fall accelerates it. This mechanism, first recognised by Marey,⁵ is of great importance, for by its means the constancy of the arterial pressure is maintained. So long as the vagi are intact, the arterial pressure cannot be greatly raised. Whether the centres are normally excited by afferent impulses, or directly by the blood pressure, is not

⁵ "La circulation du sang," Paris, 1881, p. 334.

fully determined. The heart itself possesses afferent nerves, and by means of these it is quite conceivable that it can reflexly control its own beat. The afferent nerves of the heart do not include nerves which excite sensations of touch or pain, at any rate when the organ is in a normal condition. On touching the heart of Viscount Montgomery, who had, through an accident, lost part of the thoracic wall, Harvey was unable to excite any signs of consciousness. General reflex movements can, however, be excited.¹ Thus François-Franck succeeded in producing reflex inhibition of the respiration by chemical stimulation of the inner wall of the heart.²

By excitation of the central ends of the different nerves which are found running superficially on the anterior wall of the ventricle, Wooldridge obtained the following results:³—

1. Slowing of the pulse rate and a rise of arterial pressure.
2. Slowing of the pulse rate, followed by acceleration and a fall of arterial pressure.

On stimulation of the nerves which course over the posterior wall of the ventricle, he observed—

1. Acceleration of the pulse rate.
2. Slowing of the pulse rate and a fall of arterial pressure.
3. A rise of arterial pressure.
4. A fall of arterial pressure.

While stimulation of the central end of one vagus nerve—if the other end be intact—slows the heart, the arterial pressure may rise or fall, according as depressor or pressor fibres are in the ascendancy. The result varies in different individuals. From the right or left vagi, opposite effects on the arterial pressure may be obtained. The afferent nerves examined by Wooldridge run in the vagi. The arterial pressure may reflexly excite the cardiac centres in the bulb by way of these afferent fibres. In the case of the depressor nerve we have an analogous example.

After carrying out a division of the spinal cord in the cervical region, a sudden injection of blood at a high pressure into the peripheral end of the carotid artery provokes slowing of the heart.⁴ Sudden anæmia of the bulbar centres has the same effect, whether it be produced by ligation of the cerebral arteries or by compression of the brain. The vagus centre is first excited and then paralysed. Since acute anæmia of the spinal bulb primarily causes a slow beat and a rise of arterial tension, it is curious that the vagus centre should be directly excited to greater activity by a rise of arterial tension, which increases the supply of blood to the spinal bulb. It is conceivable in the above experiment that the sudden expansion of the cerebral arteries by a high-pressure injection momentarily pinches the spinal bulb within the closed cranial cavity, and renders it anæmic.⁵ If this suggestion be accepted, and it be agreed that the vagus centre is in all cases directly excited by anæmia, how is the normal interdependence of the arterial tension and cardiac inhibition to be explained? This is a question which cannot be settled, since the afferent nerve of the heart is also the afferent nerve or channel of inhibition.

⁴ François-Franck, "Trav. du labor. de Marey," 1877, tome iii. p. 276.

⁵ Hill, "The Physiology and Pathology of the Cerebral Circulation," London, 1896, p. 135.

On the whole, there is much to be said in favour of the supposition that the terminations of the afferent nerves on the inner wall of the heart may be stimulated by intracardiac pressure, and thus the controlling centres of the circulation—vagus, vasomotor, and respiratory—excited or depressed. If this be the case, the heart possesses a reflex mechanism for regulating, not only its own rate, but the whole circulation.

By moderate expansion of the lungs the heart is accelerated.¹ The afferent nerves of this reflex arc are the vagi. The frequency of the pulse is increased by singing, coughing, sipping water, reading aloud, and forced breathing. By starvation the excitability of the vagus centre is said to be greatly increased. The normal difference between the pulse frequency in inspiration and expiration becomes then very marked.² The heart is normally greatly accelerated by severe muscular exertion, but slightly so after division of the vagi, and not at all after also dividing the accelerators. These observations have been made on the rabbit.³

According to François-Franck,⁴ stimulation of the mucous membrane of the lungs and the upper part of the larynx produces slowing of the heart. Similarly, excitation of the nasal branch of the fifth nerve always

FIG. 38.—Reflex inhibition produced by inhalation of ammonia. The upper line is the trace of arterial pressure, the lower line that of the pulse.—François-Franck.

diminishes the frequency of the pulse (Fig. 38).⁵ Thus, cardiac inhibition is of usual occurrence during the primary stage of inhalation of chloroform.

In the frog, inhibition of the heart is produced with the greatest ease by tapping the intestines.⁶ The reflex arc for this effect is formed by the abdominal sympathetic, the spinal cord and bulb, and the vagi.⁷

Almost any form of stimulation of the abdominal viscera produces slowing of the heart. Sudden distension of the stomach may be especially mentioned as a means by which this reflex may be evoked.⁸ Excitation of the central end of the sciatic or splanchnic nerves arouses to activity both the vagal and the accelerator centres. The accelerator centre is usually the more strongly excited of the two, so that increased frequency is usually the resultant effect. The excitation of the vagal centre either lasts the longer or else becomes relatively increased by

the concomitant rise of arterial tension, so that after a time inhibition takes the place of acceleration. In some cases the vagal effect may be the stronger from the first.¹ The frequency of the heart can similarly be affected by stimulation of every other afferent nerve in the body. The nasal branch of the trigeminus seems to stand alone as the one afferent nerve which always produces slowing and never acceleration of the pulse.

THE DEPRESSOR NERVE.

In the rabbit, from the junction of the vagus and superior laryngeal nerves, there arises by two roots a fine nerve, which courses down the neck.

On excitation of the central end of this nerve, Ludwig and Cyon² witnessed a surprising fall of arterial pressure, accompanied by a slight decrease in cardiac frequency. The peripheral end failed to give any response to stimulation. Thus the purely afferent nature of the nerve was established. On repeating the excitation of the central end, after section of both vagi, the arterial pressure fell to an undiminished extent, but the pulse rate, in this case, remained unchanged. After section of all the cardiac nerves, the result was still the same. This nerve was named, by Ludwig and Cyon, the depressor, for it possessed the power of depressing the arterial tension by 30 to 50 per cent. Ludwig and Cyon observed that, on stimulating the depressor, the kidney flushed red with blood, while the fall of arterial tension became insignificant after section of the splanchnic nerves.

In the lower parts of its course the depressor nerve joins the nervous strands which issue from the first thoracic or stellate ganglion; thence, passing behind the aorta, and through the connective tissue which lies between the latter and the pulmonary artery, it reaches the heart. The fibres eventually gain the cardiac wall, and course over the ventricle. At this point they have been stimulated by Wooldridge.³ Some depressor fibres are found to run in the vagi of the rabbit.

In different mammals, many variations are to be marked in the course of this nerve, but, in all, fibres with a depressor function are to be found. The same arrangement as in the rabbit, is met with in horses, hares, pigs, and hedgehogs. In dogs, and sometimes in cats, the depressor fibres are bound up with the vago-sympathetic trunk, but can often be separated as a distinct strand from the rest of that nerve. No sign of a depressor nerve has been found in any cold-blooded animal,

FIG. 39.—Dissection of the depressor nerve, rabbit. 1, sympathetic (the white line next to it is the line of the carotid artery); 2, hypoglossal; 3, descending branch of hypoglossal; 4, branch to this from cervical plexus; 5, vagus; 6, origin of superior laryngeal; 7 and 8, origin of depressor from vagus and superior laryngeal.—Ludwig and Cyon.

although it has been diligently sought for by several observers. In man, the homologous nerve arises from the junction of the vagus and superior laryngeal nerves, but quickly joins again the main trunk of the vagus.

The depressor seems to exert no tonic action on the vasomotor centre. Neither during normal conditions, nor in the state of asphyxia, is any rise of arterial pressure produced by sudden section of both depressors.¹ The depressor seems incapable of fatigue. It has maintained its full functional effect during a period of excitation lasting seventeen minutes.²

If the vagi be cut, excitation of the depressor is often followed by acceleration of the heart. This is the ordinary effect of a fall of blood pressure. If, while one depressor is under excitation, the other be stimulated, a summation of effect is produced.

The activity of the depressor abolishes or very much diminishes Traube-Hering curves, when these are present on the tracing of arterial pressure. At the same time, it lessens the extent of the respiratory undulations. On simultaneously exciting a pressor nerve, such as the anterior crural, together with the depressor, an antagonism is provoked,

FIG. 40.—Aortic pressure. Excitation of depressor. The drum was stopped in the middle of the curve, and the excitation maintained for seventeen minutes. The line of zero pressure (0, 0) should be 30 mm. lower than is here shown.—Bayliss.

and the strongest produces its effect. So when the depressor is excited, and asphyxia produced, the pressor effect overcomes and abolishes the depressor influence, while, if the excitation be continued, and respiration be supplied, the depressor effect, after a short period, regains the mastery.³ Neither pressor nor depressor effects can be obtained after the injection of strychnine, nor does the depressor act while the arteries are contracted by intravenous injection of suprarenal extract.⁴

Excitation of the depressor increases the resistance in the central nervous system in such a way as to prevent the tonic influence which is maintained by the vaso-constrictor centre. It does not appear, however, to produce anabolism of this centre during the period of rest or inhibition, for the rise of arterial tension produced by asphyxia is no greater after than before stimulation of the depressor.

³ *Ibid.*, p. 319.

⁴ Oliver and Schäfer, *Journ. Physiol.*, Cambridge and London, 1895, vol. xviii.

An alternative view is that the depressor excites a hypothetical vaso-dilator centre. There are, however, certain differences between the depressor and other vaso-dilator nerves. The latter are easily exhausted by artificial stimulation, while the former is inexhaustible. On the other hand, according to Bayliss, section of the spinal cord at the level of the second lumbar nerve-root¹ prevents, when the depressor is excited, any manifestation of dilatation in the lower limbs; and fibres producing vaso-dilatation of the legs have been found, by Bradford and Bayliss, by direct excitation of the third, fourth, fifth, sixth, and seventh lumbar roots. The question is one not yet definitely settled, and no conclusion as to the exact method of action of this nerve can be drawn. Light should be thrown on the subject by experiments on such a gland as the salivary, which possesses a distinct and powerful supply of both vaso-dilators and vaso-constrictor nerves. It should be possible to determine by section of one or other of these nerves the channel by which the depressor acts. The depressor stands alone as a distinct type of nerve. No other nerve in the body can, on excitation

FIG. 41.—Aortic pressure and volume curve of limb. A, Excitation of depressor.—Bayliss.

of the central end, uniformly produce a reflex fall of blood pressure. By all other nerves, either pressor or depressor effects are provoked, and, generally, on prolonging the excitation, the first effect is followed by the second. The depressor is purely an afferent dilator nerve.

Almost all parts of the vascular system can be thrown into dilatation by the depressor nerve. While compression of the thoracic aorta does not entirely abolish the fall of arterial tension produced by excitation of this nerve, section of the spinal cord in the cervical region does do so. It follows that parts of the body above the abdomen must share in the reflex dilatation.

By Bayliss the question has been minutely studied. He employed the plethysmographic method. The limbs were enclosed in a glass cylinder, the connection being made air-tight by means of an india-rubber collar greased with vaselin; the variations of volume were recorded by means of a tube passing from the cylinder to a delicate tambour. In such experiments, in order to avoid disturbing elements, due to movements or cardiac inhibition, it is necessary to place the animal under curari, and to divide both vagi. The limbs dilate on exciting the depressor, but the latent period is long.² This is in consequence of the primary passive constricting effect produced in the limb by the fall of arterial tension.

¹ The vaso-constrictor nerves for the lower limb come off above this level.

² Bayliss, *Journ. Physiol.*, Cambridge and London, 1893, vol. xiv. p. 304.

After clamping the thoracic aorta, or dividing the spinal cord in the dorsal region, excitation of the depressor still causes a fall of arterial pressure. This fall is abolished by section of the cervical sympathetic nerves. The vessels of the head and neck therefore share in the production of the depressor effect, and, on plethysmographing the tongue, this organ is found to dilate. So, too, the thigh muscles, free from skin, and the foot, which is practically all skin and bone, are both found to dilate (Bayliss). Thus we may conclude that the action of the depressor is almost universal, nevertheless the splanchnic area is by far the most important seat of dilatation. It is by means of this afferent nerve that the heart can relieve itself of too great a systolic strain. The splanchnic floodgates can be thrown rapidly open thereby, and the peripheral resistance lowered.

When an animal is placed in the feet-down position during excitation of the depressor, the arterial pressure, owing to splanchnic dilatation, falls to a very marked extent.¹

HÆMODYNAMICS.

The circulation of the blood follows certain definite laws; unfortunately the conditions of flow are so complicated that these laws remain for the most part still undetermined.

A viscous fluid driven by an intermittent pump which circulates through a system of branching elastic tubes of varying capacity; a system of tubes into and out of which passage of fluid takes place either by osmosis, filtration, or secretion; a fluid which varies in viscosity; a pump which varies in force, and tubes which have an ever-changing diameter and coefficient of elasticity. It is in the first case helpful to consider the flow of fluids in certain simple models, where the conditions are constant. The application of theoretical deductions thus obtained must be tested by experimental inquiry on the living animal.

Torricelli's law.—If a circular hole be pierced in the bottom of a vessel of water, the outflowing fluid, according to the law deduced by Torricelli, should have a velocity $V = \sqrt{2gh}$.

Now, the velocity of a free falling body, when it has fallen through a space h , equals $\sqrt{2gh}$. Therefore the velocity of the fluid escaping through the hole in the bottom of the vessel is equal to that which the fluid would attain if it had fallen free through the height of the column of water. In other words, the velocity of outflow is that velocity which a free falling body, starting from a state of rest at the surface, would gain on reaching the orifice. Given the velocity of outflow, and the sectional area of the orifice, the product of these two is equal in a given time to the volume of the output. The output is equivalent to the cylindrical column of fluid which has fallen through the orifice in the given time. If A is the volume of the output, then $A = \pi r^2 \sqrt{2gh}$.

Experiment, however, yields an actual result which shows that the outflow is less than that theoretically deduced. This is because the motion at the orifice is not steady. Eddies are there set up; and in consequence of their counter-action, the well-known phenomenon of the vena contracta is produced.

Thus, whenever fluid in motion meets a sharp edge, there is a breach of continuity and a consequent loss of energy. This loss can be avoided by imitating the form of the vena contracta and making the orifice bell-shaped. With a bell-shaped orifice the observed velocity is 0.99 times the theoretical value. Such an arrangement exists in the branches of the aorta. Thoma has determined this by injecting molten paraffin at blood pressure into the arterial circulation, and cutting sections at the points of branching. The shape of

¹ Hill and Barnard, *Journ. Physiol.*, Cambridge and London, 1897, vol. xxi. p. 335.

the curve formed by a plane section through the axis of a main artery and its branches is approximately a parabola, and this is found by experiment to be the best shape. Hence there is no energy lost when blood passes from a main artery into its branch.¹

If a tube be fixed to the orifice, then the mean velocity of outflow through such a tube leading from the bottom of the vessel is found to be less than through the simple orifice. This is due to the resistance to the flow in the tube, owing to viscosity of the fluid; that is, in a simple case, where the fluid wets the inner wall of the tube. Now, "rigid mathematical calculation can only be applied to the motion of actual fluids, as long as it is not turbulent; when a certain limit of velocity is exceeded the motion is disturbed."

By introducing a small stream of coloured liquid into transparent tubes, in which water was moving with a velocity nearly equal to that of the blood, Nicolls found the motion not turbulent in tubes of different diameters. We may assume, therefore, that the flow in the blood vessels is not turbulent.

Flow of fluid in cylindrical tubes.—In a cylindrical tube, the fluid particles, flowing under constant pressure, move parallel with the axis, but with varying velocity. In the axial layer the velocity is at its greatest, at the wall it is practically nil. The material of which the wall is made has no influence on the velocity, the whole friction lies between the particles of fluid. In any two tubes, equally long and wide, it is only the chemical and physical qualities, *i.e.* the viscosity of the circulating fluid, which influence the relative velocity of flow. Since the threads of fluid which are at the same distance

FIG. 42.

from the axis will move at the same velocity, the fluid may be considered as consisting of an infinite number of concentric cylindrical surfaces, which glide over one another, and move the more rapidly, the smaller their radius. The velocity which is reckoned from the outflow per second per sectional area of the tube, yields us the mean velocity of all these cylinders of fluid.

*The mean velocity in such tubes as we are considering, where the motion is steady, is equal to half the axial velocity.*²—It is the friction between the particles of fluid, or the viscosity, that causes the outflow from a tube to be less in a given time than from a free opening of the same bore. Part of the head of pressure is spent in overcoming this viscosity. The amount of head so lost in overcoming fluid friction is in a uniform tube proportional to the length of tube which has been traversed by the fluid. This may be shown experimentally by means of the apparatus sketched in Fig. 42.

In the figure, A is a vessel filled with fluid to the level shown; BC is a uniform tube attached horizontally to A; D, E, F, H, M, N, are vertical tubes (piezometers) to indicate the lateral pressure at different points along

¹ Nicolls, *Journ. Physiol.*, Cambridge and London, 1896, vol. xx. p. 416.

² v. Kries, *Arch. a. d. physiol. Anst. zu Leipzig*, 1887, S. 101.

BC, of which M and N are provided with bent nozzles, turned in the case of M to face the direction of flow, in the case of N in the direction of flow; S is a stopcock, by means of which the fluid can be allowed to flow along BC with different velocities.

So long as S is kept closed, the level of the fluid in all the tubes is the same as that in the vessel (A); but as soon as S is opened, the level falls in all the tubes, and the fall is greater, the greater the distance along BC. This gradual fall in pressure along BC is due to the loss through fluid resistance, and as the amount of this loss is proportional to the length of tube traversed (when the tube is uniform and the flow constant), it follows that the fall in head in the tubes (D, E, F, and H) will be proportional to the length at which each of these tubes is situated along BC, measured from the opening into the reservoir (A), and will be represented by the line (XY). Since the fluid resistance in a tube varies with the square of the velocity of the fluid, it follows that the loss in head when the velocity is varied will be directly as the square of the velocity. Hence, when the flow is made faster by opening more fully the stopcock (S), the line of fall of pressure becomes more steeply inclined. The tangent of the angle of slope of this line to the horizontal line (BC) is called the "pressure gradient." The pressure gradient is from this evidently equivalent to the fall in pressure per unit length.

Besides this gradual fall, due to fluid resistance along BC, there is a sudden drop in lateral pressure just at the beginning of BC, which is not due to fluid resistance, but to a portion of the pressure due to the head in A being used to give velocity to the fluid as it enters BC. The amount of head so lost is called the "velocity head." Its value is easily calculated when the velocity is known, for equating potential energy lost to kinetic energy gained, $2gh = v^2$, or $h = \frac{v^2}{2g}$, where h is velocity head, v is velocity, and g accumulation due to gravity.

The dependence of the velocity head on the velocity can be shown by manipulating the tap (S). When the flow is made very slow, the pressure in D is nearly the same as that in A; when the flow is increased, the level falls in D, showing that the initial loss in pressure due to velocity has increased. At the same time, the effect of the increased velocity on the pressure gradient is shown by the increased steepness of the line (XY). That the loss in lateral pressure due to velocity head persists all along the tube (BC) can be shown by the tubes (M and N). In M the impact of the fluid against the mouth of the tube raises the level in M above the height due to the lateral pressure alone at that point by an amount (ab) equal to the velocity head. Similarly, in the tube (N), the suction of the fluid passing the bent end depresses the column in N by an amount (ce) equal again to the velocity head. The lateral head at any given point is often called the "effective head;" and the loss in head due to fluid resistance up to any point, the "resistance head." It is evident that the sum of velocity head, resistance head, and effective head must equal the total head, or reservoir head.

In the arteries the velocity head is very small, because the velocity of flow is not great; taking the velocity in the aorta as 32 cms. per second, the velocity head, $h = \frac{32^2}{2 \times 981} = \frac{1}{2}$ cm. of blood.

Poiseuille's law.—In tubes wherein the threads of fluid move in parallel lines, Poiseuille has laid down the law that the mean velocity is directly proportional to the sectional area of the tube and the pressure gradient. In other words, we can find the mean velocity by the product of three factors—sectional area, pressure gradient, and a constant coefficient (C), which depends on the viscosity or physico-chemical nature of the fluid in the conditions of experiment. This coefficient can be defined as that mean

velocity which a current would have, with a unit pressure gradient in a tube of unit sectional area.

Jacobson¹ passed water through a tube of constant bore, 437 mm. long and 1.147 mm. in radius, with a mean velocity of 802.54 mm. per second. The pressure gradient was 0.5485 mm., and the cross-section of the tube 4.132 sq. mm. According to Poiseuille's law, then

$$802.54 = C \times 4.132 \times 0.5485 \therefore \text{the coefficient } C = 353.85.$$

Having once found the value of the coefficient, the velocity, if Poiseuille's law be right, can be reckoned in any experiment carried out under the same conditions, where the sectional area and the pressure gradient are known. Jacobson experimentally found that this was so. Let R = the radius of a tube, V = the velocity of any particle at a distance (A) from the centre. Let l = length of tube, p p' the pressures at the two ends of the tube, μ the coefficient of viscosity. Then $V = \frac{p - p'}{4\mu l} (R^2 - A^2)$ \therefore the velocity varies inversely as the

viscosity. The axial velocity = $\frac{p - p'}{4\mu l} R^2$. The mean velocity = $\frac{p - p'}{4\mu l} \cdot \frac{R^2}{2}$

The quantity of fluid which flows through in a given time $t = \frac{p - p'}{4\mu l} \cdot \frac{\pi R^4 t}{2}$

The coefficient at one and the same temperature varies for different fluids, and is found to be smaller in proportion to the viscosity of the fluid. Nicolls investigated the viscosity of blood by means of Poiseuille's viscometer. The liquid was allowed to escape from a reservoir through a capillary tube in a horizontal position. The two orifices at the ends were bell-shaped, and at the end where the fluid issued there was a lip to prevent the resistance of surface tension. The viscosity is obtained from the time occupied in emptying the reservoir.

The viscosity of blood was found by Ewald² and by Nicolls to be about five times, by Lewy³ three and a half times, that of distilled water. A mixture of blood and water is less viscous than blood. The viscosity of blood diminishes rapidly as the temperature rises. Assuming that this is true in the living body, it follows, if the quality of the blood remains unchanged, that the rise of temperature in fever diminishes the resistance, and consequently the heart has less work to do.

Duncan and Gamgee found that the velocity of flow in glass capillaries of 0.9289 to 1.259 mm. diameter was greater for unclotted than for defibrinated blood.⁴ The viscosity of the blood is increased by addition of CO₂, ether and chloral, decreased by laking the blood.

By experiments upon the flow of distilled water in capillary glass tubes, 0.15 to 0.65 mm. in diameter, Poiseuille reached the following conclusions:—

1. That the amount of outflow is proportional to the head of pressure.

2. That the time spent in the outflow of a certain volume of fluid at a constant pressure is, if the diameter be constant, directly proportional to the length of the tube.

3. That with the same head of pressure, the time spent in the outflow of a certain volume of fluid through equally long tubes is inversely proportional to the fourth power of the diameter. Thus, if A be the volume of outflow per second,

$$A = \frac{kr^4}{l} H, \text{ and } V = \frac{A}{\pi r^2} = \frac{kr^2}{\pi l} H,$$

where r is the radius, l the length of the tube, H the pressure head, and k

¹ *Arch. f. Anat., Physiol. u. wissenschaft. Med.*, Leipzig, 1860, S. 85. Quoted from Tigerstedt's "Physiol. des Kreislaufes," S. 312.

a coefficient depending on the viscosity and temperature of the fluid, but independent of the structure of the tube wall so long as this is wetted by the fluid; k is known as the transpiration coefficient:

In such a model as is shown in Fig. 42, the velocity head can be easily determined by an instrument which can be directly applied to the circulation.¹ The instrument is a glass tube (nqs, Fig. 43).

"From n to q the tube is of a fine bore, and at n there is a small bell-shaped opening. When the tube is plunged into moving liquid, so that the orifice (n) faces the current, as at I (Fig. 42), the fluid will rise to the height Ih , due to velocity and pressure; if n be turned at right angles to the current, the height will be Ia ; and if turned so that n is with the current as at J , the height Je will be less than the pressure head by an amount ce , which is nearly equal to the velocity head. By means of this instrument very accurate results can be obtained, especially for velocity, as, by taking the difference of two heights, the effect of capillarity disappears. When the pressure is high, as in an artery, the following modification can be adopted. The end of the tube (s) is connected with a rubber tube (P) provided with a clamp. P is, in its turn, connected with a glass reservoir (D) containing air; this is covered thickly with cotton-wool, to prevent changes of surrounding temperature affecting the air. The glass reservoir is connected with a mercury manometer (M) and a syringe by tubes (R and Q) provided with clamps. The tube (P) is clamped, and the pressure is raised in the reservoir to a point which is known to be

FIG. 43.

about that of the arterial tension. The tube (nq) is then introduced into the artery, and the clamp (Q) is closed and P opened."

The tube (nq), in experiments with this instrument, is filled with a solution of oxalate of potash to prevent clotting. In one of Nicoll's researches, the inferior mesenteric artery was exposed and divided in a dog, and through it the end (n) was introduced into the abdominal aorta. At the beginning of the experiment, the height of the fluid in ns indicated a pressure of 145 mm. Hg. The velocity head was a little over 6 mm. Hg, indicating a mean velocity = $\sqrt{12g} = 346$ mm., for $V^2 = 2gh$. The change of height in ns due to pulsation was 9 mm. Hg.

The flow in a tube of varying diameter.—Since fluid is incompressible, an equal amount must flow in the unit of time through every section of the tube, and thus the velocity in any part of a tube which varies in diameter stands in inverse proportion to the sectional area. In such a tube the pressure gradient is steepest in the narrowest section, for there the velocity and the friction is greatest. In two sections of equal diameter the pressure gradient is the same. Where a wide section follows upon a narrower, the lateral pressure may either sink, remain unaltered, or even rise. How this can be so will appear from the following considerations. At any point of the tube the whole pressure head (H) equals the sum of the velocity head (h') and the resistance head (h^2).

¹ Nicolls, *Journ. Physiol.*, Cambridge and London, 1896, vol. xx. p. 417.

Now, H decreases uniformly along the tube, and since where the tube widens the velocity becomes less, and h' suddenly diminishes, it follows that h^2 increases, and it is conceivable that h^2 in the wide section may become higher than h^2 in the narrow section. In other words, since more of H is spent in maintaining the velocity in the narrow section, the lateral pressure may be lower there than in the succeeding wide section.

The flow in branching tubes.—When a tube branches into a number of smaller tubes, and these collect again into one tube, we have two opposing factors to consider—

1. The increase of sectional area. The velocity is inversely proportional to the sum of the sectional area of the branches.

2. The increase of resistance, due to the great extent of surface contact between the moving fluid and the fluid that wets the walls of the tubes. The resistance is proportional to the surface area, nearly proportional to the square of the velocity, and inversely proportional to the sectional area. The formula used by engineers for what they call skin friction is $R = kSv^2$, where R = resistance; k , a constant; S , surface area; v , velocity.

On passing from a to b (Fig. 44), the velocity has decreased, but great resistance has been overcome; the total effect therefore will be a much lower lateral pressure at b . On passing from b to c the velocity increases, and a further great fall of lateral pressure will have taken place owing to the resistance that has been overcome between b and c .

FIG. 44.

The flow in elastic tubes.—The same laws which have been discussed in connection with rigid tubes obtain in elastic tubes, if the flow of fluid be continuous.

If the inflow be intermittent:—in the case of the rigid tube the whole column of fluid is driven on, step by step, by each stroke of the pump, and the outflow is also intermittent. In an elastic tube, on the other hand, if the resistance to the output be made great, as by constricting the orifice, the elastic wall of the tube is extended by the input of the pump, and the elasticity of the wall comes into play, and continues the output after the stroke of the pump has ceased.

By the heart the blood is rhythmically driven into the arteries; the arterial walls are elastic; in the small arteries, arterioles, and capillaries, there exists great resistance. All the conditions are present for converting the intermittent flow from the heart into the continuous flow through the capillaries.¹ If the arteries were rigid tubes, the heart would be required to drive on the whole blood at one and the same time in all the vessels, in place of intermittently forcing a certain small volume of blood into the large arteries. The heart is, on the contrary, saved this large expenditure of work, and after each systole retires into its diastolic rest, leaving the elasticity of the large arteries to continue the circulation. Further, if two tubes be taken, one elastic and the other rigid, and they be chosen so that each delivers the same output when fed by a continuous inflow, then, if the inflow be made intermittent, it is found that the elastic tube now yields the greater output.²

Beyond these advantages, due to the intermittent pump and elastic tubes, there is another physiological fact which as yet has received no explanation. It has been found that, if normal saline be artificially circulated by continuous pressure through the vessels of an animal, œdema of the tissue soon arises, and the outflow decreases. If, on the other hand, the inflow be made rhythmic, as in the natural condition, then the œdema is insignificant, and the outflow

¹ Stephen Hales, "Statistical Essays," vol. ii.

² Marey, *Ann. d. sc. nat. Zool.*, Paris, 1857, tome viii. p. 330.

is fourfold as great as in the first case.¹ The efficacy of an impulsive compared with a steady force is a matter of everyday observation, and we may perhaps attribute this result to the opening of the capillaries by the *impulsive* action of wave motion.²

A DISCUSSION OF SOME OF THE GENERAL PRINCIPLES OF THE CIRCULATION.

By E. H. Weber³ the model represented in Fig. 45 was constructed. This can be conveniently used as the basis for the discussion of some of the main principles of the circulation. In this model, a piece of small intestine, fashioned as a single chamber, represents the heart (*H*). The valves are formed of short pieces of intestine, which are firmly tied on to pieces of glass tube.

FIG. 45.

sponge (*C*) is inserted within this loop to take the place of the arterioles and capillaries. The model is distended with water to an extent represented by *m* and *n* in the manometers *D* and *D'*.

Suppose the model be laid upon a horizontal surface, so that the effect of gravity is eliminated, and the conditions made as simple as possible. If by squeezing it with the hand, *H* be now made to contract, the fluid contained therein is directed by the valves and forced on into *AA*. If *AA* were a rigid tube, the whole column of fluid would be forced on at one and the same time, and the flow of fluid into *V* would last only just so long as the contraction of *H* was maintained. As, however, *AA* is an extensile elastic tube, the projection of the fluid is successive. The systolic output first finds a place by distending the tube (*A*), and produces therein a positive wave, which travels with a certain velocity through the system. This velocity is independent of the velocity of flow. If the valves were not competent, and the systole passed into diastole at the moment the blood was expelled, then the expanded tube (*A*) would drive part of the blood back again into *H*, and a negative wave would arise, which, following the positive wave, would also travel with a certain velocity through the system. In the entire absence of valves, the fluid particles would swing backwards as much as forwards, and in the end would suffer no change of place. As, however, the valves are competent, there is no back swing into *H*, and each systole pushes on the fluid a step further.

If all valves were absent from *H*, the fluid would stream into it from both sides of the system at the moment when the pressure on it was relaxed;

¹ Hamel, *Ztschr. f. Biol.*, München, 1888, Bd. xxv. S. 474.

² Nicolls, privately communicated to the author.

³ *Ber. ü. d. Verhandl. der königl. Sächs. Gesellsch. der Wissensch.*, Leipzig, 1850, S. 186.

These are fixed within and to either end of the heart. The valves are prevented from turning inside out under pressure by short guiding strings, which, fastened as they are to the edges of the valves, take the place of the chordæ tendineæ. The artery (*A*) and the vein (*V*) are formed of a long loop of intestine, and a

thus two negative waves would appear; one of these would travel through *A*, the other through *V*. As on diastole the valves (*d*) shut to while the valves (*d'*) open, the fluid from *V* alone can stream into *H*, and a negative wave appears in *V* only. Thus the model is so constructed that, during the periodic systole and diastole, only waves of positive pressure appear in *A*, and waves of negative pressure in *V*. Both waves aid one another, and cause the fluid to move in one and the same direction.

If the system were formed of wide tubes, free from constrictions, each positive wave would travel with so great a velocity, that the whole system would reach the same pressure, and before the next systole occurred a condition of equilibrium would be established. On the other hand, on account of the resistance in the sponge, which represents the arterioles and capillaries, it is otherwise. The internal friction or viscosity of the fluid particles, as they pass through the interstices of the sponge, prevent the fluid from pressing through with anything like the velocity of transmission of the positive wave. Thus the positive wave becomes reflected at the sponge, and runs to and fro in

FIG. 46.—Distribution of pressure and velocity during diastole and systole of the heart.—Fredericq.

A, until it is finally damped down and lost, so that no pulse reaches *V*. Should, however, the sponge be loose in structure, and possess wide pores, then the pulse might pass through into *V*.

If the periodic systole of *H* be made to occur with a sufficient frequency, the fluid is piled up in *A*, for at each systole a fresh quantity of fluid is driven into *A*, while, in the same time, a less quantity escapes through the sponge into *V*.

With each systole the pressure mounts in *A*. In *V*, the pressure, on the other hand, may sink, but it cannot sink below zero, in spite of the continued abstraction of fluid, owing to the fact that the flaccid wall of *V* cannot support any part of the atmospheric pressure. Suppose the pressure in the arterial manometer (*D*) has risen to *O*, and in the venous manometer has sunk to *p*, and at this point imagine the action of *H* to cease, the pressure will fall in *D* and rise in *D'*, at first with greater and then with decreasing velocity, until the pressure in the two manometers is once more the same. In other words, the action of *H* has upset the balance of tension, and this balance is regained by the flow of fluid in the direction of the arrows, at first with

great, and then with an ever-decreasing velocity, until the velocity reaches zero at the moment when the pressure in D and D' becomes the same. It is therefore clear that the flow of fluid is produced by the difference of pressure in A and V . If this pressure difference be greater, the velocity of flow is greater; if it be smaller, the velocity is smaller.

So soon as the pressure difference between the artery and vein is established, the fluid will move through the sponge into the vein, not in jets, but with a constant flow. If in the model, H be working with a constant rhythm and energy, and a constant flow be established, it is obvious that any change in the output per second of H , or in the peripheral resistance, will upset the constancy of the flow, until a new condition of equilibrium is once more established.

In such a continuous system as Weber's model, a hydrostatic mean pressure is obtained when the heart is at rest. This is the average fluid pressure, as already stated, which pertains to the system, when the capacity of the model is constant, and the fluid is in a state of stasis.

The hydrokinetic mean pressure is the average fluid pressure throughout the system when the fluid is in motion. These means are obtained by measuring the pressure at each unit of length along the tube and dividing by the number of units. Weber maintained that the hydrostatic and hydrokinetic mean pressures are equivalent; that is to say, the pump cannot increase the mean pressure of the system. By so much as it increases the pressure on the arterial side it will decrease it on the venous side. This deduction of Weber's is not admissible, for the arterial tension can be raised, while the tension in the vein cannot fall below zero, for, as already stated, the flaccid wall of the vein is unable to support any part of the atmospheric pressure.

It has also been held that contraction of arterioles, by the influence of vaso-motor nerves, not only increases the peripheral resistance, but also diminishes the total capacity of the system, so that we have the same effect produced as if more fluid were poured into the system. Thus, it has been said, an increase in peripheral resistance must always connote a rise in the hydrostatic mean pressure of the system brought about by the diminution of its capacity. According to this supposition, a rise of arterial tension, occasioned by vaso-motor activity must be explained by the coincidence of two factors—(a) increased peripheral resistance; (b) diminished capacity of blood vessels.¹ Now, if the model be not filled to distension, then any diminution of its capacity will not raise the fluid hydrostatic pressure above zero, until the reduction of capacity has reached the point when the walls of the system are thrown into tension. In other words, if 1000 c.c. be introduced within an elastic bag, capable of holding without distension 2000 c.c., the capacity of the bag can be reduced from 2000 c.c. to 1000 c.c. without any alteration of the tension of the wall. On turning to the evidences of experiment, we find that the vascular system is not filled to distension. The proofs for this statement are the following :—

1. Owing to the elastic resilience of the arteries, and the influence of gravity, the blood, after the arrest of the heart, passes into the venous side, and to the most dependent parts of the body. Thus the large arteries are found after death to be empty of blood.

2. It is not possible to distend the entire vascular system of a recently killed animal even by injecting into an artery a volume of fluid equal to that of the blood. Even after the injection of 500 c.c. of water into a dog, the tension in the arteries falls with the utmost rapidity. The fluid flows until it has collected in the most dependent parts of the body. By alternately placing the animal in the horizontal and vertical feet-down postures, the fluid can be

¹ Bayliss and Starling, *Journ. Physiol.*, Cambridge and London, 1894, vol. xvi. p. 165; cf. Mall, *Arch. f. Physiol.*, Leipzig, 1892, S. 409.

pumped from the arteries past the venous valves into the veins, and the arterial tension can be rapidly driven to zero.

3. In a normal living dog, the heart is arrested by stimulation of the vagus. During the standstill of the heart, the animal is alternately placed in the vertical feet-down and horizontal positions. By these means the blood is quickly pumped from the arteries into the veins. In the vertical feet-down position, the pressure in both the aorta and the vena cava superior becomes zero. On then opening the femoral artery, only a few drops of blood escape, and on turning the animal into the vertical feet-up position, air is sucked into the artery.

From the consideration of these experimental facts, it is clear (1) that the system is not filled to distension; (2) that various pressures can occur in different parts of it, when the heart is in arrest; (3) that a reduction in total capacity of the system need not raise the mean pressure of the whole. It is owing to the great capacity of the veins that the vascular system is not filled to distension. Normally, the larger number of veins have a flattened instead of a cylindrical shape, and, owing to this fact, a large amount of fluid can pass into them, before the elasticity of their walls is brought into play. On the other hand, the arteries are fashioned of a highly elastic distensile tubing, the capacity of which is very small when undistended, while the elasticity is so great that considerable tension is required to increase the capacity. The whole of the blood within the body can pass into the roomy reservoirs of the veins, and yet the walls of the veins will scarcely be thrown into tension. It is partly owing to these differences that the blood vacates the arteries, and collects in the veins after death. Brunner¹ found that, thirty seconds after complete cessation of the heart-beat and respiration, the fall of pressure in the carotid artery was thirty-eight to fifty-seven times as great as the fall in the jugular vein.

So long as the action of the heart and respiratory pump remain constant, neither in the vena cava, nor in the pulmonary artery, is there any rise of pressure during periods of vaso-constriction.² Thus, on excitation of the peripheral end of the spinal cord (divided between the sixth and seventh dorsal nerves), a rise of aortic pressure from 72 to 230 mm. Hg has been recorded, while the pressure in the pulmonary artery remained at from 20 to 21 mm. Hg.³ In such experiments the vena cava or pulmonary pressure does not rise until the heart fails to maintain the systolic output in face of the increased peripheral resistance. Similarly the fall of arterial pressure which takes place on general vaso-dilatation, is not occasioned in any part by the increase in the total capacity of the vascular system. This is further shown by the fact that the vena cava pressure is generally unaltered (it may sometimes either rise or fall slightly) when the spinal cord is divided in the upper dorsal region. The rise of arterial pressure which takes place on constriction of vascular areas, is due to the power of the heart and the increased peripheral resistance. The constriction of the arterioles acts in the same way as the closing of a clip placed on the aorta or on the tube (A) in Weber's model. The closing of the clip scarcely diminishes the capacity of the system, but the pressure rises behind the resistance.

One of the most striking phenomena in the circulation is the comparative independence of the systemic arteries, the pulmonary vessels, and the systemic veins. Large oscillations of pressure in the systemic arteries produce little or even no effect on the blood pressure in the venæ cavæ or pulmonary artery. The vascular system is especially constructed as a discontinuous system, in order that great changes of pressure may be brought about on the arterial side, without any very great alteration of the pressures in the venous or pulmonary

¹ *Ztschr. f. rat. Med.*, 1855, S. 336.

² Hill and Barnard, *Journ. Physiol.*, Cambridge and London, 1897, vol. xxi. p. 343.

³ Bradford and Dean, *ibid.*, 1894, vol. xvi. p. 34, Fig. 1.

side of the circulation. Thus the venæ cavæ have a constant low head of pressure, from which the heart draws its supply, and the diastolic pressure within the heart is kept constant during the enormous variations of arterial pressure which are brought about by vaso-constriction.

The variations in vena cava pressure under different circumstances can be seen in the following experiments carried out on dogs: ¹—

		Femoral Artery.	Vena Cava.
1.	Normal	92-94 mm. Hg	5·2-6·3 mm. Hg

	Injection of 500 c.c. of saline	124 „	17·3 „
	Ten minutes later	122 „	7·7 „

If at any moment the right heart be unable to empty itself, owing to obstruction in the pulmonary circulation—as, for example, in Valsalva's experiment—the large veins and the liver form a reservoir for the congested blood. In those animals which remain long under water—such as the seal, otter, and diving birds—large dilatations of the vena cava inferior occur. During the time of impeded respiration accumulation of venous blood takes place in the vena cava without an unusual distension of the right heart.²

If the left heart be unable to completely empty itself, and its output per second decrease owing to great increase in peripheral resistance, the pulmonary veins and capillaries will then, in the first place, form a reservoir for the congested blood; and when the pulmonary obstruction tells back on the right heart, the liver and systemic veins form a second line of defence. *It is to be concluded that the venous side forms a low-pressure reservoir for the circulatory system, by which the diastolic pressure of the heart can be maintained constant.*

The seat of peripheral resistance lies in the small arteries. That this is so is shown by the enormous fall of arterial pressure which takes place when the splanchnic arterioles are dilated by section of the splanchnic nerves. Normally, the sum of the resistances which, at each moment, oppose the flow from the aorta is maintained at the same value. When one vascular area dilates, another constricts, and thus the arterial pressure is maintained constant. Owing to the vasomotor mechanism the necessary blood quantum is greatly reduced, for, since the blood can be sent to any organ that requires it, all the available space in the vascular system need not be filled. A high-pressure main runs to all the organs of the body. By means of the vasomotor nerves the stream can be turned on here or there, and any part flushed with blood, while the supply to the remaining parts is proportionately diminished.

THE ELASTICITY OF ARTERIES.

The coefficient of elasticity of an excised strip of an artery is not a constant factor, for with the extension it increases. The curve

¹ Bayliss and Starling, *Journ. Physiol.*, Cambridge and London, 1894, vol. xvi.

² Allen Thomson, "Todd's Encyclopædia," 1836, p. 679.

obtained by equal increments of tension from such a strip is hyperbolic in form.¹

The variations in the volume of an artery examined under different degrees of internal tension has been measured by Marey,² Roy, and others. This can be done by the apparatus shown in Fig. 47.

In healthy arteries, placed under observation immediately after death, the volume by equal increments of internal tension will be found

to increase by equal increments up to a certain point. Under continued increase of tension the extensibility decreases, or, in other words, the coefficient of elasticity increases. Thus the elasticity curve of a healthy artery is a true hyperbola. In the rabbit's aorta the maximum extensibility,

FIG. 47.—R, pressure bottle; a, artery; M, plethysmograph.—Marey.

ity, or the point at which the change to a decreased ratio of extensibility takes place, is reached at about 70 mm. Hg; in the cat's, at 110 to 120 mm. Hg. In the living dog, by measurements of the diameter, the maximum extensibility of the aorta has been found at a pressure of 75 to 100 mm. Hg.³ In many arteries, taken from the post-mortem room, the extensibility is found to be greater at lower increments of tension. This is the case with all wasting diseases; and although, on microscopical examination, no structural change is to be found, yet the more advanced the marasmus preceding death, the lower is the pressure which corresponds to the maximum extensibility of the arteries. With the advance

FIG. 48.—The height between the horizontal lines represents extension of artery under different pressures. The pressures are noted at the end of the lines. The difference in length of the lines is merely for the convenience of placing the numerals.—Roy.

of age the arteries become less and less extensile. When the arterial pressure is high, it follows from the above fact that any increase in the

¹ Wertheim, *Ann. de chim. et phys.*, Paris, 1847, tome xxi. p. 385.

² "Trav. du labor. de Marey," 1880, tome iv. p. 78; Roy, *Journ. Physiol.*, Cambridge and London, 1881, vol. iii. p. 125; 1888, vol. ix. p. 227.

³ Zwaardemaker, *Nederl. Tijdschr. v. Geneesk.*, Amsterdam, Tweede Reeks, 1888, vol. xxiv. p. 61.

output of the heart must increase the blood pressure by a very significant amount. The arteries reach their maximum extensibility at the normal blood tension, 90 to 120 mm. Hg. Beyond this point the arteries become more and more rigid, and the heart must then at each beat push on a longer and still longer column of blood.

The elasticity of an artery is very complete. On removing the tension the volume returns exactly to its previous condition. On raising the internal tension up to the normal blood pressure the cubic volume of an artery very greatly increases, *e.g.* four to six times.

If the heart-beat be brought to a standstill by vagus inhibition, the arteries almost entirely empty themselves of blood into the veins.

When an artery is dilated by an injection of fluid, it reacts, according to John Hunter, with a force greater than that of the injection pressure.¹ This resilience is much greater in the living artery than in the dead artery. It is probable that when the heart, on vagus inhibition, ceases to beat, the arteries empty themselves by contraction of their muscular coat. Some arteries exhibit a propulsive wave of contraction, as is seen in the contractile *bulbus arteriosus* of amphibia and some fishes. The same phenomenon is to be seen in the rhythmic contractility of the arteries of the ear, in the saphenous artery of the rabbit, and in the vessels of the frog's web.²

The breaking strain of a healthy artery is very great. In some experiments of Volkmann, the carotid of a goat successfully withstood a pressure of 2250 mm. Hg, *i.e.* about fourteen times the normal blood pressure. It takes an internal pressure of 3000 to 8500 mm. Hg to rupture the carotid artery of a dog. In the case of the human carotid the smallest rupturing pressure was found to be 1290 mm. Hg. The larger arteries rupture more easily than the smaller, and thus the aorta breaks asunder at a lower tension than the radial.³

According to Nicolls, to attain the greatest strength with a given amount of material, a cylinder should be constructed of layers the elastic coefficient of which gradually increases from within outwards. Now, this is exactly the arrangement of the different layers of the arterial wall; thus the greatest strength is attained by the smallest amount of material consistent with safety. Similar reasoning applies to the walls of a sphere, from which it appears that the main source of weakness in an aneurysm is, that the wall practically is composed of only one coat.⁴ As the sac enlarges the total strain increases as the cube of the radius of curvature.

The influence of the amount of blood in the body on the systolic output and arterial pressure.—The average amount of blood in the body, estimated by Welcker's method, can be taken as equivalent to 6 to 9 per cent. of the body weight in dogs, 5 to 9 per cent. in cats, 4 to 8 per cent. in rabbits. In man it has been estimated as equal to 7 per cent. of the body weight.⁵ On transfusion of fluid, the striking fact becomes apparent, that the arterial tension cannot possibly be raised by such means above that height which the tension can reach when the vessels contain a normal amount of blood. This was so even when

Worm Müller¹ transfused fluid to the extent of 12·7 per cent. of the body-weight.

Similarly, bleeding to the extent of 1·88 to 2·82 per cent. of the body-weight causes only an insignificant fall of arterial tension. The velocity of the escape of the blood has a considerable influence on the change of arterial tension produced by bleeding. Sudden anæmia of the bulbar centres excites, while slowly advancing anæmia, without any preliminary stage of excitation, paralyses these centres. Thus it is easier to obtain a fall of tension by slowly tapping a vein, than it is by allowing the same quantity of blood to escape rapidly from an artery. After rapid hæmorrhage the heart is accelerated, the action of the respiratory pump increased, and the arterioles constricted. The blood is taken from the veins, and piled up in the arteries. It has been observed in the frog that the vessels contract and the tissue lymph passes into the circulation after the loss of blood.² At the same time the secretions become diminished.

Transfusion of blood or of saline solution, in the normal animal, at first raises the arterial pressure to about 170 to 180 mm., but the pressure never passes much beyond this limit. If the cervical cord be divided, and the arterial pressure thus lowered previous to the transfusion, the pressure may reach to the same limit, and not beyond. The reason for this is not far to seek. So soon as the arterial tension reaches a certain height, the systolic output of the heart becomes less complete, the residual blood in the left ventricle increases, and the diastolic pressure rises. The diastolic rise of pressure in the left ventricle tells back in turn on the left auricle, the pulmonary circulation, the right heart, and the venous circulation. The transfused fluid thus congests in the capacious reservoirs of the veins and capillaries, especially in the lungs, the liver, and the abdominal organs. According to Cohnheim,³ injections of saline equal to 25 to 30 per cent. of the body-weight, or four times that of the amount of the blood, does not notably increase for any length of time the pressure in the femoral vein. Still larger injections may raise the venous pressure to 18 or 20 mm. Hg. "These experiments show that the vascular system is vastly more capacious than the accommodation of the normal blood quantum demands." On microscopical examination of the circulation, some of the capillaries are always seen to be empty and collapsed, except in times of vaso-dilatation. Likewise the large veins appear on examination normally more or less flattened, not round and distended with blood. By the filling out of these vessels, the capacity of the vascular system is enormously increased. On transfusion of large quantities of saline, the liver becomes swollen, hard, and tense; the lungs and other tissues œdematous. Fluid is transuded, and the abdominal organs become without exception markedly dropsical. Large quantities of urine collect in the bladder, and the stomach and intestines become distended with fluid. Almost every one of the secretions is increased, and the lymph flow from the thoracic duct may become twenty-five times greater than at the commencement of the experiment. In fact, the leakage of fluid finally becomes as fast as the rate of transfusion, and

¹ *Ber. d. k. sächs. Gesellsch. d. Wissensch. math.-phys. Cl.*, 1873, Leipzig, S. 573-664. Cf. Magendie, *Compt. rend. Acad. d. sc.*, Paris, 1838, tome i. p. 55.

³ "Lectures on Pathology," *New Syd. Soc. Translation*, vol. i. p. 457.

thus neither the arterial nor the venous pressure can be driven up beyond a certain point; and this point, it is noticeable, is not very far removed from the normal pressure. After the transfusion of large quantities of fluid, both the venous and arterial pressures return rapidly to normal. On injecting a volume of fluid equal to that of the blood, Groszlik¹ estimated that 69 to 79 per cent. transuded in the first hour. On injecting saline coloured with methyl blue into the circulation, the blue colour appears in five to ten minutes in the stomach and the bladder. Dastre and Loye² found that, on injecting saline at the rate of 1 c.c. per minute for each kilo. of body weight in the dog, the transfusion was compensated by an equally rapid excretion from the kidney.

In the diagram (Fig. 49) is exhibited the effect on the arterial, portal, and vena cava pressures produced by the injection of 500 c.c. of normal saline solution; an amount fully equal to the blood quantum of the dog. It will be seen that five minutes after the injection was finished, the vena cava pressure had risen only 60 mm. $MgSO_4$ solution, or scarcely 5 mm. Hg. In another experiment, 350 c.c. of normal saline were

FIG. 49.—Effect of injection of 500 c.c. saline solution on the arterial pressure (black line), portal pressure (fine line), and vena cava pressure (interrupted line). —Bayliss and Starling.

injected during the space of two and a half minutes into a dog. During the injection the arterial pressure rose from 60 to 70 mm. Hg, the portal pressure from 87 to 167, and the vena cava pressure from 34 to 124 mm. $MgSO_4$ solution. Ten minutes later the pressures had become —arterial 72 mm. Hg, portal 110 mm., and vena cava 50 mm. $MgSO_4$ solution.³ After the injection of saline the velocity of the blood stream is very considerably accelerated, not merely during the injection, and simultaneously with the rise of blood pressure, but also lastingly, long after the pressure has again become normal. *The cause of this is the lessening of the viscosity of the blood by dilution.* The increase of velocity can be observed in the frog's web after injection of 1 c.c. of normal saline into the vena abdominalis, "the light-coloured blood shoots with such rapidity

¹ *Arch. de physiol. norm. et path.*, Paris, 1890, p. 704.

² *Ibid.*, 1888, p. 93; 1889, p. 253.

³ Bayliss and Starling, *Journ. Physiol.*, Cambridge and London, 1894, vol. xvi. p. 128.

through the vessels, that one is absolutely unable to recognise an individual corpuscle in the capillaries."¹ More than half an hour elapses before the velocity commences to slacken. No such increase of velocity is to be observed on the injection of blood; that is to say, after the injection has ceased and the blood pressure has returned to normal.

After the injection of blood, Worm Müller found that during the next few hours a very considerable portion of the injected plasma passed out of the vessels. The surplus corpuscles disappeared in the course of a few days.

The functional power of the vascular system is lowered by pronounced plethora. Venesection of a dog, in which artificial plethora has been produced, causes the arterial pressure to fall so rapidly, that it is impossible to obtain even the quantity of blood originally transfused. When the injection of fluid into a vein is maintained for some time, the heart must be strained by the increased diastolic pressure. It is probably owing to cardiac failure that animals sometimes die during continuous injections of large quantities of fluid. The collapse of the heart may sometimes be prevented by the letting of blood.² The heart has not only to do extra work when the diastolic pressure is raised, but the emptying of the coronary veins is impeded, and thus the coronary circulation impaired. The fact that asphyxia produces no rise of arterial pressure in plethoric dogs, with the fact that they are easily killed by hæmorrhage, shows that there is general vasomotor paralysis produced by over-distension of the vascular system. The addition of blood to the extent of 150 per cent. of the normal blood quantum is the outside limit beyond which life is directly threatened.

THE PRESSURE IN THE ARTERIES.

The lateral pressure of the blood in the large arteries was first accurately measured by Stephen Hales.³ He writes—

"In December 1733, I caused a mare to be tied down alive on her back; she was fourteen hands high, and about 14 years of age, had a fistula on her withers, was neither very lean, nor yet lusty. Having laid open the left crural artery about 3 in. from her belly, I inserted into it a brass pipe whose bore was one-sixth of an inch in diameter; and to that, by means of another brass pipe, which was fitly adapted to it, I fixed a glass tube of nearly the same diameter, which was 9 ft. in length; then untying the ligature on the artery, the blood rose in the tube 8 ft. 3 in. perpendicular above the level of the left ventricle of the heart. When it was at its full height it would rise and fall at and after each pulse 2, 3, or 4 in.; and sometimes it would fall 12 or 14 in., and have there for a time the same vibrations up and down, at and after each pulse, as it had when it was at its full height, to which it would rise again after forty or fifty pulses."

Hales drew the correct inference from his experiments that "the real force of the blood in the arteries depends on the proportion which the quantity of blood thrown out of the left ventricle in a given time bears to the quantity which can pass through the capillary arteries into the veins at that time."

Simple as these experiments are, they afford us the most striking

¹ Cohnheim, *loc. cit.*, p. 457.

² Johansson and Tigerstedt, *Skandin. Arch. f. Physiol.*, Leipzig, 1889, Bd. i. S. 394.

³ "Statistical Essays," vol. ii.

demonstration of arterial pressure. Nevertheless the method of Hales is open to two objections—first, the inconvenience of a long tube; second, the speedy coagulation of the blood.

By Poiseuille¹ both these sources of difficulty in the method of experiment were removed, when he substituted for Hales' glass tube a mercurial manometer, and to prevent coagulation filled the tube of connection between the artery and the manometer with a solution of sodium carbonate.

Ludwig² completed the work of Poiseuille by adding to the mercury manometer a float carrying a writing style, and by recording thereby on a revolving drum the variations of arterial pressure. To this device of Ludwig (*kymographion*) the graphic method in physiology owed its origin.³

Owing to the inertia of the mercury, the mercurial manometer is not fitted to give a true record of the pressure changes which occur during the cardiac cycle. When the heart is beating slowly, the maximal aortic pressure, when read by this instrument, is too high, and the minimal pressure is too low; with a rapid heart the reverse obtains. Thus, no knowledge as to the true systolic and diastolic variations of pressure can be gained by it.

The mercurial manometer is nevertheless the most convenient and useful instrument for obtaining records of the mean arterial pressure. It is stated by v. Kries⁴ that the manometer should be constructed of tubing 4 mm. in diameter. The error in the mean pressure is then not greater than 3 per cent. With the use of wider or narrower tubes the error becomes greater. If the manometer tube be very considerably constricted in one part of its course, then the instrument, whatever be its diameter, gives the true mean pressure, for the oscillations of the mercury are almost entirely

FIG. 50.—Poiseuille's hæmodynamometer.

damped down by the constriction. The speed of the instrument is thereby sacrificed, for it takes some time to rise to the mean pressure. The instruments of precision now largely employed for investigations on the systolic and diastolic variations of arterial pressure, are Fredericq's modified form of sphygmoscope and the Fick, Hürthle, or v. Basch manometers (see intracardiac pressure). Before use these manometers must be graduated against a mercury manometer.

For the purpose of obtaining continuous records of arterial pressure, the writing style of the arterial manometer is brought to bear on a band of paper, covered with lamp-black. By means of clockwork this band can be made to revolve at varying speeds round two drums placed at either end of a long frame. There are also brought to write on the paper an electric signal, by which points of excitation can be marked during the course of an experiment,

¹ "Rech. sur la force du cœur aortique," Thèse, Paris, 1828.

² *Arch. f. Anat., Physiol. u. wissenschaft. Med.*, 1847, S. 261.

³ For an improved method of constructing the float of Ludwig's kymograph, see Anderson Stuart, *Journ. Physiol.*, Cambridge and London, 1891, vol. xii. p. 147.

⁴ *Arch. f. Physiol.*, Leipzig, 1878, S. 430.

and a time-marker. The band of paper is of sufficient width to enable the experimenter to record, simultaneously with the arterial pressure, the venous pressure, the respiratory movements, the intraventricular pressure, or any other phenomena which require investigation.

FIG. 51.—Hürthle's recording apparatus.

A convenient form of arrangement of such drums is that of Hering, as modified by Hürthle, which is shown in the figure; the two drums are united by a continuous band of smoked paper.

Several instruments have been contrived for estimating the arterial pressure

FIG. 52.—Hill and Barnard's sphygmometer.

in man.¹ The one which has been most extensively used is v. Basch's² sphygmomanometer. This consists of a small capsule; the cavity of this is connected with a manometer. The floor of the capsule is formed of a rubber membrane, and this is pressed upon the radial artery until the pulse vanishes

¹ See George Oliver, "Pulse Gauging," London, 1895.

² *Wien. med. Wchnschr.*, 1883, S. 673; *Ztschr. f. klin. Med.*, Berlin, Bd. ii. S. 79; *Berl. klin. Wchnschr.*, 1887, S. 181.

beyond the seat of compression. The reading of the manometer at this point is taken to be equal to that of the arterial pressure. The fallacies in the use of such an instrument are very considerable. It is impossible to avoid compressing the *venæ comites radialis*, the skin and surrounding tissues, together with the artery, and it is difficult to note the exact moment when the pulse ceases to be perceptible. Experimentally, it has been found that the errors may be as great as 30 to 70 mm. Hg.

Recently a sphygmomanometer has been invented, which possesses considerable accuracy. This instrument consists of a broad armband, which is strapped round the upper arm. The armband is formed of a watch spring or stiff leather band, on the inside of which is a bag of thin indiarubber. The rubber bag is connected by a T-tube with an air-pump and a spring manometer. The pressure within the bag is raised until the pulsation in the manometer becomes of maximal excursion. At this point the pressure indicated by the manometer is read, and this pressure is the mean arterial pressure.¹

The instrument has been tested thus: It was placed round the neck of a dog (excluding the trachea), and simultaneous readings were then taken, both of the pressure in the femoral artery, as indicated by a mercurial manometer, and of the pressure in the carotid arteries, as indicated by the instrument. The maximal excursion of the pulse gave a sharp and accurate index of the mean arterial pressure.

In the case of healthy young men the pressure in the brachial artery is from 110 to 130 mm. Hg. The pressure in a normal healthy individual is maximal in the vertical and minimal in the horizontal position.² A hot bath diminishes, and a cold bath increases, the pressure. Violent exercise raises the tension by 20 mm. Hg; this rise lasts for some fifteen minutes, and is followed by a fall. Alcohol lowers the arterial tension. During chloroform anaesthesia the tension falls 20 to 40 mm. Hg. During deep sleep the pressure may be 20 to 30 mm. Hg lower than in the active waking state. This lowered pressure is not, however, peculiar to the condition of sleep, for just as low a pressure may obtain if the body be kept at rest, and this is so even although the mind be engaged in quiet work.

It must be remembered, in using such an instrument for the purpose of obtaining a series of accurate comparative results, that certain principles of experiment must be complied with. Thus, the subject of the experiment must be placed uniformly in one position, and the arm which is under investigation must be put at a uniform level in relation to the heart. If this be not done, large errors will arise in the readings, owing to variations in the hydrostatic effect of gravity and the efforts of the vasomotor mechanism to compensate for the same.

Faivre has directly measured the arterial pressure in man during the amputation of a limb. His results gave a pressure equal to 110 to 120 mm. Hg. The arterial pressure is considerably higher in warm-blooded animals; in the former it is at least three times greater. The pressure is independent of the size of the animal, and thus may be as great in the cat as in the horse.³ In the sheep's embryo (*in utero*) the pressure has been found to be from 43 to 84 mm. Hg.⁴ The total work of the heart, however, is greater in large than

¹ Maximal pulsation was first used as an index of mean tension in an instrument invented by Roy and Adami (*Practitioner*, London, 1890). Mosso has recently employed the same index (*Arch. ital. de biol.*, Turin, 1895, vol. xxiii. p. 196).

² In conditions of asthenia the opposite obtains.

³ Volkmann, "Die Hämodynamik," Leipzig, 1850, S. 177.

⁴ Cohnstein and Zuntz, *Arch. f. d. ges. Physiol.*, Bonn, 1884, Bd. xxxiv. S. 215.

in small animals, because the ventricular output increases with the size of the heart. The work per unit weight of heart muscle in different animals has never been estimated. The mean arterial pressure, when the animal is in the horizontal position, is, within certain limits, nearly the same in arteries of different calibre, and at varying distances from the heart. Poiseuille¹ found that the mercury in the hæmodynamometer rose to nearly equal heights when the instrument was connected in turn with the iliac, carotid, radial, facial, and other arteries. This is so, on account of the slight amount of resistance in the larger arteries compared to that in the smaller arteries and arterioles.

If the measurements of mean pressure are repeated in different arteries when the animal is placed, not in the horizontal, but in the vertical feet-down posture, then the arterial pressure varies owing to the effect of gravity (see p. 90).

Although, in the horizontal posture, the mean pressure in different arteries varies but little, records of the systolic pressure show considerable differences. With his spring manometer Hürthle has obtained a series of comparative measurements, from which the following table of diastolic and systolic pressures is taken:—

	PRESSURE IN MM. HG.		DISTANCE BETWEEN THE TWO POINTS OF OBSERVATION.
	Diastolic.	Systolic.	
1. CAROTID—			
Central end . . .	80	160	} 140 mm.
Peripheral end . .	66	117	
2. CAROTID—			
Central End . . .	60	172	} 175 mm.
Lingual	58	118	
3. CAROTID	74	168	} 525 mm.
FEMORAL	78	220	
4. CAROTID	94	183	} 400 mm.
FEMORAL	94	249	

The two most striking results to be observed in this series are, first, the near agreement of the diastolic pressures; and, second, the fact that in the femoral, the systolic pressure is higher than in the carotid artery. This last result has been explained by supposing that the first centripetal positive pressure wave, which is reflected from the periphery, is of such a period that it adds itself in this artery to the primary centrifugal positive wave before the latter has passed away. It is, however, possible that the result is due to instrumental error. The rise of systolic pressure lasts longer in the femoral than in the carotid artery, and may thus be more correctly recorded. The experiments require repetition with the use of a maximal manometer.

The maintenance of a mean arterial pressure of constant height is the object of the circulatory mechanism. On the one hand, we are convinced that this object is attained during life; on the other hand, we know that countless and ceaseless variations are occurring in all parts of the circulatory system. The whole system must therefore be so craftily built and so delicately balanced, that every variation in one part is compensated by a simultaneous

¹ "Rech. sur la force du cœur aortique," Thèse, Paris, 1828.

and contrary variation in another part, and thus, throughout the wear and tear of life, the aortic pressure is kept at a constant mean height. Pawlow¹ possessed a dog so excellently trained that it lay still during any period of observation. In this dog, by means of an insignificant skin cut, Pawlow inserted a cannula into a superficial artery on the inner side of the knee. By this means he was able to measure the arterial pressure on successive days, connecting the cannula with the manometer on each occasion. As a rule, the mean pressure did not vary more than 10 mm. Hg. Neither when the animal was fed on dry food after twelve hours' abstention from water, nor after the imbibing of large quantities of drink, did the pressure vary to a greater extent.

Pawlow observed the following pressures (in millimetres of mercury) in his dog on different days in the course of a month's observation:—

Third Day.	Fourth Day.	Sixth Day.	Tenth Day.	Twenty-fourth Day.
128	131	128	129	131

The same constancy has been observed in man by means of the sphygmomanometer.

THE VELOCITY OF BLOOD FLOW.

In order that the circulation may be constantly maintained throughout the vascular system, an equal quantity of blood must on the average pass through each section of the system in the same time.

The output per second of the heart, divided by the total sectional area of the vascular system at any point, gives the mean velocity per second at that point. Thus the velocity is inversely proportional to the sectional area; and since the total sectional area of the arterial system increases from the aorta to the capillaries, the mean velocity must steadily decrease towards the periphery. On the other hand, since from the capillaries to the venæ cavæ the total sectional area decreases, the mean velocity in the veins must increase centripetally (see Fig. 46, p. 69).

The velocity and the tension of the blood in the aorta are dependent on the energy of the heart and the resistance in the peripheral vascular system. In the living animal both of these factors are constantly varying, and we can consider the effect of such variations in the following examples:—

1. The energy of the heart is constant: (a) the peripheral resistance increases. The tension in the aorta will become greater and the velocity less. (b) The peripheral resistance decreases. The velocity will become greater and the tension less.

2. The resistance remains constant: (a) the energy of the heart increases. Both the tension and the velocity become greater. (b) The energy of the heart decreases. Both the tension and the velocity become less.

3. The energy of the heart increases: the resistance at the same time becomes greater, and in proportion to the increase of cardiac energy. The tension rises and the velocity remains constant.

4. The energy of the heart increases: the resistance at the same time decreases, and in proportion to the increase of cardiac energy. The tension remains constant and the velocity becomes greater.

5. The energy of the heart decreases: the resistance increases, and in proportion to the decrease of cardiac energy. The tension remains constant and the velocity becomes less.

6. The energy of the heart decreases: the resistance becomes less, and in

¹ *Arch. f. d. ges. Physiol.*, Bonn, 1878, Bd. xvi. S. 266; 1879, Bd. xx. S. 213.

proportion to the decrease of cardiac energy. The tension falls and the velocity remains constant.

Since under the influence of the vasomotor mechanism any one section of the arterial system may become constricted, while at the same moment any other section may become dilated, it is possible that the tension and velocity in the aorta may remain constant; for a balance may be struck between such variations when of opposite sign. It follows from the above that (1) the velocity can vary in an opposite sense in different parts of the vascular system; (2) the velocity in any particular artery bears no absolute relation to the pulse frequency or the general arterial tension.

The velocity cannot be measured by simple division of an artery, and estimation of the outflow in a given time, for the peripheral resistance is almost entirely abolished thereby, while the output of the heart is rapidly diminished by the loss of blood. Volkmann¹ was the first to more or less accurately measure the velocity of blood-flow by introducing a U-shaped glass tube into the course of an artery. This tube was filled with a solution of a neutral salt, and provided with a tap. At a certain moment, the tap was turned and the rate of flow of the column of blood along the tube directly measured. Supposing the sectional area of the tube to be the same as that of the artery, the velocity in the latter is obtained without further correction. But it is practically impossible to select a glass tube which shall have the exact calibre of the artery to be measured, nor is the method suitable for comparative estimations of velocity during the course of an experiment. Among the more recent methods of investigation, Ludwig's stromuhr,² by which the amount of blood passing in a given time may be accurately measured, or its modified form, as contrived by Tigerstedt, deserves description.³

FIG. 53.—Ludwig's stromuhr, as modified by Tigerstedt.

In using this instrument, the tube (y_1) is placed in connection with the central end, and the tube (y_2) in connection with the peripheral end of the cut artery which is under investigation. The whole instrument is washed out with oil to prevent clotting, and filled with defibrinated blood. So soon as the blood is allowed to flow from the artery, the metal ball (b) is driven over by the current till it reaches the end of the cylinder (a). The instrument is then rapidly rotated on the drum (k), so that the tube (x_2) comes to lie over the tube (y_1), and the tube (x_1) over the tube (y_2). The metal ball is now once more driven by the current to the opposite end of the cylinder. This procedure is repeated several times, and the number of revolutions during the period of observation is noted. The capacity of the cylinder (a), minus the volume of the ball (b), multiplied by the number of revolutions, gives the

¹ "Die Hämodynamik," Leipzig, 1850, S. 185.

³ Tigerstedt, *Skandin. Arch. f. Physiol.*, Leipzig, 1891, Bd. iii. S. 152.

volume of blood which has passed during the period of observation, and this volume, divided by the time and the sectional area of the artery, gives the mean velocity per second. In using the stromuhr, the mean velocity in an artery is found to vary greatly. This, for the most part, is owing to the variations of resistance in the peripheral arterioles. During the operative procedure the blood-flow must for a time be cut off by clips in order that the tubes of the stromuhr may be introduced within the artery. From the anæmia thus produced there results a temporary paralysis of the tone in the arterioles. Variations of resistance arise when the blood-flow is re-established and the tone commences to recover. By means of Ludwig's stromuhr, for example, Dogiel¹ found the velocity to vary from moment to moment thus:—

Time.	Mean Velocity.	
I.		
0- 15 sec.	489 mm. per sec.	} Dog.—Carotid artery. Diameter, 2·7 mm.
15- 25 „	733 „ „	
25- 44 „	386 „ „	
44- 65 „	349 „ „	
65- 80 „	489 „ „	
II.		
0- 30 sec.	226 mm. per sec.	} Rabbit.—Carotid artery. Diameter, 1·4 mm.

84- 90 „	188 „ „	
90- 98 „	141 „ „	
98-100 „	94 „ „	

Tigerstedt has by means of the stromuhr been able to measure directly in the rabbit the velocity of the blood-flow in the root of the aorta, and thus the systolic output of the heart. Other instruments have been invented for obtaining continuous records of the variations of velocity of flow in any given vessel. Chauveau and Lortet, employing the principle of the hydrometric pendulum, constructed an instrument of this kind, named the dromograph.²

As is seen in the diagram, this instrument consists of a chamber (B), which communicates with a tube (A), and is closed at the top by a membrane. The tube (A) is inserted in the course of the artery which is under investigation. In this tube there hangs a small pendulum, which issues through the membrane in the roof of the chamber (B). The membrane affords a fulcrum to the pendulum, and the movements of the latter are brought to bear upon a tambour, which communicates by an indiarubber tube with the recording tambour (D).

FIG. 54.—Diagram of Chauveau and Lortet's dromograph.

If the mass of the pendulum be small, the accuracy of this instrument is found to be considerable. Before use, the excursion of the dromograph must be calibrated by recording the flow of water at known velocity through it.

In Fig. 55 is shown the synchronous record obtained of the velocity

¹ *Ber. d. k. Sächs. Gesellsch. d. Wissensch., Math.-Phys. Cl.*, Leipzig, 1867, S. 239.

and pressure in the carotid artery of the horse.¹ It is noticeable that the curve of velocity (V) reaches its maximum before the curve of tension. This is so, because, as the arteries become overfilled, the heart cannot maintain the initial velocity of output. Chauveau found that the velocity in the carotid artery of the horse reached 520 mm. per second during systole, while at the time of the dicrotic wave the velocity sank to 220 mm. per second, and in diastole to 150 mm. per second. Continuous records of the velocity curve afford us a valuable means of arriving at the volume of blood flowing through the vascular area supplied by the artery in question. Thus the effect on the blood-flow of vasomotorial excitement or functional activity can be investigated.

FIG. 55.—Carotid artery. V, velocity; P, pressure curves; O, O, abscissa of velocity curve; 1, 2, 3, 4, simultaneous points on both curves.—Chauveau and Marey.

By means of the dromograph, Chauveau and Lortet determined that, during the rise of systolic tension, the blood is driven from the coronary arteries back towards the aorta. Lortet determined that the velocity of flow in the carotid is five or six times greater when a horse is actively masticating than when at rest. In one experiment, while the normal velocity in the carotid artery during systole was 540 mm. per second, Chauveau noted that after section of the cervical sympathetic, and in consequence of the loss of vascular tone, the velocity became equal to 750 mm. per second. After section of the spinal cord in the upper dorsal region, the velocity in the arterial system becomes greatly accelerated during systole, and greatly diminished during diastole. Owing to the lowering of the peripheral resistance from the loss of vascular tone, the heart is able to discharge the blood with the greatest rapidity into the venous system, and in consequence, during diastole, the arterial system is emptied of blood to a great extent. If this condition be pushed to an extreme, and the frequency of the heart be small, the blood becomes discharged into the veins intermittently.

Comparative records have been obtained of the velocity of flow in the carotid and facial arteries. At the end of the diastole the velocity is small in the carotid, and relatively great in the facial artery. At the beginning of systole the primary wave of velocity rises rapidly in the carotid, and is proportionately small in the facial artery. The secondary

¹ Marey, "Circulation du sang," p. 327.

increase of velocity which is produced by the dicrotic wave, is far more evident on the carotid than on the facial curve.

These results show how the intermittent energy of the heart is stored up by the elasticity of the large arteries, and expended in maintaining a continuous flow through the small arteries. In the root of the ascending aorta, the mean velocity during systole, according to the calculations of Nicolls,¹ is ten times greater than the mean velocity in the abdominal aorta (see pp. 42, 43).

Another method of recording variations in velocity depends on the principle of Pitot's tubes. Suppose that a current is flowing constantly through the uniformly wide tube (BC) in the direction of the arrow (Fig. 42), then the lateral pressure in the piezometer (M) will be considerably higher than that in N. The pressure head in the piezometer (M) is an expression of the velocity head and the effective head, in the piezometer (N) of the effective head, minus the velocity head.

When an alteration of resistance arises in the outflow, the lateral pressures at points nearer the periphery vary by larger fractions than those at points further up the stream. As the velocity in an artery varies inversely as the peripheral resistance, any change in the velocity may be estimated by noting the changes in the lateral pressures in two such manometers placed in connection with the same artery at two different points. In Marey's apparatus the two lateral tubes are connected with two tambours. The buttons of these tambours are arranged so as to press on either side of a lever which works upon a third tambour. The pressure in this tambour varies in relation to the proportionate pressures in the other two tambours, and the variations are registered by a recording tambour.²

Cybulski contrived an arrangement, by which the two lateral Pitot-tubes are prolonged into two manometric tubes. These, connected together at the top, are filled in the lower part with fluid, in the upper part with air. The meniscus of the fluid in each tube is photographed on to a moving sensitised plate, and thus the difference in the pressures recorded.

In the following experiments, Cybulski determined the velocity to be—

	SYSTOLE.	DICROTIC WAVE.	DIASTOLE.
	Mm. per second.	Mm. per second.	Mm. per second.
1. Carotid Artery	248-238	248-225	127-156
Femoral „	356	300	177
2. Carotid „	238	...	177
„ (vagi cut)	440	...	425
3. Femoral	287
„ (vagi cut)	457

Owing to the cardiac acceleration, and the consequent increase of the output of the heart, the velocity is seen to be greatly increased by section of the vagi.

From the study of the variations of the velocity of the blood, we may conclude that the following general statements, first formulated by Marey, are true:—

¹ *Journ. Physiol.*, Cambridge and London, 1896, vol. xx.

² Marey, "Circulation du sang," p. 310.

If the resistance increases, and the output of the heart remains constant, then the arterial tension rises and the velocity becomes less.

If the output of the heart increases, and the resistance remains constant, then both the tension and the velocity become greater.

All experiments point to the fact that mere records of arterial tension give us no insight into the velocity of flow. The latter depends, not on the amount of the tension, but on the difference in tension between any two parts of the vascular system.

Certain attempts have been made to arrive at a method of recording variations in the velocity of the arterial blood in man. If a volume curve of the human arm is taken by the ordinary plethysmographic method, and the outflow of venous blood is constant, then the variations in volume of the passive arm can only be produced by the systolic expansion of the arterial system. Thus, when the volume curve rises the arterial inflow is greater than the venous outflow, and when the curve falls the venous outflow is greater than the arterial inflow. It follows that the more rapid the change of volume, the more rapid must be the variation in blood-flow. If, then, the steepness of the volume curve is estimated at different points, an approximate idea of the variations in velocity can be reached, and a velocity curve can be plotted out. The absolute worth of the measurements cannot of course be obtained, and since the venous outflow is not constant the results must be considered as only approximative. It is, however, noteworthy that the velocity curve thus obtained bears a striking resemblance to the curves recorded by the dromograph.

v. Kries has contrived an ingenious and delicate method of thus obtaining the velocity curve in man. The arm is placed in a plethysmographic chamber in the usual manner, and this is connected by a tube with a sensitive gas-burner. Every expansion of the arm drives gas out of the plethysmographic chamber, and causes the flame to leap up. The movements of the flame are photographed on a moving sensitised plate.

The records, or tachograms, thus obtained are entirely different from the pressure curves obtained with the sphygmograph (see Figs. 56-59).

FIG. 56.—Tachogram ; arm elevated.—v. Kries.

FIG. 57.—Sphygmogram ; arm elevated.—v. Kries.

FIG. 58.—Tachogram ; arm dependent.—v. Kries.

FIG. 59.—Sphygmogram ; arm dependent.—v. Kries.

The primary elevation rapidly reaches its maximum, and is followed by a fall which is not found on the arterial tension curves. This fall closely resembles that on the velocity curves obtained with the dromograph.

THE CIRCULATION TIME.

Ed. Hering injected a solution of potassium ferrocyanide into one jugular vein of a horse, while from the opposite jugular vein he collected samples of blood at intervals of five seconds. The samples thus obtained were allowed to coagulate, and after expression of the serum the latter was tested with ferric chloride. He found that in 20 to 30 seconds the salt is received by the right heart, propelled through the lungs, received by the left heart, and propelled through the carotid arteries and capillaries, into the jugular vein.¹ So astounding a result was at first received with incredulity, but Hering's experiments were fully confirmed by Poiseuille and Blake.²

After injection of barium nitrate into the jugular vein of a horse, Blake obtained evidence of the presence of this salt in the carotid artery on the opposite side in 15 seconds. Poiseuille³ found that on employing as an index weak solutions of ammonium acetate or potassium nitrate, the circulation time was accelerated, while on the addition of alcohol the period was lengthened. This agreed with results which Poiseuille had obtained in investigations on the flow of water in capillary glass tubes. By Vierordt⁴ the experimental method was improved. He affixed a number of small cups to a disc which was rotated at a uniform and known rate. The blood, subsequently to the moment of injection, was allowed to flow from the vein into these cups. Hermann⁵ replaced the cups by a continuous sheet of filter-paper, which was divided into sections corresponding to intervals of time. The venous blood flowed in a continuous stream on to the filter-paper as the drum rotated. At the end of the experiment the filter-paper was dried and tested for the presence of the salt. The innocuous ferrocyanide of sodium is more suitable than the potassium salt. Vierordt⁶ determined the circulation time in seconds in the following animals to be—

Squirrel	4.39	Horse	31.5
Cat	6.69	Cock	5.17
Hedgehog	7.61	Duck	10.64
Rabbit	7.79	Goose	10.86
Dog	16.7		

The length of the circuit is found to make but little difference. This is so because the time is chiefly spent in the passage of the blood, not through the arteries and veins, but through the capillaries. Thus Vierordt obtained the following mean results in four double determinations:—

Jugular to jugular vein	dog	16.32
Jugular to crural vein	„	18.08

Recently other ingenious methods of determining the circulation time

⁶ "Phys. d. Mensch.," 1861, S. 111.

have been devised by Stewart.¹ In these methods no collection or testing of the blood is required, and the whole procedure is extremely simple and easy of demonstration.

In his first method he proceeds as follows: The carotid artery is exposed and placed upon a sheet of insulating material; non-polarisable electrodes are then applied to the artery, and the portion of the artery between these is inserted as a resistance in one arm of a Wheatstone's bridge. After the resistances in the bridge have been balanced, and the galvanometer brought to rest, a small quantity of a solution of common salt is injected into the opposite jugular vein. So soon as the salt reaches the carotid artery the resistance of the blood is altered, the balance of the Wheatstone's bridge is upset, and the galvanometer swings.

The period between the moment of injection and the commencement of swing can be noted with a stop-watch with great precision.

In a second and still simpler method, Stewart² employs a solution of methylene blue, which he injects into the jugular vein of the rabbit. The carotid artery on the opposite side is exposed, placed upon a sheet of white paper, and illuminated with a strong light. The time is taken with a stop-watch from the moment of injection to the moment when the blue colour is seen to appear in the carotid artery.

In a rabbit weighing 2 kilos., Stewart found the time of the lesser circulation varied from 2 to 3 seconds, and the jugular to jugular time from 5 to 7 seconds. The longest circulation times were found in the kidney, the portal system, and the lower limbs. By section of the vasomotor nerves of any organ the circulation time is lessened in that organ, while it is lengthened by excitation of the vaso-constrictors.

There is yet another means of arriving at the circulation time, and that is by the injection into a vein of a powerful poison. Thus, in the horse, nitrate of potash passes from the jugular vein into the coronary circulation, and arrests the heart in 16 seconds. In the same period strychnine produces its effect on the spinal cord. In the dog, 12 seconds is sufficient for the manifestation of the action of these poisons; in the rabbit, 4 to 4.5 seconds; and in the fowl, 6 to 6.5 seconds.

The jugular to jugular result obtained by Hering's or Stewart's method yields, not the circulation time of the whole of the blood, but the shortest possible time which any particle of blood can travel through the shortest pathway round both the lesser and greater circulation. According to Poiseuille and v. Kries,³ the maximal or axial velocity is double the mean velocity. A particle of blood swept along in the axial stream, therefore, travels with far greater speed than another particle which rubs along the wet walls of the vessels. Again, the blood that takes a broad, open pathway, through wide or dilated capillaries, will arrive far more speedily at the opposite jugular vein than blood which creeps through tortuous and constricted capillaries. It is impossible to arrive by this method at the circulation time of the whole blood. Part of the blood may travel from the left to the right ventricle, and from the right to the left ventricle, with great rapidity, and part with extreme slowness. The direct observations of Tigerstedt⁴ on the output of the left ventricle show that the circulation time of the whole blood is at least five times

¹ *Journ. Physiol.*, Cambridge and London, 1894, vol. xv. p. 1.

as long as the period arrived at by the Hering method. It is therefore fallacious to use the circulation times arrived at by Hering's or Stewart's method as a basis for calculating the quantity of blood in the body.

THE EFFECT OF CHANGE OF POSTURE ON THE CIRCULATION.

The circulation is so contrived that it remains efficient, not only in the horizontal position, but also when the living animal is ceaselessly shifting the position of his body. The hydrostatic influence of gravity must have had a most important bearing on the evolution of the mechanisms which control the circulation. Especially is this so in the case of an erect animal like man, 5 to 6 ft. in stature. In a man 6 ft. high the hydrostatic pressure of a column of blood reaching from the vertex to the sole of the foot is equal to 140 mm. Hg, and from the vertex to the middle of the abdomen about 50 mm. Hg. It is obvious, then, that the influence of gravity demands careful inquiry.

Suppose a closed and rigid tube (AB) filled with water and fixed to a board (Fig. 60). When the board is placed in the horizontal position (I) the pressure

FIG. 60.

in all parts of the tube (AB) will be the same. If the board be turned into the vertical position, then the pressure at A will become *nil*, while the pressure at B will be equal to the height of the column of fluid (AB). The fluid will still equally pervade the tube in all its parts. This must be so, because the fluid is incompressible and the tube is rigid and unyielding in structure.

If the rigid tube be now replaced by an elastic tube, and this at the points A and B be made to expand into thin-walled elastic bags, then the conditions become markedly different (II). On placing such a model in the vertical position, the lower end (B) bags under the pressure of the column of fluid (AB), and while the water flows into B, A empties and collapses under the atmospheric pressure.

Suppose a pump be placed in such a model, and that the pump work with perfect uniformity and maintain a constant circulation, if the outflow tubes or arteries be made of small capacity and considerable extensibility and elasticity, and the inflow tubes or veins be valved, and be made of considerable capacity and slight extensibility and elasticity, and if a sponge be inserted as a resistance in the ends (A and B), then many of the conditions of the systemic circulation are closely represented in the model. A is now equivalent to the capillary area of the head, B to the splanchnic area of capillaries (III).

Let the distensibility of the splanchnic capillaries and veins (B) be great, and let the pump be at rest and the model be placed in the vertical position, the fluid will then collect in B, and A will empty. The increase of the pressure in the splanchnic area by the height of the column (AB) tends to enlarge the capacity of that area while it diminishes the capacity in A. Let the pump be at work, then the circulation through A will cease if the pump is unable to raise the fluid from B, or to lift the fluid to A, and drive it through the resistance in A. If the model be turned with B at the top, these results will

be exactly reversed. These hydrostatic influences are compensated for in the normal animal by vital changes in the blood vessels, in the heart, and in the respiratory movements.

In the elastic model the fluid sinks under the influence of gravity if the venous and capillary tubes be made distensible by the pressure of the column of fluid within them. In man the venous column is broken into short segments by valves in the veins of the arms, in the root of the jugular veins, in the femoral and other veins of the lower extremities. The longest column of venous blood unbroken by any valve is that which extends from the intracranial sinuses, down the intravertebral sinuses to the azygos veins, and thence to the end of the inferior vena cava. From the innominate veins down the superior vena cava to the end of the inferior vena cava there also extends an unbroken column of blood. The valves are most numerous in the veins of the extremities, and are also found in the portal system, in the veins to the stomach, spleen, and intestine. Some of the portal valves become functionless in adult life. The suspension of the heart by the deep cervical fascia, and constraint of the pericardial sac, prevent the heart from rolling over and kinking the venæ cavæ during changes of posture. The vena cava inferior passes through the central tendon of the diaphragm, at a point which is immobile during the respiratory movements. It is protected in its passage behind the liver from the weight of that organ, for it lies in a tunnel formed by the Spigelian lobe of the liver, which, in its turn, rests upon the vertebral column.

The great and capacious abdominal veins are maintained and supported under the hydrostatic stress of gravity, by means of the expiratory muscles of the abdominal wall. The tone of these muscles, and therefore the capacity of the veins, depends upon the integrity of the respiratory centre. In consequence of the valves, the veins of the limbs are constantly emptied onwards by the contraction of the skeletal muscles, and by changes in posture. If a limb be kept motionless and in the dependent posture, the veins quickly become congested. The amount of this congestion depends on the tone of the skeletal muscles, the arterioles, and the walls of the veins. By such means the distension of the veins and capillaries in the erect posture is largely prevented.

The arterioles are held in a state of tone by the vasomotor centre, and limit the output into the veins. When an animal passes from the horizontal to the vertical feet-down position, the peripheral resistance in the splanchnic area can be increased and the capacity diminished by the contraction of the arterioles; thus the circulation through the head is maintained. The blood in all cases takes the pathway of least resistance. The great splanchnic area forms the resistance box of the circulation; if it be contracted, the blood takes the pathway through the locomotor organs; if it be dilated, the blood passes into the capacious veins of the abdomen. When the splanchnic area is fully dilated, the whole of the blood can collect within the abdomen, and if the animal be in the vertical feet-down position the influence of gravity will bring about this result. The splanchnic vasomotor paralysis can, however, be then compensated for by the action of the respiratory pump. The capacity of the abdominal vessels can be reduced by the compressive action of the respiratory muscles, and while the output from the arterioles is thus held in check, the blood is pressed up the veins, and can be aspirated into the right heart by the action of the thoracic muscles.

To study this question experimentally, cannulæ are passed down the external jugular vein and carotid artery of the dog, so that the ends of the cannulæ lie respectively in the vena cava superior and the aorta,

the animal-board being constructed to turn round an axis passing through the body at the level of the intravascular openings of the cannulae.¹ Then the effect of posture on the venous and arterial pressures is recorded.² On placing the animal in the feet-down posture the arterial³ and venous pressures immediately fall. The venous pressure remains down until the horizontal posture is once more assumed (Fig. 61). The arterial pressure rapidly rises again to normal, and often

FIG. 61.—Aortic pressure. A, feet-down; B, horizontal posture.—Hill.

it may be found to rise above normal. The respiratory undulations are frequently intensified while the animal is in the feet-down posture.

If the spinal cord be divided at the level of the first dorsal vertebra, the influence of the bulbar centres on the parts below the section is removed. Abdominal and intercostal respiration is paralysed, and the breathing becomes purely diaphragmatic. The tone of the great splanchnic area of arterioles is lost; the tone of the abdominal wall is abolished, and thus the capacity of the abdominal vessels is greatly increased. The total effect on the animal,

FIG. 62.—Aortic pressure and intracranial pressure. Spinal cord divided at first dorsal vertebra. Effect of feet-down posture.—Hill.

when lying in the horizontal posture, is a considerable fall of arterial pressure, and a marked diminution of the respiratory undulations of pressure.

If the animal be now dropped into the vertical feet-down posture, the arterial pressure falls rapidly, and may reach zero (Fig. 62); the

¹ Any alteration in the level of the extravascular column of fluid in the manometer tubing is thus avoided.

² Hill, *Journ. Physiol.*, Cambridge and London, 1895, vol. xviii, p. 15; Hill and Barnard, *ibid.*, 1897, vol. xxi, p. 323; Hill, "Cerebral Circulation," London, 1896.

³ This fall had been previously observed by Cybulski, *St. Petersburg. Med. Wchnschr.*, 1878, S. 93; and Friedmann, *Med. Jahrb.*, Wien, 1882, S. 225.

circulation is then at an end. This is so, because the great abdominal veins bag out under the hydrostatic pressure; in them the whole of the blood collects, for it can pass rapidly through the dilated arterioles; there is no mechanism left for filling the heart; thus the heart, empty of blood, continues to beat to no purpose.

If the abdominal wall be compressed with the hand, the capacity of the veins and splanchnic area is reduced, the right heart is once more filled with blood, and the arterial pressure rises, and the circulation is renewed. On taking off the hand, the heart once more empties, the arterial pressure falls, and the circulation ceases. When the animal is returned to the horizontal position, the influence of gravity is abolished, and the circulation immediately becomes re-established. Such experiments prove that in the normal animal there are two chief compensatory mechanisms by which the hydrostatic effect of gravity is overcome, namely, the vasomotor mechanism of the arterioles and the respiratory muscles. It is necessary to examine these separately, and estimate the relative power of each.

The vasomotor tone of the great splanchnic area can be easily abolished, and without affection of the respiratory mechanism, by section of the splanchnic nerves; that is to say, if these nerves are reached by a lumbar incision, and all interference with the thorax or abdominal wall is avoided.

The effect of section of the splanchnic nerves is shown in Fig. 63. The arterial pressure in the vertical feet-down posture falls very considerably, but nevertheless the circulation remains efficient, on account of the action of the respiratory muscles. A form of respiration is evoked which consists of thoracic inspiratory aspirations, combined

FIG. 63.—Aortic pressure. Morphinised dog.—Hill and Barnard.

- B, Effect of compressing abdomen.
- C, Abdominal wall divided.
- D, Thorax opened.

with powerful expiratory abdominal compressions. Thereby the diastolic filling of the heart is maintained, and the velocity of flow through the splanchnic capillaries checked. On dividing the abdominal wall by a crucial incision, the support of the abdominal muscles is withdrawn, the splanchnic vessels dilate, and the pressure falls to a further extent. Finally, on suddenly opening the thorax, the pressure falls to zero, and the circulation ceases. By compression of the abdomen, or by a return to the horizontal posture, the circulation can be once more renewed.

This experiment shows that the respiratory muscles can compensate for the influence of gravity when the vasomotor mechanism is paralysed.

The respiratory mechanism can be thrown out of gear by itself, and without damage to the vasomotor mechanism by the injection of curari. The power of the heart is then sufficient by itself to maintain the circulation in the feet-down position, so long as the capacity of the abdominal vessels is kept under control by the vasomotor nerves.

The effect on the circulation of rendering the intrathoracic pressure positive, is dealt with in the section relating to the diastolic filling of the heart. Here it may be briefly stated that the blood stagnates in the abdomen, and the circulation ceases, whenever, by any means, the thoracic pressure is rendered sufficiently positive to overcome the venous pressure produced by the driving power of the heart. Owing to the influence of gravity, this state of affairs is brought about more easily in the vertical feet-down position than in the horizontal posture. Compensation for the positive intrathoracic pressure is supplied by firm compression of the abdomen, the heart then fills, and the arterial pressure regains its normal level.

The arterial pressure depends on the energy of the heart, and on the peripheral resistance. It is clear that the arterial pressure likewise depends on the hydrostatic effect of gravity. If a normal man be placed in the vertical feet-down position, the pressure in the femoral artery will be higher than the pressure in the common carotid artery, by the height of the column of blood which reaches from the carotid to the femoral artery. In a man 6 ft. in stature this difference will amount to about 45 mm. Hg. On the assumption of the vertical feet-up or head-down posture the pressure in the common carotid will rise to a like extent above that of the femoral artery, owing to the influence of gravity. In the feet-up posture there exists no great vascular field like the splanchnic area to expand under the hydrostatic pressure. The face and neck alone become injected, for the brain is confined within the rigid wall of the cranium, and thus the cerebral vessels cannot expand.

FIG. 64.—Aortic and vena cava pressures. Morphinised and curarised dog.—Hill and Barnard.

- A, Artificial respiration withdrawn. Vertical feet-down posture.
 A-B, Asphyxial rise of aortic pressure. Traube-Hering curves.
 B and C, Effect of compression of abdomen. At C this produced paralytic dilatation of the heart.

In changes of posture, it is apparent, from the experiments related, that the pressure in the carotid artery is maintained at practically a constant height by the tone of the splanchnic arterioles and action of the respiratory muscles. If the splanchnic arterioles are in an efficient state of tone, and if the abdominal veins are supported by the tone of the abdominal wall, then the splanchnic vessels are similar in nature to a model of rigid tubes, and will not dilate under the hydrostatic stress of gravity. The nervous mechanism involved is probably of the simplest nature, for if the arterial pressure suddenly rise or fall at the moment of change in posture, the bulbar centres are thereby either directly or reflexly excited to decreased or increased activity. A sudden fall of arterial tension always provokes acceleration of the heart, amplified respiration, and increased vaso-constriction. A sudden rise of tension, on the other hand, provokes a slow heart, shallow respiration, and vaso-dilatation.

When the compensatory mechanism is abolished by destruction, exhaustion, or inhibition of the bulbar centres, the circulation fails and becomes inadequate to maintain life in the vertical feet-down posture. The blood passes into the capacious reservoirs of the toneless abdominal veins, the heart empties, and the cerebral circulation ceases. There can be no doubt that the control of this compensatory mechanism is one of the most important and absolutely necessary functions of the group of bulbar centres, a function which must have been evolved to its highest point as the anthropoids slowly assumed the erect posture.

During the course of each day the compensatory mechanism becomes exhausted, and especially is this so after severe muscular exertion.¹ By sleep the compensatory power is restored. In conditions of neurasthenia, weakness and exhaustion after disease, shock after severe injury or hæmorrhage, this power may be almost entirely lost.

By sudden fright in the standing posture the respiration is often arrested, the vasomotor tone inhibited, and syncope induced by the rush of blood from the brain to the abdomen. Recovery from syncope is brought about by the assumption of the horizontal position. When the compensatory mechanism is entirely lost, the circulation is only possible in the recumbent position, and life is at its lowest ebb. Among the anæsthetics in common use, chloroform stands prepotent as a drug which has the power to abolish the compensatory mechanism. Chloroform causes cardiac and vascular dilatation, weakens the respiration, and abolishes the tone of the abdominal muscles.²

A useful clinical guide to the condition of the compensatory mechanism in man is afforded by the rate of the pulse on change of posture. If the heart becomes greatly accelerated on rising from the horizontal to the vertical position, the vasomotor tone is deficient.

The alteration in the distribution of the blood by the influence of gravity has been studied on man by Mosso.³ He balanced the body on a horizontal board, turning on a transverse axis. The head-end soon becomes the heavier, owing to the increased outflow from the legs in the horizontal posture. If the legs have previously been dilated by standing in a hot bath, this effect becomes more marked. The change in weight may be as much as 260 c.c. of blood. At each inspiration the foot-end becomes heavier on account of the compression of the vena cava inferior by the descent of the diaphragm. The volume of one arm is increased if the other be raised up, and similarly in the case of the legs.

THE PULSE.

The most difficult problem connected with the hydrodynamics of the circulation is that of wave motion.

Suppose an extensile elastic tube (AB) to be divided into two parts by the membrane (O) (Fig. 66).¹ If the membrane be made to move towards A, a positive wave will be propagated along OA, and a negative wave along OB. If, however, the membrane be imperfect, then a wave,

FIG. 66.

partly positive and partly negative, will be propagated in both directions. The pulse wave is formed in a similar manner.

Suppose O to be the

aortic orifice, B the heart, and the membrane the aortic valve. As blood is forced from B into A, it develops a positive wave along OA. The fluid is driven into OA, with first, an increasing, and secondly, a diminishing velocity, and finally the force of propulsion comes to rest. If we consider the tube (OA), which is now expanded, to be divided into sections *a, b, c, d, e, f, g, h, i* (Fig. 67),² it is obvious that, when the ventricular output ceases, pressure will be exerted by the expanded elastic wall in the direction shown by the arrows: that is to say, the fluid particles are propelled towards *i*, retarded and brought to rest towards *a*.

FIG. 67.

Thus section *a* returns to rest and its original diameter, while section *i* expands. Likewise the sections *f, g, h* swell, since more particles of fluid are propelled through the wider sections *d, e* than can escape in the same time through the narrow sections *f, g, h*. Similarly, the sections *a, b, c* will shrink. Thus the wave of expansion travels from section to section along the tube (A). Since the return of the blood towards A, in the direction of the arrows, will close the aortic valve (O), and drive it as a whole towards B, a negative wave will be developed in OA. This wave will likewise be propagated along the tube (A). On the motion towards B coming to rest, the valve (O) will again move towards A, giving rise to a second positive wave, which in its turn will travel down the tube (A). Thus are produced in the arterial system the primary wave of expansion, and the secondary wave of expansion (dicrotic wave).

A wave in an elastic tube to a certain extent produces a translation of the particles of fluid, but the wave must be regarded mainly in the light of a translation of a change of form. The propulsion of each particle of fluid occasions a successive disturbance of the stability of contiguous particles; thus the impact of the blood, which is thrown from the heart into the aorta, travels down the arterial system. So an impact travels from truck to truck, when an engine strikes the end of a long railway train. If the train be in motion at the moment

¹ Nicolls, *Journ. Physiol.*, Cambridge and London, 1890, vol. xx. p. 425.

² Weber, *Ber. d. k. Sächs. Gesellsch. d. Wissensch.*, *Math.-Nat. Cl.*, Leipzig, 1850, Bd. i. S. 164-204.

of impact, the rate with which the impact travels from truck to truck will be quite independent of the constant velocity of the train, while the impact will momentarily increase the velocity of each truck and translate it forwards. That a wave must be considered mainly as the propagation of a change of form, is shown by the consideration of the following case. Suppose a long trough to be filled with water, and the water be pumped rhythmically out of it, then the water, with each stroke of the pump, will move towards the exit, but a negative wave at the same time, and in a contrary direction, will travel along the trough. The negative wave will slightly retard the velocity of flow towards the exit, but in itself it is a propagation of a change of form, which is entirely independent of the velocity of the fluid.

From mathematical consideration of a wave in an artery, where the blood and the vessel wall are held to be constants, the motion of the blood is assumed to be irrotational, and, to avoid the complication of gravity, the portion of the artery is supposed to be horizontal, Nicolls draws the following conclusions:—

1. That all particles of blood which lie on any cross-section continue to lie on the same cross-section during the passage of a wave; that is to say, each cross-section moves forward as a whole, and thus each particle, when the wave has passed, is left in advance of its original position.

2. The distance to which each particle is advanced is equal to the total increase in volume, divided by the area of the cross-section. Thus the passage of a positive wave slightly increases the velocity of the blood.

3. That the square of the velocity of the wave varies inversely as the density of the fluid and the radius of the tube.

4. That the less elastic the vessel the greater the velocity.

5. That the amplitude of the wave varies directly as the radius. In vessels of very small diameter the pulse becomes imperceptible, since, for a given wave length, the artery must have a certain diameter before pulsation be possible.

6. That the effect of the viscosity of the blood on the pulse is too small to be of any importance.

7. That normally the pulse wave is mainly the effect of lateral vibration, but in conditions where the range of pressure is very great, as in aortic regurgitation, longitudinal vibrations, which become visible as capillary pulsations, may occur.

Some of these deductions are in close agreement with the experimental determination of Moens.

The wave of expansion, according to Moens,¹ travels through such a tube as an artery with a constant velocity, which is expressed by the following formula:—

$$v = k \sqrt{\frac{gea}{Dd}}$$

where v = the velocity per second.

g = the acceleration due to gravity.

e = the elastic coefficient of the wall.

a = the thickness of the wall.

d = the diameter of the tube.

D = the density of the fluid.

k = a constant.

It is postulated that the thickness of the wall is small, and the wave length

¹ "Die Pulscurve," Leyden, 1878, S. 87, cf. Grunmach, *Arch. f. Physiol.*, Leipzig, 1888, S. 129; v. Kries, "Stud. zur Pulslehre," Freiburg, 1892, S. 7.

very long in comparison with the diameter of the tube. Thus, according to Moens, the velocity of the wave varies inversely as the square root of the diameter of the tube and the density of the fluid, and directly as the square root of the thickness and elastic coefficient of the wall.

As a wave travels down an elastic tube it is altered in form, owing to the viscosity of the fluid. Thus it becomes smaller, less steep, and more drawn out the further it travels from its source.

If water be rhythmically pumped into an elastic tube, a positive wave starts with each input and travels through the tube; and similarly, with each cessation of the input, there starts a negative wave. If the tube be sufficiently long, these waves are entirely spent; but if the tube be short, the waves may be reflected and run to and fro several times. Thus there may arise—

1. The primary positive or input wave;
2. The first centripetal reflected wave;
3. The second centrifugal reflected wave;
4. The second centripetal reflected wave;

and so on until the input wave is entirely spent.

Similarly, on the cessation of input there may arise—

1. The primary negative wave;
2. The first centripetal reflected wave;
3. The first centrifugal reflected wave;

and so on until the wave is spent.

If the end of the elastic tube be shut, the wave is completely reflected, and without change of sign. If the end be fully open, the wave is completely reflected with change of sign.

In the case of a wave travelling up and down a tube, one end of which is open and the other shut, the change of sign takes place at the open end only. If one end of a tube be partly open and partly closed, then the sign of the wave when reflected will be partly changed and partly unchanged. Thus reflected waves of opposite sign arise, and these, according to their comparative size, may more or less interfere with one another. It follows that with a certain size of opening the reflected waves will completely interfere, and thus they will disappear.

It has been experimentally determined by v. Kries that if an elastic tube be of sufficient width, and no reflection of the wave takes place, *the seat of maximal and minimal velocity in the tube will be found to be the same as the seat of maximal and minimal pressure.* Thus, if the pressure be found to increase in an artery, where the velocity decreases, a significant proof of reflection is obtained.

In addition to the waves which travel through the fluid in an elastic tube, the wall of the tube is itself thrown into vibration with each throb of the pump, just as a rubber band vibrates when it is suddenly and momentarily thrown into tension. These vibrations, according to v. Kries, are of such frequency as to be extraordinarily difficult to observe, and they cannot be considered to have any effect on the main features of the pulse curve.

Thus far we have considered the simplest possible conditions, the production of waves in an elastic tube of uniform bore and of uniform structure. In the circulatory system the conditions are, on the other hand, of considerable complexity. The arteries continually change, their walls become more or less elastic, the lumen wider or narrower, and finally

the arteries end in a multitude of narrow branches. Reflected waves are produced by any change in the conditions of the tube through which the primary waves are passing. An increase of frictional resistance acts in just the same way as a change in the diameter of the lumen or the elastic coefficient of the wall. Thus v. Kries¹ inserted fibres of cotton-wool in an elastic tube. The sectional area of the tube was 150 sq. mm., while the total sectional area of the cotton-wool fibres was only 3 sq. mm. Reflected waves were produced in this case almost to the same degree as if the tube had been completely blocked. Similarly v. Frey,² in experiments with a preparation of the aorta and its branches, found that reflected waves were less easily obtained when the vessels were filled with salt solution, than when filled with defibrinated blood. The blood corpuscles increase the resistance in the capillaries, and thus probably lead to the reflection of waves.

In the multitudinously branched system of tubes which the arteries form, any reflected wave, arising in any branch, will propagate itself through all the other branches. We have then, in the arterial system, all the conditions for the origin of primary and of reflected waves, and for the interference of these waves, and it necessarily becomes a matter of the greatest difficulty to determine the origin of the secondary waves which contribute to the peculiar form of the pulse curve. To the consideration of the experimental methods of obtaining and analysing the pulse curve, we must now turn, seeing that the theoretical treatment of such a subject, where most of the conditions are as yet unknown, is of very slight value.

Terms used in describing the pulse.—The exploration of the pulse by the finger of the physician has led to the origin of many descriptive terms, which are commonly used to define the quality of the beat. Thus, according to the number of beats per minute, the pulse is described as *frequent* or *rare*. The size of the excursion of each beat is defined as *large* or *small*; the speed with which the excursion is executed, as *quick* or *slow*. If the pulse is compressible beneath the finger, it is said to be *soft*; if incompressible, *hard*.

A strong pulse is both large and hard. A weak pulse is both small and soft. A contracted pulse is small and hard. In a full pulse largeness rather than hardness is the predominant quality, and in an empty pulse smallness rather than softness.

Variations in the rhythm of the pulse are likewise described by set terms. Thus, when an imperceptible beat occurs in a series of regular beats, the pulse is said to be *intermittent*, and when one or more small beats occur in a row of regular and larger beats, the pulse is termed *intercurrent*.

Sphygmography.—Vierordt³ first applied the graphic method to the investigation of the pulse, and Marey⁴ in 1860 constructed an instrument, the sphygmograph, which possessed all the essential qualities of accuracy.

A pelotte, attached to a steel spring, rests upon the radial artery, and its movements are communicated by a toothed rod and wheel to a lever. The inertia of the instrument is very small, and since the movements of the spring

¹ v. Kries, "Stud. zur Pulslehre," Freiburg, 1892, S. 24.

⁴ *Journ. de physiol. de l'homme*, Paris, 1860, tome iii. p. 241.

are also very small, the error due to the momentum of the mass is inappreciable. Buisson¹ experimentally proved that the instrument is free from any swing of its own.

If a small mirror² be fastened over the radial artery, and a beam of light thrown upon the mirror, the excursion of the pulse can be photographed on a moving sensitised plate. If a small puncture be made in an artery, the jet of blood can be brought to play on a sheet of white paper moved by clock-work, and a hæmautograph can be thus obtained.³ Both these methods yield exactly the same type of curve as the Marey sphygmograph. The instrument has been modified in many ways. Dudgeon has constructed a less cumbersome and more convenient form, suitable for the obtaining of clinical records.

These sphygmographs are less suitable for taking continuous records during long periods of observation. For this purpose air transmission is employed, and the pulse trace is obtained by means of a receiving and a recording tambour.

The frequency of the pulse.—If for a space of twenty-four hours a man be kept in bed, perfectly quiet, uniformly covered with clothes, and without food, it will be found that the variations of the pulse rate during the day are very small. Such variations as arise are due to changes in temperature. Much clothing increases the frequency, while exposure to cold lowers it. The variation due to the change of clothing may be as much as ten beats per minute.⁴

The hot room of a Turkish bath greatly increases the pulse rate. In an air-chamber at 65° C., the heart may attain to a frequency of 160 per minute. In the tropics the pulse of a traveller quickens, while in the arctic regions it becomes slower. Drinking hot water accelerates the pulse, while the imbibing of a large quantity of cold water slows it. Every sensation of warmth, pressure, or discomfort in the stomach accelerates the heart. The taking of cold foods does not alter the rate, but hot meals increase it by as much as ten per minute. The heart lies in apposition to the stomach, warmth increases the rapidity of the heart; and we may therefore assume that the warm food in the stomach directly raises the excitability of the rhythmic mechanism of the heart. The effect of meals on the pulse rate is shown in the following example:⁵—

⁵ Adapted from Tigerstedt, "Physiol. des Kreislaufes," Leipzig, 1893, S. 27.

In a condition of fasting and resting the pulse rate decreases slightly during the day, up to 2 P.M., and is then slightly accelerated again.

The *seasons* have little effect on the pulse rate. Coste,¹ in a period of five years' examination, found his pulse to beat less frequently in the summer, and more frequently in the winter.

Change of position of the body, whether such change be brought about actively or passively, has a marked effect on the pulse rate. In one hundred men averaging 27 years in age, Guy² found the average rate of pulse to be—

78.9	Standing
70.1	Sitting.
66.6	Lying.

After debilitating disease the change of frequency between the horizontal and erect postures may reach 30 to 50 beats per minute.³ Active movement has a very great effect on the pulse rate. The frequency may, for example, be 100 when slowly walking, and rise to 150 on running as fast as possible. The exertion of climbing steps may raise the pulse 58 per minute, and produce marked diastole.⁴ After a series of pendulum movements executed for a period of 30 seconds by the right arm, which was loaded with a weight of 2 lb., the pulse rate was noted to rise in one case from 82 to 156 per minute. When active movements have been executed for a short period only, the frequency quickly returns to normal, while if continued long the pulse rate may subsequently remain increased for an hour or more. Sleep lowers the rate of heart-beat slightly in adults, and markedly in children.

The pulse frequency is greater in women than in men, but this difference almost disappears if men and women of equal stature are compared.

Large animals always have a slower pulse rate than small animals; thus elephants have a frequency of 25 to 30, and rabbits 150; and tall men have as a rule slower rates than short men. The acceleration in small animals is due to the fact that the surface exposure is greater in these, in proportion to the cubic contents of the body; therefore, as the loss of heat is greater, and the metabolism more rapid, a quicker circulation is required. Individual variations in healthy men may be very great. It is said that Napoleon had a constant pulse rate of 40. Rates of 20 and 26 have even been recorded. On the other hand, a constant rate of 120 has been noted in a healthy woman.⁵ We can sum up from the above facts that a small size of body, the female sex, muscular movement, hot food, and rise of temperature of body, increase the pulse rate. In the following table is shown the average pulse rate at different ages up to 20 years. The observations were taken in the resting and sitting posture, and not immediately after food.⁶ From 20 years onward the rate remains practically constant; in old age there may be a very slight increase.

The velocity of the pulse wave.—The fact that the carotid pulse is earlier in time than the radial pulse is determinable by the fingers of a practised observer. With the help of a clock beating thirds of a second, E. H. Weber³ found the difference time between the perception of the pulse in the maxillary and anterior tibial artery to be respectively $\frac{1}{3}$ to $\frac{1}{7}$ second. From this result the velocity of transmission was calculated to be 7.92 to 9.24 metres per second.

Later observers have obtained, by means of tambours, synchronous graphic records from two different arteries. Some selected examples of the results obtained by different workers are given in the following table:⁴—

	DISTANCE.	TIME DIFFERENCE.	VELOCITY OF TRANSMISSION.	
A. femoralis . } A. dorsalis pedis }	991 mm.	0.154	Metres per second. 6.43	Landois. ⁵
A. axillaris . } A. radialis . }	500 ,,	0.087	5.77	Landois.
A. carotis . } A. radialis . }	580 ,,	0.080	7.37	Koyt. ⁶
A. carotis . } A. femoralis . }	460 ,,	0.070	6.83	Keyt.
A. carotis . } A. radialis . }	600 ,,	0.079	7.63	Edgren. ⁷
A. carotis . } A. femoralis . }	520 ,,	0.084	6.20	Edgren.
A. carotis . } A. dorsalis pedis }	1200 ,,	0.133	9.00	Hoorweg. ⁸

The variations in the rate of transmission depend on the elastic coefficient of the arterial wall. With a rise of arterial pressure the

velocity of transmission and the coefficient of elasticity increase. Thus Moens¹ determined that in the same individual the velocity was greater when the arterial pressure was higher. In Valsalva's experiment the filling of the heart is impeded by the increase of intrathoracic pressure, hence the arterial pressure falls. During this condition, the velocity of the pulse wave has been estimated to be 7 metres per second, while during quiet respiration the velocity rose to 8 metres per second.

Before stimulation of the peripheral end of the vagus, Moens estimated the velocity to be 11·5 metres per second. During the first six beats, after the cessation of cardiac inhibition, the velocity was 4·5 metres, 4·5 metres, 6·0 metres, 7·5 metres, 12 metres, 13·5 metres, respectively, per second. Similarly, when the arterial pressure is lowered by a condition of deep anæsthesiation, or by dividing the spinal cord, the velocity is lessened, while it is increased by excitation of the divided spinal cord.²

By placing the arm in hot water, the velocity of transmission from the carotid to the radial artery may be lowered by 14 per cent., owing to the local dilatation of the blood vessels. The velocity may be found to be different in the arm and in the leg, owing to the variations in the elastic coefficient of the arteries of these parts—variations which may depend upon the structure of the arterial wall, upon the hydrostatic effect of gravity, or upon the local condition of vascular dilatation. When the arteries are sclerosed, and the rigidity of the wall is increased, as in the degenerative condition which accompanies chronic Bright's disease, the velocity is increased.

The length of the pulse wave is the product of the velocity of transmission of the wave into the time occupied by the wave in passing any given point; which time, in the case of the pulse wave, is about the time of a cardiac cycle, *i.e.* 0·8 second.

If the velocity of transmission be taken as 6 metres per second, then the length of the wave will be 6 metres \times 0·8, *i.e.* about 5 metres. From this it follows that the pulse wave reaches the periphery long before it has left the aorta.

The characteristic features of the pulse curve.—The radial artery is surrounded by veins. A vena comes lies on either side, whilst a superficial vein (a branch of the median or radial) often lies directly over or just to the side of the artery (Fig. 68, *e*).

In Figs. 68, 69, there is represented (drawn to scale) the arrangement of the veins and artery. The plane of the section (Fig. 68) passes through the spot where the radial pulse is usually explored by the finger or the sphygmograph. The artery and veins lie in a space between the styloid process of the radius and the tendon of the flexor carpi radialis. This space may be conveniently termed the radial sulcus.

If, after ligation of the upper forearm in a corpse, the radial artery be distended from above, and the venæ comites from below, it appears to the finger as if one broad flat band filled the radial sulcus. If the artery be then pulsed by rhythmically compressing the tube connected with the arterial pressure bottle, both artery and veins seem to share in the pulsatile movement.

¹ "Die Pulscurve," Leyden, 1878, S. 111.

² Grunmach, *Arch. f. Physiol.*, Leipzig, 1879, S. 424.

To the finger, both the breadth of the pulse and the apparent diameter of the radial artery is increased by distension of the venæ comites. Such being the case, on examining the radial sulcus with the finger, we can speak of—

1. The size or breadth of the band-like swelling, composed of the artery and the veins, which more or less occupy this space.
2. The tension of the band. By this we mean the sense of pressure necessary to obliterate the calibre of the artery, and stop the pulse.
3. The condition of the arterial wall, which can be investigated by flattening the artery with the finger and rolling it upon the bone.
4. The oscillation or wave of expansion.

The wave of expansion admits of description in these particulars—(1) Frequency; (2) regularity; (3) amplitude of excursion; (4) period of excursion; (5) dirotism.

A radial sphygmogram is a pressure curve, for the movements of the lever of the sphygmograph are produced by the changes in pressure in the vessels which lie in the radial sulcus. The scale by which the ordinates of the curve should be measured is, however, an unknown quantity. The arterial pressure acts not only on the arterial wall, but also on the surrounding tissues; and since the pad of the instrument rests partly upon the venæ comites, not only the arterial tension, but any turgidity arising from venous congestion, affects the height of the sphygmographic curve.¹ That this is so, is shown by the effect of compression of the veins of the arm.

In Fig. 70, tracing 1, the whole of the upper arm at the point (A) was compressed by the hands of the observer; at the point (B) the compression

¹ Hill, Barnard, and Sequeira, *Journ. Physiol.*, Cambridge and London, 1897, vol. xxi. p. 148.

was withdrawn from the brachial artery, but maintained in the veins. As the veins fill, the abscissa line of the sphygmographic curve shows a gradual rise. This rise is considerable. The excursion of the wave is at the same time diminished. On withdrawing the compression, as the veins empty, the pulse tracing slowly returns to the normal condition.

To the finger, the breadth or fulness of the vessels in the radial sulcus appears greater during the compression of the veins, and the amplitude of the excursion is diminished. On compressing the brachial artery, at the moment when the elevation of the tracing produced by compression of the veins is at its maximum, the line of the trace does not fall, because the venous outlets are entirely blocked (Fig. 70, tracing 2).

FIG 70.

- Tracing 1.*—A, Compression of the veins of the arm and the brachial artery; B, compression of the veins of the arm only; C, compression withdrawn.
- Tracing 2.*—A, Veins of the arm compressed; the double arrow marks the height of the base line before the compression was applied; B, brachial artery occluded; C, compression withdrawn from the artery and veins.
- Tracing 3.*—Sphygmograph resting on the femoral artery and vein of a dog. A, Femoral vein compressed; B, compression withdrawn.
- Tracing 4.*—Sphygmograph resting on the femoral artery of the same dog. A, Femoral vein compressed; B, compression withdrawn.
- Tracing 5.*—Sphygmograph resting on the femoral vein of the same dog. A, Femoral vein compressed; B, compression withdrawn.—Hill, Barnard, and Sequeira.

In Fig. 70, tracing 3, there is recorded the effect of compressing the femoral vein in the dog, while the pad of the sphygmograph rested upon the femoral artery and vein. In this experiment all the other venous exits were blocked by means of a ligature, which was drawn round the thigh, excluding the femoral vessels. As the vein is compressed it can be seen to gradually distend, until in diameter it more than equals the artery. When entirely occluded, the tension within the vein rises to that of the artery. By the distension of the vein the pad of the sphygmograph is elevated above the artery; thus the line of the tracing rises, while the excursion of each pulse is considerably diminished. Owing to the elevation of the pad of the instrument by the vein above the artery, the bottom of each curve is cut off. That the alteration of the tracing is due to the rise of pressure within the vein, is shown by the next two figures. In Fig. 70, tracing 4, the femoral vein was compressed, while the pad of the sphygmograph rested on the femoral artery only, and in Fig. 70, tracing 5, the experiment was repeated while the instrument rested on the femoral vein only.

Valsalva's experiment—forced expiration with the mouth and nose shut—produces the same effect on the pulse as compression of the veins of the arm. By the rise of intra-thoracic and abdominal pressure, the outlet of the veins of the limbs and head and neck is blocked, and the pressure in the venæ comites radiales rises to the mean arterial tension.

Thus the pad of the sphygmograph is elevated, the line of the tracing is raised, and the bottom of each pulse curve is cut off (Fig. 71, tracing 1).

If the brachial artery be occluded at the height of the expiratory effort, the line of the tracing does not fall so long as the venous outlets are blocked. It is, on the other hand, lowered so soon as the veins are emptied by one or two deep inspirations (Fig. 71, tracing 1, CCC).

During the expiratory rise of intra-thoracic pressure in Valsalva's experiment, the blood in the abdominal veins is at first driven on into the right heart, and the outlet through the abdominal capillaries is at the same time diminished. Owing to these effects, the arterial tension rises to a slight extent. In the next stage, by the rise of intrathoracic pressure, the lungs are emptied of blood, the filling of the right heart is opposed, the blood is congested in the peripheral veins, and the pressure in these rises

FIG. 71.

to the mean arterial tension. The arterial pressure may then begin to gradually fall, but before any considerable fall has taken place the expiratory effort ceases from exhaustion of the subject of the experiment, and a deep gasping inspiration is taken. During this inspiration the whole of the blood delivered by the right heart is swallowed up in the roomy reservoirs of the expanded lungs; thus several beats of the left ventricle become abortive (Fig. 71, tracing 2). The radial pulse is then felt with the finger to stop, the face blanches, and the subject turns faint owing to acute cerebral anæmia.

At the moment of the deep inspiration, not only are the peripheral veins emptied into the thorax, but the blood in the peripheral arteries is also sucked back into the thoracic aorta. Thus the tension in the radial vessels falls below zero; in fact, the systemic circulation entirely ceases until the left ventricle once more becomes filled with blood from the pulmonary veins. These experiments are performed with far greater effect by a man with a compressible than with a rigid thorax.

The sphygmogram shows variations synchronous with the respiratory movements. Normally these are slight, but they become marked whenever the respiration is either deep or partially obstructed. During deep inspiration the line of the tracing falls, whilst the excursion of the primary wave decreases, and the dicrotic wave becomes more evident. The *venæ comites radiales* are here emptied, and the expanded lungs swallow up the blood so that the arterial tension falls slightly. When expiration follows, the line of the tracing rises, and the excursion of each pulse is increased. During a deep inspiration the vessels in the radial sulcus appear to the finger of less breadth and lower tension. In obstructed breathing the pulse beats may, during inspiration, almost disappear, for the air cannot then enter freely, and thus the force of the inspiratory movement is thrown largely on to the intra-thoracic vessels and the heart.

Passive compression of the thorax produces the same effect on the pulse as Valsalva's experiment, if the breath be held (Fig. 71, tracing 4). If, on the other hand, the breath be allowed to escape as the thorax is compressed, the line of the tracing falls, and the pulse beats become abortive (Fig. 71, tracing 5). In this latter condition the outlet of the peripheral veins is not blocked, while the beat of the heart is mechanically opposed by the compression.

So soon as the fact is once grasped that the veins which surround the radial artery bear an important share in the production of the phenomena of the pulse, almost all the difficulties which have hitherto surrounded the explanation of sphygmographic tracings under these conditions disappear. In place of these, an absolute agreement between the results obtained on animals by manometric observations, and those recorded on man with the sphygmograph, becomes apparent.

In all pathological conditions of obstruction of the circulation, arising from pulmonary or cardiac disease, wherein by back pressure the general venous tension is raised, and the arterial tension lowered, the veins which surround the artery must have an important share in giving to the pulse the quality of breadth or fulness which is so commonly combined with that of low tension. When the quality of fulness is estimated to be present between the pulse beats, this does not betoken a high arterial tension, but rather an engorgement of the venous system.

FIG. 72.—Two examples of the effect of occluding the brachial artery. A, Artery compressed; B, compression withdrawn.—Hill, Barnard, and Sequeira.

By recording with the sphygmograph the effect of occlusion of the brachial artery, we possess a method of investigating the condition of the circulatory system. If the fall of the line of the curve is steep and rapid on sudden compression of the artery, a high arterial tension, a low venous pressure, and a rapid escape of the venous blood is indicated (Fig. 72, tracing 2); if the fall is shallow and slow, the opposite conditions exist, for then the indication is that the arterial and venous pressures are more approximate to each other, and that the escape of the venous blood is obstructed¹ (Fig. 72, tracing 1).

Analysis of pulse curve.—Each pulse curve begins with an ascending limb of considerable steepness, which corresponds with the positive wave produced by the systolic output of the heart. As a rule, the ascent forms an unbroken line until the apex of the curve is reached, and the descent commences. The descending limb is marked by several minor waves, of which one, the dicrotic, is present in all forms of pulse curve.

The minor waves on the descending limb of the curve are termed *katarotic*, and if such waves appear on the ascending limb these are termed *anacrotic*.²

FIG. 73.—Velocity of pulse wave. Carotid and radial pulse.—After Edgren.

The difference in time between b and b' = 0.786 sec.

The distance between radial and carotid = about 60 cm.

∴ velocity of transmission = about 7 m. per sec.

The dicrotic wave.—There has been much dispute over the origin of the secondary waves, and the matter cannot yet be considered definitely settled. It cannot be doubted that the dicrotic wave is a positive centrifugal wave, for, if synchronous tracings be taken from two arteries, the dicrotic wave, like the primary wave, appears earlier in time in the artery which is nearer the heart. Although the dicrotic wave runs centrifugally, it does not follow that it is entirely central in origin. Several authors have maintained that the dicrotic wave travels with less velocity than the primary wave down the arteries of the lower limb, while it travels with approximately the same velocity down the arteries of the upper limb.³

¹ In taking such observations the sphygmograph must be arranged so as in each case to give the maximal pulsation. The wrist also should be placed on the same level as the heart.

² Landois, "Die Lehre vom Arterienpuls," S. 108.

³ v. Kries, *Arch. f. Physiol.*, Leipzig, 1887, S. 275; Edgren, *Skandin. Arch. f. Physiol.*, Leipzig, 1889, Bd. i. S. 104; for the contrary conclusion, see Hürthle, *Arch. f. d. ges. Physiol.*, Bonn, 1890, Bd. xlvii. S. 28.

Such results as these have been obtained:—

	VELOCITY.	
	Primary Wave.	Dicrotic Wave.
Upper extremity . . .	7·32 metres per sec.	7·32 metres per sec.
Lower extremity . . .	6·59 „	5·24 „

If this be so, it is argued, the dicrotic wave must either be modified, or produced, by waves reflected from the periphery. On the other hand, this difference in velocity time may be due simply to differences in arterial pressure, which may exist at the period of the dicrotic wave. The greater the tension of the arterial wall, the greater is the velocity. No doubt reflected waves may be produced in such a system of branching tubes as the arteries form. Such reflected waves must arise at different distances from the heart, spread into every branch of the system, and modify, not only each other, but the primary waves by interference.

FIG. 74.—Experiment to show central origin of dicrotic wave.—Grashey.

v. Kries bled an animal to death, placed a spring manometer in connection with the femoral artery, and a bag filled with fluid in connection with the aorta.¹ This bag was suddenly compressed, and retained in the compressed position. Thus a primary positive centrifugal wave was propagated through the arterial system. This gave rise to secondary waves, which v. Kries attributed to reflection. On the other hand, it must be borne in mind that these waves were obtained under the most favourable conditions, and it is very doubtful whether such waves would be visible when produced under the conditions of the ordinary pulse curve. Moreover, the waves may have been occasioned rather by oscillations of the wall of the aorta, than by reflections from the periphery.

In order to demonstrate the central origin of the dicrotic wave, Grashey²

¹ v. Kries, "Studien zur Pulslehre," S. 62, cf. v. Frey, "Die Untersuch. des Pulses," S. 164.

² "Die Wellenbewegung elastischer Röhren," Leipzig, 1881, S. 165.

employed the arrangement shown in Fig. 74. Into the left auriculo-ventricular opening was fastened a tube (*B*). This tube ended in two branches (*P* and *N*). The branch (*P*) was connected with a pressure bottle (*A*), and the branch (*N*) formed an exit tube. A tap was placed in these branches, so that *N* was opened when *P* was closed, and *P* was opened when *N* was closed. Into the aorta was fixed a long elastic tube (*V*). Water was allowed to flow from the pressure bottle through the heart and the aorta. If the tap was now suddenly turned so as to shut *P* and open *N*, the pressure sank to zero in the ventricle, and a positive wave appeared in the aortic tube, which was produced by the closure and vibration of the semilunar valves, and not by reflection from the periphery.

Hoorweg¹ employed a circulatory model in which a current through a Rumkorff coil was completed by the closure of the semilunar valves. The coil sparked on to the smoked paper, and knocked away the soot at the point where the lever style recorded the pulse wave on the drum. The closure of the valves was thus found to take place exactly at the foot of the ascent of the dicrotic wave.

Hoorweg found that the dicrotic wave appeared at the same interval of time, after the commencement of the primary wave, in

FIG. 75.—Effect of inhalation of amyl nitrite. A, Normal trace; C, maximal effect of the drug.

a dwarf as in a man of tall stature. If the dicrotic wave were of peripheral and reflected origin, it should assuredly have occurred earlier in the dwarf, for in the dwarf the length of artery to be travelled by the reflected wave would be much smaller.

Under the influence of inhalation of amyl nitrite, the dicrotic wave may, it is stated, almost disappear during the maximal effect of the drug (Fig. 75). Those who seek to explain the origin of this wave by the production of reflected waves suggest

that this is so, because the arterioles are so dilated by the drug that little reflection can take place.² The evidence in favour of this statement is, however, unsatisfactory, and, holding to the central origin of the dicrotic wave, the phenomenon can equally well be explained by the fact that the heart force is diminished while the peripheral resistance is lowered, and therefore the back swing of the blood against the

¹ *Arch. f. d. ges. Physiol.*, Bonn, 1890, Bd. xvi. S. 143.

² v. Kries, *loc. cit.*

semilunar valves is greatly enfeebled. On a review of the whole evidence, the central origin of the dicrotic wave must be taken as an assured fact.

Reflected waves, however, if synchronous in time, may possibly modify the dicrotic wave, and, according to the sign of these waves, the height of the dicrotic wave may be diminished or increased in different arteries; the time relations of the dicrotic wave to the primary wave may also be altered thereby.

The question of interference between reflected waves and the primary pulse waves is inextricably complicated, owing to the fact that it is necessary to take into account not only the centripetal reflected waves which arise in the peripheral field of an artery, but also the reflected waves which arise in other arterial fields, and which, after being again centrally reflected, course centrifugally down the observed artery.

That the pulse wave is affected by purely local conditions, is shown by the following facts:—

1. The primary and dicrotic waves of the radial pulse are greatly diminished by occlusion of the veins of the arm, by the dependent position of the limb, or by plunging the arm into cold water.

2. They are greatly increased when the arm is elevated above the head, or plunged into hot water.¹

When the general and not the local conditions of the circulation are varied, the dicrotic wave is found to be most marked in the following conditions:—

1. When the arterioles are dilated, the arterial tension low, and the systole of the heart vigorous; for example, after a hot bath, or in the first stage of asthenic fever.

2. When the systolic output of the left ventricle is, from any cause, diminished; for example, on taking a deep inspiration, in the second stage of a forcible expiratory effort, and after severe hæmorrhage.

The dicrotic wave is most marked in youth when the arteries are elastic. In any individual it is increased at times of exhaustion, and diminished in times of vigour. The amplitude of the dicrotic wave, so long as the local conditions are not varied, can be taken as a sign of low arterial tension.

The predicrotic wave, which is sometimes observed preceding the dicrotic wave, is, according to v. Kries, due to reflection for a comparison of the pressure and velocity curves shows that, at the point of occurrence of this wave, the pressure and velocity are most divergent. If the predicrotic wave become very marked, it may rise to a higher elevation than the primary wave. The pulse curve is then marked by an anacrotic wave. The curve is anacrotic in type when the

FIG. 76.—Six curves taken during the escape of the heart from vagal inhibition.—v. Frey.

¹Hill, Barnard, and Sequeira, *Journ. Physiol.*, Cambridge and London, 1897, vol. xxi.

arterial pressure is very high, katechrotic when the pressure is low. The change of form, as the arterial tension rises, is seen very well in the six curves taken with a spring manometer during the escape of the heart from vagal inhibition (Fig. 76). By compression of the abdominal aorta, the carotid pulse can easily be made to exhibit an anacrotic wave.

To sum up, then—1. The form of the pulse curve in any artery is produced by (1) the aortic centrifugal primary waves; (2) the centripetal waves reflected from the peripheral field of the observed artery; (3) the waves reflected from other arteries. These waves modify each other by interference. The sphygmograms from different arteries show certain main and constant features, which in each artery are modified by peculiar local characteristics. For example, in femoral tracings, the primary and dicrotic waves are much more prolonged than in radial curves.

2. Since the form of each pulse curve depends not only upon the systole of the heart, but also on the peripheral resistance, the tone of the arteries, the turgescence of the venæ comites, and the amplitude of the reflected waves, it is obvious that no sure deductions can be drawn from the amplitude of the oscillation, either as to the power of the heart or the height of the arterial tension.

Finally, it must be remembered that the sphygmograph can never be applied twice to the same artery in exactly the same way, and with the same amount of pressure. This vitiates the instrument for comparative work. The best rule to follow is to always so adjust the instrument as to obtain the maximal excursion that can be possibly obtained in any given case.

THE CAPILLARY CIRCULATION.

The blood is brought into intimate relation with the tissues by diffusing through the endothelial wall of the capillaries, and this wall is of the greatest tenuity; thereby takes place that exchange of material which maintains the combustion of the body and the fire of life. The whole aim of the circulation is attained, so long as the arterialized blood is driven with a constant velocity through the capillaries.

The capillaries vary in size in different organs. In the brain the length has been estimated to be 0·709 mm. (pons), and 0·42 mm. (optic thalamus), in the mucosa of the stomach 0·6 mm., and in the liver 0·5 to 1·1 mm.¹ The diameter of the capillaries varies from ·007 to ·013 mm.

Malpighi² (1661) first observed under the microscope the capillary circulation. He examined the lung, the mesentery, and the bladder of the frog. It has since been seen in many other transparent or translucent parts of animals.

The microscopical examination of the circulation.—By using a low power it is possible to simultaneously examine arteries, capillaries, and veins in the same field. The first thing which strikes the observer is the different direction of the stream in the arteries and in

¹ Lewy, *Arch. f. d. ges. Physiol.*, Bonn, 1896, S. 461.

² "De pulmonibus epistola," ii., Opera omnia, London, 1686.

the veins. On account of the reticular arrangement of the capillaries, the direction of the stream through them is by no means constant; for a period there may be a complete cessation of the flow in a capillary channel, or the direction of the current may even be reversed for a longer or shorter time. The flow through the arteries is by far the most rapid. In the veins also the stream is so rapid that it is difficult to catch the contour of the corpuscles. The stream is slower in the small veins, and in the capillaries the movement is, as a rule, so tardy that the individual corpuscles can be followed without any difficulty. The inconstancy of the capillary stream is generally apparent. If a group of capillaries be kept for some time under observation, the blood is occasionally seen to hurry suddenly through a number of these with increased rapidity; this continues for a while, and then the stream becomes again slower and slower, till after an interval it reassumes the usual quiet rate of flow which has been maintained without interruption in the neighbouring capillaries. These variations depend on alterations in the lumen of the afferent arteries.¹

The arterial stream is pulsatile, and each systole may be recognised even in very small arteries by the rhythmical acceleration and retardation of the blood stream. Such a rhythmical movement is absent from the capillaries and veins in a normal condition; the stream is a continuous one in both. In the arteries the mass of red corpuscles does not completely occupy the lumen, but moves along the axis of the stream. To the outside there lies a clear layer of plasma, in which here and there a stray white corpuscle rolls along. In the veins there is also a similar peripheral plasmatic layer, in which the white corpuscles roll slowly along, sticking now and again to the wall of the vessels in their course. In the smallest capillaries the plasma layer cannot be distinguished, the red corpuscles march in single file, and often become distorted and bent as they pass. These capillaries are invisible if by any chance the file of corpuscles ceases to pass through them. Thus in the course of an observation capillaries may be seen to appear and vanish from view. In the angles of the capillary network, red corpuscles may sometimes be seen to stick and hang in the balance, bent round the angle, half in one branch and half in another, until finally swept on into the rush and hurry of the stream.

The white corpuscles progress with a slow rolling motion in the plasmatic layer. The axial stream travels with the greater velocity, and thus the side of the leucocyte which at any moment lies nearer the axis is driven on with the greater speed; hence the rolling movement. The white corpuscles travel in the peripheral layer, the red in the axial layer, for the latter are the heavier. It is not, as has been supposed, that the white are lighter and the red corpuscles heavier than the plasma; both forms are of a higher density than the plasma.

Schklarewsky² found that, when he circulated particles of graphite and carmine through glass capillaries, the carmine travelled in the peripheral layer. When he substituted resin in the place of graphite, the carmine travelled in the axis. When he circulated pus corpuscles and milk globules, the pus corpuscles occupied the axial stream.

The capillary circulation no longer remains pulseless, if the resistance

¹ Cohnheim, "Lectures on General Pathology," *New Syd. Soc. Translation*, 1889, vol. i. pp. 152, 153.

² *Arch. f. d. ges. Physiol.*, Bonn, 1868, Bd. i. S. 603.

in the arterioles be lowered to a certain point. Bernard stimulated the chorda tympani nerve, and found that the blood issued in pulses from the veins of the submaxillary gland. By plunging the hand in very hot water, the pulse may be seen to reach even the turgid veins on the back of the hand. In cases of aortic insufficiency, a capillary pulse is readily obtained in any area of congestion which is produced by scratching the skin.

The effect of vaso-dilatation can be observed under the microscope with the greatest ease. On brushing the tongue of a curarised frog, an appearance of intense redness shows that arterial congestion has set in. In the words of Cohnheim, a really magnificent spectacle now presents itself. All the vessels, arteries, capillaries, and veins are wide and strongly distended with blood; innumerable capillaries are perceptible at a glance, where previously a few red-coloured threads were toilsomely sought for; and in all these vessels, small and large, the blood rushes on with the greatest rapidity—so rapidly that even in the capillaries the eye in vain strives to catch the outline of a single corpuscle.

By the application of a piece of ice to the tongue of the frog, vaso-dilatation can be converted into constriction. The arteries become narrow, the tongue pale. The eye has difficulty in finding any except the larger vessels; few capillaries appear to contain blood; and where a considerable quantity of blood is still present, as in the arteries and veins, the flow is tardy, and even in the arteries the individual corpuscles can now generally be recognised.

In a warm-blooded animal the results of exposure to an irritant are much more rapidly established; after exposure of the rabbit's ear to water at 56° C., the blood is altogether unable to penetrate the arteries. A change has taken place in the relations between the blood and the vessel wall as regards friction and adhesiveness, and thus complete stasis of the circulation arises. If the change be less intense the porous nature of the vessel is affected, and a quantitative and qualitative change in the transudation from the capillaries ensues. The rabbit's ear, with exception of the central artery and vein, may be entirely separated from the body. After thus dividing all the vasomotor nerves, vascular dilatation will be greatly increased by rubbing the ear, and all the phenomena of inflammation occur in just the same way after the application of an irritant or as a result of ischaemia. We have here to deal, not with a nervous mechanism, but with a molecular change of the vessel wall. The circulation through the capillaries is possible only so long as the vessel wall is in the normal physico-chemical condition which characterises the living state.

In spite of considerable variations of internal tension, the capillaries show only slight variations in width. After amputation of the hind-limb of a frog, the capillaries in the swimming-web scarcely become reduced in size.

Rate of flow.—Hales¹ reckoned the velocity of a blood corpuscle in the capillaries of the frog's muscles to be 0·1 inch in 9 seconds (0·28 mm. per second). The method most conveniently used is to employ an ocular micrometer, and to follow the course of a corpuscle during a period of time given by a clock beating one-fifth seconds. The velocity has been thus found by various observers to be 0·25 to 0·57 mm. per second in cold-blooded animals.

Vierordt² reckoned the velocity in the retinal capillaries by the entoptic method. He projected the shadow of the corpuscles on an

¹ "Statical Essays," 1733, vol. ii. p. 63.

² "Die Erscheinungen und Gesetze der Stromgeschwindigkeit des Blutes," Frankfurt, 1858, S. 41, 111.

illuminated ground-glass screen, held 11 to 16 cms. from the eye, and on this screen he reckoned the progression of a corpuscle in a given time. He found that a blood corpuscle could be thus followed over a space of 20 to 30 mm. If A represents the distance of the screen from the anterior nodal point, and B the distance of the retina from the posterior nodal point of the eye, and C the distance travelled by the corpuscle on the screen, then $\frac{BC}{A} = x$, the real distance which is covered by the corpuscle in the capillary.

The mean velocity was thus found to be 0.75 mm. per second. The red corpuscles travel in the axial parts of the stream, and as the mean velocity is less than the axial velocity, the true mean velocity of flow is less than the above; it may be taken to be about 0.5 mm. Since the velocity at any point in a system of tubes stands in inverse proportion to the sectional area, the relationship of the total sectional area of the capillaries, at any one time patent, to that of the aorta can be reckoned.¹ Thus, if the mean velocity be taken as 320 mm. per second in the aorta and 0.5 mm. per second in the capillaries, the relation is 1:640. In man the sectional area of the aorta is 4.4 sq. cms. The total sectional area of the capillaries would thus be equal to about 2800 sq. cms. This result is, of course, only roughly approximate.

The capillary blood pressure.—The pressure was first obtained by v. Kries.² He placed a glass plate, 2.5 to 5 sq. mm. in size, in a suitable place on the skin, such as the last joint of the finger. There depended from this glass plate a small scale pan. On this, weights were placed until the pressure was reached at which the skin was blanched and the capillaries compressed.

In using this method, the reading is taken when the change of colour in the skin just begins to appear, that is, when the superficial capillaries are obliterated. Thus the error due to the elasticity of the epidermis is avoided as far as possible. It is presupposed that the elasticity of the capillary wall is negligible, and that the blood pressure, in all the area of capillaries under observation, is equally great.

If a weight of g grammes be placed on a surface of f square millimetres, then the formula $h = \frac{g}{f}$ gives the hydrostatic pressure in mm. H_2O which is required to obliterate the capillaries. Thus, suppose the square surface of the glass plate be 4 sq. mm., and the weight be 1 gm., then an area of 4 sq. mm. carries 1 gm. = 1 c.c. H_2O = 1000 cub. mm. The height of the column of water supported by one sq. mm. is therefore $\frac{1000}{4} = 250$ mm. H_2O .

0.25 grms. is the smallest difference in weight which can produce the index of colour change. To obtain the index with a smaller glass plate, a heavier weight is needed than with a larger plate. The method is therefore very rough and inaccurate.

Roy and Graham Brown³ employed a method of directly determining how great a hydrostatic pressure is necessary to obliterate the capillaries while under microscopic observation. The web or mesentery of a frog

¹ Vierordt, *Arch. f. physiol. Heilk.*, Stuttgart, 1848, S. 184.

² *Ber. d. k. Sächs. Gesellsch. d. Wissensch., math. phys. Cl.*, Leipzig, 1875, S. 148.

³ *Journ. Physiol.*, Cambridge and London, 1879, vol. ii. p. 328.

is laid on a glass plate, and compressed by a thin and transparent membrane, which forms the base of a glass capsule. The latter is filled with water, and connected with a pressure bottle and manometer.

They found that a pressure of 100 to 150 mm. H_2O is sufficient to stop the circulation in the capillaries and veins of the frog's web; to expel the blood from the arteriole 200 to 350 mm. is necessary. From time to time the pressure varies 20 to 30 mm. H_2O . On producing splanchnic paralysis, by striking the abdomen, the pressure sank to zero, and then rose again in the veins to 70 or 100 mm., owing to venous congestion. Temporary anæmia of the web caused dilatation of the vessels, and this produced in its turn a higher capillary pressure.

v. Kries found that, in the sitting posture, the position of the arm influenced the capillary pressure in the fingers very markedly. Thus the pressure varied with the distance from the vertex of the head in the following way:—

Mm. H_2O .	Distance of finger below vertex.
328	0 mm.
397	205 "
513	490 "
738	840 "

The pressure is seen not to increase by the full hydrostatic effect, and v. Kries failed to explain this fact. It is probably due to a compensation for the effect of gravity, which is brought about by the vasomotor mechanism. In the ear, v. Kries found the mean capillary pressure to be 20 mm. Hg; in the gums of the rabbit 33 mm. Hg; or one-third of the aortic pressure.

If the finger be ligatured, so as to block the venous exits, the capillary pressure rises to the statical arterial tension; after loosening the ligature the capillary pressure remains for some minutes at a high level, owing to the paralytic dilatation of the arterioles produced by the venous blood.¹

In the brain, the capillary venous pressure can be estimated by finding the tension which is just sufficient to balance that which the brain exerts against the skull (see p. 143). This pressure in the horizontal position of the animal is usually about 10 mm. Hg. The capillary pressure varies widely with changes in the general venous and arterial pressures, and with the position of the animal. Thus, in the brain, the pressure may fall below zero in the vertical feet-down position, and rise to almost 50 mm. Hg during the height of strychnine convulsions.

The capillary pressure stands in closer relationship to the venous pressure than to the arterial pressure. Between an artery and its capillaries lies the unknown and varying resistance of the arterioles; between the capillaries and vein there is no such resistance. It is most fallacious to argue that a fall of arterial pressure necessarily produces a fall of pressure in all the capillary areas of the body. In the want of a good method of direct determination of the capillary pressure, we can only judge of changes which take place under varying experimental conditions in that pressure, by recording the tension in both the afferent and the efferent vessel. Thus, for example, in dealing with the capillary pressure in the liver, the tension both in the portal vein and vena cava

¹ Natanson, *Arch. f. d. ges. Physiol.*, Bonn, 1886, Bd. xxxix. S. 386.

inferior must be estimated. In the brain, similarly, the pressure in the carotid artery and in the venous sinuses must be taken.

If in any area the resistance in the arterioles does not vary, then if both arterial and venous pressures rise together, or if one pressure rise while the other remains constant, we may say with certainty that the capillary pressure is increased. If both pressures fall, or if one falls while the other remains constant, the capillary pressure is diminished. A rise of arterial pressure, with a fall of venous pressure, or a fall of arterial with a rise of venous pressure, renders the determination of the capillary pressure a matter of considerable difficulty.¹ This difficulty is intensified when the arterioles in the area under investigation also vary in calibre.

Variations in capillary pressure are given in the following experimental conditions² (the animals are placed in the horizontal posture):—

EXPERIMENT 1.—*Section of Spinal Cord at First Dorsal Vertebra.*

Intestinal.	Hepatic.	Cerebral.
Fall.	Slight rise or fall.	Fall.

In this case the capacity of the venous system is greatly increased, and the peripheral resistance in the arterioles greatly lowered. The pressure in the intestinal and cerebral capillaries falls in consequence of the fall of arterial pressure. The hepatic capillary pressure varies but slightly, for the vena cava pressure remains almost unaltered.

EXPERIMENT 2.—*Arrest of the Heart by Excitation of the Vagus.*

Intestinal.	Hepatic.	Cerebral.
Fall.	Rise.	Fall.

The intestinal and cerebral capillary tensions fall in sequence to the enormous fall of arterial pressure. The hepatic capillary pressure rises in sequence to the congestion of blood in the venous system.

EXPERIMENT 3.—*Asphyxia (Animal curarised).*

Intestinal.	Hepatic.	Cerebral.
Preliminary rise, then fall.	Rise.	Rise.

During asphyxia the arterial pressure rises, and finally falls; the venous pressure rises when the heart fails. The portal pressure rises at first, owing to the forward expression of blood by the constricting splanchnic arterioles, then falls in consequence of the diminished input. The hepatic pressure rises, in sequence to the venous rise, owing to the back effect from the failure of the heart to maintain the systolic output. The cerebral pressure rises greatly, owing both to the arterial and venous rise of tension.

EXPERIMENT 4.—*Severe Bleeding.*

Intestinal.	Hepatic.	Cerebral.
Fall.	Fall.	Fall.

Here, there is a general fall of venous and arterial pressure.

¹ Bayliss and Starling, *Journ. Physiol.*, Cambridge and London, 1894, vol. xvi. p. 160.

² *Ibid.*, 1894, vol. xvi. p. 190; Hill and Bayliss, *Ibid.*, 1895, vol. xviii. p. 334; Hill, "Cerebral Circulation," London, 1896.

EXPERIMENT 5.—*Injection of a Large Quantity of Normal Saline.*

Intestinal. Rise.	Hepatic. Rise.	Cerebral. Rise.
----------------------	-------------------	--------------------

Here, there is a general rise of venous and arterial pressure.

EXPERIMENT 6.—*Obstruction of the Thoracic Aorta.*

Intestinal. Fall.	Hepatic. Rise.	Cerebral. Rise.
----------------------	-------------------	--------------------

The intestinal pressure falls in consequence of the diminished input, the cerebral tension rises owing to the increased pressure in the cerebral arteries. The hepatic pressure rises by a back effect, for the heart, in the face of the increased resistance, is unable to maintain the systolic output.

EXPERIMENT 7.—*Obstruction of the Inferior Vena Cava above the Liver.*

Intestinal. Doubtful.	Hepatic. Rise.	Cerebral. Fall.
--------------------------	-------------------	--------------------

The blood congests in the abdominal veins, therefore the hepatic pressure rises, the arterial pressure falls enormously, and thus the cerebral tension decreases. On the one side of the intestinal capillaries the arterial pressure falls, on the other side the venous pressure rises greatly; which effect will have the most influence is doubtful.

By many authors it has been suggested that osmotic force, capillary attraction, and the ceaseless removal of particles from the blood to supply the materials of the various secretions, may be factors in the maintenance of the capillary circulation.¹ Hitherto this theory has defied experimental proof. We may rest assured that if the action of the heart cease, no other force operates sufficiently to cause a continued and progressive motion of the blood.

THE CONDITIONS OF BLOOD-FLOW IN THE VEINS.

The most striking difference between the structure of an artery and its venæ comites is a decrease of elastic and muscular tissue in the veins, together with an increase of white connective tissue. Accompanying these changes, there is, on the side of the vein, a general and considerable decrease in the thickness of the wall, and increase in the capacity. In consequence of these structural differences, the maximal extensibility of the veins, as measured by their increase in cubic volume, is found to occur at very low pressures. At higher pressures the extensibility rapidly decreases. The veins are tubes with flaccid walls, which fall together when empty, and under very slight pressure expand to their full capacity. Beyond this point, the walls, on account of the quantity of connective tissue entering into their structure, can extend but little. Thus a rise of pressure from 0 to about 40 mm. Hg doubles the cubic content of a vein, and enlarges it to its utmost capacity. It follows that the great variations of volume which are seen to occur in the veins are occasioned less by changes of pressure than by changes in the volume of blood passing into the veins.² In this respect an artery shows

¹ Alison, "Outlines of Physiology," 3rd edition, 1839, p. 63; Cappie, "The Intracranial Circulation," Edinburgh, 1890.

² Roy, *Journ. Physiol.*, Cambridge and London, 1881, vol. iii. p. 136.

a marked contrast to a vein, for by a rise of internal tension from 0 to 200 mm. Hg the cubic content increases three and a half to seven times, and therefore the arterial capacity entirely depends on the magnitude of the internal tension.

The resistance to a breaking strain on the part of the veins is very great. It requires a higher pressure to rupture a vein than the corresponding artery.¹ The rupturing strain is found to be some 3·7 to 9·2 atmospheres.²

If, by external compression, or by a forced expiratory effort, the various outlets be blocked, the tension may rise in the vein to the full statical pressure in the artery. For this reason the veins must be strong enough to bear any such increased strain. There is, however, another need for strength of veins, and that is, that they may be able to bear the strain which may arise from external violence. The superficial veins are endowed with more muscular and elastic tissue than those more deeply situated; while those veins which run in the muscles and in the bones, and are thus protected from violence and supported by firm structure, possess no muscular elements. When exposed, a superficial vein contracts on mechanical stimulation and on cooling, while it may be made to dilate by applying warmth. On rough mechanical stimulation, the external jugular vein is often seen to shrink up so as completely to obliterate the lumen, and some minutes may elapse before the blood again finds a pathway through the constricted portion.

Pressure in the venous system.—The venous pressure is very low. In investigations on the subject, all conditions which affect the flow must be borne in mind. The manometer tube must not be inserted into a vein in the direction of the periphery, but must be placed in a branch forming a T-junction with some larger vein. It is necessary to destroy any valve which may lie at the seat of junction. The side pressure in the larger vein is then obtained. Thus, when a cannula is pushed down the jugular vein, the lateral pressure of the vena cava superior is obtained. Hales³ estimated the venous pressure in a limb to be 6 in. H₂O. The mean pressure in the venæ cavæ within the thorax is negative.⁴ Weyrich, by means of a Hg manometer, estimated the negative pressure in the right auricle to be - 2 to - 3 mm. Hg on each cardiac oscillation, and - 5 to - 8 mm. Hg on each respiratory undulation.⁵ Several observers have recorded the venous pulse thus produced, but the reading of the complicated curves so far obtained is as yet too undetermined for discussion to be profitable.⁶ The venous pressure is recorded by manometric readings, taken at stated intervals of time, from which curves can afterwards be plotted out. The use of either a delicate tambour, or piston-recorder, which has been previously calibrated against a manometer, will give equally satisfactory

results. The manometer employed for venous work is filled with a semi-saturated solution of sodium or magnesium sulphate.

Jacobson¹ found in the sheep, during normal quiet respiration, the following venous pressures:—

	Mm. Hg.		Mm. Hg.
Left innominate	- 0·1	External facial	+ 3·0
Right jugular	+ 0·2	Brachial	+ 4·1
Right subclavian	- 0·1	Branch of the brachial	+ 9·0
Left jugular	- 0·1	Crural	+ 11·4
Left subclavian	- 0·6		

The pressure is lowest nearest the heart and thorax, and becomes higher in proportion as the vein is placed more peripherally. The negativity in the central veins is due to the suction of the thoracic cavity produced by the elastic pull of the lungs. Owing to this negative pressure, when a large vein is opened in the neighbourhood of the thorax, air can be sucked into the circulation. Air that has thus obtained an entry has been observed to pass right through the pulmonary circulation, and to enter the arteries. The danger of air entering during operations has been over-rated. A large amount of air can be slowly injected into a vein without killing an animal.²

A rapid injection, such as would be caused by blowing air into the venous cannula, kills by causing frothing in the heart, embolism in the lungs, and perhaps embolism in the coronary arteries. The danger of embolism from the entry of air is much greater in a small than in a large animal, for the smaller the heart the less the amount of air required to hinder its action by frothing.³

Effect of muscular movements.—Muscular movement is a most important agency which aids the venous flow. On account of the valves the blood can only be expressed from those veins which are compressed by muscular contraction, in one direction, viz. towards the heart. Continued tetanic spasm stops the flow, but clonic or repeated movements, by the alternate filling and expression of the veins, materially favours the flow. The pressure in the vena cava may be considerably raised by general tetanic spasm of the whole body, as is seen after injection of strychnine or essential oil of absinthé; and this is so, in spite of a general arterial constriction which diminishes the inflow into the veins. The rise of venous pressure in such a condition of tetanus is of mixed origin. It is due, first, to compression of the veins by the spasm of the muscles; and, secondly, to general vaso-constriction of arteries and portal veins. Thus, while the capacity of the venous system is diminished, the output of the heart is, owing to the high arterial pressure, lessened, and the blood is congested into the veins.

Pressure of the body against external objects influences the venous flow in the same manner as muscular contraction. Sitting or lying in one posture retards the venous circulation, while, on the other hand, exercise and constant change of posture not only accelerate the circulation on the arterial side, but also aid the flow in the veins.

By rhythmic compression of the thigh muscles the blood can be discharged in jets from the femoral vein of a dog, and the flow of blood greatly increased. The rhythmic contractions of the spleen and the

³ Hill and Barnard, *Journ. Physiol.*, Cambridge and London, 1897, vol. xxi. p. 335.

peristalsis of the intestines greatly promote the portal venous flow. Respiration not only aspirates and compresses the venous blood into the right heart, but promotes the flow into the left heart from the pulmonary veins.

It was determined by Braune¹ that, if the thigh be rolled outwards and backwards, the pressure in the femoral vein under Poupart's ligament falls 5 to 10 mm. H₂O below zero, and becomes positive again when the leg is placed in the opposite position. The bones, the muscles, and the fascia, together with the vein, make a suction and force pump, and thus, by this mechanism, walking can aid the flow in the femoral vein. Extension of the veins in their long diameter has been found to increase their capacity, and thus aspiration may be produced therein by alternate extension and flexion of the body or limbs.

When the arterial supply to any part of the body is entirely cut off, the pressure in the vein which drains the part in question sinks to the pressure of the great vein into which it opens. When, on the other hand, all the venous exits from any part are ligatured, then the pressure rises, peripherally to the seat of ligature, to the arterial pressure.

If the arteries conveying blood to the part are few and narrow, a few veins are sufficient to secure an adequate escape of blood; conversely, where the arterial supply is great, a moderate obstacle to the venous flow causes marked stasis and transudation. For example, on ligaturing in the rabbit all the large veins of both ears, and dividing the cervical sympathetic nerve on one side, the ear on this side will, within a few hours, display a considerable swelling, while the other will remain unchanged. If, on occlusion of the central end of the femoral vein, the pressure therein is equal to 80 to 100 mm. MgSO₄ solution, it will be found, after division of the sciatic nerve, to rise to 280 mm. MgSO₄ solution in a few minutes.²

Rate of flow in the veins.—Turning to the question of the velocity of the venous flow, it is obvious that the average input of the veins per second must equal the average output per second, in order that the circulation may continue. If the veins that enter the heart were of the same sectional area as the arteries that leave it, then the velocity would be the same in these veins as in the arteries. When the venæ cavæ are filled with blood, their total sectional area is found to be considerably greater than that of the aorta. But, as normally these veins are never filled to their full capacity, it is probable that the velocity of flow in them is approximately equal to that in the aorta. The velocity in the carotid artery and jugular vein, or in the umbilical artery and vein of the sheep's embryo, has been measured with Ludwig's stromuhr, and has been found to be almost the same.³

That the progression of the blood in the veins is primarily maintained by the driving force of the heart, was shown by Magendie. He divided the whole of the thigh, except the femoral artery and vein, from the body. Pressure on the artery immediately stopped the flow in the vein. The velocity, on account of the centripetal diminution of the capacity of the venous system, must increase from point to point, while the pressure must steadily decrease. The oscillations of pressure and velocity are not conducted from the arteries into the veins, because the pulse waves are reflected from the resistance in the arterioles and

¹ *Ber. d. k. Sächs. Gesellsch. d. Wissensch., math.-phys. Cl.*, Leipzig, 1870, S. 261.

capillaries, and lost in the arterial system. In conditions of local vasodilatation, where the peripheral resistance is greatly lessened, the pulse may travel through the capillaries into the veins. The steady increase of velocity and decrease in pressure are masked in the venous system by other agencies, besides the systole of the heart, which affect the venous circulation. The discussion of these will be found in the sections on the influences of gravity and respiration on the circulation.

INFLUENCE OF RESPIRATION ON THE PULMONARY AND SYSTEMIC CIRCULATION.

In his classical researches on blood pressure, Stephen Hales¹ records the following observation:—"When the blood has subsided a little in the tubes which were fixed to the arteries of these dogs, it would, as in the horse's, rise on a sudden considerably on deep sighing, as also on pressing the dogs' bellies hard with the hand, the blood would immediately rise about six inches, and subside as much on taking off the hand; and it was the same on several repetitions." Early in this century the inspiratory suction power of the thorax was urged by Carson² and Barry,³ as a mechanism for forwarding the progression of the blood in the veins. Carson estimated the elasticity of the expanded lung of the sheep as equal to the tension of a column of water seven inches high. Barry observes that if one end of a bent tube be introduced down the jugular vein, and the other end rest in a vessel containing water, then the water within the tube can be seen to rise during each inspiration, and sink during each expiration. Although by this experiment Barry proved that a negative pressure is established in the venæ cavæ during inspiration, yet the importance of the suction power of the thorax was not generally admitted. In opposition to such a doctrine, Davies⁴ declared that on compressing the vena cava inferior in the abdomen, the upper portion of the vein is not emptied by the aspiration of the thorax. On the other hand, on obliterating the vena cava just below the auricles, after first squeezing the blood within it onward into the heart, the vein immediately fills up again from below. Thus, he argued, the driving force of the left heart is by itself sufficient to return the blood to the right heart, and complete the circulation. In experiments with the hæmadynamometer, Poiseuille and Magendie⁵ noticed an elevation of arterial pressure during the period of expiration, and so soon as Ludwig,⁶ by the completion of the kymograph, succeeded in taking tracings of the arterial pressure, he observed that variations in arterial tension constantly occurred synchronously with the movements of respiration.

Accepting the explanation of these undulations which at first sight appeared obvious, Ludwig taught that the expiratory rise of intrathoracic pressure aids the systolic output of the heart, propels the blood onward into the arteries, and raises the arterial tension. The researches of Donders, on the changes of intrathoracic pressure during the phases of

respiration, for a time lent support to the doctrine of Ludwig, but this had to be abandoned so soon as the time relations of the respiratory movements and the undulations of arterial pressure were definitely settled.

The synchronous records of respiration and arterial tension obtained by Ludwig and Einbrodt,¹ showed that the rise of arterial pressure takes place mainly in the inspiratory and not in the expiratory phase.

FIG. 77.—Effect of respiration on arterial pressure. The numbers on the left denote centimetres of mercury pressure.—Fredericq.

The respiratory undulations of arterial tension have been recorded, not only in mammals, but also in birds.

By Einbrodt three different types of the respiratory effect are distinguished:—

1. The respiration is quick and shallow. No marked effect either on the frequency of the heart or the blood pressure is seen.

2. The respiration is deep, the inspiratory movement is executed more rapidly than the expiratory, and the periodicity is such that several heart-beats occur during each complete act of respiration. The arterial pressure falls at the beginning of inspiration, rises during inspiration until expiration has commenced, and falls during expiration. The heart-beat increases in frequency during inspiration.

3. The respiration is deep and slow, and the heart-beat is frequent; these conditions are established by vagotomy. The changes of arterial tension are the same as in 2, but increased in amplitude.

In order to explain the origin of the respiratory waves of arterial tension, it is necessary to grasp the conditions which pertain to the thoracic cavity. The heart and the large blood vessels which enter and leave the heart lie in a closed and air-tight chamber, the thoracic cavity. The remainder of this space is occupied by the lungs. The thorax is formed of a bony and muscular wall, which possesses rigidity sufficient to

¹ *Sitzungsber. d. k. Akad. d. Wissensch., math.-naturw. Cl., Wien, 1860, Bd. xl. S. 361.*

In smaller animals, such as the dog and rabbit, the negative pressure within the pericardium is equal to -3 to -5 mm. Hg, rising in dyspnoea to -9 mm. Hg.¹

Within the lungs the tension of the air varies but slightly during the phases of quiet respiration. In inspiration the pressure of the intratracheal air equals -0.1 mm. Hg; in expiration $+0.13$ mm. Hg. In certain conditions, however, the intra-pulmonary pressure may vary enormously. Thus in Valsalva's experiment, when, after a deep inspiration, the mouth and nose are shut and a forcible expiratory movement is made, the intra-pulmonary pressure may rise to 100 mm. Hg. On the other hand, in Müller's experiment, when, after a deep expiration, a forced inspiratory movement is executed with the mouth and nose shut, the negative pressure within the thorax and lungs may sink as much below zero. Thus it seems clear that, while in quiet inspiration the extrathoracic vessels lie under the full pressure of the atmosphere, the intrathoracic vessels are exposed to a pressure of -9 mm. Hg. Likewise the pressure on the pulmonary capillaries = -0.1 , while the pressure on the pulmonary arteries and veins within the thoracic cavity = -9 mm. Hg. In Valsalva's experiment both the intrathoracic and intra-pulmonary pressure will increase, but the latter will always remain higher than the former by the amount of elastic tension exerted by the lungs. In Müller's experiment both pressures will diminish, but the intra-pulmonary pressure will again remain higher than the intrathoracic pressure by the amount of elastic tension exerted by the lungs.

The changes in intrathoracic pressure naturally affect the calibre of the thin-walled inelastic veins and auricles far more than the elastic and thick-walled ventricles and arteries. The veins and auricles are flaccid bags, which can be easily distended up to their full capacity, while to expand the arteries and the ventricles a considerable amount of force is required. A negative pressure of 9 mm. Hg has but an insignificant effect on the capacity of the aorta, wherein the tension is equal to 120 mm. Hg, or more. The total effect of the negative pressure within the thorax is to increase, during inspiration, the diastolic filling of the heart, while the systolic output is not materially hindered.

Experimental facts.—1. Poiseuille² discovered that the circulation of a certain volume of blood through the pulmonary vascular system occupied a longer time when the lungs were blown out than when they were collapsed.

2. On microscopical examination of the pulmonary circulation in the frog, it can be seen that the blood-flow is less rapid the more the lungs are distended.

3. If the thorax be opened in a mammal, and artificial respiration supplied, the aortic pressure mounts when the lungs collapse, while it falls when the lungs are expanded.

4. If the lungs be excised and placed within an artificial thorax, and

FIG. 79.

¹ Adamkiewicz and Jacobson, *Centralbl. f. d. med. Wissensch.*, Wien, 1873, S. 483.

² *Compt. rend. Acad. d. sc.*, Paris, 1852, tome xli. p. 1072.

the natural expansion of the lungs be imitated by the aspiration of this chamber, it is then found that a flow of blood through the pulmonary vessels is quickened by expansion and lessened by collapse. Experiments 3 and 4 thus yield exactly contrary results. Now, on examining the diagram (Fig. 79), it becomes obvious that the elastic tube which passes through the thorax and along the base of the lung would be compressed by a rise of pressure in the lung. On the other hand, if the thorax were aspirated, this elastic tube would expand.¹

It must be noted, however, that the conditions in the thorax are not exactly imitated in this model, for the head of pressure, or pump, should also lie within the chamber.

Funke and Latschenberger have more exactly imitated the natural conditions in the following way (Fig. 80).² The lungs and heart are placed in an artificial thorax; the pulmonary artery is fed with defibrinated blood (tube 2) from a pressure-bottle, which is so arranged as to come under the influence of the intrathoracic pressure (tube 6). The outflow from the left auricle into the thoracic chamber is measured (tubes 3 and 4). Under these conditions an expansion of the lungs brought about by thoracic aspiration (tube 5) favours the flow, while an expansion produced by blowing down the trachea (tube 1) lessens the pulmonary circulation.

There are four chief factors which influence the pulmonary circulation:—

1. The positive pressure in the force-pump, the right ventricle.
2. The negative pressure in the suck-pump, the left auricle.
3. The pressure of the alveolar air exerted on the pulmonary capillaries.
4. The calibre of the pulmonary capillaries dependent upon the expansion of the lung.

On artificial expansion of the lungs, the thorax being opened, the third and fourth factors are increased, but the former is greater in effect than the latter, and the circulation is lessened. By natural inspiration the third factor is decreased, the second and fourth increased; the circulation is therefore augmented.

In artificial respiration, when the lungs are blown out, the pulmonary vessels are compressed by the rise of intra-pulmonary pressure. At first the blood within them is expelled, and subsequently the flow of blood through the lungs is diminished. When the lungs collapse the

FIG. 80.—Model illustrating the effect of intrathoracic pressure on the circulation.—Funke and Latschenberger.

¹ Quincke and Pfeiffer, *Arch. f. Physiol.*, Leipzig, 1871, S. 90; de Jäger, *Arch. f. d. ges. Physiol.*, Bonn, 1879, Bd. xx. S. 426.

² *Arch. f. d. ges. Physiol.*, Bonn, 1878, Bd. xvii. S. 547.

pulmonary vessels dilate. At first the blood collects in the dilated vessels; subsequently the blood-flow is increased. If the thorax be closed, the intrathoracic pressure is increased when the lungs are expanded, and decreased when the lungs are collapsed. The diastolic filling of the heart is diminished by expansion, thus the pressure in the pulmonary artery falls. It follows from the above that, with a slow rate of artificial respiration, the maximal pressure is obtained in the aorta at the commencement of expansion, the minimal at the beginning of collapse. If the rate of artificial respiration be rapid, the first effect only has time to appear in either case; that is to say, the expulsion of the blood from the pulmonary capillaries in expansion, and the retention of the same in collapse. In consequence, the pressure rises in inspiration and falls in expiration.¹

In natural respiration the results are diametrically opposite. During inspiration, the intrathoracic pressure falls, the intra-pulmonary pressure exerted on the pulmonary capillaries becomes less, the sectional area of these capillaries increases, the diastolic filling of the heart is favoured. The blood at first fills up the enlarged pulmonary vessels,

FIG. 81.—Aortic pressure. Artificial respiration. *y-e*, effect of clamping trachea, the lungs being expanded; *e, x, i*, effect of removing clamp.—Kowalewsky.

and subsequently flows in increased volume. Thus the pulmonary arterial pressure falls,² while the aortic tension rises after a preliminary fall. During expiration the intra-pulmonary pressure increases, the sectional area of the pulmonary vessels decreases, the intrathoracic pressure rises, and the diastolic filling of the heart is lessened. The blood is at first expelled from the pulmonary vessels, and subsequently flows in diminished volume. Thus the pulmonary arterial pressure rises, while the aortic tension falls after a preliminary rise. These typical results of natural breathing can be observed in the most marked form when the respiration is slow and at the same time deep; for example, after section of the vagi. In rapid breathing only the first phase has time to appear in either case; that is to say, the retention of the blood in the pulmonary capillaries in inspiration, and the expulsion of the same in expiration.

In addition to the influence of the thoracic aspiration, the diastolic filling of the heart is aided by the inspiratory descent of the diaphragm, and expiratory contraction of the abdominal muscles, both of which compress the abdominal contents and drive the blood into the heart. Respiration acts both as a suction and a force pump.

After section of the spinal cord at the first dorsal vertebra, in

¹ Kowalewsky, *Arch. f. Physiol.*, Leipzig, 1877, S. 419 *et seq.*

² Talma, *Arch. f. d. ges. Physiol.*, Bonn, 1882, Bd. xxix. S. 332.

consequence of the paralysis of the thoracic and the abdominal wall, the respiratory undulations on the arterial tracing are greatly reduced.

According to Marey, the rise of arterial pressure in man is inspiratory when the breathing is diaphragmatic, and expiratory when the breathing is thoracic in type. In the rabbit, an animal which breathes rapidly, the respiratory waves of aortic pressure can be reversed in time by turning the animal alternately on its back and on to its belly.

Heger and Spehl¹ split the sternum without opening the pleural cavities, and passed a ligature round the aorta and pulmonary arteries. In one animal, they tightened this ligature in the inspiratory phase, and in a second animal in the period of expiration. The lungs were in each case excised, and the amount of blood therein estimated. They found that in the phase of natural inspiration, $\frac{1}{12}$ to $\frac{1}{13}$ of the whole blood in the body was contained in the lungs; in the phase of expiration, $\frac{1}{15}$ to $\frac{1}{18}$. On the other hand, when the lungs were artificially blown out, only $\frac{1}{80}$ of the whole blood was found therein. The amount of blood found in the lungs in the state of deepest expiration may be called the residual blood. The difference between this amount, and that found in ordinary expiration, will then be known as the supplemental blood, while the increase of the volume of blood in ordinary inspiration is called the tidal blood. Lastly, the difference between the volume of blood in ordinary inspiration, and the deepest inspiration, may be named the complementary blood. Thus, the changes in blood volume can be brought under the same nomenclature as the changes in the volume of intra-pulmonary air. *In natural breathing, the air and the blood volume change together, and in the same way.*

The effect of raising the intrathoracic pressure can be studied in animals by placing the tracheal tube in connection with a chamber in which the pressure of the air can be suddenly raised or lowered. On maintaining the intra-pulmonary pressure at a certain positive height, the arterial pressure falls to zero, and the blood congests in the veins. Conversely, on lowering the intra-pulmonary pressure considerably, the arterial tension is increased.² These effects are similar to, but more pronounced than, those produced by expansion and collapse of the lungs in ordinary artificial respiration.

The breathing of compressed or rarefied air has been applied as a therapeutic agent by means of pneumatic cabinets.³ It is found that—

1. If the expiratory air be conducted by a tracheal tube into compressed air, while the inspiratory air be drawn from rarefied air, then both the normal expiratory and inspiratory effects are heightened, and the respiratory waves on the arterial trace are magnified.⁴

2. If, on the other hand, the inspiratory air be drawn from compressed air, while the expiratory air be conducted into rarefied air, then the normal effects are opposed, and the respiratory waves of arterial tension are lessened. By the inspiration of highly compressed air through a tracheal tube the circulation is rendered difficult, owing to the rise of intra-pulmonary pressure. In consequence, an asphyxial rise of arterial tension may take place, arising from the lack of oxygenation of the bulbar centres.

3. If the lungs be supplied with air at the normal atmospheric pressure through a tracheal tube, and the body be exposed to a lessened pressure in the pneumatic cabinet, then the arterial pressure falls very considerably. Thus an extrathoracic pressure of -27 mm. Hg produced a fall of arterial pressure equal to 120 mm. Hg. In this condition, the intra-pulmonary pressure is

³ Waldenburg, *Berl. klin. Wchnschr.*, 1873, S. 465.

⁴ Zuntz, *Arch. f. d. ges. Physiol.*, Bonn, 1878, Bd. xvii. S. 374.

raised above the pressure exerted on the extrathoracic vascular system, the blood congests in the veins, and the heart fails to fill.

In the case of the balloonist or the diver, both the intra-pulmonary and extrathoracic pressures fall or rise together, and thus the circulatory mechanism remains unaffected.

The frequency of the heart is increased by inspiration, and as this change is brought about by a lessening of the vagal tone, it fails to appear when the vagi are cut. How the vagus centre is thus influenced is not clear. Moderate artificial expansion of the lung increases the frequency of the heart. Fredericq finds the change in frequency still occurs synchronously with the respirations when the thorax is widely open, the lungs collapsed, and the respiration ineffectual.¹ The vasomotor centre is also said to be influenced rhythmically and directly by the respiration. To show this, Fredericq opened the thorax and belly of an animal, divided both vagi and phrenic nerves, and stopped the artificial respiration. The aortic pressure then rose with each expiratory and fell with each inspiratory spasm. This experiment is not conclusive, for although the suction action of the thorax and the compressing action of the abdominal muscles were to a great extent abolished, yet the general asphyxial spasms of the muscles still promoted the venous flow and the diastolic filling of the heart. The three centres—the respiratory, the cardio-inhibitory, and the vasomotor—lie closely bound up together in the medulla oblongata, and it is therefore conceivable, although not proved, that the other two may be directly influenced by irradiation of the rhythmic discharge from the respiratory centre. The exciting agent is certainly not the chemical nature of the blood, for the alteration of frequency takes place when the thorax is opened and the respiration is totally ineffectual. The inspiratory acceleration may be due to local mechanical excitation of the heart, since, during vagal inhibition, respiratory gasps or compressions of the abdomen excite beats of the heart.

From the preceding discussion the following conclusions can be tabulated² as to the effect of respiration on the circulation:—

Conditions of Heart and Blood Flow, favoured or the reverse.	Natural Inspiration.	Expiration.	Artificial Expansion.	Collapse.
1. Aspiration of blood to right heart	+	-	-	+
2. Diastole of heart	+	-	-	+
3. Systole of heart	-	+	+	-
4. Sectional area of pulmonary vascular system	+	-	-	+
5. Flow of blood through the lungs	+	-	-	+
6. Retention of blood in pulmonary vascular system	+	-	-	+
7. Pressure on abdominal contents— By abdominal muscles	-	+
By descent of diaphragm	+	-	+	-
8. Frequency of heart	+	-

The total effect on the aortic tension in slow-breathing animals is maximal at the commencement of expiration, minimal at the beginning of inspiration.

¹ *Arch. de biol.*, Gand, 1882, tome iii. p. 86.

² After Tigerstedt, "Phys. des Kreislaufes," S. 460.

In animals with quick respiration, such as cats, rabbits, and guinea-pigs, the total effect is maximal at the height of expiration, minimal at the depth of inspiration.

THE VASOMOTOR MECHANISM.

Historical.—As early as 1733 the notion that the small arteries change their calibre was put forward by Stephen Hales.¹ Among the many ingenious experiments he devised is the following:—Tying a brass tube into the aorta of a dog, and employing a head of pressure equal to the normal aortic tension, he injected water and measured the outflow, per minute, from the divided vessels of the intestine. He found that while cold water diminished, hot water increased the outflow. Further, from investigations on the action of such drugs as alcohol and infusion of cinchona bark, he concluded that while one set of agents, by constricting the vessels, lessens the outflow, another set widens the vessels and increases the outflow.

On scratching the femoral or the carotid artery with the point of a knife, the local constriction of these vessels can be evoked. Likewise by chemical irritation, or the application of the galvanic current, the peripheral arteries of the frog can be thrown into contraction. Observations of this kind were recorded by several experimentalists towards the end of the eighteenth and the beginning of the nineteenth centuries.

Hunter observed that the carotid artery of the dog gradually contracts if it be exposed to the air, while Parry obtained the same result on loosely tying a ligature round an artery. Mayo² records that the diameter of an artery is markedly increased by rubbing it for the space of half a minute between the finger and thumb.

Some time after this it was recorded, and more than once, that congestion of the head and neck follows after division of the cervical sympathetic nerve, or excision of the superior cervical ganglion.³

By Krimer⁴ the interesting observation was made, that the application of salt to a frog's web does not, when the nerves of the part are injured, produce its usual effect of dilatation of the capillaries.

By E. H. Weber⁵ the direct proposition was made, for the first time, that pallor and blushing could be explained, if it were once taken for granted that the calibre of the peripheral arteries could under nervous influence become smaller or larger.

The position in which the question of the contractility of the arteries stood in 1836 is illustrated by the following observations of Allen Thomson:—

"It may be remarked that the coldness and impaired nourishment common in palsied limbs, the known increase or diminution of the various secretions from mental emotions, and direct or sympathetic affections of the nerves belonging to the glands or other secreting organs, the phenomena of blushing, erection, inflammation, and the like, are all very direct and satisfactory proofs that the small vessels and the capillary circulation may be influenced by affections of the nerves."⁶

Physiological ideas drawn from experiments thus forestalled anatomical discovery, for the muscular coat of the arteries remained undiscovered until

1840. In this year Henle¹ established the existence of a plentiful supply of involuntary muscle cells in the middle coat of the small arteries, and thus laid the anatomical foundation of the doctrine that while the general circulation of the blood depends upon the heart, its distribution to any one part depends on the calibre of the arteries supplying that part. The final link in the chain of anatomical evidence was not wanting, for many observers had traced filaments of nerves along the course of the arteries as far as their ultimate ramifications in the tissues. To these nerves Stilling² gave the name "vasomotor," ascribing to them the function of maintaining the tone and ordering the contractions of the capillaries, arteries, and veins.

The exact discovery of the vasomotor mechanism, a discovery fraught with the utmost importance to the advance of physiological and pathological knowledge, dates from Claude Bernard's observations on the cervical sympathetic nerve of the rabbit, published in 1851.³ He found, after dividing this nerve, or exciting the superior cervical ganglion, a noticeable increase in the vascularity and the temperature of the ear on the same side as the lesion.

In such case the temperature may be raised some 4° to 6° C. above that of the opposite ear. Bernard was at first inclined to believe that the sympathetic nerve, apart from its influence on the blood supply, exerted control over the production of heat.⁴

In 1852, Brown-Séguard crowned Bernard's discovery by the publication of this observation: "If galvanism is applied to the superior portion of the sympathetic, after it has been cut in the neck, the vessels of the face and of the ear after a certain time begin to contract; their contraction increases slowly, but at last it is evident that they resume their normal condition, if they are not even smaller. Then the temperature and the sensibility diminish in the face and the ear, and they become in the palsied side the same as in the sound side. When the galvanic current ceases to act, the vessels begin to dilate again, and all the phenomena discovered by Dr. Bernard reappear."⁵

Unwitting of the fact that Brown-Séguard had forestalled him, Bernard⁶ himself discovered that excitation of the cervical sympathetic nerve produced constriction of the blood vessels of the ear. The same conclusion was arrived at independently by Waller.⁷

The amount of dilatation in the ear which follows section of the cervical sympathetic nerve is a sign of the strength of vascular tone. It must be borne in mind that dilatation is not always produced thereby, seeing that the tone of any particular vascular area is constantly varying. Thus, if the rabbit be placed in a warm atmosphere, division of the cervical sympathetic will induce but little change in the vascularity or temperature of the ear; while, if the atmosphere be cold, the temperature of the ear may rise after the operation 5° C. or even 10° C.

Schiff made a further discovery of great importance. After dividing one cervical sympathetic nerve, he found, on exciting the animal, or taking it for a run in the warmth of the sun, the ear on the uninjured side became slightly the warmer, and the vascularity of the ear more pro-

nounced. So soon, however, as the animal became quiet these conditions were once more reversed. Schiff explained this result by supposing the existence of vaso-dilator nerves.¹

The existence of vaso-dilator nerves, thus foreshadowed by Schiff, was conclusively proved by Bernard.² Exposing the submaxillary gland of a dog, he opened one of the efferent veins, and observed the outflow of blood. On dividing the cervical sympathetic nerve, the blood flowed in increased volume and became more arterial in colour. On exciting the same nerve, the outflow entirely ceased, and the gland became pale in colour. He next excited the chorda tympani nerve, the gland blushed red, and almost immediately bright arterial blood gushed out from the vein. The vascular dilatation was in this case so great that the blood, with each pulsation of the artery, flowed from the vein in jets.

By this fundamental experiment, Bernard proved that there exist two kinds of vasomotor nerves. The one, the vaso-constrictors, which exert a tonic action, for on section of these the gland blushes; the other, the vaso-dilators, which exert no tonic action, but can, when excited, throw the vessels into the widest dilatation.

Evidence that the vaso-constrictor nerves have their origin in the spinal cord was afforded by Schiff, who found that vascular dilatation and a rise of temperature in various parts of the body followed destruction of certain parts of the cord.

Budge,³ by unilateral extirpation of the cord between the last cervical and third thoracic nerve, obtained the same vaso-dilatation as is seen after section of the cervical sympathetic. Waller⁴ constricted the vessels of the ear by excitation of the cervical cord. The vasomotor fibres issue by the anterior roots. The first observation of this fact (on the frog) is attributed to Pflüger.⁵

These experiments of Bernard, Brown-Séguard, Waller, and Schiff have led to a vast amount of inquiry into the physiological action and anatomical distribution of vasomotor nerves.

The methods which have been employed are these:—

1. Direct observation of the colour of any part, or of the amount of blood which flows from a wound.

This method has been used with advantage in the case of the rabbit's ear, the submaxillary gland, the mucous membrane of the mouth. Microscopical observation and measurement of the calibre of the arterioles has been employed in investigations of the frog's web, mesentery, mylohyoid muscle.

2. Thermometric observations of the temperature of any organ. This is best carried out by means of thermo-electric junctions.

3. Estimation of the output of blood per minute from the efferent vein of an organ.

4. Records of the velocity of blood flow in the artery supplying an organ. This can be effected either by using Chauveau's dromograph or Cybulski's photohæmatochrometer.

5. Estimation of the changes in volume of an organ, such as the spleen, the kidney, the brain, the lung, the intestines, or the limbs. This is effected by means of the plethysmograph. The organ is placed in an air-tight box, and this in its turn is connected with a recording tambour.

⁴ *Ibid.*, p. 381.

⁵ *Allg. med. Centr.-Ztg.*, Berlin, 1855.

6. Observation of the lateral pressure in the peripheral end of an artery, that is to say, at a point peripheral to the origin of anastomotic branches, which are sufficient to maintain the circulation through the organ. Hürthle employed this method in a research on the brain. He recorded the pressure in the peripheral end of the internal carotid artery. Dastre and Morat similarly observed the lateral pressure in the peripheral end of the femoral artery, below the origin of the profunda femoris.

7. Simultaneous records of the lateral pressure in the afferent artery and the efferent vein of any organ. This method has been used in researches on the portal system, the brain, and the lungs.

8. Estimation of the capillary pressure. The intra-cranial and intra-ocular pressures have been studied by this method.

The greatest accuracy and scientific acumen is required in the execution of researches on the more delicate vasomotor mechanisms. It must constantly be borne in mind that changes in the vascularity of an organ may depend on central as well as peripheral alterations in the circulatory system. Thus, for example, during the rise of arterial pressure which occurs during asphyxia, the kidneys decrease in volume, and the limbs increase; the vessels of the rabbit's ear may either contract or dilate; the vessels of the intestines contract; in either the cerebral or the pulmonary veins the pressure rises, while the pressure in the portal vein may either rise or fall. From the mere observation of the circulatory changes in any of these organs, we cannot tell whether the above effects are passive or active. The question of peripheral change is complicated in each case by the passive effects produced by general changes. Owing to this fact, it is usually necessary to record the aortic and vena cava pressures simultaneously with the observations of the organ which are made by one or other of the above methods.

If the general venous and arterial pressures remain constant, while the circulation in the organ varies, then unequivocal evidence is obtained of the existence of a vasomotor mechanism in that organ. Such is the case also if the circulation in the organ vary in the opposite sense to the changes which take place simultaneously in the general circulation.

In many cases it is necessary to abolish, as far as possible, all passive effects produced by changes in the general circulation.

Thus, to exclude the effect of the respiratory pump, the animal can be curarised and a constant artificial respiration supplied. In the case of the brain or fore-limbs, the circulation, by ligature of the thoracic aorta and vena cava inferior, can be limited to these parts; thus all changes occurring in the splanchnic circulation can be eliminated. The same result can be arrived at by section of the spinal cord above the origin of the splanchnic vasomotor nerves. The splanchnic vasomotor mechanism is by far the most powerful in the body, and in investigations on the limbs, lungs, or brain, it is absolutely necessary to eliminate its action in order to obtain unequivocal evidence for or against a vasomotor supply to these parts. Attempts have been made to avoid all these difficulties by the establishment of an artificial circulation through the particular organ under investigation. Vasomotor tone is, however, so easily abolished by alterations in the temperature and quality of the blood, that this method has as yet neither proved trustworthy nor of any particular value.

To distinguish the existence of vaso-constrictor and vaso-dilator fibres, running in one common nerve trunk, special means must be

employed. The fact that both kinds of nerves exist in the common nerve trunks was first demonstrated by Goltz.¹

1. If vaso-constrictors and dilators are stimulated simultaneously, the constrictor influence at first overpowers the dilator. The dilator effect, however, appears as an after-result, for the vaso-dilator fibres are the less easily exhausted. This result can be observed in the salivary gland, while the chorda tympani and cervical sympathetic nerves are excited at the same time.² That the vaso-constrictors and dilators are antagonistic in action, is shown by an experiment of v. Anrep and Cybulski,³ who recorded the variations in volume of the tongue by the plethysmograph method, and determined that the constriction of the tongue, induced by stimulation of the hypoglossal nerve, could be put aside by an excitation of the lingual nerve. Similarly, the vaso-dilation induced by excitation of the lingual could be put aside by stimulation of the hypoglossal nerve. The constrictor influence is usually by far the strongest. Thus Bayliss⁴ found, on asphyxiating an animal during excitation of the depressor nerve, that the arterial pressure rose, and the

FIG. 82.—Plethysmograms of hind-limb. Excitations of sciatic nerve. *A*, One per second. *B*, Four per second. The tracings in this and the next figure are to be read from right to left.—Bowditch and Warren.

pressor completely overcame the depressor effect. On renewing the respirations, the depressor nerve again exerted its power, and the arterial tension fell once more below the mean.

2. If the leg be cooled, excitation of the sciatic nerve evokes vaso-dilatation, while if the leg be warmed it produces vaso-constriction.⁵ Similarly, if the rabbit's ear be warm, asphyxia provokes constriction; if cold, dilatation.

3. After separation of the vasomotor nerves from the central nervous system, the vaso-constrictor fibres degenerate much more rapidly than the vaso-dilator fibres; the vaso-dilator fibres maintaining their excitability for some six to ten days after division, while the vaso-constrictor became inexcitable on the third or fourth day.⁶

4. While the vaso-dilator fibres are excited by single induction shocks repeated at intervals of not more than 5 per sec. (Fig. 82), the constrictor fibres are aroused to action most easily by a rapid tetanising current (Fig. 83).⁷

5. If the tetanising current be strong, primary vaso-constriction

always appears; if the current be very weak, primary vaso-dilatation usually occurs.

6. On cooling the sciatic nerve to 3° C., the vaso-constrictor fibres are paralysed before the dilator.¹

For the vaso-dilator nerves, the latent period (between excitation and result) is usually longer than it is for the vaso-constrictor fibres. In the case of the hind-limb, the vaso-dilator latent period is about 3.5 seconds, the vaso-constrictor 1.5 seconds. The latent period of the *nervi erigentes* is recorded as being 3.4 to 4.0 seconds.² Likewise, the maximal dilator effect is reached much more slowly, and dies away much less rapidly than the maximal constrictor effect.

To sum up, then, the vaso-dilator fibres are more easily excited by an infrequent rate and weak form of stimulus. The vaso-constrictors

FIG. 83.—Plethysmograms of hind-limb. Excitations of sciatic nerve. *A*, Sixteen per second. *B*, Sixty-four per second.—Bowditch and Warren.

degenerate more rapidly after division, and are paralysed more easily by cold. The vaso-dilator effect appears after a longer latent period, while it reaches its maximum and disappears more slowly.

Hypotheses on the action of vaso-dilator nerves.—It is easy to imagine that, excited by the influence of the vaso-constrictor nerves, the muscular coats of the arterioles should constrict the calibre of these vessels. It is a more difficult task to explain by what method the vaso-dilator nerves work their effect.

The hypothesis that first suggests itself is that the vaso-dilator inhibit the tonic action of the vaso-constrictor fibres. Before accepting this hypothesis, we are confronted with the difficulty that the vessels of any organ are dilated to a greater degree by excitation of the vaso-dilators than they are by paralysis of the vaso-constrictors. In spite of the destruction of the vaso-constrictor nerves, the vessels, after a certain period, recover their tone. That the tone is not even for a time abolished completely, is shown by the fact that a local dilatation can be produced by certain chemical irritants. Thus it is clear that some peripheral mechanism exists, a mechanism which, in its turn, can be paralysed by the local application of such a drug as chloroform.

¹ Howell, Budgett, and Leonard, *Journ. Physiol.*, Cambridge and London, 1894, vol. vi. p. 306.

² Bowditch and Warren, *loc. cit.*, p. 440; v. Anrep and Cybulski, *Jahresb. ü. d. Fortschr. d. Anat. u. Physiol.*, Leipzig, 1884, S. 53.

It seems highly probable that the vascular muscles are maintained in a state of tone by the tension of the blood within the vessels. This would be in close analogy with the fact that the heart is excited to contract by a rise of internal tension. Accepting this hypothesis, we may then suppose that the vaso-constrictor nerves increase the excitability of the vascular muscle to the stimulus of blood tension, while the vaso-dilator nerves diminish the excitability. The vaso-dilator fibres would thus be brought into analogy with the cardio-inhibitory nerves. These lessen the irritability of the heart towards the intracardiac tension,¹ and relax the cardiac muscle.

On this hypothesis, section of the vaso-constrictor nerves abolishes that tonic condition of exalted excitability to internal tension which is maintained by the vaso-motor centre. It does not, however, entirely destroy the excitability of the vascular muscle to tension, and with time the tone is fully restored. On the other hand, the vaso-dilator influence completely relaxes the muscle by altogether inhibiting its excitability to tension. It is conceivable that the quality as well as the tension of the blood may be the exciting cause of vascular tone. An increase in the alkalinity of the blood favours the development of tone. Certain glands, such as the suprarenals, appear to secrete a material into the blood which produces vascular contraction.

Vasomotor centres.—Ludwig and Dittmar were the first to localise a vasomotor centre. By excitation of the central end of the sciatic nerve, after the great brain had been separated from the medulla oblongata, they obtained a reflex rise of arterial pressure. This centre was minutely localised by Ludwig and Owsjannikow. While a section of the brain carried out below the corpora quadrigemina did not produce any noteworthy change in the arterial pressure, they found, on slicing away the spinal bulb by successive cuts, that the pressure fell with each cut, until a maximal depressor effect was reached. By such experiments the centre was located in the rabbit to a spot 3 to 4 mm. in length, commencing 1 to 2 mm. below the corpora quadrigemina, and ending 4 mm. above the tip of the calamus scriptorius.² The centre is bilateral, and in the area which it covers there is situated a group of nerve cells known as the antero-lateral nucleus of Clarke.³

The bulbar vasomotor centre is constantly in action, maintaining the tone of the small arteries.

Thus Bernard noticed, after section of the cervical cord, that the arterial pressure fell markedly. By excitation of the peripheral end of the cervical cord, v. Bezold⁴ drove the pressure up to no less than seven times the height it reached after section of the cord. Ludwig and Thiry⁵ showed that the same result can be obtained after section of all the cardiac nerves; and, moreover, that while tying of the aorta below the renal arteries causes but a slight rise of tension, ligation of the thoracic aorta causes a very great rise. These experiments indicate the overwhelming importance of the splanchnic vaso-constrictor nerves.

The vasomotor centre is not only excited reflexly, but responds to every change in the circulation through the spinal bulb. A rise of

pressure in the cerebral arteries provokes a fall of aortic tension; conversely, a fall of pressure in the cerebral arteries provokes a rise. In other words, cerebral anæmia, however produced, excites the centre, and increases vascular tone, while cerebral hyperæmia decreases vascular tone.

Besides the bulbar centre, there are other subsidiary centres in the spinal cord. (The word centre is here used to signify nothing more than a portion of the central nervous system, wherein afferent impulses are changed into efferent impulses.) The existence of these spinal centres was first established by Goltz. After destruction of the whole brain of a frog, the vascular tone is not abolished completely. It is abolished after destruction of the spinal cord.¹

In mammals the same statement holds true. If, after section of the spinal cord in the lower dorsal region, a dog be maintained alive, reflex vascular dilatation causing erection of the penis can be evoked, and, while the vessels of the lower limbs are at first dilated, they return with the lapse of time to a state of tone. The temperature of the lower limbs, at first much raised, returns gradually to the same as that of the fore-limbs. On destruction of the lumbar cord, the temperature in the hind-limbs once more rises, for the vessels again dilate.² After section of the spinal cord in the mid-dorsal region, evidence of reflex vasomotor effects can be obtained. Thus, on sensory excitation of one leg, constriction of the blood vessels in the other limb has been observed.³

An asphyxial rise of arterial pressure is sometimes witnessed after section of the spinal cord. This rise is not obtained if the cord be destroyed.⁴

Other observations showing the existence of subsidiary vasomotor mechanisms in the spinal cord are (1) that, after division of the spinal cord in the upper cervical region, section of the splanchnic nerves causes a further depression of arterial tension, and (2) excitation of the central end of one sciatic nerve causes a considerable rise of tension.

A certain amount of evidence as to the path of the vasomotor fibres down the spinal cord has been brought forward. By studying the results of hemisection of the cord, it has been determined that these fibres for the most part follow a direct but partly a crossed pathway. If the cord be completely divided in the cervical region, and be hemisected in the mid-dorsal region, then, on faradising the cervical cord, both kidneys shrink in volume, but the kidney on the side of the hemisection contracts less than that on the other side.⁵

After section of the posterior columns and grey matter of the cord, Dittmar⁶ obtained the usual pressor effect which follows excitation of the central end of the sciatic. We must conclude, then, that the tracts pass in the antero-lateral columns.

Local vasomotor tone.—Even after complete separation of the vascular areas from the central nervous system, recovery of tone in the vessels eventually takes place. Thus, when Goltz and Ewald removed the lower part of the spinal cord of a dog for the length of 80 mm. or

more, the hind-limbs, which were at first hotter and more flushed with blood, became eventually as cool or cooler than the fore-limbs. In pathological cases, the same phenomenon is constantly observed to follow on section of all the nerves.

The tone of the great splanchnic area is completely restored some eight days after section of all the splanchnic nerves.

It has been suggested that the sympathetic ganglia are centres of reflex vasomotor action. An experiment quoted in favour of this view is the following:—If the first thoracic ganglion be entirely separated from connection with the spinal cord, and the ganglionic end of one branch of the annulus Vieussenii be stimulated, the vessels of the head and neck contract. This and similar phenomena are perhaps not true reflexes. The effect may be produced by the stimulus running up the efferent fibres and thence down the collaterals of the same fibres. These collaterals pass into several branches of the ganglionic system.¹

To show the tonic influence of the peripheral ganglion cells, Dastre and Morat bring forward this experiment. On section of the cervical sympathetic nerve below the superior cervical ganglion, scarcely any vaso-dilatation is to be seen in the mucous membrane of the mouth, but on destruction of the ganglion the dilatation becomes unmistakable.²

In certain places rhythmic contractions and dilatations of arteries can be observed, movements which are apparently independent of the central nervous system, or of any change taking place in the general vascular system.³ This phenomenon can be witnessed in the central artery of the ear or saphena artery of the rabbit (especially when the animal is excited), and in the web or mesenteric arteries of the frog. The contractions or dilatations may not affect the whole length of an artery, but be localised to one or other part. Certain drugs, such as chloroform and amyl nitrite, when applied locally, produce dilatation of the blood vessels. These drugs act on the peripheral mechanism, for if injected into a carotid artery they primarily excite the vaso-constrictor centre; when injected into a jugular vein they produce, on the contrary, primary vaso-dilatation. According to Stefani, dyspnoëic blood locally causes dilatation of the blood vessels, centrally it provokes vaso-constriction.⁴

An extract of the medulla of the suprarenal gland exerts a most powerful local vaso-constrictor effect. If one drop of a 1 per cent. extract of the dried organ in normal saline be placed upon the mesentery of a frog, the arterioles are constricted for thirty to sixty minutes, and to such a degree that the onward flow of blood in the capillaries may entirely cease, and be replaced by a back-eddy from the veins. The same result is obtained after destruction of the spinal cord. Similarly, after the conjunctiva of the rabbit's eye has been congested by the application of acetic acid, the vessels may be again constricted by a drop of suprarenal extract.⁵

Traube-Hering curves.—In addition to the ordinary respiratory

oscillations, rhythmic variations of tension frequently appear in the tracings of arterial pressure.

These variations are known as Traube-Hering curves.¹ They can be evoked with the greatest ease by the injection of a little magnesium sulphate solution into the circulation of the dog (Fig. 84). During the asphyxial rise of arterial pressure in the curarised dog, these curves are of constant occurrence, and also after injection of a large dose of

FIG. 84.—Traube-Hering curves produced by injection of magnesium sulphate ; dog.—Hill.

morphia. In conditions of anæmia of the bulbar centres, produced either by tying the cerebral arteries or compression of the brain, or after injection of chloroform into the cerebral arteries, Traube curves frequently become apparent. Very often these oscillations of arterial pressure are accompanied by a periodicity of the respiration, which is known as Cheyne-Stokes breathing. It would appear as if each oscillatory rise of arterial pressure excited the respiratory centre, and evoked a group of respirations.²

These oscillations of arterial pressure are produced by periodic constriction and dilatation of vascular areas. On recording the volume of the kidney, this organ is found to contract when the arterial tension rises.³

They are usually to be ascribed to a periodical excitement

of the vasomotor centre. A deficient circulation through the bulb excites the centre, the arterial pressure in consequence rises, the rise of pressure flushes the bulbar centres with more blood, the centres then cease to be excited, the pressure falls again, and the cycle of events is repeated. Traube curves may in some cases be peripheral, and not central, in origin.

By the injection of essential oil of absinthe in a curarised animal, the vasomotor centre can be excited to the discharge of a succession of powerful

spasms, by each of which the arterial pressure is driven up to a great height.¹ This phenomenon suggests a clonic fit of the centre, the clonus of involuntary muscle naturally taking place at a far slower rate than that of skeletal muscles.

FIG. 86.—Injection of absinthe. Curarised dog. A, aortic pressure; B, vena cava pressure; C, intracranial pressure; D, cerebral venous pressure.—Bayliss and Hill.

The vasomotor mechanism of the veins.—The portal venous system.—If the thoracic aorta be clamped, the pressure in the carotid artery rises; if the splanchnic nerves be then excited, the pressure in the carotid artery is raised to a still higher level. This further rise is to be attributed to the increased diastolic filling of the heart, which in its turn is caused by the expulsion of the blood from the portal system, an expulsion which is brought about by constriction of the splanchnic and hepatic vessels. After ligation of the portal vein, the same result is obtained, owing to constriction of the hepatic vessels.²

Bayliss and Starling localise the outflow of vaso-constrictor nerves to the portal system in from the third to the eleventh anterior thoracic roots. By excitation of the eighth to the eleventh roots, they obtained, first, a rise of pressure in the portal vein, due to constriction of the mesenteric arteries, forcing blood on into the portal vein; secondly, a fall due to the diminished flow of blood through the mesenteric arteries; and, lastly, a rise due to constriction in the hepatic branches of the portal vein.³

The portal venous system is peculiar in its structural arrangement, and generally bears a close analogy to an arterial vascular area. As to the innervation of the other veins we know very little. Thompson,⁴ after tying the crural artery and on excitation of the peripheral end of the divided sciatic nerve, has witnessed contraction of the superficial veins of the rabbit's leg. He has also witnessed the same in abdominal veins, on stimulation of the peripheral end of the divided cervical spinal cord. The contraction is usually in the form of band-like constrictions, between which the veins appear full of blood. Such contractions appear

on mere exposure of the veins. The skeletal muscles, and especially the abdominal respiratory muscles, act as a tonic mechanism to the veins. Thus the abdominal wall is of the utmost importance, in so far as it tonically maintains the calibre of the great abdominal veins, and can at any moment compress these vessels or allow them to expand.¹

CIRCULATION IN SPECIAL PARTS.

THE CIRCULATION IN THE HEAD.

Vasomotors of face and mouth.—The vaso-constrictor fibres for the head issue by the upper thoracic anterior roots (1 to 5 in the dog), and pass into the cervical sympathetic nerve.²

The vaso-dilator supply to the face and mouth has been investigated by Dastre and Morat.³ These fibres issue also from the upper thoracic roots, and pass up the cervical sympathetic nerve to the Gasserian ganglion, and thence to the fifth nerve. Some of the dilator fibres issue directly from the cranial origin of the fifth nerve, for stimulation of this nerve between the pons and the Gasserian ganglion causes flushing of the face. Excitation of the lingual and glosso-pharyngeal nerves dilates the vessels of the tongue, while stimulation of the hypoglossal nerve causes them to contract. These constrictor fibres come from the superior cervical ganglion.

The circulation in the mucous membrane of the mouth has been examined by direct observation, while the volume of the tongue can be investigated with a suitable plethysmograph.⁴ By observing the effects of section or excitation of the cervical and thoracic sympathetic nerve, during ophthalmoscopic examination of the eye in the curarised rabbit, both vaso-constrictor and vaso-dilator nerves have been found to pass to this organ.⁵

Vasomotors of salivary glands.—The vaso-constrictor fibres to the submaxillary gland issue from the first and second, or the second and third, thoracic anterior roots, and pass up the cervical sympathetic nerve. The cell stations for these fibres lie in the superior cervical ganglion.⁶

The vaso-dilator fibres to the submaxillary gland pass by way of the chorda tympani from the facial nerve, and have their cell stations in contiguity with the gland. The vaso-dilator fibres to the parotid gland issue from the glosso-pharyngeal nerve, and pass to the gland by way of the auriculo-temporal nerve (see vol. i. p. 482). The circulation in these glands has been studied by placing a cannula in an efferent vein and observing the outflow, or by exposing the gland and directly inspecting its colour.

Cerebral circulation.—Observations on the movements of the brain are to be found recorded in the earliest medical writings. Whenever the brain is exposed by defects in the wall of the cranium, the brain can be seen to pulsate. This phenomenon can be demonstrated with

the greatest ease, by applying a sensitive recording tambour to the fontanel of a newborn child.¹

Galen and his followers thought that by the diastole of the brain, the *πνεῦμα*, the spirit of life, was sucked in through the cribriform plate, and mingled with the vital spirit, which ascended by the arteries from the heart. It was supposed that the dura mater pulsated, and by driving onward the animal spirits, produced movements of the muscles, and stimulated the soul. De la Mure, Haller,² and Lorry,³ in the eighteenth century, by finally establishing the cardiac and respiratory

FIG. 87.—Respiration (A) and cerebral pulse tracing. Downstroke=inspiration.—Mosso. origin of the cerebral pulsation, proved that the dura possessed no independent power of movement in itself. They showed that the collapse of the chest wall pressed upon the thoracic veins, and drove back the venous blood, thus causing the expiratory expansion of the brain.

The movements of the brain in the closed cranium can be demonstrated in the following way:—

FIG. 88.—Cerebral pressure gauge.—Hill.

membrane is tied. This second tube is passed into the steel tube, and the two are screwed together by means of a male and female screw.⁴ By means of this mechanism the indiarubber membrane comes into exact apposition with the brain. Attached to the end of the brass tubing is a piece of glass tubing of a fine bore. This is connected with a T-piece, one branch of which leads to a pressure bottle, and another to a mercury manometer. The whole apparatus is completely filled with water, and a bubble of air, to act as an index, is introduced within the fine-bored glass tubing. Before the apparatus is screwed in, the normal no-pressure position of the air index, when the tube is held

with a mechanic's tap, the dura mater carefully divided without causing any hæmorrhage, and a piece of steel tubing (B) screwed into the hole. Over the end of a piece of brass tubing (A), of smaller diameter than the steel tube, a piece of thin indiarubber

⁴ Hill, "Cerebral Circulation," p. 9.

horizontally and the membrane is flat, is marked on the glass tube. On screwing in the apparatus, the air index, which is at first forced out, is again, by raising the pressure bottle, brought to the normal position. That is to say, the brain, which is slightly bulged outwards by the intracranial pressure, is forced into that flattened position, which it naturally must assume against the closed cranial wall. The elevation of the manometer, consequent on this procedure, gives the normal intracranial tension. The pressure of the cranial contents against the skull wall is exactly balanced, and the skull becomes once more a closed cavity. The air index in the "cerebral pressure gauge" exhibits cardiac and respiratory undulations of intracranial pressure.

The brain pulsates in the direction where the resistance is least. Thus, when the cranium is trephined, and the dura opened, the pulse can scarcely be seen in the occipito-atlantal membrane, for the trephine hole has become the seat of least resistance. Similarly, when the trephine hole is closed by a glass window, the occipito-atlantal membrane becomes the seat of least resistance, and the pulsation appears there.

The diastole and systole of the brain are made possible in the unyielding box of the cranium in two ways—

1. By the ebb and flow of the cerebro-spinal fluid. The occipito-atlantal and other vertebral ligaments extend in cerebral diastole, and allow the fluid to escape from the cranial cavity, while in systole, through the elasticity of these ligaments coming into play, it is driven back.

2. By expression of the blood in the cerebral veins another mechanism is provided. The cerebral venous pressure can be studied in the following way:—In the dog, the superior longitudinal sinus, with its tributaries, opens into a large venous cavity within the occipital protuberance. This bony cavity is the torcular Herophili. The transverse sinuses lie within the osseous part of the tentorium cerebelli, and lead out of this cavity. Part of the blood finds its exit by the post-glenoid foramen, and reaches the external jugular vein, but a large portion passes into the large sinuses which run down the vertebral canal. It is quite simple to drill a hole into the torcular, and then immediately to screw into the hole a brass tube filled with magnesium sulphate solution. This tube is connected with a manometer containing $MgSO_4$ solution.

The manometer can be directly observed, or, if connected with a delicate tambour, its movements can be recorded. In this way a continuous record of cerebral venous pressure can be obtained with little dissection and considerable ease. The manometer exhibits all the cardiac and respiratory pulsations, the latter in a marked way.

The brain is an organ which pulsates with every stroke of the heart, and with every respiratory movement, and, owing to its peculiar conditions, enclosed as it is in the unyielding cranium, the cardiac pulse is not entirely spent in distending the arterioles and capillaries, but is transmitted to the venous sinuses. The brain is lifted up by the stroke of the arteries at its base, and is thrown against the pial veins and the venous sinuses. By rise of pressure in the thoracic veins in expiration, the blood is dammed back into the sinuses, and the brain must then expand more, at the expense of the cerebro-spinal fluid. The contrary occurs in inspiration; the veins are emptied by the suction action of the thorax, the brain collapses, and the cerebro-spinal fluid re-enters the cranial cavity. Normally, the brain is more affected by the expiratory rise of general venous pressure; this is in contrast with such an organ as the kidney, which follows the inspiratory rise of general arterial pressure. If the inspiratory arterial rise of cerebral capillary tension becomes in any way increased, so as to be greater than the expiratory venous rise, then the respiratory curve of the brain is reversed. The

cerebral pulsation is least when the intracranial tension is normal. In the living animal, the chief contents of the cranial cavity, beside the brain substance, is blood, and not cerebro-spinal fluid. The living brain, with its circulating blood, almost entirely fills the cranium, and the fluid that moistens its surfaces is little more in amount than the synovial fluid in a joint. The cerebral subarachnoid space is chiefly a potential rather than an actual space. The rate of transudation of the cerebro-spinal fluid seems to depend directly on the difference between the cerebral venous and the subarachnoid pressure.

In 1783, Alexander Monro the younger¹ put forward the view that the quantity of blood within the cranium is almost invariable. "For, being enclosed in a case of bone," he writes, "the blood must be continually flowing out of the veins, that room may be given to the blood which is entering by the arteries. For, as the substance of the brain, like that of the other solids of our body, is nearly incompressible, the quantity of blood within the head must be the same, or nearly the same, at all times, whether in health or disease, in life, or after death, those cases only excepted in which water or other matter is effused or secreted from the blood vessels; for, in these, a quantity of blood equal in bulk to the effused matter will be pressed out of the cranium."

Monro's conjecture is confirmed by experiment. If a glass plate be screwed into a trephine hole, on compressing the innominate and subclavian arteries, the pial vessels can be seen to become less in size. The brain, however, does not collapse or retreat from the glass window. If, on the other hand, the glass window be faultily placed, and allow leakage into the cranial cavity, air passes within, and the brain collapses under atmospheric pressure. This experiment proves that the brain in the closed cranium can by no means completely empty itself of blood, even though the arterial pressure should fall to zero.

The brain can only empty itself of blood in so far as the cerebro-spinal fluid—and this is small in amount—can take the place of the blood. If an animal be placed in the vertical feet-down position, and the skull be trephined, then, on opening the dura mater, the brain, which before was in close apposition with that membrane, can be seen collapsing, as it is emptied of blood by atmospheric pressure.

It is evident that in all physiological conditions the blood content of the brain can vary suddenly only to a slight degree by the ebb and flow of the cerebro-spinal fluid, and that Monro's doctrine is, to all intents and purposes, true. No sure evidence of the condition of the cerebral circulation can be drawn from examination of the brain after death, for in many different ways the relative volume of blood and of serous fluid within the cranium may be altered by post-mortem changes.

The following methods have been employed in investigations on the cerebral circulation:—

1. Direct observation of the pia mater.
2. A record of the volume of the brain.
3. A measurement of intracranial pressure.
4. Measurement of the blood pressure in the cerebral vessels.
5. Measurement of the velocity of blood flow in the cerebral vessels.

¹ "Observations on the Structure and Functions of the Nervous System," Edin., 1783. Cf. Abercrombie, *Edin. Med. and Surg. Journ.*, 1818, vol. xiv. p. 553; "Pathological and Practical Researches on Diseases of the Brain," etc., 1828.

The essential point which is required in all experiments on the cerebral circulation is, that the cranial cavity should be a closed cavity, as in the normal condition.

Changes in intracranial tension cannot be registered by screwing an ordinary manometer¹ into the skull, because, with any increase of tension, the brain floats up against the trephine hole, and acts towards it as a valve, so that no more fluid can escape into the manometer. The cranio-vertebral cavity cannot be put in connection with a tambour, or used as an oncometer,² because the brain on its expansion closes up, not only a trephine hole in the roof of the cranium, but the foramen magnum in the base. Moreover, the cerebro-spinal fluid leaks from the cavity.

Of considerably greater value, as a method, is the record of the outflow of blood, per second, from the lateral sinuses.³ Hürthle and Cavazzani have recorded the arterial pressure in the circle of Willis⁴ by placing a cannula in the peripheral end of the carotid artery, after tying all but the cerebral branch.

Cybulski, by means of his instrument, the photohæmatometer, has investigated the rate of flow in the internal carotid artery under varying conditions of experiment.⁵

Roy and Sherrington,⁶ by an ingenious plethysmographic method, recorded the variations of the vertical diameter of the brain with the cranium open. The conditions here are not normal. In the closed cranium, large alterations of blood volume are impossible. In the open cranium, with the atmospheric pressure brought to bear on the cerebral capillaries, the physical conditions of the cerebral circulation are altered.

Hill and Bayliss⁷ have simultaneously recorded the aortic pressure, the vena cava pressure, the intracranial pressure, and the cerebral venous pressure; the cranium being, as in the normal condition, a closed cavity. The intracranial pressure is measured by means of the brain-pressure gauge, while the cerebral venous pressure is obtained by placing a cannula in the torcular Herophili. The pressure of the cerebro-spinal fluid can be measured by trephining the atlas, opening the dura mater, screwing a tube into the trephine hole, and connecting this tube with a water manometer.

By these means, the following principles of the cerebral circulation have been determined.

When the aortic pressure rises, the expansion of cerebral volume can take place only to a certain limited amount, for, as soon as all the cerebro-spinal fluid has been driven out from the cranium, the brain is everywhere in contact with the rigid wall of the skull. Any further expansion of the arteries can only take place by an equivalent compression of veins, for the semifluid brain matter is incompressible. The reservoirs of blood in the veins will therefore be so far constricted, until the cerebral venous pressure rises to the pressure of the brain against these veins. Thus, as the arterial tension rises, the whole

¹ Salathé, "Trav. du labor. de Marey," 1876, tome ii. p. 362.

circulatory system of the brain will assimilate itself more and more to a scheme of rigid tubes. The velocity of the blood flow will be increased, and the relative distribution of the blood in the arteries, capillaries, and veins will be changed. A rise of arterial pressure does not by any means, as has been supposed,¹ produce an anæmia of the brain, through compression of the cerebral capillaries and veins, but rather it causes an increased velocity of blood flow.

The intracranial pressure is, in all physiological conditions, the same as the cerebral capillary and venous pressure. The intracranial tension is, in fact, that tension which remains after the force of the heart has been expended in driving the blood through the cerebral arterioles.² It is therefore an ever-varying quantity.

In normal conditions, with the animal in the horizontal position, the intracranial pressure in the dog is generally equal to about 100 mm. H₂O.

There is no compensatory mechanism by which the brain matter can be protected from great changes of circulatory pressure. In the spasms of strychnine poisoning, the intracranial tension may rise to 40 or 50 mm. Hg. This is due, not only to the rise of arterial tension, but to the enormous diminution of capacity of the venous system and rise of vena cava pressure produced by general muscular spasm. On the other hand, the writer has measured the intracranial tension in a certain patient when standing upright, and found it to be slightly below zero. This patient had been trephined for symptoms of lunacy. Men in the spasms of strychnine poisoning are conscious, and the above patient was also conscious. It is clear, therefore, that the functions of the brain can continue at circulatory pressures varying from zero to 50 mm. Hg.

No evidence has been found of the existence of cerebral vasomotor nerves, either by means of stimulation of the vasomotor centre, or of the central end of the spinal cord, after division in the upper dorsal region; or by stimulation of the stellate ganglion. That is to say, the whole of the cranial nerve supply, and the whole of the sympathetic supply to the carotid and vertebral arteries, have been stimulated, and the result has been negative.³

Nor is there any anatomical evidence of the existence of a local vasomotor mechanism. Gulland has entirely failed, by every known histological method, to demonstrate vasomotor nerves in the vessels of the pia mater.⁴

In every experimental condition the cerebral circulation passively follows the changes in the general arterial and venous pressures. The intracranial or cerebral venous pressure varies directly and absolutely with vena cava pressure, but only proportionately with aortic pressure. If both alter, the cerebral venous or intracranial pressure is affected by both, and an alteration of pressure of equal amount, and in opposite directions in both, will affect the intracranial or cerebral venous pressure from the venous side to a far greater degree than from the arterial side, because it is on the arterial side that the peripheral resistance lies. If the torcular Herophili be opened in the freshly-killed animal, and the

¹ Grashey, *Festschr. f. L. A. Buchner*, München, 1892, S. 61; Geigel, "Die Mechanik der Blutversorgung des Gehirns," Stuttgart, 1890; *Virchow's Archiv*, 1890-91, Bd. cxix. S. 93; cxxi. S. 432; cxxiii. S. 27; cxxv. S. 92.

⁴ *Journ. Physiol.*, Cambridge and London, 1895, vol. xviii. p. 361.

abdominal veins be compressed, venous blood can be driven out of the torcular in a continuous stream. If in the living animal the torcular venous pressure and the vena cava pressure be simultaneously recorded in manometers placed side by side, and if at the same time the abdomen be compressed, then the pressure rises in both by equal increments, when the arterial pressure remains constant, and by greater increments in the torcular if the arterial pressure rises also. Between the vena cava and the torcular there lies no appreciable resistance, between the aorta and the cerebral capillaries or veins there lies the unknown resistance of the arterioles. Thus, the variations of arterial pressure, read in millimetres of mercury, only produce variations in cerebral venous pressure which can be read in millimetres of water.

Every change in the position of an animal, owing to the influence of gravity on the vascular system, affects the cerebral circulation. Every

FIG. 89.—Effect of asphyxia. Curarised dog. variation in respiration and every muscular movement is followed by passive changes in the circulation within the brain. Compression of the jugular veins or of the abdomen causes a marked rise in cerebral venous pressure. The movements of the muscles of the neck by pressing on the jugular vein are sufficient to affect the cerebral circulation.

Every stimulus that enters the organism and affects the general vasomotor centre produces a passive effect on the cerebral circulation. It is by means of the great splanchnic area that the blood supply to the brain is controlled. An anæmia of the spinal bulb excites the vasomotor centre, the splanchnic vessels contract, the blood pressure

rises, and more blood is driven through the brain. At the same time, the respiratory centre is excited, and by the increased action of the respiratory pump more blood is driven to the right heart, and thence to the brain. We have in the vasomotor centre a protective mechanism, by which blood can be drawn at need from the abdomen and supplied to the brain. At the moment that excitation from the outside world demands cerebral response, the splanchnic area contracts, and more blood is driven through the brain. The brain has no direct vasomotor mechanism, but its blood supply can be controlled indirectly by the vasomotor centre acting on the splanchnic area. The vasomotor centre is part of the central nervous system, and feels the same needs and is stimulated by the same centripetal impulses as affect the rest of that system, and thus it maintains a supply of blood to the central nervous system which corresponds to its functional activity.

The arterial supply to the brain is in the lower animals so superabundant, that, in the dog,

FIG. 90.—Effect of drawing a ligature gently round the neck, after placing a cannula in the trachea. A, aortic pressure; B, cerebral venous pressure; C, vena cava pressure.—Bayliss and Hill.

four of the arteries—two common carotids and two vertebrals—which supply the brain can be tied in the course of ten minutes, and yet the animal either at once, or after a temporary period of idiocy and paralysis, completely recovers. In the monkey, on the other hand, ligation in one operation of one vertebral artery, in addition to the two carotids, produces either death in twenty-four hours or softening of the great brain, accompanied by idiocy and paralysis of movement and sensation. The efficiency of the anastomosis

through the circle of Willis varies in different individuals. Sudden compression of one common carotid artery in some men produces epileptic spasm, and ligation of this artery has been followed in some by more or less temporary paralysis on the opposite side of the body; in others the effect is *nil*.

THE PULMONARY CIRCULATION.

The first physiologist who succeeded in making observations on the pressure in the pulmonary artery was Bentner.¹ The more important recent investigations on this subject are those of Bradford and Dean,² and François-Franck.³ By Bradford and Dean, dogs were placed under the influence of morphia and curari, and artificial respiration was established. The artery to the lower lobe of the left lung was reached by

¹ *Ztschr. f. rat. Med.*, 1852, Bd. ii. S. 97.

² *Proc. Roy. Soc. London*, 1889, vol. xlv. p. 362; *Journ. Physiol.*, Cambridge and London, 1894, vol. xvi. p. 34.

³ *Arch. de physiol. norm. et path.*, Paris, 1896, pp. 178, 193.

resection of two or three ribs in the back, and a cannula was inserted therein. Both the carotid and pulmonary arterial pressures were recorded synchronously with mercurial manometers.

Chauveau and Faivre passed a trocar connected with a manometer directly into the pulmonary artery of the horse, through an intercostal space, and without opening the thorax. This method, since the conditions are absolutely normal, is far preferable, but it is only possible to carry it out in large animals, such as the horse.

The following determinations of the pulmonary arterial pressure, with the chest opened, have been recorded:—

Name.	Animal.	Mean Pressure.	Proportionate Relation to Aortic Pressure.
Bentner	Rabbit	12·07 mm. Hg.	1-4·2
„	Cat	17·6 „	1-5·3
„	Dog	29·6 „	1-3·1
Knoll ¹	Rabbit	12·2 „	1-6·8
Bradford and Dean . .	Dog	16-20 „	1-5

There can be no doubt that these figures are lower than normal, owing to the severity of the operative procedure, and to the necessity of opening the thoracic cavity.

By passing a cannula into the right ventricle, de. Jager found the intraventricular pressure to be equal to 27 to 59 mm. Hg. By Chauveau and Faivre's method, which is free from the objections pertaining to the other procedures, the relation of pulmonary to aortic pressure was found to be as 1 to 3. If the aortic pressure in man be equal to 100 to 120 mm. Hg, the pulmonary arterial tension is probably equal to 30 to 40 mm. Hg.

In some experiments, conducted under conditions of artificial respiration with the thorax open, Lichtheim² found that the greater number of the branches of the pulmonary artery could be ligatured without lessening the input into the left heart, or lowering the aortic pressure. After tying the left pulmonary artery, and driving melted paraffin by way of the jugular vein into the branches of the right pulmonary artery, Lichtheim even occluded as much as three-fourths of the channels of communication between the right and left hearts, and yet obtained no fall of aortic pressure. This result was not due to any compensatory constriction of the systemic arterioles.

Astounding as these experiments seem, yet their results are probably entirely to be explained as due to the effect of artificial respiration. To begin with, the capacity of the circulatory system of the lungs must be very great in comparison with that of any other organ, for in a given time as much blood must stream through the lungs as through the rest of the body. Secondly, the high tension of the air artificially blown into the lungs diminishes the capacity of the pulmonary vessels. So long, therefore, as the vascular system is not reduced by ligature beyond that amount which is rendered impervious by the artificial respiration, the aortic pressure will not vary. The conclusion thus reached is that only about one-third of

¹ *Sitzungsber. d. k. Akad. d. Wissensch., math.-naturw. Cl.*, Wien, 1888, Bd. xcvi. Abth. 3, S. 212.

² "Die Störungen des Lungenkreislaufes," Berlin, 1876, S. 20.

the circulatory pathway through the lungs is open during vigorous artificial respiration.

In confirmation of this view, Landgraf's observations on the rabbit may be quoted.¹ He split the sternum in the middle line without opening the pleural cavities or interfering with natural respiration. In this condition he found that ligature of one pulmonary artery lowered the aortic pressure, markedly lessened the filling of the left heart and dilated the right heart. The experiments of Lichtheim, and also those of Landgraf, prove how markedly different the pulmonary circulation is in the states of artificial and natural breathing.

Apart from the effect of respiration, the pulmonary circulation may be influenced passively by the following agencies:—

1. By changes in the rate and force of the heart-beat, the circulatory system otherwise remaining constant.

2. By congestion in the left auricle, a "back effect," consequent on increased resistance to the aortic outflow.

3. By a fall of pressure in the left auricle, due to diminished resistance in the aortic outflow.

4. By a "forward effect," or increased input into the right heart, such as is produced by the sudden constriction of a large area of arteries emptying the blood into the veins, or by compression of the abdomen.

5. By a diminished input into the right heart, such as is produced by loss of vascular tone.

6. By the influence of gravity and the effect of position, producing an increased or diminished input into the right heart.

It is important to consider in further detail how, by a "back effect," a rise of aortic pressure may congest the pulmonary circulation.

The left ventricle has to vary its power of contraction in accordance with alterations of arterial pressure which are far greater than ever fall to the lot of the right ventricle. The left ventricle is thus found to become exhausted, while the right still continues unaffected. Thus on inducing asphyxia, after dividing the vagi, the left heart begins, when the aortic pressure reaches its maximum, to give weak and irregular beats, while the right heart continues for a time to contract strongly and regularly.

On stimulating the cervical spinal cord, Waller² found that the left ventricle could not empty itself against the high aortic pressure consequent on the general condition of vaso-constriction. The left auricle thus became congested, and even ceased to show any signs of contraction. Meanwhile the right heart continued to beat normally, and while the pressure in the left auricle rose to 25 or 30 mm. Hg, the pressure in the right auricle was only 5 mm. Hg. The lungs act to the left heart as a blood reservoir, as the liver and large veins stand in the same relation to the right heart. Thus the "back effect" on the right heart is small during a short period of increased resistance to the aortic outflow. By the combined effect of stimulation of the spinal cord, ligature of the aorta, and compression of the abdomen, the pressure in the right auricle has been raised to 22 mm. Hg. In this case a "back effect" is combined with a "forward effect," and the input into the right heart is increased while the output is resisted. Finally, when the output of the right heart also becomes incomplete, and the reservoirs of the lungs are filled, the blood congests in the liver and large veins.

Bradford and Dean observed that compression of the thoracic aorta,

¹ *Ztschr. f. klin. Med.*, Berlin, 1892, Bd. xx. S. 181.

² *Arch. f. Physiol.*, Leipzig, 1878, S. 525.

if maintained for only a short period, produced no "back effect" on the pulmonary artery. When, in one experiment, the period of compression was increased, the pressure rose in the pulmonary artery from 24 to 30 mm. Hg, while the aortic pressure rose from 90 to 135 mm. Hg. On excitation of the peripheral end of the great splanchnic nerve, the pulmonary arterial tension at first rises very slightly, and at the same time there occurs a great rise of aortic pressure. By continuing the excitation the blood congests in the left heart, and the pressure in the pulmonary vessels then rises.

The devising of experimental means by which purely active changes can be evoked in the pulmonary circulation, and thus the proof of a vasomotor control established, has been extremely difficult; so that some physiologists have gone so far as to maintain that the vascular system of the lungs is not under the direct influence of the central nervous system. The difficulty arises from the susceptibility of the pulmonary circulation to passive changes such as we have discussed, and which arise secondarily to active alterations in the conditions of the

FIG. 91.—Pulmonary and carotid arterial pressures. Curarised dog. Vagi divided. Cord divided at level of seventh dorsal root. Effect of excitation of peripheral end of cord.—Bradford and Dean.

systemic circulation. It is necessary in the experimental investigation of this question to provoke vasomotor changes in the pulmonary circulation by the excitation of some portion of the nervous system, while the diastolic filling of the right heart and the systolic output of the left heart remain unaltered by any synchronous variation in the systemic circulation. These postulates have not been carried out in most of the experiments which have been made on the pulmonary vasomotors.¹

The most exhaustive research on this difficult subject has been carried out by Bradford and Dean.² Their evidence in favour of a vasomotor mechanism appears to be conclusive, and is based upon the following experiments:—

¹ Brown-Séguard, *Lancet*, London, 1872; *Compt. rend. Soc. de biol.*, Paris, 1872, p. 180; Badaud, "Ueber den Einfluss des Hirns auf den Blutdruck in dem Lungenarterie," Würzburg, 1874; Couvreur, *Compt. rend. Soc. de biol.*, Paris, 1889, p. 731; Bokai, *Jahresb. u. d. Fortschr. d. Anat. u. Physiol.*, Leipzig, 1880, Bd. ii. S. 71; Henriques, *Skandin. Arch. f. Physiol.*, Leipzig, 1892, Bd. iv. S. 229; Waller, *Arch. f. Physiol.*, Leipzig, 1878, S. 525; Lichtheim, "Störungen des Lungenkreislaufes," Berlin, 1876; Openchowski, *Arch. f. d. ges. Physiol.*, Bonn, 1882, Bd. xxvii. S. 233.

² Bradford and Dean, *Journ. Physiol.*, Cambridge and London, 1894, vol. xvi. p. 34.

1. On excitation of the central end of the divided vagus in a curarised dog, the pressure in the pulmonary vein fell, in the pulmonary artery rose, in the aorta fell. These results, brought about by reflex excitation of the vasomotor centre, seem to point conclusively to constriction in the pulmonary arterioles.

2. After section of both vagi in a curarised dog, excitation of the peripheral end of the spinal cord, divided at the level of the seventh dorsal root, produced a rise of aortic pressure equal to 160 mm. Hg. During the period of stimulation, the pulmonary arterial pressure rose 1 mm. Hg (Fig. 91). On the other hand, excitation of the vasomotor centre immediately afterwards produced a rise of 57 mm. Hg in the aorta, and 6 mm. Hg in the pulmonary artery (Fig. 92).

The rise of pressure by 6 mm. Hg, in the latter case, cannot well be explained by a passive back effect, because, just before, a rise of aortic pressure thrice as great had only raised the pressure in the pulmonary artery 2 mm. Hg. Since the vagi were divided this experimental result cannot be explained by change in the rate of the heart.

Carrying the investigation a step further, these authors divided the

upper thoracic nerve roots, and stimulated the peripheral ends. Accepting the anatomical researches of Gaskell, it is from this part of the spinal cord that we should expect to find the outflow of the pulmonary vasoconstrictor nerves.

Excitation of the third thoracic root accelerated the heart, raised the tension in the pulmonary artery at the same time, and frequently caused a slight fall in aortic pressure. Here the aortic fall is neither produced by loss of cardiac power, nor by dilatation of any vascular area, and must be ascribed to the diminished input, consequent on contraction of the pulmonary arterioles.

On excitation of the succeeding roots, the proportionate change in the aorta and pulmonary artery were found to be as follows:—

Fourth thoracic (1)	Aorta, . .	+ 10 mm.	Pulmonary artery, . .	+ 4 mm.
	(2) " . .	+ 20 "	" " . .	+ 4 "
Fifth " "	" . .	+ 26 "	" " . .	+ 3 "
Sixth " "	" . .	+ 50 "	" " . .	+ 2 "

These results show conclusively that the pulmonary rise is not produced passively. On passing down from root to root, the excitation produces less effect on the pulmonary vascular system, and more on the systemic system, for the splanchnic fibres become stimulated towards the middle thoracic region.

3. On producing asphyxia in the curarised animal, Bradford and Dean observed the following:—(1) A great rise in aortic tension, followed

by a more gradual fall; (2) a considerable rise in the pulmonary artery, synchronous with the commencement of the aortic rise but overlasting the latter, and followed by a gradual fall; (3) a great rise in the pulmonary venous pressure synchronous with the aortic fall.

After complete division of the spinal cord at the level of the sixth or seventh dorsal root, asphyxia produced the same rise in the pulmonary

FIG. 93.—Pulmonary and carotid arterial pressures. Curarised dog. Spinal cord divided at level of sixth dorsal root. Effect of asphyxia.—Bradford and Dean.

arterial pressure, and this was now accompanied by but a slight rise in aortic pressure (Fig. 93).

Thus in one case the aortic pressure rose from 117 to 123 mm. Hg, while the tension in the pulmonary artery rose from 14 to 26 mm. Hg. The rise of pulmonary venous pressure in the last stage of asphyxia is due to failure of the left heart, and a consequent decrease in the systolic output. In all these experiments the animals were curarised as

FIG. 94.—Pressure curves of pulmonary artery, left auricle, and femoral artery. Effect of excitation of central end of crural nerve.—François-Franck.

well as anæsthetised, in order to eliminate all changes in the circulation which might arise from muscular movements. Turning to the effects of reflex excitation of the pulmonary vasomotor mechanism, Bradford and Dean noted that stimulation of the central end of any posterior root in the upper thoracic region caused a rise both in aortic and pulmonary arterial pressure, but the rise was proportionately greater in the latter.

On excitation of the central end of an intercostal nerve, there occurred a rise of aortic pressure followed by a fall, or a fall was obtained from the first. The pressure in the pulmonary artery fell also, but not proportionately. It is thus evident that the pulmonary circulation can be affected to a certain extent by sensory stimulation of the chest wall. In confirmation of Bradford and Dean's work, François-Franck¹ obtained, by excitation of the central end of the anterior crural nerve, a rise of pressure in the pulmonary artery and in the aorta, accompanied by a fall of pressure in the left auricle. On stimulation of the central end of the splanchnic nerve, he recorded a maintained rise of tension in the pulmonary artery, while the aortic pressure varied, owing to the reflex excitation of the dilator as well as the constrictor fibres which govern the splanchnic vascular system.

François-Franck recorded the volume of one lobe of the lung by the plethysmographic method. A paradoxical result is obtained on plethysmography of the lung, since the organ does not diminish, but swells on contraction of the arterioles. This is owing to the distension of the large and extensile pulmonary arteries, in consequence of the increased resistance to the outflow, and the continuance of the input from the right heart. Excitation of the peripheral end of the vagus in the atropinised animal was found by Bradford and Dean to have no effect on the pressure in the pulmonary artery, and they were unable to find any evidence of pulmonary vaso-dilator fibres in this or any other nerve.

On stimulating the depressor nerve, both the aortic and the pulmonary arterial pressures fall together.

Among the points which become manifest in these experiments the following are of especial interest:—

1. The lesser circulation is independent of the systemic circulation, within certain limits. Increased resistance to aortic flow does not immediately produce a back effect in the pulmonary vascular system, but only when the aortic tension has been maintained at a high level for a considerable period, and when the ventricle becomes fatigued. The left heart then fails to keep up the systolic output. Even when this happens, the lungs act as reservoirs for the blood, and the pressure does not materially rise in the right heart till the back effect has continued for some time. Finally, the output of the right heart is affected, and the blood congests in the venous system. To grasp how back effects are produced in the circulatory system is of the utmost importance for the proper understanding of the pathology of the circulation.

2. The pulmonary vascular system is undoubtedly innervated from the upper thoracic nerve roots, and thus comes under the influence of the central vasomotor mechanism. From the results of the experiments which have been considered, it might be concluded that the vasomotor effects are very small. In the light, however, of Lichtheim and Landgraf's researches on the ligature of the pulmonary arteries, this conclusion may be wrong. If ligature of three-fourths of the arterial channels produces no effect when the thorax is opened and artificial respiration is maintained, we cannot expect that a constriction of the arterioles should produce a very great result in Bradford and Dean's experiments, since these authors worked with the thorax open, and with the aid of artificial respiration. In the normal animal, the vasomotor phenomena may be found to be somewhat more important, just as Landgraf discovered that a great fall of aortic pressure and a rise of tension in the right heart is produced when he ligatured one pulmonary artery without opening the pleural cavity.

¹ *Arch. de physiol. norm. et path.*, Paris, 1896, p. 184.

THE CIRCULATION THROUGH THE LIMBS.

By far the greater quantity of the blood, 50 to 70 per cent., lies within the roomy reservoirs of the abdominal and thoracic organs. Thence, by means of the vasomotor mechanism, the blood is distributed at need to the locomotor organs.

In the organs of locomotion the quantity of blood during rest has been roughly estimated to be 36 per cent., and during activity 66 per cent. of the whole blood quantum.¹

Spehl reckoned the proportionate weight of each organ, washed free of blood, to the weight of the whole body washed free of blood. He likewise estimated the proportionate weight of the blood found in each organ to the weight of the whole blood in the body. Dividing the proportionate weight of the bloodless organ by the proportionate weight of the blood within it, he obtained the blood capacity of the organ. If the blood were equally distributed throughout the parts of the body, the blood capacity should equal 1. In the lungs he found the blood capacity to be 11 to 13 in inspiration, 9 to 12 in expiration. The blood capacity of the muscles was 0.327 to 0.343 during rest, and 0.520 to 0.664 during maximal activity.²

Chauveau and Kaufmann estimated the amount of blood flowing in one minute through the levator labii superioris of the horse to be five times as great during activity as during rest of the muscles.³

The blood flow from the deep femoral vein of the dog during an epileptic fit (excited by essential oil of absinthe) is three to five times as great as during rest.⁴ The clonic contractions alternately suck the blood into the vessels of the muscles, and then compress the blood on into the veins.

Similarly, massage greatly increases the flow of blood through the muscles. Massage of a considerable muscular area produces a fall of general arterial pressure, in consequence of the derivation of blood into the dilated muscular vessels. This fall may amount to one-fifth of the initial pressure.⁵

Gaskell⁶ observed the circulation in the mylo-hyoid muscle of the frog directly, and measured the diameter of the vessels with a micrometer. On stimulating the trigeminus, the vessels dilated after a latent period of 5 to 6 seconds. Venous congestion occurred only at the commencement of tetanus, owing to the pressure of the muscle fibres. During the rest of the period of excitation the blood flow was increased.

In the curarised animal the outflow from the muscular veins of the lower limb is increased on excitation of the motor nerves. Vaso-dilator fibres must run, therefore, in these nerves. On the other hand, Gaskell obtained evidence of a diminished outflow on stimulation of the peripheral end of the abdominal sympathetic in the curarised dog. We must therefore admit the existence of vaso-constrictor fibres. They are, however, but poorly developed in the muscles.

At times of great muscular effort, a man closes his glottis, and main-

tains his thorax and abdomen in the position of forced expiration. By this means the intrathoracic pressure is raised, the outlet from the veins blocked, and the muscles are distended with blood. The pressure rises in the capillaries and veins of the muscles almost to arterial pressure.

The control of the blood supply to the limbs has been studied by the thermometric and plethysmographic methods. The temperature in

FIG. 95.—Limb plethysmograph. A, glass chamber filled with air; B, broad india-rubber band; C, Marey tambour. The junction between the limb and the plethysmograph is rendered air-tight by the free application of thick vaseline beneath the rubber-band (B).

the upper limb is raised by destruction of the first thoracic ganglion, and by section of the brachial plexus or midthoracic roots.¹ In the hind-limb, a rise of temperature occurs after dividing the sciatic nerve. The vasomotor fibres have been traced from this nerve to the lower thoracic roots. They pass down the sympathetic chain in the lower lumbar region.² On excitation of these vasomotor nerves, the greatest change of temperature is found in the feet. This is so, because the pad of an animal's foot is free from a furry coat, and thus forms one of the more important places for the regulation of the temperature of the body.³

By Bradford and Bayliss⁴ the vasomotor nerves of the limbs have been minutely studied, with the aid of the plethysmograph. According to these authors, the vasoconstrictor fibres which supply the fore-limb leave by the anterior roots

FIG. 96.—Record of aortic pressure and the volume of the fore and hind limbs. Curarised dog. Effect of excitation of the thirteenth dorsal root. Passive dilatation of the fore-limb, contraction of the hind-limb.—Bradford and Bayliss.

of from the third to the eleventh thoracic nerves. The hind-limb is supplied by fibres from the eleventh thoracic to the third lumbar nerve. By each root the volume of the whole limb is affected.

³ Lewaschew, *Arch. f. d. ges. Physiol.*, Bonn, 1882, Bd. xxviii. S. 397 seq.

⁴ *Journ. Physiol.*, Cambridge and London, 1894, vol. xvi. p. 10.

The chief outflow of constrictor fibres occurs from the sixth dorsal to the first lumbar nerve. Thus the limbs and the abdominal viscera get their supply approximately from the same part of the spinal cord. The vasomotor mechanism of the limbs is not powerfully developed.

By stimulation of any sensory nerve the vessels of the limbs can be constricted. Usually, however, the limbs expand owing to the passive

FIG. 97.—Effect of excitation of a superficial branch of the crural nerve on the arterial pressure, and on the volume of the spleen, jejunum, kidney, and feet.—Hallion and François-Franck.

dilatation produced by the rise of aortic pressure which follows reflex constriction of the splanchnic vessels. The reflex constriction of the limbs can be obtained after section of the splanchnic nerves.

Langley's¹ observations on the vaso-constrictor fibres of the feet agree closely with those of Bayliss and Bradford. He further finds that the sympathetic cell stations for the fibres of the upper limb are in the stellate ganglion; of the hind-limb, in the sixth and seventh lumbar and first sacral ganglia. The vasomotor fibres to the trunk follow the same distribution as the pilomotor fibres.

The general changes which take place on exciting the central end of an afferent nerve are seen exceedingly well in Fig. 97. In this there is shown a simultaneous record of—

¹ *Journ. Physiol.*, Cambridge and London, 1891, vol. xvi. p. 375; 1894-5, vol. xvii. p. 307.

1. The pressure in the femoral artery.
2. The volume of the spleen.
3. The volume of the jejunum.
4. The volume of the kidney.
5. The volume of the left hind-limb.
6. The volume of the right hind-limb.

On exciting the central end of the sciatic nerve, the arterial pressure rose, the spleen, jejunum, and kidney contracted. The feet¹ expanded (perhaps passively by the rise of arterial pressure). The arterial pressure then fell somewhat (owing to cutaneous vaso-dilatation and pulmonary vaso-constriction).²

The volume of the limbs depends both upon the arterial and the vena cava pressures. If the arterial pressure remain constant, and the vena cava pressure rise, as on performing a Valsalva experiment, then the volume of the limb increases greatly. Here the venous tension rises towards the mean arterial tension, for the outlet of the veins is blocked by the rise of intrathoracic pressure. If the vena cava pressure rise while the arterial pressure fall, the two effects may balance each other, and the volume of the limb remain constant.

The tracing of the limb volume shows all the respiratory and cardiac oscillations. The limb may expand more, either with expiration or with inspiration, according as the expiratory rise of vena cava pressure, or the inspiratory rise of arterial pressure, has the greater effect upon the capillary pressure.

During Traube-Hering oscillations of arterial pressure the volume of a limb follows the rise and fall of aortic pressure.

It has been said that an antagonism exists between the vasomotor mechanisms of the splanchnic and locomotor organs. Thus, while during asphyxia the splanchnic vascular area contracts, the vessels of the skin and muscles dilate.³ The dilatation of the latter, however, is in all probability not occasioned by active dilatation, but is due to the over-mastering power of the splanchnic constrictors. By the rise of aortic tension the vessels in the remaining parts of the body are passively dilated, and the blood flow is thus increased through the skin and muscles. That this is so is suggested by the fact that after the circulation has, by ligature of the thoracic aorta and vena cava inferior, been limited to the fore-part of the body, either asphyxia or excitation of the vasomotor centre produces a slight rise of arterial tension, owing to the constriction of the vascular areas of the face and fore-limbs. Previous to the double ligature the same excitation produces splanchnic contraction, a great rise of aortic tension, and dilatation in the face and fore-limbs. Bayliss⁴ has obtained plethysmographic evidence of contraction of the leg during asphyxia.

By driving normal saline through the vessels of a recently dead animal, and measuring the outflow, Stefani⁵ determined that a given head of pressure dilates the vessels of the skin and muscles to a far greater extent than the splanchnic vessels. The cerebral vessels enclosed in the rigid cranium dilate

¹ By means of the foot the circulation in the skin is studied.

least. It is noteworthy that the dilated pulmonary vessels recover their original calibre very slowly.

Whether the dilatation of the locomotor organs be active or passive is of no particular importance. The fact remains that the splanchnic area forms the resistance box of the circulation, and when the splanchnic vessels are contracted, the blood is driven with increased velocity through the locomotor organs, and is determined from the deep to the superficial parts of the body.

THE RENAL CIRCULATION.

The circulation in the kidney is studied with great ease by the plethysmographic method. Cohnheim and Roy¹ constructed a metal oncometer for this purpose. A box similar to that used by Schäfer and Moore in their investigations upon the spleen (see Fig. 99), can be moulded without difficulty out of guttapercha.² The kidney having been exposed by a lumbar incision, is drawn out of the wound and placed in the box. The pedicle of the kidney passes out through a groove in one side of the chamber. The box is closed by a glass cover, and this is made air-tight by a free application of thick vaseline. The alterations in the volume of the kidney are recorded by means of a tambour. The tracing of renal volume follows exactly the curve of arterial pressure, and exhibits both the cardiac and respiratory oscillations.

By the use of Roy's oncometer, Bradford³ localised the renal vasomotor fibres to the anterior roots of from the sixth to the thirteenth thoracic nerves. Most of the renal vasomotor fibres are found in the eleventh, twelfth, and thirteenth nerves.

By reflex excitation, it is more common to obtain contraction than expansion of the kidney, but expansion is frequently witnessed when the central end of the eleventh, twelfth, and thirteenth posterior thoracic roots are stimulated. Vaso-dilator fibres in the anterior roots are evidenced by employing a slow rate of excitation (one per second). Rapid excitation of the splanchnic nerve causes marked contraction of the kidney of its own

FIG. 98.—Aortic pressure and renal volume. Excitation of thirteenth dorsal root. *A*, fast rate of excitation contracts; *B*, slow rate dilates the kidney; *a*, arterial pressure; *k*, kidney volume; *s*, signal.—Bradford.

side, and sometimes contraction of the kidney of the opposite side as well (Cohnheim and Roy).

Landergren and Tigerstedt¹ have studied the circulation in the kidney by estimating the velocity of blood flow in the renal artery. They employed for this purpose Tigerstedt's stromuhr. After section of the renal nerves, they found that injections of normal saline, of 2 to 3 per cent. nitrate of soda solution and of caffeine greatly increased the velocity in the renal artery. Hence the diuretic action of these drugs. If urea be injected, it produces local dilatation of the kidney, while it excites the vasomotor centre and causes general vaso-constriction.²

THE CIRCULATION IN THE GENERATIVE ORGANS.

Eckhard³ showed that excitation of the first and second sacral nerves in the dog produces erection of the penis (*nervi erigentes*), and Goltz⁴ determined the existence of a centre in the lumbar region of the cord, by means of which erection could be reflexly excited. In the rabbit, Gaskell⁵ found the vaso-dilators to the penis in the second and third anterior sacral roots. The same fact has been determined for the monkey and the cat.⁶ The vaso-constrictor fibres issue from the third, fourth, and fifth lumbar anterior roots.

The changes in volume of the penis have further been recorded by the plethysmographic method,⁷ and by measurement of the rate of flow of blood from the veins of the organ. The outflow from the vena pudenda communis is increased as much as eight times on excitation of the *nervi erigentes*.⁸

The internal generative organs are supplied with vaso-constrictor nerves from the lumbar anterior roots.

All the vaso-constrictor fibres to the generative organs pass through cells stationed in the inferior mesenteric and sacral ganglia of the sympathetic. The vaso-dilator nerves, as elsewhere, pass through cell stations in scattered ganglia, situated in or near the organs they supply.

THE MESENTERIC CIRCULATION.

The vaso-constrictor nerves to the intestines are supplied by the splanchnic nerves. The course of the fibres is interrupted by nerve-cells placed in the semilunar ganglia. Painting these ganglia with nicotine abolishes the usual effect which follows excitation of the splanchnic nerves.⁹

Hallion and François-Franck have investigated the origin of the intestinal vasomotor nerves by the plethysmographic method.¹⁰

The animal is placed by these authors belly downwards, the abdominal

wall is freely opened, and a loop of intestine ligatured at either end, and separated from the remaining guts, is allowed to hang down into a glass vessel partly filled with warm saline. At the orifice of the glass vessel the mesentery is surrounded by a broad band of thin indiarubber, which is kept sufficiently tight by means of a clip. By this means the chamber is rendered air-tight, and yet the mesenteric vessels are not over-compressed. From the top of the chamber a tube passes to a sensitive tambour. Bunch has also worked at the innervation of the intestinal vessels, using Schäfer's visceral plethysmograph (Fig. 99).¹

Hallion and François-Franck² applied plethysmographs to other abdominal organs, and took simultaneous tracings of the volume of the kidney, intestine, and spleen, together with the arterial blood pressure (see Fig. 97).

They found that excitation of the central end of the sciatic nerve produces reflex vaso-constriction in the small intestine, the spleen, the liver, and the kidney, and vaso-dilatation of the colon, and that excitation of the peripheral end of the vagus in the atropinised animal (*i.e.* cardio-inhibitory fibres paralysed) produces marked vaso-dilatation in the intestines.³

The vaso-constrictor fibres issue from the fifth thoracic nerve downwards. The upper roots supply the duodenum and jejunum, the lower roots the ileum and colon. On exciting the eleventh, twelfth, and thirteenth thoracic, and first and second lumbar roots, marked vaso-dilatation follows, after a fugitive preliminary constriction. This vaso-dilatation is accompanied by a fall of arterial pressure. The usual effect on exciting the splanchnic nerves is a great rise of arterial pressure, followed by a fall. This double effect is due to the presence of both vaso-constrictors and dilators in these nerves. The vaso-constrictors are exhausted before the vaso-dilators.

THE HEPATIC CIRCULATION.

By simultaneous records of aortic and portal pressures, Bayliss and Starling⁴ determined that the constrictor fibres to the branches of the portal vein issue by the anterior roots from the third to the eleventh thoracic nerves. Cavazzani and Manca⁵ attempted to investigate the innervation of the hepatic blood vessels by artificially circulating warm normal saline solution through the organ, and measuring the output from the vena cava inferior. They ascribe both constrictor and dilator fibres to the splanchnic nerves, and dilator fibres to the vagus.

François-Franck and Hallion have investigated the hepatic circulation by the plethysmographic method. On excitation of the central end of the sciatic nerve, the liver vessels are constricted. The pressure in the portal vein rises slightly, in spite of the concomitant contraction of the mesenteric vessels. On exciting the central end of the vagus, either contraction or dilatation follow. By stimulation of the thoracic sympathetic cord, blood was actively expelled from the liver. If the hepatic nerves were divided, this stimulation of the sympathetic, by causing contraction of the spleen, produced dilatation of the liver. Nicotine, when injected into the hepatic circulation, contracted the

⁵ *Arch. ital. de biol.*, Turin, 1895, vol. xxiv. pp. 33, 295.

hepatic vessels, and raised the pressure in both the portal vein and the hepatic artery.¹

The liver is exceedingly vascular, and forms an enormous reservoir for the venous blood at periods when the diastolic filling of the right heart is impeded; for instance, during an intense muscular effort, or a prolonged dive under water. The portal circulation is aided considerably by the action of the respiratory pump. The abdominal wall compresses the blood, while the thorax sucks the blood from the liver. The circulation through the liver is thus greatly accelerated by muscular exercise.

THE SPLENIC CIRCULATION.

The spleen must be looked upon as a sponge full of blood, the trabeculae of the spongework and the capsule being formed of muscular tissue. Roy² found the spleen to be normally subject to regular alternations of volume (systole and diastole). These succeed one another in the case of the dog and cat, without intermission, at regular intervals of about a minute. In consequence of this power of contractility, the circulation through the spleen is somewhat modified, and the spleen may itself act as a pump to the portal system.

The method employed for investigating the splenic circulation is that of the plethysmograph. The first records were obtained by Roy, with the help of a special hinged metal box or oncometer, in which the spleen was enclosed.

FIG. 99.—Schäfer's visceral plethysmograph.

The oncometer was, in its turn, connected with a piston recorder, termed the oncograph.

A suitable box for the spleen, or for any other separable viscus, can be made of gutta-percha.³ It should have flattened edges, on which a flat plate of glass accurately fits.

The viscus is exposed by a free abdominal incision, and placed within the plethysmograph, the blood supply to the organ passing over one side of the box, which is made lower than the others. The glass cover is maintained in position with the help of indiarubber bands, and the box is rendered air-tight by a free application of thick vaseline. Any gap at the side of the vessels is plugged with cotton-wool soaked in vaseline. A tube leads from the plethysmograph, and this is connected by an indiarubber tube with a recording tambour or a piston recorder. The whole apparatus is filled with air.

Fig. 100 shows a typical spleen tracing. Two splenic contraction waves are visible, and upon these are seen the respiratory and cardiac undulations of arterial pressure.

¹ *Arch. de physiol. norm. et path.*, Paris, 1897, pp. 434, 448.

² Roy, *Journ. Physiol.*, Cambridge and London, 1880-2, vol. iii. p. 203.

³ Schäfer and Moore, *Journ. Physiol.*, Cambridge and London, vol. xx. p. 5.

By the use of the above instrument Schäfer and Moore found—

1. That the spleen volume is extremely responsive to all fluctuations in the general blood pressure, and not independent of these, as had been supposed by Roy.

2. That when the nerves going to the organ are intact, other fluctuations in the volume of the spleen may occur, which exactly correspond to Traube-Hering curves of arterial pressure. On the other hand, these fluctuations of volume may not correspond, and the arterial curve may be rising while the splenic is falling. In the first case, the variations in splenic volume are purely passive, and follow the rise and fall of arterial pressure. In the second case, the spleen-arterioles, like those of the kidney, share in the general rhythm of contractility, contracting when the arterioles contract, and expanding when the arterioles generally dilate.

3. That the specific rhythmic variations in splenic volume are almost entirely abolished by chloroform.

4. That rhythmic contraction and dilatation occur in the spleen when excised and fed by an artificial circulation of defibrinated blood.

FIG. 100.—Aortic pressure and splenic volume.¹—Schäfer and Moore.

These movements may therefore be carried out quite independently of the central nervous system.

5. That certain conditions, such as diminution of oxygen in the blood, produce not only a general contraction of the organ, but also a subsequent increase in the extent of its rhythmic movement. Extract of suprarenal gland produces an extreme condition of contraction.

6. That certain drugs, such as curari, or a watery extract of dried brain, greatly increase the contractions of the spleen. Anaemia of the organ acts in the same way, whether produced by compression of the artery, or otherwise.

The innervation of the spleen was first investigated by Bulgak,² and has recently been worked out more fully by Schäfer and Moore. Bulgak observed the spleen directly, and described the nerves in the gastro-splenic omentum as of two kinds, afferent and efferent. Stimulation of the peripheral end of the efferent fibres caused marked contraction of the spleen. The organ became pale in colour, its edges rounded, and its surface crinkled. Excitation of the central end of the afferent nerves produced well-marked reflex contraction of the organ. Bulgak

¹ The line of zero blood-pressure should be placed some millimetres lower.

² Bulgak, *Virchow's Archiv*, 1877, Bd. lxxix. S. 181.

traced the efferent fibres to the semilunar ganglion and to the greater splanchnic nerve of the left side only. Thence he traced them to the anterior roots of the thoracic nerves on the left side from the third to the tenth. Schäfer and Moore have shown, however, that contraction of the spleen is obtained on stimulating either splanchnic nerve.¹ They determined the outflow of splenic fibres to arise from the anterior roots of both sides, from the third to the fourteenth post-cervical nerves. The largest effect was obtained by excitation of the sixth, seventh, and eighth roots. Each left root produced a relatively greater contraction than the corresponding right one. They were unable to confirm Bulgak's observations as to the afferent fibres of the organ.

In one case dilatation of the spleen was obtained by weak excitation of the splanchnic nerve, and constriction by strong excitation, and hence they conclude that this nerve contains both constrictor and dilator fibres.

They further found, in opposition to Roy, that excitation of the peripheral end of the thoracic or of the atropinised cervical vagus produces no effect on the spleen. There appeared to be no means of separating the vasomotor effects on the splenic vessels from the contractility of the muscular tissue of the spleen itself. Apparently the whole organ acts in the same manner as the muscular wall of the arterioles, and thus the organ controls its own blood supply.

THE PANCREATIC CIRCULATION.

After tying some of the branches of the arteria pancreatico-duodenalis, François-Franck and Hallion² placed the pancreas in a plethysmograph of suitable shape. They obtained evidence of vaso-constriction on excitation of the splanchnic nerves on either side, and traced the origin of the constrictor fibres to the anterior roots from the fifth thoracic to the first lumbar nerves. Expansion of the pancreas seemed to follow excitation of the peripheral end of the vagus. Reflex constriction of the organ was produced by stimulation of any sensory nerve, or of the cerebral cortex; reflex dilatation, by excitation of the central end of the vagus. During the first stage of an asphyxial rise of blood pressure the pancreas is contracted in volume.

THE CORONARY CIRCULATION.

In the dog, the left coronary artery supplies the left ventricle and intraventricular septum. From thence arise the ramus descendens and the ramus circumflexus. The ramus descendens passes down the intraventricular groove, and gives off the septal branch; the ramus circumflexus passes to the left along the auriculo-ventricular groove. The right coronary artery supplies the right ventricle and auricle; it is much smaller than either branch of the left coronary artery. The branches of these arteries are physiologically, but not anatomically, terminal. The resistance in the narrow communicating branches is too great for an efficient circulation to be maintained through them. Thus, closure of any one of them is followed by sudden anæmia and infarction of the capillary areas which they supply. That the part of the heart wall supplied by the infarcted artery degenerates, has experimentally been determined in the dog.

¹ *Loc. cit.*; cf. Schiff, "Leçons sur la physiologie de la digestion," Paris, 1867, tome ii. p. 451.

² *Compt. rend. Soc. de biol.*, Paris, 1896, p. 561.

In 1698, Chirac¹ tied one of the coronary arteries in the dog, and found that the heart soon ceased to beat. Jenner established a pathological connection between angina pectoris and the reduction of the coronary circulation attending calcification of these arteries.

"The death of John Hunter in a paroxysm of angina, and the discovery that his coronary arteries were indeed calcareous, as Jenner had predicted, was a great stimulus to the clinical and pathological study of these vessels." Erichsen² tied the coronary arteries in the dog, and found the ventricles ceased to beat in a few minutes. The musculature of the ventricles speedily passes into inco-ordinate fibrillar contractions (*delirium cordis*). Ligaturing one of the large branches only is frequently sufficient to cause arrest,³ especially when the heart is lowered in vigour by cooling and exposure, or when the circulation is feeble. Arrest is produced in over 60 per cent. of the cases when the ramus circumflexus is ligatured alone. Ligature of either the right coronary artery or the ramus descendens far less frequently produces a fatal result. As the heart begins to fail after the ligation has been effected, the intraventricular and the aortic pressures steadily fall, while the diastolic pressure in the left ventricle and auricle rises, the ventricular beat becomes irregular, and the systolic output greatly lessened.

The heart after arrest, and even after it has passed into *delirium cordis*, can often be revived by re-establishing the coronary circulation. The failure of the heart is due to the anæmia produced.⁴ This is so, because (1) the severity of effect depends on the size of the artery; (2) the arrest can be produced by the injection of lycopodium spores⁵ into the coronary circulation, and without any mechanical interference with the heart; (3) the arteries may be exposed and prepared for ligation, and no arrest follows until the ligatures are drawn tight.⁶

Closure of all the coronary veins produces fibrillar contraction of the heart in the rabbit. This does not occur in the dog, owing to the fact that the blood can still find an exit into the cavities of the heart through the *venæ Thebesii*.

On establishing an artificial circulation through the left coronary artery of the isolated heart of a cat, Porter⁷ found that strong and regular contractions were maintained by a circulation of 4 cm. of blood per minute. Probably about 10 to 20 cms. of blood per minute must pass through the coronary circulation to maintain the heart of a moderate-sized dog in efficiency. While the force of the ventricular contraction is immediately increased by a greater flow of blood through the coronary arteries, the frequency of the heart is largely independent of the blood supply.⁸

⁸ Magrath and Kennedy, *loc. cit.*

The circulation in the heart is peculiar, because, during each systole, the tension of the ventricular muscle rises above the aortic tension. The blood in the coronary arterioles and arteries is thus driven on into the veins, and back towards the aorta, and the cardiac vessels empty during systole and fill again during diastole. Porter's observations on the veins of the heart, made with minimum manometers, give no support to the view that the heart acts on the coronary circulation to any extent as a suction pump, although efficiently as a force pump.¹ A shortening of the diastolic period lessens the nutritive supply to the heart. Similarly, diastolic distension of the left heart by "back pressure" lessens the coronary flow. These are facts of great pathological importance.

Newell Martin² observed that the coronary arteries dilated on excitation of the peripheral end of the vagus nerve, and during asphyxia. In the latter case, the dilatation occurred before the rise of aortic pressure. These effects Martin ascribed to the influence of coronary vasomotor nerves. Roy and Adami³ also obtained some evidence of the existence of vaso-dilators passing to the heart by the vagus and vaso-constrictors by the sympathetic.

VASOMOTOR REFLEXES.

The arterial pressure is affected reflexly by stimulation of any sensory nerve in the body. Sudden pallor of the face resulting from severe pain, blushing from emotional causes, erection of the cavernous tissue of the genitals from sexual excitement, are examples of common observation. Experimental stimulation of any sensory nerve in the body can produce vaso-constriction; it may, in certain conditions, produce vaso-dilatation.

It seems probable that vasomotor reflexes can be excited from excitation of sensory nerves in the walls of the vessels themselves.⁴

In regard to local reflex vasomotor changes, the following observations of Marey are of considerable interest. If the point of a pencil be drawn across the forearm, a white line due to the expression of the blood immediately results. This line rapidly disappears, but after an interval of half a minute reappears once more, and then lasts for some minutes. The white line, on its second appearance, irradiates into neighbouring parts. If the pencil point be drawn down the arm with violence, the primary white line is replaced by a red line. Around this there appears secondarily a white area of some extent. The irradiation of the white area into neighbouring parts, and its slow appearance, suggest that the phenomenon is of reflex origin.⁵

Reflex vasomotor effects generally appear in the vascular area from which the sensory excitation arises. Thus, on stimulating the tongue, the submaxillary gland flushes.⁶ On exciting the posterior auricular nerve in the rabbit, the vessels of the ear either first contract and then

¹ Porter, *Rep. Brit. Ass. Adv. Sc.*, London, 1897.

⁶ Bernard, *Journ. de la physiol. de l'homme*, Paris, 1858, tome i. p. 656.

dilate, or primarily dilate.¹ On stimulation of the central ends of the posterior roots of the eleventh to the thirteenth thoracic nerves, the kidney expands.² Excitation of the entrance to the glottis flushes the mylo-hyoid muscle of the frog.³

The sensory excitation of one side of the body frequently evokes vasomotor changes on both sides. Thus a drop of mustard, introduced into the lymph sac of the frog's leg, causes congestion of the leg on the same side, and contraction of the vessels on the opposite side.⁴ Compression of the median artery of the rabbit's ear with the finger-nail causes dilatation of that ear and contraction of the opposite ear. Stimulation of the central end of the posterior auricular or sciatic nerve on one side, may cause vasomotor changes in both ears or both hind-limbs. Excitation of the mucous membrane of the nose may cause vascular dilatation all over the face, but more on the same side as the stimulus.⁵

It is a simple experiment to verify the fact that the vessels of the one arm contract, if the other be placed in hot water. Similarly, by electrical excitation of the arm, vasomotor changes may be evoked in the opposite arm.⁶ The latent time between the excitation and the reflex results usually occupies several seconds. The place and the kind of stimulus influence the reflexes obtained. For example, greater changes of general arterial pressure are evoked by excitation of the posterior roots of the thoracic nerves than by stimulation of the peripheral nerves.⁷ The afferent fibres from the viscera produce the most marked vasomotor reflexes.⁸

In lightly curarised rabbits, a rise of arterial pressure can be evoked by blowing on or stroking the skin, while more violent stimulation by chemical irritants or heat scarcely produces any effect.

Although the usual result of stimulating a sensory nerve is a reflex rise of arterial pressure, a fall may occur. There is one afferent nerve, and one only, which constantly produces this result, and that is the depressor nerve (see p. 59). Efforts have been directed towards finding depressor fibres in the common nerve-trunks. General reflex dilator effects are often obtained on excitation of a sensory nerve, when the vasomotor tone is weakened after prolonged experiment,⁹ or during administration of chloral and chloroform.

Hunt¹⁰ has succeeded in demonstrating afferent depressor fibres in the central end of the sciatic nerve by the following methods:—

1. On regeneration of the nerve after section, the depressor fibres are the first to recover their function. Thus, a rise of arterial tension results from stimulation of the central end of a normal sciatic, a fall of tension from excitation of the regenerating sciatic. 2. Excitation with a feeble strength of current is more likely to produce a fall, while a strong current produces a rise of pressure. 3. After cooling or long exposure of the sciatic nerve, depressor effects may be evoked.

Hunt classifies the afferent nerves in reference to their reflex vasomotor

powers as follows:—1. Nerves which always produce a fall of arterial tension (*e.g.* the depressor). 2. Nerves which sometimes produce a fall, sometimes a rise (*e.g.* the vagus). 3. Nerves which usually occasion a fall (*e.g.* the glosso-pharyngeal). 4. Nerves from which primary depressor effects can only be obtained by special means (*e.g.* the sciatic, anterior crural, ulnar, median, and intercostal).

He states that the power of the depressor nerve, which acts mainly on the splanchnic area, is not abolished by curari. On the other hand, the depressor power of other afferent nerves, which act mainly on the vascular areas of the skin and muscles, is abolished by curari.¹

¹ It has been stated on p. 146 that Gulland has failed to demonstrate vasomotor nerves in the vessels of the pia mater. Since then, however, various observers, including Gulland himself, have been able to show the usual perivascular nerve-plexuses upon the cerebral vessels, *Brit. Med. Journ.*, London, 1898, vol. ii. p. 781. The existence of cerebral vasomotor nerves cannot therefore be denied, and we must assume that the experimental evidence remains as yet inconclusive, owing to the extreme difficulty of separating passive changes, brought about by the slightest alterations in the general circulation, from active vasomotor effects.—*Note added in September 1898.*

THE CONTRACTION OF CARDIAC MUSCLE.

By W. H. GASKELL.

THE MEANING OF THE HEART-BEAT.

IN the early days of physiology, *e.g.* in the time of Haller, the beat of the heart was supposed to be caused by the direct action of the blood as it flowed through the cavities of the heart. It was soon, however, apparent that the heart of such an animal as the frog could beat out of the body when there was no blood flowing through it; the heart-beat, consequently, was clearly not due to the movement of the blood, but to some peculiarity of the heart-tissue itself; it was therefore said that the tissue of the heart possessed in itself automatic rhythmical power. Then came the discovery of Remak,¹ that groups of ganglion cells were present in the sinus venosus of the frog's heart, with the subsequent discovery of Bidder² of the two large masses of ganglion cells at the junction of auricles and ventricle, and of Ludwig³ of the ganglion cells in the inter-auricular septum. At this period the automatic rhythm of respiration was ascribed to the action of groups of nerve cells in the respiratory centre, so that it was natural, indeed inevitable, that a similar mechanism should be assumed to explain the automatic cardiac rhythm. Hence arose the conception that Remak's ganglia in the sinus venosus acted the part of an automatic rhythmical centre, sending out impulses to the cardiac muscular tissue at regular intervals, and so caused the beat of the heart.

This view received apparently its confirmation and its proof by the well-known experiments of Stannius,⁴ which, according to Rosenthal,⁵ were to be explained on the same principles as he had already laid down for the respiratory centre.

¹ *Arch. f. Anat., Physiol. u. wissenschaft. Med.*, 1848, S. 139.

² Bidder and Rosenberger, *ibid.*, 1852, S. 172.

³ *Ibid.*, 1848, S. 139.

⁴ *Ibid.*, 1852, S. 85.

⁵ "Bemerkungen ueber die Thätigkeit der automat. Nervencentra insbesondere ueber die Athembewegungen," Erlangen, 1875.

In both cases Rosenthal ascribed the rhythmical activity to the automatic action of groups of easily excitable nerve cells. In the case of respiration, these cells were those governing the movements of the ordinary muscles of inspiration; in the case of the heart, the cells in the sinus venosus. In both cases, additional, subsidiary, less excitable centres were assumed to exist, which required a stronger stimulus to make their presence manifest; such centres were, in the case of respiration, the centres connected with the extraordinary muscles of respiration, which were thrown into activity by increasing vensity of the blood; and in the case of the heart, Bidder's ganglia in the auriculo-ventricular groove, which, though normally inactive, were capable of being aroused by a sufficiently strong stimulus. The first Stannius ligature, or cut, at the junction of sinus and auricles, caused standstill, according to this view, because it removed the automatic motor centre or Remak's ganglia; the second Stannius ligature, in the auriculo-ventricular groove, caused the ventricle to beat again, because it supplied the extra stimulus necessary to set in action the less excitable motor cells of Bidder's ganglia.

Such, then, was the conception of the heart-beat. A motor centre was supposed to exist in the sinus, which was usually active, thus resembling the ordinary centre for respiration, and which sent out discrete impulses to the muscular tissue of the auricles and ventricle. This centre was supposed to be supplemented by a less excitable motor centre between auricle and ventricle, which was normally inactive, but available, like the extraordinary centres of respiration, for employment upon an emergency.

This view soon began to receive modification, when, in consequence of the experiments of Eckhard¹ and Foster and Dew Smith,² it was proved that the ganglion-free apex of the frog's heart was thrown into rhythmical activity by the passage of a constant current through it, and also that this same apex would beat rhythmically when supplied with a nutritive fluid under pressure, as proved by the experiments of Bowditch³ and Merunowicz⁴ in Ludwig's laboratory.

These experiments were proof positive that, under certain conditions, the muscular tissue of the heart would beat rhythmically without the presence of motor nerve centres. It was however argued, that such rhythmical contractions had nothing to do with the normal beating of the heart, but were due to the foreign stimulus of the electrical current on the one hand, and of the chemical ingredients of the nutritive fluid on the other; and Bernstein⁵ showed, by clamping the ventricle between the base and apex, that if the apex were cut off from the base, then, although kept still supplied with blood from the contractions of the base, it yet remained motionless, and never contracted of itself. In other words, the stimulus of its own blood was not sufficient to arouse rhythmical contractions in the apex of the frog's ventricle. Bernstein, however, did not realise the importance of another factor in the causation of rhythm in the isolated apex, namely, the pressure in its cavity; and at Foster's suggestion I was able to show, by clamping the aorta, and so increasing the pressure in the cavity of the ventricle, that the apex of the frog's heart, when isolated after Bernstein's method,

⁵ *Centralbl. f. d. med. Wissensch.*, Berlin, 1876, S. 385.

would beat rhythmically, provided that there was sufficient tension of its walls.¹ The importance of the tension of the walls in the production of rhythmical contractions of the apex of the heart was also, about the same time, insisted on by J. M. Ludwig and Luchsinger,² who showed that the rate of rhythm was closely associated with the pressure within the cavity.

From these experiments the conclusion followed, that the muscular tissue of the heart was of such a character, that a sufficiently powerful constant stimulus, whether electrical, chemical, or mechanical, did not produce a constant tonic contraction, but was manifested as a rhythmical series of contractions.

The net result of these facts upon the minds of the upholders of the motor ganglia theory was to cause them to put forward the proposition, that the impulses sent out by the centre in the sinus were not discontinuous but continuous, and that the cardiac muscle responded to this continuous stimulation by a rhythmical contraction.

Pari passu with the question of the meaning of the cardiac rhythm goes the question of the sequence of the contractions of the different parts of the heart, and here again we see the ganglion cells conspicuously pressed into service. The original view held by Haller, and others of his time, was that a peristaltic wave of contraction passed over the heart from the great veins to the aorta. This conception of a peristaltic muscular wave was given up largely, because it was noticed by Schiff and others that the ventricle of the dying heart frequently beats at a different rate from that of the auricle; it was therefore asserted that such a phenomenon could not be due to a peristaltic wave, but showed that a co-ordinating mechanism of a presumably nervous nature had got out of gear, and therefore the ventricle no longer responded in due sequence to the auricle.

This co-ordinating mechanism was held to be situated in the cells of Bidder's ganglia, in consequence mainly of the experiments of Eckhard³ and Marchand,⁴ which appeared to indicate that the sequence of the contraction of ventricle upon that of auricle depended upon the integrity of these ganglia; also, that the time which elapsed before the ventricle contracted upon stimulation of a point in the auricle was too long for the passage of a wave of muscular contraction; this greater length of time must therefore be explained by a delay caused by the passage of the impulse through a special nerve centre—in other words, through Bidder's ganglia.

So far, then, the conception formed was:—Motor ganglia in the sinus send out a continuous impulse along nerve fibres to auricle and ventricle; such impulse produces a discontinuous rhythmical result, owing to the nature of the muscular tissue; the sequence of the contraction of the ventricle upon that of the auricle is due to a delay in the impulse, owing to its passage through the ganglia at the auriculo-ventricular junction.

Such was the condition of things when I commenced my investigations in 1881, and it seemed to me that the question whether continuous

³ *Beitr. z. Anat. u. Physiol. (Eckhard)*, Giessen, Bd. vii. S. 191.

⁴ *Arch. f. d. ges. Physiol.*, Bonn, 1878, Bd. xvii. S. 137.

or discontinuous impulses passed from the sinus to auricle and ventricle, could be easily answered by increasing the excitability of ventricle or auricle respectively. A more excitable ventricle must respond to a constant stimulus with contractions at a more rapid rate than a less excitable one; while, on the other hand, the rate would remain unaltered if the impulses from the sinus were discontinuous, and the excitability of the ventricle only were altered.

For this purpose I made use of a method of registering the heart contractions which up to that time had not been used, and has since proved of great value; this method is the suspension method. The contraction of the auricle and ventricle are registered separately by means of two levers, which are attached by means of threads to the apex of the ventricle and auricle respectively; the one lever is pulled downwards against an elastic spring, and the other upwards. The heart is held fast by means of a screw-clamp in the

FIG. 101.—Frog's heart. Suspension method. Clamp in auriculo-ventricular groove. Auricles and sinus above clamp, ventricle below. Coil round auricles and sinus; heated between the vertical lines. The ventricular contractions at first keep pace with the quickening auricular, then are unable to do so, and at *a* the ventricle contracts to every second of the auricular contractions.

auriculo-ventricular groove. This clamp is provided with a fine screw, which can easily be adjusted so as to hold the heart firmly, without injuring the tissue. In this way the contractions of auricle and ventricle can be registered separately.

The excitability of a tissue can be increased by raising its temperature up to a certain limit. In my experiments I made use of a coil of thin wire, which was heated by the passage of a galvanic current through it. This coil was placed so as to surround either the auricles and sinus or the ventricle, so that in this way the auricular or ventricular side of the heart could be heated separately. Curves so obtained are given in Figs. 101 and 102, taken from my paper in the *Philosophical Transactions*,¹ and it is seen that, whereas heating the auricles and sinus causes a great increase in the rapidity of the beats both of auricles and ventricle, no alteration of rate of rhythm in the ventricle is produced by heating the ventricle alone, but the force of its contraction is altered.

¹ "On the Rhythm of the Heart of the Frog and the Nature of the Action of the Vagus Nerve," *Phil. Trans.*, London, 1882, p. 993, Figs. 1 and 2, Pl. lxxvii.

From this experiment I concluded, on the assumption that the motor ganglia in the sinus are the cause of the heart-beat, that they send out discrete and not continuous stimuli to the muscular tissue of the various cardiac chambers. The next question that arose in my mind was, Is it really clear that the sinus ganglia do originate nerve impulses to the cardiac muscle? or is it not that, whereas all parts of the

FIG. 102.—Heart of toad. Suspension method. Clamp in auriculo-ventricular groove. Ventricle above clamp, auricle and sinus below. Coil round ventricle heated between the vertical lines. The ventricular contractions diminish in force during the heating of the ventricle, but no alteration whatever occurs in the rate of beat.

muscular tissue of the heart possess the power of rhythmical contraction to a greater or less degree, some parts possess that power to such an extent that their contractions are automatic?

To answer this question it appeared to me very necessary to investigate other hearts than that of the frog, for in the frog the nerves and ganglion cells between the sinus and ventricle are situated in the septum of the auricles, and are therefore not easily exposed for the purposes of experiment. On the other hand, in the case of the tortoise, the septum between the auricles is free from nerve trunks and nerve cells, and all the nerves and cells lie superficially in the flat base which connects the two auricles, and continues on from the sinus to the ventricle.¹

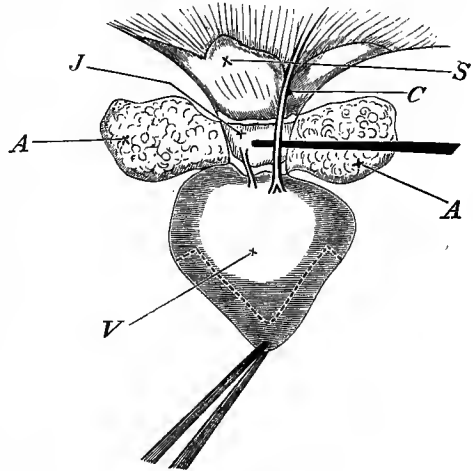

FIG. 103.—Heart of tortoise. Description of letters in text.

This flattened part or junction-wall between the two auricles is represented in Fig. 103, *J*. On each side of it is seen the reticulated tissue of the auricle proper (*A*), and the manner in which the junction-wall connects the sinus (*S*) and ventricle (*V*) is also shown. This basal auricular wall exists also in fishes (described by MacWilliam² as *sinus-extension*), in crocodiles, and in *Chelonia* generally, and in all cases carries the nerve trunks and coronary veins wherever

¹ Gaskell, "On the Innervation of the Heart, with especial reference to the Heart of the Tortoise," *Journ. Physiol.*, Cambridge and London, 1883, vol. iv. p. 43.

² "On the Structure and Rhythm of the Heart of Fishes, with especial reference to the Heart of the Eel," *Journ. Physiol.*, Cambridge and London, 1885, vol. vi. p. 192.

a coronary system is present. A well-defined coronary system exists for the ventricle of the tortoise, and the coronary veins empty into the sinus venosus. In the land-tortoise (*Testudo græca*) it very frequently happens that one of these coronary veins runs free from ventricle to sinus, so that, as is shown in Fig. 103, a seeker can be slipped under it without injury to any part of the heart; it also usually happens that one of the nerve trunks which pass from the sinus to the auriculo-ventricular junction, accompanies this free coronary vein, so that in this animal we have a free intracardiac nerve between sinus and ventricle, whose functions can be examined without injury to the rest of the heart. This nerve, which experiment shows to be connected with the vagus, I have called the *coronary nerve*. In Fig. 104 the appearance of the heart when suspended is shown, and the position of the coronary nerve, *C*. In the tortoise, as in all other animals, the cardiac ganglion cells are found in connection with the main trunks of the intracardiac vagus nerves. As described in my paper (p. 62), the largest accumulations of them are found at the bifurcation of the larger vagus nerve trunks in the sinus, in the junction-wall or sinus-

extension between the two auricles, and in the termination of this wall in the auriculo-ventricular ring. In all these places the ganglion cells are also found on the smaller branches of the nerves which ramify over the sinus, and form a rich plexus in the junction-wall between the two auricles, and at the junction between auricles and ventricle. The nerves, with their accompanying ganglion cells, are distributed around the whole junction of the sinus and the auricles, and from this ring, as well as from both sides of the junction-wall between the two auricles, nerve fibres with ganglia are plainly seen passing into the auricular tissue; as the nerves pass further into the tissue the ganglia become more and more scarce, and soon disappear. If, then, we call the junction-wall between the two auricles the flattened part, and the rest of the auricles the bulged part of the auricles, we find that the larger nerve trunks and ganglia of the auricles are found only in those parts of the bulged portion which are in the immediate vicinity of this flattened part. Again, at the junction of the auricles and ventricle the nerve trunks passing from the junction-wall of the two auricles form a rich plexus, containing large

groups of ganglion cells along the line where this junction-wall passes into the auriculo-ventricular ring—along, that is, the side of the ring furthest removed from the aorta, which may be called the basal part of the ring. Thence a plexus of nerve fibres, also containing ganglia, though much more sparingly than the basal portion, passes round the auriculo-ventricular ring. From this ganglionic nervous ring, fibres ramify over both the ventricle and the auricles, in each case accompanied by ganglion cells for a short distance.

We see, then, that the ganglion cells in the sinus and sino-auricular junction correspond to Remak's ganglia in the frog. The cells in the junction-wall between the two auricles correspond to those on the inter-auricular nerves in the septum between the auricles of the frog, and the cells of the auriculo-ventricular ring correspond to Bidder's ganglia in the frog.

In the tortoise, as in the frog, the Stannius experiment succeeds; we see here, however, very plainly, what had been already observed by Stannius¹ in the frog, that the standstill after removal of the sinus is not permanent; the auricle and ventricle commence after a time to beat again, at first slowly, then gradually quicker and quicker, until at last a good steady rate of rhythm is observed. This rhythm of development is characteristic. If the cut is anywhere between sinus and ventricle, the same thing may be observed; the difference being that the primary standstill is longer the nearer to the ventricle the cut is made; and the rate of rhythm finally obtained is liable to be less the nearer to the ventricle. In all cases the first effect of the section is to cause one or more contractions followed by standstill.

When the cut is made close against the ventricle in the auriculo-ventricular groove, *i.e.* corresponds to the second Stannius ligature, the ventricle beats rapidly for a time, gradually slowing more and more, until at last it stands still; then after a time it begins to beat again, at first very slowly, steadily gaining in rate until it has reached a steady uniformity.

We see, in fact, that the ligature or section in the auriculo-ventricular groove produces two different rhythmical phenomena in the ventricle; on the one hand, a series of rhythmical contractions take place immediately upon the section or ligature, which are characterised by the peculiarity that the rate of the contractions is quickest at the commencement, and then gradually becomes slower and slower, until a standstill occurs; this may be called a rhythm of excitation. On the other hand, in contradistinction to this rhythm of excitation, a subsequent more permanent series of rhythmical contractions, which may be called the rhythm of development, occurs under favourable conditions in the ventricle, after the rhythm of excitation is over.

This rhythm of development, like the similar rhythm in the auricle after the first Stannius ligature, or section, is characterised by its slow rate at the commencement, and its gradual development to a steady rate, the rapidity of which depends upon the rhythmical modulus of the tissue and the conditions of nutrition, temperature, etc. If, then, we can remove this rhythm of excitation, the effect of the ligature at the auriculo-ventricular groove would be no different from that of the ligature at the junction of sinus and auricles, or across any part of the auricles. This can be done in the frog by means of a clamp with a fine screw adjustment, for it is then possible, by very slowly tightening the clamp in the auriculo-ventricular groove, to bring the ventricle to a

¹ Stannius, *Arch. f. Anat., Physiol. u. wissenschaft. Med.*, 1852, S. 81.

standstill without provoking any more rhythm of excitation than an occasional beat or two upon each separate turn of the screw, just as may be seen when the ligature or the clamp is applied to any part between the sinus and the ventricle.

I conclude, then, that the phenomena following upon section are of the same kind wherever that section is situated; the part in connection with the sinus continues its regular beat; the part separated from it remains still for a variable time, and then, according to its inherent rhythmical power, develops a rhythmical beat of its own, the rate of that rhythm when fully developed, and the length of time that the standstill lasts, being correlated with the rhythmicity of the tissue. Further, the same experiment can be applied to every part of the heart, for I have seen the same kind of standstill, followed by a rhythm of development, take place when a strip of muscle, taken from the apex of the ventricle or the auricle, is suspended in the same way as the whole ventricle or auricle.¹ It is true that the development of this spontaneous rhythm is assisted by the occasional stimulation of the strip by means of a weak tetanising current, and the regular testing of the condition of the strip by means of single induction shocks; but it is not true that such rhythm is dependent upon such artificial stimuli, and owes its existence to polarisation phenomena in the strip, as suggested by Langendorff,² for, as pointed out in my paper,³ I have seen control strips develop a spontaneous rhythm, when they have simply been suspended, and have not received a single electrical stimulus of any kind; the only difference between the two strips being, that the one which had been taught to beat commenced its spontaneous contractions quicker than the control.

In addition, as mentioned in the same paper,⁴ the strip from the ventricle, when once spontaneously beating, will continue to beat for as long as thirty hours; since then I have once observed a strip from the apex of the ventricle, suspended in a moist chamber, beat for as long a time as a hundred hours. Clearly, then, this rhythm cannot be explained by any artificial electrical action. It is, I think, highly probable that the tension of suspension plays a distinct part in its causation, just as the tension of distension in the case of the apex of the frog's ventricle; though, that it is not entirely dependent on the stimulus of tension, is seen by the fact that the strip or even parts of the strip will continue beating rhythmically in a watch glass, after the spontaneous rhythmical beat has once become well established. The main condition necessary for the establishment of this rhythm is, it appears to me, some unknown factor in the nutrition of the tortoise, for since the publication of that paper I have attempted to demonstrate to my class the spontaneous beat of the strip whenever I have managed to obtain a tortoise, and have been much annoyed to find that again and again I have failed to obtain any sign of rhythmical activity in the strip, and, even more than that, I have sometimes failed to obtain any spontaneous activity in the isolated entire ventricle. During the years 1882 and 1883, when my tortoise experiments were in constant progress, I had a large supply of animals, carefully tended, fat and healthy, in the very best condition, and I never failed once in obtaining the results described in my paper.

¹ *Op. cit.*, pp. 51-56.

² "Rhythmik und Automatik des Frosch-herzens," Leipzig, S. 57.

³ *Op. cit.*, p. 54.

⁴ *Ibid.*, p. 53.

The evidence, then, points absolutely to the conclusion that the muscular tissue of the heart possesses the power of rhythmicity, *i.e.* answers to a sufficient constant stimulus with a series of contractions, and that certain parts are more rhythmical than others, so that in them the rhythmical contraction takes place automatically, without the necessity of any continuous external stimulus.

Upon what does this difference of rhythmicity depend? It is acknowledged on all sides that such difference is real, and it has been largely supposed that the difference is due to the presence or absence of ganglion cells, because ganglion cells are found in the sinus, in the auriculo-ventricular junction, and between sinus and ventricle—in those parts, in fact, where the spontaneous rhythm is most easily observed; also, because a rhythmical action is supposed to necessitate a central nervous system, and finally because there is apparently nothing else to which to attribute this difference of rhythmical power.

But is there really nothing else peculiar to those parts where rhythm is easiest?

If we consider its mode of development, we find that in all vertebrates the heart arises from two longitudinal veins, or venous sinuses, which coalesce to form the sub-intestinal vein and heart; the simple tube so formed, with its circular muscular coat, becomes twisted on itself, and parts of it develop bulgings, the commencement of the auricles and ventricles, in consequence of which the simple circular arrangement of muscle fibres becomes the complex arrangement which is ultimately found. With this special growth of the parts of the tube by which the heart cavities are formed, is correlated a more rapid contraction of the specialised parts of the muscular walls, so as to ensure a more rapid emptying of the separate cavities, and thereby make the heart more efficient as a force-pump. The development of this nearer approach to striated muscle is made at the expense of the original rhythmical power, so that finally the muscular tissue of the heart becomes differentiated into muscle of varying rhythmical power, according to the amount of deviation from the original embryonic rhythmical muscle.

Those parts which remained least altered, both in the circular arrangement of their fibres and in their physiological status, are naturally the large veins, sinus, and junction of sinus and auricles; then the circularly arranged fibres of the auriculo-ventricular groove, *i.e.* the compressed remains of that portion of the original tube which, known as the *canalis auricularis*, separated the auricular from the ventricular bulgings; and, lastly, the *conus arteriosus*, which represents the final part of the tube beyond the ventricular bulging. In addition, there is in the tortoise a basal portion of the tube leading from sinus to ventricle, from which the bulged part of the auricles springs; this may be looked upon as a portion of the original tube, which has been only very slightly differentiated.

In fact, as can be readily understood, if the auricular and ventricular bulgings are special modifications of the muscular tissue, for the purpose of forming rapidly contracting roomy chambers—in other words, for the purpose of forming a heart rather than a rhythmically contractile tube—then the very parts which were left unmodified would naturally continue to carry the main intracardiac nerves with their accompanying ganglion cells; so that in the sinus, in the auricles, and in the auriculo-

ventricular ring, the ganglionic structures and the less modified muscular tissue would be coterminous.

If, then, the rhythmical power depends upon the presence of more embryonic muscle, we ought to find those parts which we suppose to contain such muscle especially rhythmical, quite independently of the presence or absence of ganglion cells in them. We ought, in fact, to find, according to our theory, that the *bulbus arteriosus* contracts rhythmically with great ease, either spontaneously, or with such slight constant stimulus as is implied by a steady distension of its walls; we ought to find that the muscular auriculo-ventricular junction will respond to a stimulus with a series of contractions, and not with a single contraction, as in the case of the auricular or ventricular muscles proper—in this way, explaining incidentally the phenomenon of the second Stannius ligature; we ought to find that in the large veins, even in those parts which are outside the region of ganglion cells, spontaneous rhythmical contractions take place upon isolation.

With respect to the bulbus, the experiments of Engelmann¹ in 1882 have shown most conclusively how easily this part, when isolated, will beat rhythmically; and the observations of Munk,² Löwit,³ and others, with respect to the presence of ganglion cells in the bulbus, have failed to convince Engelmann that ganglion cells are really present there. What Engelmann has observed for the bulbus arteriosus in the frog can be still better seen in the conus arteriosus of the skate, where there is a long stretch of circularly arranged muscular tissue, the merest touch of any part of which is sufficient to start a regular rhythmical series of contractions.

Passing now to the remains of the *canalis auricularis*, the auriculo-ventricular ring of muscle, we see that the second Stannius ligature, or cut, not only stimulates this ring of tissue, but also the two Bidder's ganglia as well, so that the rhythmical series of contractions which results may be due to the stimulus affecting the special rhythmical tissue of the ring, or directly stimulating the nerve cells of Bidder's ganglia. The supporters of the motor ganglia theory of the heart's beat have always attributed this rhythm to a stimulation of Bidder's ganglia, and the latest supporter of this theory, viz. Kaiser,⁴ asserts definitely that, if Bidder's ganglia are removed, then ligature or section of the auriculo-ventricular junction produces no special effect; that, in fact, each stimulus applied now produces only a single contraction, just as in the case of the auricular or ventricular muscle, and not, as is always the case before the removal of the ganglia, a series of contractions. It is impossible to imagine a stronger piece of evidence that the rhythm is dependent on motor ganglia than this—a particular part of the heart always responds with a series of contractions to a single stimulus, but upon removal of the ganglion cells gives only a single contraction to a single stimulus. If this experiment is true, then most assuredly the motor ganglia theory is put on a basis such as it never had before, and, however improbable it may appear, must be taken into serious consideration.

Kaiser's argument is—Any stimulus applied here always gives a series of contractions, not a single contraction; this is due to the stimulus exciting a nerve

¹ *Arch. f. d. ges. Physiol.*, Bonn, 1882, Bd. xxix. S. 425.

² *Arch. f. Physiol.*, Leipzig, 1878, S. 569.

³ *Ibid.*, 1881, S. 399.

⁴ *Ztschr. f. Biol.*, München, 1894, Bd. xxx. S. 302.

centre in the shape of Bidder's ganglia, because when that centre is removed then only a single contraction takes place upon a single stimulus. It follows, therefore, that if Bidder's ganglia and the muscular tissue of the auriculo-ventricular ring be exposed, a stimulus to either ganglion ought to give a series of contractions, while a stimulus to the auriculo-ventricular muscular ring ought to give only a single contraction.

It is possible to test this question in the following manner:—Slit up one auricle and the ventricle, and pin back so as to expose the septum; the two vagi nerves on the septum, with their terminations in Bidder's ganglia, are then most easily seen, as well as the muscular ring between auricles and ventricle, and the whole field can be explored under a lens with the point of a needle before and after removal of the septum and Bidder's ganglia. Now, cut away the sinus, the whole preparation remains quiescent; touch the outlying auricular or ventricular tissue with the needle point, each time a single contraction takes place, and no more; touch either of Bidder's ganglia, not a single contraction takes place; pierce it again and again, and pull it about, no sign of contraction. Touch the auriculo-ventricular ring of muscle with the slightest stimulus, immediately a series of rhythmical contractions occurs. It is most striking to see, after removal of the septum, how every portion of auricular and ventricular tissue can be explored up to the very edge of the ring, without obtaining more than a single contraction, while immediately the needle touches the muscular ring a series of rapid contractions results. Conversely, the two Bidder's ganglia can be cut away, and yet stimulation of the ring will produce a rhythmical result. In this latter experiment, it is of course difficult to say whether all the cells have been removed; and it is this fact, that the certainty of having removed all the cells of the ganglia carries with it the probability of nearly complete destruction of the auriculo-ventricular ring, which renders Kaiser's experiment of doubtful value. The exploration of the uninjured tissues by the fine point of the needle is much more valuable, and appears to me conclusive against his view. Unfortunately, the experiment, simple as it appears to be, is not always successful, because it is not always possible to obtain standstill by the removal of the sinus when the heart has been cut open. I performed the experiment successfully many times during the winter months, but have hitherto failed to obtain standstill during the spring months. Further investigation of this crucial experiment is advisable.

Finally, Engelmann,¹ in a recent paper, has shown that parts of the large veins which continue to beat normally and spontaneously after separation, which in fact are part of the normal rhythmical tissue from which the heart-beat starts, are outside the region of ganglion cells, and that, therefore, the spontaneous heart-beat starts from a non-ganglionic region of muscular tissue.

It still seems then, to me, that the explanation which I gave in 1883, of the reason why different parts of the heart differ in rhythmical power—an explanation dependent upon morphological differences of the muscular tissue and not upon the presence or absence of ganglion cells—is right. Nothing that has since been written has tended to make me alter that opinion. On the contrary, Engelmann² and W. His, junior,³ in their recent papers, have both come to the conclusion that the varying rhythmicity of different parts of the heart is due to exactly the same morphological arrangement of the muscular tissue as I had already pointed out.

¹ *Arch. f. d. ges. Physiol.*, Bonn, 1896, Bd. lxx. S. 109.

² *Ibid.*, 1897, Bd. lxx. S. 535.

³ *Arch. a. d. med. Klin. zu Leipzig*, 1893, Bd. i. S. 14-49.

We may then sum up this section by saying that the beat of the heart of cold-blooded vertebrates depends upon the rhythmical power of the muscular tissue of the large veins and sinus being greater than the rhythmical power of the other parts of the heart, and that in all cases the greater or less rhythmicity of any part of the heart depends upon the nature of the muscular fibre of which that part is composed, and not upon the presence or absence of ganglion cells.

ON THE SEQUENCE OF THE CONTRACTIONS OF THE DIFFERENT PARTS OF THE HEART.

In the same way precisely as we have been driven to the conclusion that the beat of the heart depends upon the inherent rhythmical power of its muscular tissue, and that some parts beat more easily than others, because their rhythmical power is greater, so also are we driven to the conclusion that the sequence of the contractions of the different parts of the heart is due to a peristaltic wave of contraction which starts from the most automatically rhythmical tissue, and travels over the rest of the heart with varying speed, quickest over the tissue which has become modified so as to approach more nearly in its properties to ordinary striated muscle, namely, the reticulated bulged portion of the auricle and ventricle, more slowly over those parts which retain a more embryonic character, namely, the auriculo-ventricular muscular ring, and the bulbus or conus arteriosus. Starting with a tube of equal character throughout, we see how, by the modification of portions of that tissue in the two regions of the auricle and ventricle into a more rapidly contracting, more rapidly conducting, less rhythmical tissue, we obtain an efficient heart, which shall not merely pass the blood on, but, by the forcible and nearly simultaneous contraction of all parts of its auricular and ventricular walls respectively, keep up in a most efficient manner a high blood pressure in the arterial system, while at the same time, owing to the absence of modification of the tissue between the auricles and ventricles, *i.e.* the *canalis auricularis*, whereby it still retains its original more rhythmical but slower conducting power, the useful purposeful pause between the auricular and ventricular contractions is brought about.

The experimental evidence which I brought forward in 1883,¹ shows clearly that such an explanation is the true one, and that therefore the sequence of the contractions of the different parts of the heart is not dependent upon the presence of ganglion cells any more than the heart-beat itself.

The fundamental experiment, and it is one of very great importance for all questions connected with the heart, is an experiment of the same character as that originally performed by Romanes² on the muscular tissue of the *Medusæ*; an experiment, namely, of cutting the muscular tissue of the heart, so as to leave only a small bridge of tissue over which the contraction must pass, and then studying the block to the passage of that contraction caused by reducing this bridge more and more.

If the heart of the tortoise be suspended, as in Fig. 104, and one auricle be cut away, then a section through the basal part of the auricles into the auricular tissue proper will divide all the nerves with their ganglion

¹ *Journ. Physiol.*, Cambridge and London, 1883, vol. iv. pp. 61-81.

² *Phil. Trans.*, London, 1875, vol. clxvi. p. 269.

cells which pass from the sinus to the auriculo-ventricular junction, so that, as seen in Fig. 105, if the cut be carried far enough, the auricle is divided into two parts, *As*, a part connected with the sinus, and *Av*, a part connected with the ventricle, and the only connection still left between sinus and ventricle is by means of a narrow bridge of tissue at the apex of the auricle which connects *As* and *Av*. Conversely, owing to the presence of the free coronary nerve between the sinus and auriculo-ventricular junction, it is possible to cut through the whole of the auricle and leave only the coronary nerve as connection between sinus and ventricle.

These two experiments show conclusively that the sequence of ventricular upon auricular contraction is not dependent upon the integrity of the nerve trunks which pass from the sinus to the auriculo-ventricular groove. For, in the first case, the sequence is never affected until the bridge of tissue at the apex of the auricle has become very small; and, in the second case, when the coronary nerve only is left, the rhythm of the beats of the ventricle and that part of the auricle still in connection with it never bears any relationship to the rhythm of the sinus, and that part of the auricle still left in connection with the sinus.

From these experiments it is seen that the ventricle contracts in sequence to the auricle, only when a wave of contraction is able to pass along *As* and *Av*.

I was able further to show that if the piece of tissue between *As* and *Av* is reduced sufficiently, then a block to the passage of the contraction from *As* to *Av* takes place of such a character, that, if the block is very slight, a distinct pause occurs at this point when the contraction wave which passes from the sinus along *As* reaches it before it passes along *Av*, a pause distinctly comparable to and resembling the pause which takes place at the auriculo-ventricular junction between the contraction of *Av* and the ventricle. If the block is more severe, then, instead of every contraction passing the blocking point, only every second contraction is able to pass, and therefore a contraction of the ventricle follows upon only every second auricular contraction. With a still more severe block it is possible to see only every third or every fourth contraction able to pass, and therefore to see the ventricle beating to every third or fourth contraction of the auricle. This latter rhythm cannot be obtained for any length of time, but it is

FIG. 105.—Heart of tortoise, suspended as in Fig. 104, to show appearance of preparation when a block is caused by slitting up the auricle.

easy to obtain a partial block, so that every second contraction passes, which may last a long while unaltered. Finally, if the cut is more severe still, then the block becomes absolute, and no contractions are able to pass; consequently *Av* and the ventricle remain absolutely still until they commence to beat with their own independent rhythm. Even when the block is apparently absolute, as long as a very small bridge of intact tissue remains, it is as a rule possible by vagus stimulation and other methods to overcome the block to a greater or less extent, with the result that as soon as a contraction passes, the quiescent ventricle immediately responds with a contraction.

A precisely similar experiment can be performed on the frog by means of the screw-clamp in the auriculo-ventricular groove.¹ According to the tightness of the clamp, the ventricle can be made to beat synchronously with the auricles, to respond to every second contraction of the auricles, to respond to every third, fourth, or other contraction, or to remain quiescent.

In fact, we see that we can artificially reproduce, by means of blocking to a greater or less extent the passage of the contraction wave from one portion of auricular muscle to the other, all the phenomena which are characteristic of the normal blocking at the auriculo-ventricular junction between the contractions of the auricle and ventricle. The muscular tissue of all parts of the heart can be blocked in this way—ventricle or auricle, it is all the same; by means of the clamp the apex of the ventricle can be made to respond to only every second contraction of the base, just as the whole ventricle to every second contraction of the auricle; it matters not the least whether nerve trunks and ganglion cells are present, all that is necessary is a continuity of muscular substance along which a contraction can travel.

Clearly, then, the natural pause between the contractions of auricle and ventricle, and the sequence of ventricular upon auricular beat, can be explained without the intervention of any special nervous mechanism, if the contraction of the heart signifies the passage of a contraction wave from one end of the heart to the other, over muscular tissue of varying power of conductivity. If part of the muscular tissue has been modified, so as to contract with greater rapidity, the contraction wave will necessarily pass more quickly over that part than over the more primitive, less modified tissue of other parts; in other words, the contraction wave will pass more rapidly over the reticulated tissue of auricle and ventricle than over the unaltered *canalis auricularis*, i.e. auriculo-ventricular muscular ring, or the *conus arteriosus*.

Precisely as in the question of the rhythm, so also of the sequence, the more rhythmical tissue of the auriculo-ventricular ring, and the *conus arteriosus*, conducts the contraction wave more slowly than the less rhythmical, more rapidly contracting tissue of the ventricle and auricle proper.

In strict accordance with this explanation of the meaning of the sequence, are the observations of Fano² on the rate of the contraction wave in the heart of the embryo. He found that the rate of travel of the wave in the heart of a chick on the third day of incubation, at 38° C., varied from 11.5 to 3.6 mm. per second, very much less than the rate observed by Engelmann,³ and by

¹ *Phil. Trans.*, London, 1882, pp. 999 and 1031.

² *Arch. per le sc. med.*, Torino, 1890, vol. xiv.

³ *Arch. f. d. ges. Physiol.*, Bonn, Bd. xi. S. 480.

Marchand,¹ in the muscular tissue of the ventricle of the frog, which they estimated as greater than 20 mm. per second.

If it be necessary still further to prove that the sequence of the ventricular upon the auricular contraction has nothing to do with the presence of ganglion cells at the auriculo-ventricular junction, it may be mentioned that the removal of the auriculo-ventricular ring in the tortoise bit by bit shows that those parts of the ring which contain ganglion cells in largest quantity, namely, the parts where the large nerves enter the ring, are not so efficient in maintaining the sequence of the contractions as those parts near the aorta where ganglion cells are comparatively scanty. It is also evident that the experiments which have been relied upon as strongly suggesting a co-ordinating centre for the due sequence of ventricular and auricular contractions, can be explained on the theory of blocking of a muscular wave of contraction. The three principal arguments used are—

1. Schiff's observation, that in the dying heart the ventricle beats more slowly than the auricle, and therefore the contraction is not of the nature of a peristaltic wave. The phenomena of the apparent independence of the beats of the various heart cavities during the process of dying are all beautiful illustrations of a gradually increasing block, first at the auriculo-ventricular junction, and then at the sino-auricular.

2. Eckhard's² observation that section of the septum together with its nerves in the frog causes the ventricle to beat independently of the auricle. In this case the slower beat of the ventricle observed by Eckhard was clearly not independent of the auricular beat, for he himself says that both auricular and ventricular contractions were stopped by stimulation of the vagus nerve, although the nerves of the septum were cut; plain proof that the ventricular rhythm in his experiments was not independent of the auricular, and that in cutting through the septum he had damaged the auriculo-ventricular muscular ring, and so caused a partial block.

3. Marchand's³ observation, that the time taken before the ventricle contracts when a stimulus is applied to the auricle is too long to be accounted for by the travel of a wave of contraction along muscular tissue; the delay he accounted for as due to processes going on in Bidder's ganglia, and to prove this he removed Bidder's ganglia, and then found the sequence gone. The first part of Marchand's proof is based on the erroneous assumption, that the rate of travel in the muscular tissue from auricle to ventricle is the same as that shown by Engelmann's observations in the ventricular muscle, whereas we have seen that the low conducting power of the auriculo-ventricular muscular ring is quite sufficient to explain Marchand's figures. As to his second argument, it is very difficult to remove Bidder's ganglia without seriously damaging the auriculo-ventricular muscular ring, especially if, as in Marchand's case, the attention is not particularly directed towards this ring. I have, however, succeeded in doing so, and found,⁴ as indeed did Bidder himself, no alteration of sequence whatever as the result of such removal. I conclude, therefore, that Marchand, as well as Eckhard, caused a block by damage to the auriculo-ventricular ring when he removed the two ganglia.

This, then, is the explanation of the sequence of the contractions. A rhythmical series of contractions start from the sinus, traverse the heart as peristaltic waves, and come out at the bulbus arteriosus; and with such an explanation one thing clearly follows—such contractions must pass over the heart, whether they start at one end or the

¹ *Arch. f. d. ges. Physiol.*, Bonn, 1878, Bd. xvii. S. 137.

² *Beitr. z. Anat. u. Physiol. (Eckhard)*, Giessen, Bd. vii. S. 191.

⁴ *Journ. Physiol.*, Cambridge and London, 1883, vol. iv. p. 75.

other; we must, in fact, be able to obtain a reversal of beats, as in the heart of the Ascidian. The ease with which a reversal of the sequence of the beats of the heart can be observed is well exemplified in the hearts of the skate¹ and tortoise, and in both cases it is clearly seen that the only factor requisite is to start a rhythm with a rate quicker than that of the natural sinus rhythm; that, as might be expected, the heart-beat starts from the place where the rate of the spontaneous contractions is quickest. If the heart of a large skate is taken out of the body, and the auricle slit up so as to make a long strip of tissue, then it is very easy to see the peristaltic wave travel along this strip to the ventricle, and reappear after the quick, apparently simultaneous contraction of the ventricle as a peristaltic wave slowly traversing the long muscular *conus arteriosus*. If, then, the *conus arteriosus* be stimulated by any pointed instrument, it is excited to a rhythm of excitation, the rate of which at first may be quicker than that of the sinus rate. Immediately the peristaltic wave is reversed, and all the beats can be seen travelling in the reverse direction along the elongated auricular strip, until, with the subsidence of the stimulation, the rate of the conus beat becomes just less than that of the sinus beat, when forthwith all the contractions pass along in the normal direction. The same thing can be seen in the tortoise² by starting a spontaneous beat in the ventricle and auriculo-ventricular junction with a rhythm quicker than that of the sinus. This can be obtained as follows: The auricle is slit up, not sufficiently to cause any blocking, but so as to allow every contraction to travel easily, and a cannula is placed in the aorta in connection with a pressure bottle filled with a blood solution. The pressure of the fluid closes the aortic valves, and forces blood into the coronary system, which is developed to a certain extent in the tortoise. This blood drops out of the cut coronary veins, and does not reach the sinus. In this way the rhythmical tissue of the auriculo-ventricular ring is brought nearer the condition of spontaneous rhythmical activity, but still the sinus holds its own. Now cool down the sinus, which, owing to the conditions of the experiment, can easily be done without affecting the ventricle, the sinus beat gets slower and slower, and at last every contraction suddenly passes in the reverse direction, first *V*, then *Av*, then *As*, and finally sinus. If now the sinus be cut away, there is no Stannius standstill, but the ventricle and auricle continue to beat with the same rate of rhythm as before removal of the sinus.

We come, then, to the conclusion that the beat of the heart starts from that part which is most rhythmical, *i.e.* which beats spontaneously at the quickest rate, and travels as a wave of contraction over the rest of the heart at rates of speed which vary in different parts according to the nature of the muscular tissue.

So far I have not attempted to decide the question whether the sequence in question is due to the actual passage of a wave of contraction over muscular fibres, or whether, owing to the presence of a nerve plexus coincident with the muscular structures, or to the nervous nature of the muscular substance itself, it is possible to conceive of a stimulation wave travelling along the neuro-muscular tissue without an accompanying contraction. Granted, in fact, that the nerve trunks and nerve cells are not concerned in the sequence, is it still possible that the ventricle may contract, in response to a contraction of the sinus, without an intermediate contraction of the auricle?

¹ Gaskell, *op. cit.*, p. 78.

² *Op. cit.*, p. 88.

Such is asserted to be capable of experimental proof, and is the strongest argument used against the sequence being simply due to the passage of a wave of contraction. Two methods have been especially prominently brought forward by Engelmann.¹

1. Biedermann² has shown that ordinary striated muscle can be completely deprived of all power of shortening its fibres, without any loss of its excitability to electrical stimulation, or its power of conduction, by soaking it in ordinary water, so that the part of the muscle so treated behaves to the rest of the muscle like a motor nerve. Engelmann has made trial of this same method in the case of the heart, and asserts that if the auricles and sinus of the isolated heart are dipped under water, while the ventricle is left free and its contractions are registered, then, after a time, the auricles lose all muscular character, and behave as though they were motor nerves to the ventricle; each stimulus of the auricle producing a contraction of the ventricle without the slightest trace on the ventricular curve of any antecedent auricular contraction.

2. Engelmann has sometimes succeeded in reducing the contractions of the auricles to invisibility, while the contractions of the ventricle still continue, by means of a reflex stimulation of the vagus nerve on the heart, in consequence of stimulation of the wall of the stomach. This implies, according to him, that the normal impulse from the sinus can reach the ventricular muscle, and cause it to contract without any necessary intermediate contraction of the auricular muscle.

To my mind it is very doubtful whether either of these experiments are conclusive, for the simple reason that it is very difficult to be quite certain that *no* contraction passes along any part of the auricle.

The difficulty of being certain that no part of the heart is contracting, when it is apparently absolutely still, was brought home to me very strongly when I was making the experiments recorded on p. 217, for the purpose of seeing whether the accelerator (augmentor) nerve was able to make a quiescent heart beat again; as mentioned there, I was deceived again and again; in each case the heart was apparently absolutely motionless, stimulation of the nerve made it beat vigorously. Any graphic method, such as that used by Engelmann, would most certainly have led to the conclusion that the augmentor nerve was able to set up rhythmic contractions in the non-beating heart, and yet such a conclusion would have been wrong, for in every case examination of the sinus with a powerful lens showed that the heart had not really ceased to beat, but only that the beats, which were perfectly regular, were confined to infinitesimal movements of the muscular tissue of the sinus. So also with respect to the vagus nerve, I have shown in my paper in the *Philosophical Transactions* (Fig. 12, *a* and *b*) that the vagus is able upon stimulation to reduce the contractions of the auricle to invisibility, as far as registration on a blackened surface goes, and yet, from the very comparison of 12*b* with 12*a*, I feel sure that in both cases the auricle was contracting.

Again, MacWilliam³ has pointed out that a contraction wave may travel from the sinus to the ventricle in the case of such a heart as that of the tortoise or eel in two different ways—(1) Over the auricular tissue proper, *i.e.* the reticulated portion; (2) over the flattened basal part of the two auricles or sinus extension. If then, as is possible, the septum between the auricles in the frog's heart corresponds to the sinus extension of the tortoise's heart, a contraction might reach the ventricle through the muscular tissue of the septum, while the auricles proper remained absolutely quiescent.

Engelmann, too, has demonstrated most conclusively that the rate of travel of the wave of stimulation over the heart is strong evidence that such wave

¹ *Arch. f. d. ges. Physiol.*, Bonn, 1894, Bd. lvi. S. 199.

² *Sitzungsb. d. k. Akad. d. Wissensch.*, Wien, 1888, Bd. xxvii. S. 101.

³ *Journ. Physiol.*, Cambridge and London, 1885, vol. vi. p. 192.

takes place in muscular rather than in nervous tissue, so that when he considers that his experiments prove that the ventricle may contract after the sinus without an intermediate contraction of the auricles, he still considers at the same time that the stimulus to contraction of the ventricular muscle reaches the ventricle by way of the muscular tissue of the auricle, although the molecular change in the auricular muscle is not sufficient to cause a change of form in it.

Such a conclusion is greatly strengthened by Fletcher's¹ recent observation that water rigor in striated muscle does not cause a discharge of CO₂ similar to heat rigor, and by Biedermann's observation that the electromotive phenomena of water-clotted muscle are not at all comparable with those of true rigor, since the difference of potential between a normal and water-clotted part of the muscle is insignificant. Both these observations point to the conclusion that the action of distilled water upon the muscle is physical and not chemical; that therefore the wave of contraction would travel along the water-clotted auricle in Engelmann's experiment without showing any alteration of form, just as it would along an auricle which was mechanically prevented from altering its form.

Considering, then, the difficulty of deciding whether in any given case a contraction does or does not take place, we may sum up this section by saying that in all cases the sequence of the contractions of the different parts of the heart is most probably due to the passage of a wave of contraction along muscular tissue, even though under certain conditions this contraction may be so small as not to be visible by ordinary methods of investigation.

The causation of the beat of the heart and of the sequence of the contractions of the separate cavities is the same in warm-blooded as in cold-blooded animals.—A considerable amount of very difficult and laborious experimental investigation has been carried out by various observers upon the mammalian heart on the assumption that it is not safe to draw the conclusion that what is known to be true of the cold-blooded heart will necessarily be true of the warm-blooded; and it has even been argued again and again, that although it may be proved up to the hilt that the beat of the frog's heart is due to the rhythmical properties of its muscular tissue, yet the beat of the dog's heart may be totally different, and may be due to the presence of special nerve centres.

This view of a fundamental difference between the innervation of the hearts of the cold- and warm-blooded animals has received especial support from the supposed impossibility in the case of warm-blooded animals, of attributing the sequence of ventricular upon auricular beat to the passage of a peristaltic wave over muscular tissue at the auriculo-ventricular junction. The explanation of the sequence of beats in the mammal must, it is said, be due to special nervous arrangements, because the muscular tissue of the auricles is absolutely disconnected from that of the ventricles. As might have been anticipated, all recent work on the mammalian heart tends more and more strongly to prove that there is no fundamental difference between it and the cold-blooded heart, any difference there may be being a difference in degree, not in kind.

Thus the observations of Kent,² and of Krehl and Romberg,³ have shown that there is muscular continuity between the auricles and ventricles quite sufficient to account for the passage of a contraction

¹ *Journ. Physiol.*, Cambridge and London, 1897, vol. xxiii. p. 85.

² *Ibid.*, 1892, vol. xiv. p. 223.

³ *Arch. f. exper. Path. u. Pharmakol.*, Leipzig, 1892, Bd. xxx. S. 71.

wave, just as in the hearts of the frog, tortoise,¹ eel,² etc. Further, MacWilliam³ has shown that in the mammalian, just as in the cold-blooded heart, a reversal of the sequence takes place when the ventricle is made to beat at a quicker rate than the great veins and auricles; so also does a block take place at the auriculo-ventricular junction, of precisely the same character as in the cold-blooded, so that the ventricle responds to every second contraction of the auricle, etc. Another difference of a fundamental character was said to exist by Waller and Reid,⁴ who concluded, from the measurement of the time relations of the electrical variation at two points on the ventricle, that the apex of the ventricle in the beat of the warm-blooded heart contracts before the base, while in the beat of the cold-blooded the base contracts before the apex. Bayliss and Starling,⁵ however, have shown that this conclusion is erroneous, and that the contraction travels over the mammalian ventricle from base to apex, just as in the hearts of the frog and other cold-blooded animals.

With respect to the rhythmical power of the different parts of the heart, we find the same results as in the cold-blooded, the main difference being that the mammalian ventricle, when isolated, appears to possess greater rhythmical power than that of cold-blooded animals. Thus the observations of Wooldridge,⁶ of Tigerstedt,⁷ by means of the atriotome, and of MacWilliam,⁸ all show that the ventricle when separated from the auricles beats immediately with its own rhythm, without any marked preliminary standstill. The mammalian heart, therefore, is said not to correspond to that of the cold-blooded in this important respect, that the Stannius standstill does not exist. In these experiments, it is important to remember one thing, namely, that the circulation of blood in the ventricle is retained, in Wooldridge's experiment, by the removal of the *écraseur*; in Tigerstedt's, by the application of the atriotome, while in the experiments upon cold-blooded hearts, the ligature or section between sinus and ventricles removes all blood supply from the ventricle. In the case of the tortoise, I have to all intents and purposes seen the same result as described for the mammalian heart, by means of the simple expedient of supplying the ventricle with blood through its coronary system (as already mentioned). Then, just as in the mammalian heart, the Stannius standstill is either cut short, or does not occur, and the ventricle commences immediately upon isolation to beat with its own rhythm. In this respect, then, the mammalian ventricle does not fundamentally differ from that of the cold-blooded animal.

Quite recently, still further proofs that the same explanation of the cause of the heart-beat applies to the heart of the warm-blooded as to that of the cold-blooded animal, has been given by Porter,⁹ for he has shown, in the first place, that the isolated strip from the ventricle of the mammalian heart resembles that from the heart of the tortoise in its

⁸ *Op. cit.*, p. 177.

⁹ "On the Cause of the Heart-beat," *Journ. Exper. Med.*, New York, 1897, vol. ii. p. 391.

inherent rhythmical power; and, in the second place, Pratt,¹ working with Porter, has shown that the isolated ventricle of the cat can be tied on to a perfusion cannula and fed with blood at the temperature of the body through the *foramina Thebesii*, and then, just as in the case of the frog's ventricle, it will beat regularly and well for many hours. The strip from the mammalian ventricle, even when taken from the apex of the ventricle, will beat regularly at its own rate of rhythm, apart from the beating of the rest of the heart, provided that care be taken to keep intact the circulation of blood through the coronary vessels supplying the strip.

Owing to this inherent rhythmical power of the mammalian ventricle, when supplied with blood through the coronary system, it seems, according to the general consent of all experimenters on the mammalian heart, that it is much more easily possible to obtain standstill of the auricles with the ventricle still beating than in the case of the cold-blooded animal. This is said to be of special frequent occurrence on stimulation of the vagus. MacWilliam,² Roy and Adami,³ Krehl and Romberg,⁴ and others, have all noticed cases where vagus stimulation has caused cessation of auricular beats, while the ventricle has continued to beat, though with altered rhythm. It is said, in fact, that stimulation of the vagus has brought to light the independent ventricular rhythmical beat, which could not manifest itself previously owing to the greater rapidity of the veno-auricular beat. MacWilliam here gives the same warning as I have already given, as to the difficulty of being sure that the standstill of the auricles is absolute; and he expressly mentions cases where his curves show complete cessation of auricular contractions, although upon close inspection he convinced himself that the auricles were still beating very feebly. The fact, however, that an independent ventricular rhythm can be unmasked by a vagus stimulation, which causes standstill of the auricles, is shown most clearly by an example given by me in my paper on the tortoise heart (Fig. 8, PLATE IV.), where an independent ventricular rhythm, with a reversed sequence of auriculo-ventricular contraction, was unmasked at every stimulation of the vagus which caused sino-auricular standstill. The development of this ventricular rhythm could be seen, by means of a series of stimulations of the vagus nerve, to take place in the same way as its development in an isolated ventricle; and its complete independence of the auricles and sinus was seen at the end of the experiment by simply cutting away the auricles; the ventricle then immediately went on beating at the rate it had been shown to have attained at the last stimulation of the vagus. In the case of the mammalian heart, this last decisive proof of the unmasked ventricular rhythm being truly independent, is unfortunately wanting.

The peculiarities of the cardiac muscle by which the rhythm and sequence may be explained.—As is well known, the cardiac muscle, though striated, differs in respect to stimulation from the ordinary striated skeletal muscle in various important points, of which the principal are:—

¹ "The Nutrition of the Heart through the Vessels of Thebesius and the Coronary Veins," *Am. Journ. Physiol.*, 1898, vol. i. p. 86.

² *Journ. Physiol.*, Cambridge and London, 1888, vol. ix. pp. 167, 345.

³ *Phil. Trans.*, London, 1892.

⁴ *Op. cit.*, 1892.

1. The strength of the contraction does not vary with the strength of the stimulus. The heart's motto, as Ranvier and Kronecker and Meltzer put it, is, "All or none"; either it will not contract at all, or it will contract to the fullest extent possible at the time, whether the stimulus be weak or strong.

2. The cardiac muscle cannot be tetanised.

3. The cardiac muscle possesses a long refractory period.

These three facts of stimulation of cardiac muscle are due almost certainly to one common cause, and to that same cause is due in all probability the rhythmical power of the cardiac muscle and the peculiarities of the conduction which are manifested in the due sequence of the contraction of the various chambers.

At the present time it is impossible to give any explanation of the difference between striated skeletal and cardiac muscle, which will account for the fact that the extent of contraction in the former varies with the strength of the stimulus, while in the latter the extent of the contraction is independent of the strength of the stimulus. It is possible to imagine that, in the former case, only a portion of the muscle is thrown into contraction with a weak stimulus, while in the latter the whole of the muscle is affected; or it is possible to imagine that the greater slowness of the metabolic processes, both anabolic and katabolic, which take place in cardiac muscle, as evidenced by the greater length of the refractory period, combined with a difference in the stability of the contractile material when formed, may account for the fact that minimal stimuli are at the same time maximal. Certainly, as far as the other two peculiarities of cardiac muscle are concerned, the absence of tetanus and the length of the refractory period, they are to be explained as a necessary consequence of a slow rate of repair after a contraction. The impossibility of tetanising the cardiac muscle is a necessary corollary of the fact that the tissue is inexcitable to the strongest stimulus for some time after the commencement of a contraction.

In all striated muscles this refractory period is said to exist; in all striated muscles, therefore, a time must elapse after a contraction before the tissue is ready for a new contraction; the only difference then is, that this time is longer in cardiac muscle than in skeletal. During this inexcitable period, it is natural to suppose that a process of repair is going on in the tissue, so as to bring it back to the condition it was in before the contraction took place; if this is so, we may express the difference between cardiac and skeletal muscle, by saying that the process of repair after a contraction takes place more slowly in the former than in the latter.

It is then possible, it seems to me, to find for all three phenomena—the length of the refractory period, the absence of tetanus, and the absence of any relation between strength of contraction and strength of stimulus—one common hypothetical cause, namely, the metabolic processes, which accompany and are caused by a contraction, take place in the cardiac muscle much more slowly than in ordinary striated muscle.

The length of the period of inexcitability after an effective stimulus explains why a continuously acting stimulus, such as the constant current, or the pressure of suitable fluids within the cavity of the ventricle, etc., or the tension of the suspended muscular strip, causes a series of contractions instead of one continuous contraction; and if we

choose to use the term "inner stimuli" to express the causation of the internal changes which are going on in the automatic rhythmical tissue of a normally nourished heart, then we can explain the normal rhythm in the same way as the artificially produced rhythm, as a necessary consequence of a constantly acting internal stimulus upon a muscular tissue in which the refractory period is exceedingly long.

By the refractory period was originally meant by Budge and Marey, the time during which the tissue was inexcitable to any stimulus of any strength: This period of complete inexcitability lasts during the time of systole; afterwards, during the diastole and pause, the excitability recovers itself, not suddenly but gradually, so that, according to Engelmann's¹ latest researches, the power of response to very weak stimuli is not regained until after the completion of the diastole. By the refractory period, therefore, we mean at the present day a sudden complete loss of excitability, caused by the contraction, with a gradual slow recovery of excitability after the contraction is over. It follows from Engelmann's measurements that the inner stimuli upon which the normal rhythmical beat depends must be extremely weak.

What is true of the rhythmical tissue in the sinus and large veins on which the beat depends, is true also of the less rhythmical tissue over which the contraction wave passes, such as the reticulated tissue of auricle and ventricle; here, too, each contraction is followed by a slow recovery of conductivity, and the question whether the next contraction wave, which reaches any particular spot, will be able to cause a further travelling of the wave or not, depends upon the extent to which the muscular tissue there has been able to recover its conductivity. Anything, therefore, which diminishes the conductivity of any part of the tissue, will tend to cause a block in the contraction wave at that part; and the question whether any block will be manifested or not, will depend upon the rate of the heart-beat in relation to the extent of the diminution of conductivity in the damaged part. A very excellent example of the dependence of a blocking upon the rate of beat can be shown in the following manner:—

Slit up the auricle of the tortoise so that every contraction is just able to pass the blocking point, then remove the sinus and apply electrodes, arranged so as to give single induction shocks at regular intervals to the part of *As* near the sinus. Owing to the removal of the sinus, the auricle and ventricle remain still, and now by means of the electrodes on *As*, we can produce a regular artificial rhythm, the rate of which can be varied at will; we can, for instance, send through single shocks every ten seconds, with the result that every contraction of *As* causes a contraction of *Av*, and therefore of *V*. We may then see that single induction shocks sent in to *As* every five seconds will cause a regular series of contractions in *As*, but only every second contraction can pass the blocking point and cause a contraction of *Av*, and therefore of *V*. We see, in fact, a longer time after a contraction is required for the recovery of the conductivity of the tissue at the blocking point than of that of the rest of the auricle.

This experiment illustrates many important facts concerning the heart: it shows that that part of the heart which possesses the quickest rhythm must of necessity be the leader; under normal conditions, therefore, the great veins and sinus. It shows also, that in the beating

¹ *Arch. f. d. ges. Physiol.*, Bonn, 1894, Bd. lix. S. 309.

heart the wave of contraction must travel always in one direction, for all the parts immediately in the rear of the part which is contracting are blocked (being in the inexcitable phase), so that no backward wave is possible.

The experiments of Bowditch,¹ Kronecker,² and v. Basch³ have shown that a series of single induction shocks, sent in to the muscle of the frog's ventricle, are able to produce an infallible response to each shock only when they are sent in at a slow rate—two seconds being the limit—and that if they are sent in at a quicker rate than this, then a contraction occurs only with every second stimulus. In fact, whether the contraction be due to the travelling of a contraction wave, or to a direct external stimulus, it will not take place unless sufficient time be allowed for the tissue to recover its conductivity or excitability respectively after a previous contraction.

From these experiments of Kronecker and v. Basch, combined with my experiments upon the blocking of contraction waves, we see that very similar laws apply to the recovery of excitability and the recovery of conductivity after a contraction, and it makes no difference at any spot whether that contraction is the natural contraction due to the normal beating of the heart, or an artificial contraction induced by an interpolated stimulus between the natural contractions; just as such stimulus cannot cause a contraction in the ventricle unless it be applied a sufficient time after the commencement of the natural contraction, so also the normal contraction will be blocked if it reaches the ventricle before the tissue has had time to sufficiently recover its conductivity after the commencement of the interpolated or forced contraction. For this reason it is self-evident that an interpolated contraction of the ventricle in the case of a normally beating heart may be followed by a longer pause than usual, because the normal contraction following the beat of the auricle, which ought to take place during that pause, cannot take place, as it arrives during the inexcitable phase of the interpolated contraction. This lengthened pause has been called the "compensatory pause," and attempts have been made to look upon it as an inhibitory phenomenon. It is, however, so clearly due to a blocking of the natural contraction wave by the interpolated contraction, owing to the existence of the refractory period, that it is not necessary to discuss it further.

In connection with the observations of Kronecker⁴ and v. Basch,⁵ upon the effects of sending in single induction shocks to the cardiac muscle at definite intervals, are observations of v. Basch upon the effect of sending in single induction shocks, the strength of each one of which is insufficient to cause a contraction. He finds that such stimuli will produce a rhythmical series of contractions, the rate of which is less than the rate at which these insufficient stimuli are sent in. The explanation appears to be⁶ that a stimulus which is insufficient to cause a contraction increases the excitability of the muscle, and so enables a second or third stimulus of the same strength to be powerful enough to cause a contraction. This observation of v. Basch is in accordance with

another phenomenon, observed originally by Bowditch,¹ namely, the phenomenon of the "Treppe," or staircase phenomenon, which consists in the fact that, when a series of single induction shocks of the same strength are sent in to the muscular tissue of the quiescent frog's ventricle or apex, the contractions are not all of the same size, but the first is the smallest, and they then gradually increase up to a maximum. From this experiment it is concluded that every stimulus which causes a contraction produces in addition a beneficial change in the muscular tissue, so that it is more excitable and able to contract more strongly than before the contraction. How such beneficial effect is brought about, whether, as Hering would say, by the assimilation process which is produced by the dissimulation stimulus being greater than is necessary to produce autonomous equilibrium, or in some other way, such, for instance, as by means of nerve fibres, which are excited simultaneously with the muscular tissue, cannot be determined at present. The question will, however, be considered again in connection with the action of the intracardiac nerves.

ON FIBRILLAR CONTRACTIONS.

Another question which arises in connection with the conductivity of cardiac muscle, is the question of the co-ordination of the different parts of the ventricle or auricle. Why is it that the contraction of the ventricle takes place as a whole, and not as a series of separate contractions? In the case of warm-blooded animals, a marked inco-ordination of the different parts of the muscular tissue of the ventricle, known by the name of fibrillar contractions, can be brought about by the application of a strong tetanic current to the surface of the ventricle, or by the ligature of one or more coronary arteries. How are these fibrillar contractions to be explained?

According to the observations of Kronecker and Schmey,² a puncture in a particular spot on the septum between the ventricles always brings about this kind of inco-ordination, and they conclude, therefore, that the ventricle possesses here a co-ordination centre which harmonises the contractions of all the ventricular muscle fibres, and so causes a single contraction of the whole ventricle at each heart-beat, instead of the disorderly disjointed contractions of separate muscle-strands, such as are seen in the condition of fibrillar contraction. Against this view it has been pointed out by MacWilliam,³ that nothing of the nature of any nerve centre is to be found at the place indicated; that after the destruction of this supposed centre the ventricle will frequently recover from these inco-ordinated movements, and beat again regularly and well, and that the same fibrillar contractions can be induced in the regularly beating isolated apex of the heart—in tissue, therefore, entirely removed from this supposed co-ordination centre.

With respect to the fibrillar contractions produced by strong tetanic stimulation, they are, it would appear, confined to the hearts of warm-blooded animals. In these animals there is a distinct difference between auricle and ventricle in this respect—when the ventricle muscle is thrown into this condition of inco-ordinated fibrillar contraction, it is said not to recover either by nerve stimulation or other means; when, however, similar movements are

¹ *Op. cit.*

² *Sitzungsb. d. k. Akad. d. Wissensch. zu Berlin*, 1884, S. 87.

³ *Journ. Physiol.*, Cambridge and London, 1887, vol. viii. p. 296.

induced in the auricle by strong stimulation, the recovery to a normal co-ordinated contraction takes place quickly and easily after the stimulus is over. According to Gley,¹ fibrillar contractions may be induced in the ventricle of a new-born dog upon strong stimulation just as in older dogs, but the ventricular muscle at this stage behaves like the auricular muscle of the adult, and the inco-ordination can pass off easily and give place to regular normal contractions. After the dogs are twenty-nine to thirty-three days old, no such recovery is possible under ordinary conditions. But Porter² has shown that even in adult animals the normal contractions may be renewed, provided the nutrition of the muscular substance be restored by perfusing blood of the same animal, at the temperature of the body, through the muscular substance, either by way of the coronary arteries or by way of the vessels of Thebesius, as in Pratt's experiment (cf. p. 188). In many cases the artificial circulation alone will not transform the condition of fibrillation into that of regular co-ordinated beating; it is, however, always possible to obtain this result if the fibrillar contractions are first caused to cease by the application of cold, and then, when the ventricle is quite motionless, the warmed blood solution is sent through its muscular substance.

Besides electrical stimulation, these fibrillar contractions have been observed as the effect of bromide of potassium in large doses, under conditions of anæmia and other weakening agencies, and exceptionally as the result of the intravenous injection of extract of the suprarenal capsules,³ the actual cause in this case being probably excessive contraction of the coronary arterioles. It would appear that the fibrillar contractions, which occur upon ligation of the coronary arteries, must be ascribed to anæmia and not to any stimulation of nerve fibres by the ligation,⁴ and it is very instructive to notice the order of sequence of the events which follow ligation of the coronary arteries, according to Sée⁵ and Cohnheim.⁶ After the arteries have been tied, the first effect is that the ventricle drops beats, *i.e.* does not respond to every auricular beat; this partial block between auricle and ventricle is then followed by a complete block, so that the ventricle remains still; this standstill is then followed by fibrillar contractions of the ventricle.

These observations suggest very strongly that the condition of fibrillar contraction is brought about by a blocking in the connections between the branching muscle cells of the ventricle itself; that, in fact, a difference of conductivity takes place in the different portions of the ventricular muscle, owing to anæmia, just as in the tissue of the auriculo-ventricular ring; in consequence of which contractions travel at different rates, and are blocked at different distances throughout the whole ventricular muscular mass, thus giving the appearance of inco-ordinated contractions, known as fibrillar contractions. That this is the probable explanation of fibrillar contractions follows, it seems to me, from my experiments on the stimulation of a strip of muscle cut from the apex of the tortoise ventricle. In such a strip the very action of the section has of necessity brought about a series of blocking places; in consequence of this, the single induction shocks applied to one end of the strip at first cause contractions which are limited to the tissue in the immediate neighbour-

hood of the electrodes; then, as the single stimuli continue, and especially if at intervals a weak tetanising current is sent through the whole strip, we see that the contractions are not all of the same strength; some are stronger, some weaker, although the strength of the induction shocks remains the same. The reason of this variation is clear on inspection: those contractions which are stronger travel further along the strip from the point of stimulation than the shorter contractions; we see, in fact, that every now and then a contraction succeeds in forcing a previously existing blocking place, so that different contractions travel to different degrees along the strip. As time passes, more and more of the blocking places are overcome, until at last a regular series of contractions takes place, every contraction passing rapidly and easily from one end of the strip to the other. When this has occurred, when the conduction power has been fully restored along the whole strip, then is the time when the strip begins to contract rhythmically of its own accord, without the necessity of any regular external stimuli.

ON THE TONICITY OF THE CARDIAC MUSCLE.

So far we have considered various properties of the cardiac muscle, such as rhythmicity, excitability, conductivity, and have found that different parts of the heart differ in the extent of their possession of these different properties. It is impossible at present to lay down absolute laws of the relations which exist between these several properties in the different parts of the heart, but still we may with advantage sum up our knowledge by suggesting that the present direction of research seems to point roughly to some such series of laws as the following:—

1. The rhythmicity of the cardiac muscle varies inversely as its conductivity.

2. The rhythmicity of the cardiac muscle varies directly as its excitability.

3. The rate of recovery of the excitability, after a contraction, varies directly as the rate of recovery of the conductivity after a contraction.

In other words, the most quickly contracting parts of the heart are the least rhythmical, and, conversely, a block in the passage of the contraction wave is most likely to occur in the more rhythmical tissue.

The end result of the different modifications of the different parts is not only to form an efficient force-pump, the different chambers of which shall always act in regular order, but also, as Engelmann¹ has pointed out, to render as harmless as possible to the economy any accidental irregularity in the beat of the pump. For we see from his experiments, that not only does a contraction travel at different rates over the different muscular tissues of the heart, but also the rate of travel in any one tissue depends upon the phase of that tissue at the time. For just as the excitability of the tissue is restored gradually after a contraction, so also is the restoration of the full power of conductivity a gradual one after a contraction. It follows, therefore, that an interpolated wave of contraction, starting at the sinus soon after a normal contraction, will travel to the ventricle over tissue which has not yet regained its full power of conduction, and consequently will take a longer time to reach the ventricle than the previous normal

¹ *Arch. f. d. ges. Physiol.*, Bonn, 1897, Bd. lxx. S. 153.

contraction wave. Therefore the time between the normal and interpolated ventricular contractions will be longer than the time between the normal and interpolated contractions of the sinus; in other words, any irregularity in the beat at headquarters will tend to be compensated by the time the ventricle contracts, so that the contractions of the ventricle will occur at much more regular intervals than those of the sinus. Seeing that the main importance to the economy is to ensure a regular ventricular beat, it is clear that this more or less complete obliteration of any irregularity in the rhythm, by means of the varying rates of conduction at different phases of the beat, is a very important factor in maintaining the efficiency of the heart.

All these different properties are possessed, not only by cardiac muscle, but also by all other contractile tissue, so that the differences of the cardiac muscle are differences of degree rather than of kind. In addition to these properties, other muscular tissues are said to possess tonicity, a property which is especially well marked in the muscles of the vascular system; by analogy, the cardiac muscle ought also to possess tone, and it would not be unreasonable to expect that different parts of the heart should vary in the extent of their tonicity, just as they vary in the extent of their rhythmicity, in their power of rapidity of contraction, and their other properties.

The question whether cardiac muscle does or does not possess tone is by no means easy to answer off-hand, owing to the beating of the heart; for it is clear that the extent of relaxation between the contractions depends, not only upon the tone of the muscular tissue, but also upon the rate of beat: with a slower beat there is more time for complete relaxation to take place than with a quicker beat, and it is very doubtful whether, with the normal rate of beat of the cold-blooded heart, complete relaxation does take place between the beats. It is therefore difficult to speak of an alteration of tone in the cardiac muscle, if such apparent alteration is accompanied with the corresponding change in the rate of beat. Still there is evidence which points distinctly to a power of tonicity in the cardiac muscle. This evidence is especially dependent upon the action of various drugs and solutions upon the nature of the cardiac contraction. Such solutions may be divided into two groups: those which tend to produce a tonic contraction of the ventricle or apex of the ventricle, so that a less and less complete relaxation takes place between the beats, and finally the ventricle remains in a condition of systolic standstill; and those which tend to produce an atonic condition of the ventricle or apex, characterised by the greater and greater feebleness of the contractions, until finally the ventricle stands still in the condition of complete relaxation or diastolic standstill. The type of the first group is given by the action of alkaline sodium compounds, and of the second by the action of acid substances, such as lactic acid.¹

The nature of the action of sodium hydrate in very weak solution (1 part to 20,000 normal saline) is shown in Fig. 106, which represents samples *a*, *b*, *c*, *d*, *e*, taken at intervals from a continuous curve,² and the corresponding action of lactic acid (1 part to 10,000 normal saline) in Fig. 107. In both cases the time when the solution was sent in is represented by a vertical arrow. We see from the figures that not only is the relaxation after each beat hindered more and more by the alkaline salt, but also the muscle remains at each beat a longer time in the

¹ Gaskell, *Journ. Physiol.*, Cambridge and London, 1880-82, vol. iii. p. 53. ² *Ibid.*

condition of complete contraction, till at length it is almost or quite impossible to recognise the separate beats at all.

Precisely similar curves can be obtained by the action of such drugs as antiarine, veratrine, digitalin, which are known to act upon ordinary striated muscle in a similar manner; and it is of great interest for the physiology of the heart, to find that muscarine solutions act in the opposite direction, and produce a diastolic standstill of the same nature as that produced by lactic acid. The opposing effect of the acid and alkaline solutions can be seen in the same preparation, so that all the intermediate steps between a systolic and a diastolic standstill can be brought about by the administration of the alkaline solution, followed by that of the acid solution, and *vice versa*. Precisely similar curves can be obtained by the alternate administration of digitalin and muscarine solutions,¹ so that we are, it seems to me, driven to the conclusion that muscarine acts upon the apex of the ventricle, or upon the whole ventricle, in the opposite sense to digitalin, and therefore, if, as we have every reason to believe, digitalin produces its effect by

FIG. 106.—Beat of ventricle of frog registered by Gaskell's modification of Roy's tonometer. Perfusion cannula in ventricle; blood solution flowing through at constant pressure; at arrow, sodium hydrate solution was sent through instead of blood solution.

FIG. 107.—Same experiment as Fig. 106. After Fig. 106 had been obtained, blood solution was sent through for seven minutes, and then at arrow the lactic acid solution was sent through instead of the blood solution.

direct action upon the muscle substance, in the direction of bringing about a tonic condition of that muscle, muscarine must also directly act upon the muscle in the opposite direction, and produce its effect by bringing about an atonic condition of that muscle. This action of muscarine will be considered further in a subsequent section. Of such nature is the evidence that the cardiac muscle possesses tonicity as well as rhythmicity.

In addition to the evidence of the action of chemical substances, Fano² has published evidence of another kind of tonic contraction which is more mysterious and more difficult to understand. He finds that a clamp or ligature placed in the auriculo-ventricular groove, will cause in *Emys europæa* a rhythmical variation of tone in the auricles, of a most marked and striking character. The phenomenon is confined to the auricles, and is not seen in any other animal to the extent described in the case of *Emys*. The rate of rhythm is not very regular; the phenomenon, according to Fano, very often does not appear until the beats of the auricle have been registered for a long time. It

¹ Gaskell, *op. cit.*, Fig. 106, Pl. III.

² "Ueber Tonuschwankungen der Atrien des Herzens von *Emys europæa*," *Beitr. z. Physiol. C. Ludwig z. s. 70 Geburtst. gew.*, Leipzig, 1887.

is seen in the isolated heart out of the body, and necessitates a clamp in the auriculo-ventricular groove for its production. I have never seen anything of the sort in the auricle of the land-tortoise.

Since the publication of Fano's paper, Botazzi¹ has observed a somewhat similar phenomenon in the auricles of *Rana esculenta* and *Bufo viridis*. He has failed to see it in *Testudo græca*, *Tropidonotus natrix*, *Lacerta viridis*, *Anguilla vulgaris*, *Rana temporaria*. In *Bufo vulgaris* he has observed something of the same kind.

The curves which Fano obtained from the auricle of *Emys* resemble closely the curves obtained by v. Frey,² when a muscle is stimulated with rhythmical isochronic stimuli, and at the same time supported to different extents. In consequence of this resemblance, Fano was led to the conclusion that the rhythmical tonic contractions were due to slow rhythmical contractions of some contractile substance, different to that to which the normal or fundamental contractions were due. This different contractile substance may be a different kind of muscular tissue, more nearly approaching unstriated, interspersed among the auricular fibres proper, or, according to Botazzi, the phenomenon may be due to the contraction of the sarcoplasm as distinct from that of the anisotropic substance of the muscle. This latter explanation seems to me difficult to accept, considering that the phenomenon is confined to the auricles of the hearts of only a few cold-blooded animals; the other explanation seems more possible; it requires, however, careful histological examination of the auricles of *Emys*, such as has not yet been done.

THE MEANING OF THE GANGLION CELLS IN THE HEART, AND THEIR RELATION TO THE CARDIAC NERVES.

So far, I have explained all the phenomena, both of the beat of the heart and the sequence of its contractions, etc., without bringing in ganglion cells at all, and the upholders of special nerve centres in the heart have a perfect right to ask, What then are the ganglion cells in the heart? What function do you attribute to them? That is a question which I am ready to answer, and to answer with confidence, as follows:—The ganglion cells in the heart are part of the great group of ganglion cells which are situated on the course of the small-fibred efferent nerves supplying the viscera. These cells form the outlying vagrant groups of nerve cells which are known by the name of the sympathetic and cerebro-spinal ganglia. In the case of the heart, the ganglion cells are the cells belonging to the small-fibred efferent cardiac fibres of the vagus, just as some of the cells in the ganglion stellatum and in the inferior cervical ganglion are the cells belonging to the small-fibred efferent cardiac fibres of the augmentor nerve. There is no more reason to assign special functions to these cells than to any of the other peripheral efferent nerve cells. They are cells connected only with the inhibitory fibres of the vagus, and as such are simply part and parcel of the mechanism of inhibition, just as the corresponding cells in the ganglion stellatum are simply part and parcel of the augmentor mechanism.

The evidence upon which these statements is based will be best appreciated, if I relate the history of our present knowledge of the relations between the cardiac nerves and these peripheral ganglion cells.

¹ *Journ. Physiol.*, Cambridge and London, 1897, vol. xxi. p. 1.

² *Beitr. z. Physiol. C. Ludwig z. s. 70 Geburtst. gew.*, Leipzig, 1887, S. 55.

In 1845, when the brothers Weber discovered the inhibitory action of the vagus nerve upon the heart, it was known that the heart was also supplied with fibres from the sympathetic system, and E. Weber,¹ in Wagner's "Handwörterbuch," considered that the two nerves which went to the heart, vagus, and sympathetic, were of opposite function; that the latter were motor nerves, and the former inhibitory. He was unable to obtain any effect from stimulation of the sympathetic fibres themselves, but evidently looked upon those nerves as entering at the aortic end of the heart, while the vagus entered at the venous end; for he says that the sympathetic fibres in the frog are too delicate to stimulate, but by direct stimulation of the aorta he was able to obtain acceleration, which he imagined to indicate that sympathetic fibres passed into the heart in this direction. Continuing this idea, he pointed out the difference between direct stimulation of the bulbous and ventricle on the one hand, and of the vena cava and auricle on the other. In the former case he obtained acceleration and increased systolic contraction, in the latter case standstill in diastole and weaker contractions.

Such then was Weber's conception: the heart was supplied with two nerves, which entered at opposite ends, and their stimulation was opposite in effect both on rate of rhythm and force of contraction. Of these two nerves he and his brother clearly demonstrated that the inhibitory fibres ran in the vagus nerve, but were unable to demonstrate the course and existence of the accelerator fibres either in warm or cold-blooded animals.

Following upon the great discovery of the brothers Weber, physiologists were engaged for many years upon a controversy as to the meaning of this standstill, the majority agreeing with Weber, that the inhibition of the heart is caused by the vagus in the same way as inhibition by nervous action in the central nervous system; that, in fact, Weber's discovery did not imply the discovery of a new class of nerves which acted on the muscular tissue in the opposite direction to motor nerves, but rather that a motor nerve centre, in the shape of the ganglion cells, existed in the heart, of the same character as the centres in the central nervous system, the action of which the vagus was able to inhibit. The strongest opponent of this view was Schiff,² who objected *in toto* to the conception of inhibition, and maintained that the vagus was the motor nerve of the heart up to its termination in the muscular tissue, that the beat of the heart depended upon the stimulation of the terminal nerve fibres in the heart itself, and that the so-called inhibition was due to over-stimulation, causing exhaustion of these motor nerve fibres. Schiff laid especial stress on the fact that direct stimulation of the muscular tissue of the ventricle caused a local diastole of that part of the heart, so that it remained relaxed and distended when the rest of the ventricle was contracting; also, this effect was removed by atropine, just like the corresponding effect of vagus stimulation. In other words, Schiff argued that the terminal fibres of the motor vagus nerve in the muscular tissue could be directly exhausted by over-stimulation as well as indirectly by stimulation of the vagus trunk, and that therefore this experiment was clear evidence that the vagus did not act by inhibiting any central nervous apparatus in the shape of ganglion cells.

Schiff's view that the vagus was the motor nerve of the heart, which was easily exhausted by over-stimulation, was largely based upon the fact that a weak stimulation of the frog's vagus often produced acceleration when a strong stimulation produced inhibition. This acceleration upon stimulation of the frog's vagus was noticed by many observers, especially by Wundt and Schelske³ in 1859, after strong curari poisoning, but it was not until 1870 that Schmiede-

¹ "Handwörterbuch d. Physiol.," 1846 (3), Bd. ii. S. 42-48.

² *Arch. f. physiol. Heilk.*, Stuttgart, 1849, Bd. viii.

³ *Verhandl. d. naturh.-med. Ver. zu Heidelberg*, 1859.

berg¹ (and Ludwig) discovered that, after the administration of nicotine, stimulation of the vagus in the frog always produced acceleration, and concluded from their experiments that the vagus of the frog contained accelerator fibres as well as inhibitors. Previously to this, v. Bezold,² in 1862 and 1866, had shown, by section of the cord in the upper thoracic region and stimulation of the cervical cord, that accelerating fibres left the spinal cord of mammals to reach the heart at the region of the first thoracic ganglion; and the brothers Cyon,³ in 1867, showed that destruction of the ganglion stellatum removed this accelerating effect of stimulation of the cervical cord. Finally, in 1871, Schmiedeberg⁴ and Ludwig traced out the course of the accelerator nerves in the dog, and thus completed the proof of Weber's suggestion, that the sympathetic nerves to the heart produce the opposite effect to the vagus nerves.

This paper of Ludwig and Schmiedeberg definitely settled the anatomical course and position of the accelerator nerves in the mammal, and we see that, whereas the inhibitory nerves were first discovered in the vagus of the frog, and then found to exist in the same nerve in the mammal, the accelerator fibres were first discovered in the mammal, and it was supposed for some time that the accelerator fibres in the vagus of the frog belonged to that nerve, and that therefore the cold-blooded differed from the warm-blooded animal in this important respect; in fact, one finds, even up to the present day, in the literature of the innervation of the heart, continued assertions that what is true for the cold-blooded heart is not necessarily true for the warm-blooded, as the differences between them are so great.

In 1881⁵ I read a paper before the International Medical Congress, London, the substance of which was afterwards (1882) published more fully in the *Philosophical Transactions of the Royal Society*, in which I showed, among other things, that the frog's vagus on stimulation was able to cause not only acceleration, but also very striking augmentation of the force of the contractions both of the auricle and ventricle. Heidenhain,⁶ in 1882, described the same thing; and further showed that stimulation of the medulla oblongata, with the cord cut just below it, never produced either acceleration or augmentation, but only pure inhibitory effects. From this he concluded that the accelerator fibres in the vagus did not leave the medulla oblongata in the roots of the vagus nerve, but joined the vagus after its exit from the brain.

In order to clear up the question of the accelerators in cold-blooded animals, and to determine definitely their course, I determined to investigate them in the higher cold-blooded animals, and for that purpose obtained, through the kindness of Sir Joseph Fayrer and Dr. Kynsey of Colombo, a number of young crocodiles from Ceylon. I was rewarded by finding a very definite accelerator nerve, which arose from the first ganglion below the cervical region and passed directly to the heart.⁷ Passing to the tortoise,⁸ I found that here also accelerator nerves passed from the ganglion belonging to the first nerve posterior to the brachial

plexus, and that in this animal a regular annulus of Vieussens, strictly corresponding to the arrangement in mammals, existed. I then carefully investigated the sympathetic system of the frog and toad,¹ feeling sure that they could not prove an exception, and found that from the ganglion on the third nerve, *i.e.* the first postbrachial nerve, an annulus of Vieussens passed to the ganglion on the second nerve, *i.e.* the brachial plexus, and from thence the sympathetic nerve passed to the vagus at the region of the vagus ganglion, some of the fibres turning back with the vagus to go to the heart, while others went on to the Gasserian ganglion of the trigeminal. Here, then, was precisely the same arrangement as in the mammal or tortoise, and the experiment showed that stimulation of any part of the course of these fibres, between the anterior roots of the third nerve and the vagus ganglion, gave pure augmentor and accelerator effects; while, on the other hand, stimulation of the roots of the vagus within the cranium gave pure inhibitory effects.

Thus the proof was obtained that the innervation of the heart is the same both in cold-blooded and warm-blooded animals. In all cases the inhibitory fibres leave the central nervous system in the roots of the vagus, while the augmentor fibres leave in the roots of the nerves immediately succeeding those which form the brachial plexus; and the reason was clearly seen why Weber and others following him were unable to find the accelerators in the frog, for they expected them to leave by the third or fourth ganglion and go direct to the aorta, and so to the heart; they were therefore stimulating the nerve in the wrong direction.

In the course of these investigations I was struck with the histological difference between the two sets of nerves on their way to the heart; the inhibitory nerves of the vagus being medullated, while those of the accelerator were non-medullated. This led to the investigation of the histological nature of the accelerator nerves in the whole of their course, and to the conclusion that both inhibitory and accelerator nerves belonged to the great system of efferent ganglionated nerves; a system characterised by the fineness of their fibres, which are always medullated when they leave the central nervous system, by the presence on each one of these fine medullated fibres, in some part or other of its course, of a ganglion cell, from which fibres of the same physiological character pass to the end-organ. This system includes, not only the cells of the sympathetic system, but all vagrant motor cells, such as are found on the course of the accessory part of the vagus in the ganglion trunci vagi, on the course of the third nerve in the ciliary ganglion, etc. The fibres which pass from these cells are, in the majority of cases, non-medullated.² Seeing, then, that the vagus fibres entered the heart as medullated fibres, and that no medullated fibres are to be found in the ventricle proper or auricles, but only non-medullated, it was immediately evident that the ganglion cells in the heart had the same relation to the medullated inhibitory fibres of the vagus, as the ganglion cells of the ganglion stellatum to the medullated accelerator fibres in the white *rami communicantes*, from the second, third, and fourth thoracic nerves. In other words, the intrinsic cardiac ganglion cells belong to the same system as the extrinsic cardiac and vasomotor ganglion cells, and there is no justification whatever for ascribing special central nervous system

¹ Gaskell and Gadow, *Journ. Physiol.*, Cambridge and London, 1884, vol. v. p. 362.

² Gaskell, "On the Structure, Distribution, and Function of the Nerves which innervate the Visceral and Vascular System," *Journ. Physiol.*, Cambridge and London, 1885, vol. vii.

qualifications to the one and not to the other. One possibility remained, namely, that the ganglion of the inhibitory system, which corresponded to the ganglion stellatum, etc., of the augmentor system, was not to be looked for in the intrinsic ganglia of the heart, but in the ganglion trunci vagi, and that the intrinsic ganglion cells formed a still further ganglionic system upon which both sets of nerve fibres could act. This seemed possible, because, on the one hand, I had shown clearly that this ganglion in the crocodile, which in this animal is situated at the entrance of the thoracic region, is a motor ganglion, from some of the cells of which the terminal motor nerves to the œsophagus and stomach arise; and, on the other hand, that the fibres of the short ciliary nerves are medullated, although they are the terminal nerves of those cells in the ciliary ganglion, which are the motor cells of the fine medullated fibres of the third nerve. It seemed, therefore, plausible that the cardiac fibres of the vagus might enter the heart as fine medullated fibres, even though they were connected with cells in the ganglion trunci vagi. This question received its answer¹ by means of section of the vagus nerve in the crocodile, in the neck, between therefore the ganglion jugulare and ganglion trunci vagi, and subsequent degeneration of the fibres. I then found that, whereas after periods varying from twenty-five days to three hundred days, stimulation of the peripheral end of the cut nerve in the neck produced neither inhibition nor contraction of the œsophagus, stimulation of the nerve peripheral to the ganglion caused as good a contraction of the œsophagus as before, but no sign of any inhibitory effect upon the heart. This experiment conclusively proved that the cardiac fibres of the vagus did not connect with any ganglion cells of the ganglion trunci vagi, and further that the cells on the course of a motor visceral nerve were nutritive to the fibres in the peripheral direction only. I was also able in the dog to trace those fine medullated fibres, among which the inhibitory fibres must have been, from the accessory roots of the vagus, past the ganglion jugulare into the ganglion trunci vagi, without a possibility of the presence of any ganglion cells on that part of their course, so that we may say with certainty there are no efferent cells on the course of the cardiac fibres of the vagus nerve, until we reach the intrinsic ganglia of the heart, such as Remak's and Bidder's ganglia and the other ganglion cells found on the course of the nerve fibres in the heart itself. Finally, Langley's² experiments with nicotine have shown that the action of this drug is to break the connection between the efferent medullated fibre from the central nervous system or pre-ganglionic fibre and its vagrant nerve cell, while it does not impair the action of the processes from the nerve cell to the muscular tissue, *i.e.* the post-ganglionic fibres; and by a series of such observations, he has come to the conclusion that each efferent visceral nerve possesses upon its course, from the central nervous system to its termination in the peripheral tissue, one and only one nerve cell.

Taking into consideration also the recent investigations of Ramón y Cajal and others,³ as to the connection of nerve fibres with nerve cells,

we may formulate our present knowledge of the meaning of the ganglion cells in the heart as follows:—

Efferent fibres of opposite function leave the central nervous system to supply the viscera; they pass out of the central nervous system as the fine medullated processes of nerve cells in the central nervous system. These nerve fibres, the pre-ganglionic fibres, do not pass directly into the tissue of the peripheral organ, but each one terminates in connection with an efferent nerve cell, from which a number of fibres, the post-ganglionic fibres of the same physiological value, pass to the tissue. The efferent nerve cells of the augmentor system are situated in the ganglia of the so-called sympathetic system; the corresponding efferent nerve cells of the inhibitory system are situated in the heart itself.

This simple explanation of the meaning of the cardiac ganglion cells, combined with Langley's discovery that nicotine acts upon the junction between the nerve fibre and its efferent cell, like curari upon the termination of the motor nerve in striated muscle, while it does not affect the termination of the post-ganglionic nerve fibre in the end tissue, immediately gives (as pointed out by Langley and Dickinson¹) a straightforward explanation of Schelske's and Schmiedeberg's experiment with respect to the action of the vagus nerve in the frog, after curari and nicotine respectively; for it is clear that in stimulating the so-called vagus in this case, they were really stimulating the post-ganglionic fibres of the augmentor system and the pre-ganglionic fibres of the inhibitory system. The former fibres, therefore, were unaffected by the poison, while the junction between the latter and their efferent ganglion cells was interrupted, consequently acceleration and augmentation alone took place, although direct stimulation of the venous sinus still caused standstill, because, with the electrodes in that position, the post-ganglionic fibres from Remak's ganglia were stimulated. Atropine, on the other hand, prevented the inhibition upon direct stimulation, because, as will be shown later, it paralyses the action of the post-ganglionic fibres upon the muscular tissue.

Again, the evidence that these intrinsic ganglion cells belong to the same system as the extrinsic efferent ganglia, is borne out by the results of embryological investigation, which may be shortly summed up by saying that the observations of Balfour² and Onodi³ have led to the conclusion that the sympathetic chain of ganglia is formed as offshoots from the spinal ganglia; and the recent observations of His,⁴ and of His and Romberg,⁵ have shown that the same method of origin applies also to the cells in the heart itself. They are found in connection with the vagus nerves as offshoots from the vagus ganglia, at first outside the forming heart, and afterwards become included within the heart itself. These workers further confirm previous observations, to the effect that the heart has already begun to beat before the ganglion cells have become included in its tissues. Although in most animals the intracardiac ganglion cells belong to the vagus nerve, yet in some, especially in man, according to His, they are chiefly derived from the sympathetic ganglia. If such a difference really exists, then it is possible that in all animals a varying number of fibres belonging to the augmentor nerves may not reach their ganglion cell until they enter the heart itself.

But the upholders of the special cardiac nerve centre theory may argue, "You have given away your case; you acknowledge that the ganglion cells of the heart must be looked upon as precisely of the same character as the ganglia of the sympathetic system; and seeing that there is evidence that these latter do act as an independent central nervous system, so it must also be with the former."

Undoubtedly, the efferent nerve cells, both in the heart and in other places, are the trophic centres of the fibres which spring from them, and in so far as the nutrition of the muscle fibre and its condition of well-being is dependent upon the integrity of its efferent nerves, these nerve cells may be considered as nerve centres governing the muscle; but a central nervous system means more than this, it means essentially a system of nerve cells and fibres connected with both afferent and efferent nerves, by means of which reflex action is able to take place; and it is because there is no evidence in any part of this vagrant ganglionic system of any connection between afferent and efferent nerves constituting a true reflex arc, that I for one am unable to attribute the function of a central nervous system to any part of it.

The evidence, as far as it goes at present, seems to point directly to the conclusion that the trophic centre of all the afferent visceral nerves is situated in the stationary ganglia of the posterior roots, and that, therefore, all the nerve cells of the vagrant ganglia are efferent; that, further, as shown by Langley and Anderson,¹ the so-called reflexes from isolated sympathetic ganglia are not true reflexes, but rather actions along branching efferent nerves. All the conditions necessary for a reflex action of this kind are present in the heart, and in all probability the same explanation as that given by Langley and Anderson for the hypogastric reflex holds good for the reflex which I have described in the heart of the tortoise,² upon stimulation of the ventricle, when the auricles are cut away from the ventricle, so that the coronary nerve is the only communication left between ventricle and sinus. In such an experiment the sinus and auricles are beating regularly, and the auricular contractions are registered, while the ventricle remains quiescent. Stimulation of the coronary nerve near the ventricle, or of the surface of the ventricle in the neighbourhood of the coronary nerve, caused, whenever I tried it, a slowing of the rate of beat and a diminution in the strength of the auricular contractions; caused, in fact, the same effect as a weak vagus stimulation. The strength of stimulus to the ventricle, which produced this effect, was not necessarily enough to cause a contraction in the quiescent ventricle. It is to be remarked that the effect was always in the direction of inhibition, as must necessarily be the case if the ganglion cells of the heart are efferent vagus cells, and if the effect of the stimulation was not due to an escape of current but to an efferent reflex action of the kind suggested.

THE NATURE OF THE ACTION OF THE CARDIAC NERVES.

1. **The action of the inhibitory nerves.**—As already stated, Weber pointed out that stimulation of the vagus in the frog not only slows the heart, but also weakens the contractions. In the controversies that followed, this latter fact was largely lost sight of, until, in Ludwig's laboratory

¹ *Journ. Physiol.*, Cambridge and London, 1894, vol. xvi. p. 410.

² *Ibid.*, 1888, vol. iv. p. 92.

in 1869, Coats¹ pointed out that the contractions of the heart registered by a mercurial manometer were markedly diminished in force upon stimulation of the vagus nerve. These observations were followed by those of Nuël,² who observed that the contractions of the auricle were diminished to a greater extent than those of the ventricle, and were afterwards confirmed both by myself and Heidenhain in 1881 and 1882. This very fact, that a diminution in strength of contraction as well as in rate, taken in connection with the observed fact that the force of the cardiac contraction does not vary with the strength of the stimulus, ought of itself to have been sufficient to convince physiologists that the inhibitory nerve acts on the muscle itself, and not by diminishing a stimulus from motor ganglia. So strong, however, is the incubus of a dominant theory, that even up to this day the action of the vagus nerve is spoken of as diminishing impulses to the muscle rather than as affecting the muscle itself.

Quite early in the investigation of the action

of the vagus nerve on the heart, Schiff³ pointed out that the muscular tissue, both of auricle and ventricle, in the frog, responded less readily to a stimulus during standstill, or even would not respond at all, although the stimulus was a strong one. This was confirmed by Eckhard,⁴ and is now universally allowed, and is evidence that the vagus nerve diminishes the excitability of the muscular tissue.

FIG. 108.—Heart of toad. Suspension method. Clamp in auriculo-ventricular junction. Weak stimulation of the intracranial roots of the vagus nerve.

Next came the work of myself and Heidenhain, which showed the necessity of separating the inhibitory from the accelerator fibres in the frog's vago-accelerator nerve, in order to obtain the pure effects of inhibitory action. The contrast between the stimulation of the vagus in the frog or toad, as ordinarily given, and that of its two components, the intracranial vagus on the one hand and the sympathetic on the other, is given in Figs. 108, 109, 110, 111, 112, 113; and in my paper in the *Philosophical Transactions*, a number of tracings show how variable is the extent of the inhibitory effect when the augmentor fibres are stimulated simultaneously. In my experiments upon the effect of stimulation of the intracranial vagus, I have been struck with three phenomena,⁵ which

¹ *Ber. d. k. Sächs. Gesellsch. d. Wissensch.*, Leipzig, 1869, S. 360.

² *Arch. f. d. ges. Physiol.*, Bonn, 1874, Bd. ix. S. 83.

⁵ *Trans. Internat. Med. Cong.*, Copenhagen, 1884, Section of Physiol., p. 29.

are in marked contrast with what is seen when the vagus is stimulated in the ordinary manner. In the first place, I have been able to obtain absolute standstill with a strength of current immensely weaker than what is required to obtain any effect when the vago-augmentor nerve is stimulated. In one case the strength of current was as weak as is just necessary to cause contraction of a striated muscle upon stimulation of its motor nerve, the secondary coil being at 35 cms. from the primary with one Daniell cell; at the distance of 12 cms. from the primary it was just perceptible to the tongue. In the second place, it is astonishing how long the standstill sometimes lasts after the stimulation is over. Thus one of my tracings shows that a stimulation of the intracranial vagus, lasting thirty-eight seconds, caused the suspended heart to remain absolutely still for 290 seconds, *i.e.* for 252 seconds after the end of the stimulation. In the third place, it is possible to keep the heart absolutely still by means of continued stimulation for a very much longer time than is possible when the vagus is stimulated in the ordinary manner. Thus, as I mentioned at Copenhagen, I have kept the heart absolutely quiescent for as long a time as twenty-eight minutes by continued stimulation of the intracranial vagus with a weak stimulus (sec. coil between 12 and 11 cms. from primary).

In order to investigate more fully the action of the inhibitory fibres alone, I turned my attention to the land-tortoise (*Testudo graeca*) an animal which not only has the advantage that its inhibitory nerve is separate from its accelerator, but also possesses,

as already described, a free coronary nerve, the fibres of which belong to the vagus system. It is possible to cut this nerve and stimulate it without in any way damaging the heart, and so an insight can be obtained into the action of the inter-auricular nerves in an intact heart. The presence of this free nerve, between the sinus and auriculo-ventricular junction, has proved invaluable in increasing our knowledge of the action of the inhibitory nerves. Fig. 114 shows the effect of stimulation of the isolated coronary nerve, the sinus end having been cut and ligatured. If Fig. 114 be compared with Fig. 115, which shows the effect of stimulation of the right vagus in the neck, we see that the difference between the two curves consists simply in this, that the coronary nerve diminishes the strength of the contractions of the auricle without affecting the rate of the beat, while the vagus diminishes both the rate and the strength of the auricular contractions. In this instance the slowing of the rate of

FIG. 109.—Heart of toad. Suspension method. Clamp in auriculo-ventricular groove. Short stimulation of the intracranial vagus roots with current of moderate strength. The change of level in the auricular tracing during the stimulation is due to the movement of the laryngeal and trapezius muscles.

FIG. 110.—Heart of toad. Suspension method. Ventricle only registered. Long stimulation of the intracranial vagus roots with moderately strong current.

FIG. 111.—Heart of toad. Suspension method. Clamp in auriculo-ventricular groove. Stimulation of augmentor (sympathetic) nerve before it joins the vagus.

FIG. 112.—Heart of toad. Suspension method. Clamp in auriculo-ventricular groove. Stimulation of vagus (*i.e.* vago-sympathetic) nerve in neck.

FIG. 113.—Heart of frog. Suspension method. Clamp in auriculo-ventricular groove. Stimulation of the vagus in the neck (*i.e.* the combined vagus and sympathetic nerve), showing the effect of the simultaneous stimulation of the two nerves.

the auricular, and therefore also of the ventricular, contractions is not due to a slowing of the rate of the heart-beat, for, as is seen, the sinus continues beating at the same rate as before; but is due to a partial blocking at the sino-auricular junction, caused by the stimulation of the vagus nerve. In the majority of instances the vagus of the tortoise

FIG. 114.—Heart of tortoise. Suspension method. Stimulation of the peripheral end of the cut coronary nerve.

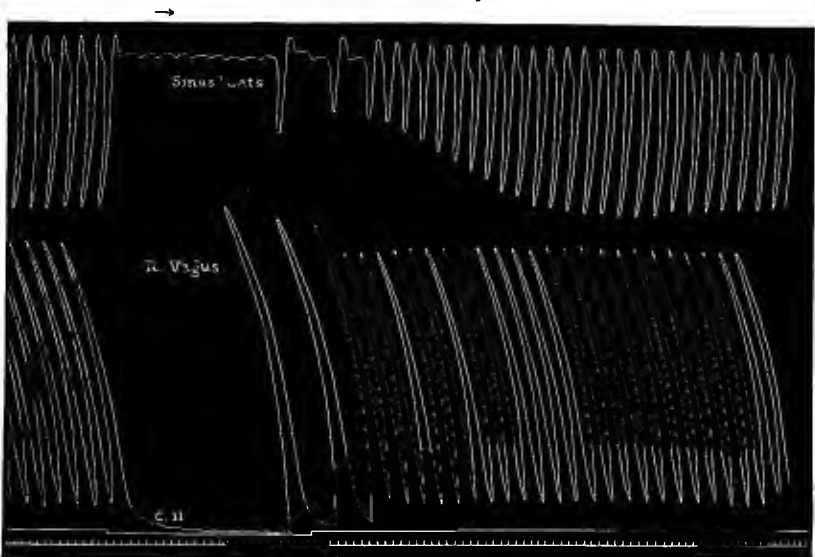

FIG. 115.—Heart of tortoise. Suspension method. Stimulation of right vagus nerve in the neck.

(especially the right vagus) causes a slowing or stoppage of the whole heart-beat, just as in other animals. It is further noticeable in these two curves that when, as in Fig. 114, the rate of the auricular contractions is unaltered, the contractions of the ventricle remain absolutely unaffected, while in Fig. 115 the contractions of the ventricle, instead of being diminished by the stimulation of the nerve, are increased in strict accordance with the amount of slowing of the auricular contractions.

Such curves are to be explained as follows:—

If the muscular fibres are initiating a rhythm, then the effect of stimulating the fibres of the vagus which supply them is to diminish both rate and contraction force, as is the case in the sinus muscle; if the muscle fibres are not initiating a rhythm, but only responding to a regular series of contraction waves from the sinus, then the stimulation of the fibres of the vagus which supply these muscle fibres cannot influence rate, but only the force of their contraction, as is seen in the case of the auricle when the coronary nerve is stimulated.

This experiment proves that the nerve fibres of the vagus which diminish the force of the auricular contractions act in the same manner after they have passed the ganglia in the sinus as before. Still it does not prove that the post-ganglionic fibres which pass directly into the auricular muscle act in the same way as the pre-ganglionic fibres, for at the junction of auricle and ventricle groups of nerve cells exist with which the fibres of the coronary nerve or some of them—for many, if not all of them, are medullated—do certainly have connection; and it is possible to argue that these cells are part and parcel of an inhibitory centre, just as much as those in the sinus. It is, however, easy to show that the post-ganglionic nerve fibres in the muscle itself still produce the same effect upon the auricular contractions as the pre-ganglionic fibres.

A strip of muscle is taken from the apex of the auricle, suspended and attached by means of a thread at one extremity to a lever, so as to register its contractions. Single induction shocks at regular intervals are sent in to the muscle at the fixed end; and by means of very thin wires, fixed at the two extremities of the muscle, which do not interfere with the free movements of the muscle strip, a weak interrupted current can be sent through the whole length of the strip. When the strip is first suspended, each contraction is able to travel only a little way, owing to the number of blocking places caused by the section.

These blocking places are gradually removed, their removal being assisted by the application of a weak interrupted current at intervals, until at last every single induction shock produces a strong contraction which travels quickly and uniformly from one end of the strip to the other. When this result has been obtained, the strip will often begin to beat spontaneously. If now a weak interrupted current, too weak to cause any contraction, is sent through the strip, whether the contractions are spontaneous or not, these contractions are diminished in size, or even inhibited altogether, just as if the vagus nerve had been stimulated. Further, atropine applied to the strip removes this effect of the interrupted current, just as it removes the action of the vagus nerve. Finally, if the strip be clamped in the middle, and the single induction shocks applied to the lower half only, while the weak tetanising current is applied to the upper half, it is possible to clamp so tightly that only the lower half will respond to the single induction shocks, and yet these contractions will be diminished in size by the stimulus of the weak interrupted current applied to the upper half only. Clamp tighter, and then the weak interrupted current produces no effect upon the contractions of the lower half. In other words, the upper part of the strip behaves like a nerve to the lower half of the strip.

These experiments are, it appears to me, very strong evidence that the post-ganglionic inhibitory fibres in the auricular muscle itself act in the same way as the pre-ganglionic, and that such fibres are stimulated

simultaneously with the muscle, whenever the muscle is directly stimulated. The interpretation, in fact, which Schiff gave to the local diastole, caused by direct stimulation of the frog's ventricle, is confirmed and elucidated by these experiments on the behaviour of the strip of tortoise auricle to direct stimulation.

One of the most striking primary depressing effects of stimulation of the vagus nerve is the depression of conductivity. In the intact heart such depression takes place at the two natural blocking points, namely, the sino-auricular and auriculo-ventricular junctions; in my experiments with the suspended heart I have frequently obtained upon stimulation of the vagus, especially in the case of the crocodile, tortoise, and snake, an absolute standstill of both auricle and ventricle, although the sinus has continued to beat regularly. In these cases it was perfectly clear upon inspection that the contractions of the sinus stopped absolutely at the sino-auricular junction, and did not pass into the auricle. Fig. 115 affords an example of this phenomenon.

So also in the case of the suspended heart of the frog, with the clamp at the auriculo-ventricular junction, I have seen instances where stimulation of the vagus nerve has caused the ventricle during the stimulation to respond to only every second auricular contraction. In such cases, owing to the simultaneous stimulation of the accelerator nerve fibres, the rate of rhythm was not slowed, and in consequence the diminution in conductivity was able to be manifested.

This depression of conductivity at the auriculo-ventricular junction, as the result of stimuli of inhibitory fibres, gives a simple explanation of Eckhard's experiment,¹ that stimulation of the cut septal nerves in the frog causes the ventricle to stand still, although both auricle and sinus continue beating.

Perhaps the clearest evidence of the primary influence of the vagus nerve upon the conductivity of the auricular muscle is given by stimulation of the nerve when the auricle of the tortoise is slit up so as to cause a partial block in the passage of the contraction wave over the two parts of the auricle as in Fig. 105. In this case for a long time the contractions of *Av* and *V* follow only upon every second contraction of *As*, and the result of stimulation of the inhibitory fibres supplying the auricle is to make the block complete, so that during the stimulation no contractions pass from *As* to *Av*, and the ventricle therefore remains still. Naturally this experiment succeeds only when stimulation of the vagus does not cause a standstill of the whole heart, and is therefore most easily seen upon stimulation of the coronary nerve, rather than of the vagus nerve itself.

It is clear from what has been said, that apparent standstill of the heart, *i.e.* of the auricle and ventricle, may be produced by stimulation of the vagus in three distinct ways—

1. By the depression of rate in the sinus.
2. By the depression of conductivity at the sino-auricular junction, so that the sinus continues beating, but the auricle and ventricle remain still.
3. By the depression of the force of the contraction to invisibility, so that, although the contractions pass from the sinus into the auricle, these latter are so diminished in force as to be not apparent.

Such a depression of the force of the contractions of both auricle

¹ *Beitr. z. Anat. u. Physiol. (Eckhard)*, Giessen, 1876, Bd. vii.

and ventricle has only been observed by me in the heart of the toad or frog, where, in consequence of the combination of the accelerator nerves with the vagus, the diminution of contraction force has been accompanied with acceleration of rate.

In addition to the depression of rhythmical power, of excitability, of contraction force and of conductivity, the vagus produces as a primary effect a depression of tonicity, so that the muscular tissue relaxes when the nerve is stimulated.

Ever since the action of the vagus has been studied by physiologists, the flaccid condition of the heart distended with blood, which is seen during standstill, has attracted their attention, and has been, again and again, attributed to an active relaxation of the cardiac muscle due to the stimulation of the inhibitory nerve. The difficulty has always been to prove that such relaxation does in reality take place, owing to the difficulty already mentioned

FIG. 116.—Modification of Roy's tonometer.

of proving that the cardiac muscle possesses tone in addition to its rhythmical contraction. The extent of relaxation between the contractions depends on the rapidity of rate of beat; any influence, therefore, such as the action of the vagus nerve, which slows rate, must increase the relaxation between the contractions without necessarily altering the tone of the muscle. In order, then, to be sure that the nerve does alter the tonicity of the muscle, the rate of beat must be unaltered or even quickened at the same time that the relaxation of the muscle is observed. Also it is clear that the extent of relaxation can be more easily observed by the measurement of the volume of the ventricle or auricle, than by any linear measurement, such as is given by the method of suspension. In order to estimate this relaxation, I have made use of a modified Roy's tonometer,¹ as seen in the accompanying Fig. 116.²

It consists essentially of two parts—a glass chamber *a*, which contains the heart and its nerve, and a recording chamber *b*, which contains oil, and is

¹ Roy, *Journ. Physiol.*, Cambridge and London, 1878, vol. i.

² Cf. *Phil. Trans.*, London, *op. cit.*, p. 1019.

fitted with a piston and membrane as in Roy's tonometer. The chamber *a* is hermetically sealed with a vulcanite stopper, which holds a cannula *e*, which can be fitted into the vena cava inferior, a small glass cannula *h*, which is fixed into one of the aortic trunks, a cork slab *f*, on which the heart is fixed, and a glass tube *g*, containing the platinum electrodes, which is closed, except for two small holes which are blown exactly opposite each other in the middle of this tube. Through these holes the vagus nerve can be drawn by a thread attached to its extremity, and by pinning the thread on to the cork slab *f*, the nerve will always remain in contact with the electrodes. The fluid within the chamber *a* cannot penetrate within this glass tube, and therefore the nerve lies on the electrodes surrounded with moist air, although the chamber *a* is filled with salt solution or other fluid. The lower extremity of the reservoir *b* is on the same level as the top of the chamber *a*, so that *b* can be filled with oil without any fear of contamination from the salt solution or other fluid in *a*. A vulcanite plug is provided in one of the holes in the vulcanite stopper, for the purpose of removing all air from the chamber *a*. The tap and indiarubber tube *d* is for the purpose of allowing oil to pass out of *b*, and so, by means of the negative pressure thus caused, of raising the piston until the lever is in the horizontal position. In tying the superior vena cava care must be taken not to injure the vagus nerve.

By means of this apparatus the heart can be kept beating for days, if necessary, and the vagus stimulated. The fluid which flows through the heart may be varied at will, and the effect of the vagus tested with different fluids. The heart may be placed in a fluid of a composition different to that which is flowing through its cavities. The whole heart may be used, or only the ventricle or apex.

The curves so obtained are difficult to interpret, owing to the fact that the volume measured at any moment is the volume, not of the ventricle or auricle alone, but of the whole heart; so that if, as seems the case in the normal beat of the frog's heart, there is no moment of time when both auricles and ventricle are simultaneously fully relaxed, it necessarily follows that an action like that of the vagus, which causes a simultaneous cessation of their contractions, must cause a marked increase in the volume registered by the apparatus. As mentioned in my paper, I have endeavoured to eliminate the action of the auricles by raising the pressure within them to a height sufficient to prevent their contraction, and therefore to estimate the change of volume caused by the stimulation of the vagus nerve in a heart consisting of quiescent auricles and a contracting ventricle. Also, owing to the presence of the accelerator nerves in the frog's vagus, I have been able to obtain curves in which an increase of volume has been distinctly shown without any slowing of rate of beat, or any indication of auricular contractions. From these curves I conclude that the vagus is able to diminish the tonicity of the frog's ventricle and *a fortiori* of the frog's auricle.

So far I have described the primary effects of the vagus nerve upon the beating heart, and shown that such effects are produced by the direct action of the nerve upon the active muscular tissue. It is therefore of great interest to show the nature of this action upon the cardiac muscle when that muscle is at rest. Such an experiment is possible in the case of the tortoise, owing to the presence of the coronary nerve, for by means of that nerve the vagus in the neck still remains in communication with the auricle and ventricle when the sinus is cut away without injuring the coronary nerve. In such a preparation—equivalent

to the first Stannius ligature—the auricle and ventricle at first remain absolutely quiescent naturally, and then begin to contract with their own independent rhythm. It is then found that the contractions of the auricle are diminished in force when the vagus nerve in the neck is stimulated, showing that the vagus in the neck can affect the auricular muscle, through the coronary nerve.

This experiment shows that the vagus produces an effect upon the muscle of the auricle, which is manifested as a diminution of the force of its contractions, as soon as the auricle begins to beat. It follows clearly that this action of the nerve on the muscle must still exist during the period of quiescence, before the spontaneous contractions begin, although the stimulation of the nerve at this time produces no visible change of form.

This invisible action of the nerve on the muscle can be rendered

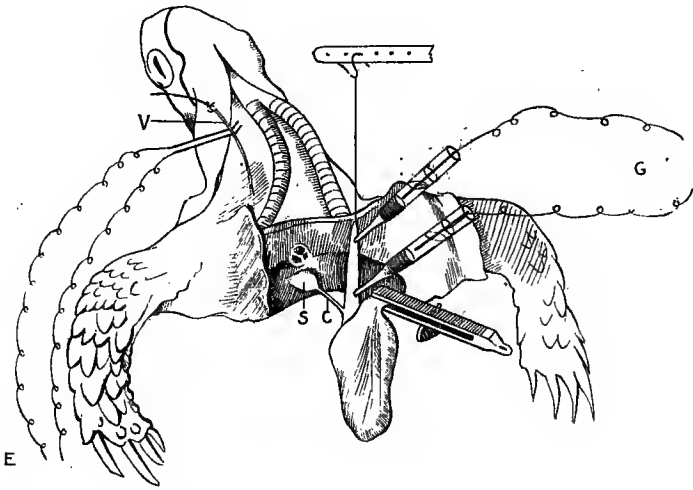

FIG. 117.—Method of preparation of the heart of the tortoise in order to demonstrate the action of the vagus nerve on the quiescent auricles. S, sinus and part of auricle; C, the coronary nerve and vein; V, the right vagus nerve; E, electrodes connected with interrupted current; G, non-polarisable electrodes connected with the galvanometer.

visible by means of the galvanometer, and it is then seen that the action of the inhibitory nerve is of the opposite character to that of a motor nerve, in that it produces a positive and not a negative variation of the demarcation current.¹

The experiment is carried out in the following way:—

The heart is cut through between the sinus and the auricles so as to leave the coronary nerve intact, and the apex of one auricle and that of the ventricle are attached to the levers in the usual way. Fig. 117 shows the preparation. The apex of the auricle is heated, so as to cause a strong demarcation current, and non-polarisable electrodes are placed on the heated apex and on the uninjured auricular tissue near its base. The electrodes are attached to the galvanometer, and the demarcation current is registered every five seconds by an observer stationed at the galvanometer, who is therefore not necessarily aware

¹ Gaskell, *Beitr. z. Physiol. C. Ludwig z. s. 70 Geburtst. gew.*, Leipzig, 1887, S. 114; also *Journ. Physiol.*, Cambridge and London, 1887, vol. viii. p. 404.

when the nerve is stimulated. The curve so obtained is given in Fig. 118, and shows clearly the fact of the positive electrical variation in consequence of vagus stimulation, and also that such electrical change takes place so slowly that its course can easily be registered by an observer who is noting the position of the galvanometer needle only every five seconds. Such a rate of change is remarkably different from the rapid movement in the opposite direction, which occurs when a contraction takes place. This action of the vagus is abolished by atropine, or by ligaturing the coronary nerve tightly, so as to destroy its physiological continuity with the vagus in the neck.

Such, then, are the primary effects of the stimulation of the vagus nerve: depression of rate, depression of excitability, depression of con-

FIG 118.—Curve of demarcation current caused by heating apex of auricle. Divisions of ordinate represent divisions of the galvanometer scale in centimetres. Fine divisions of abscissæ represent intervals of five seconds. As is seen, the demarcation current diminishes at first rapidly, then more slowly, during the course of the experiment. At intervals, as represented by the arrows, the right vagus or right augmentor nerves were stimulated.

traction force, depression of conductivity, depression of tonicity, and increased positivity of the muscular substance.

We may therefore conclude that the nerve acts in the same way on all the attributes of auricular muscle, that its terminal fibrils in the muscle act in the same way as its main fibres in the neck, and that atropine paralyses these terminal fibrils; and that, therefore, as far at all events as the auricle is concerned, any explanation of inhibition must be consistent with a direct action of an inhibitory nerve on muscle.

The evidence shows, further, that in all cold-blooded animals, without exception, the vagus acts powerfully on the auricle. When, however, we consider its action upon the ventricle, we come immediately face to face with one of the most puzzling and most important facts in the innervation of the heart of cold-blooded vertebrates, namely, that as far as is at present known the vagus has no effect whatever upon the ventricle of any cold-blooded vertebrate except the Amphibia. In my experiments¹

¹ *Journ. Physiol.*, Cambridge and London, 1887, vol. viii. Pl. XII. Figs. 1 and 2, a.

on the tortoise, I could not find any diminution in the force of the contraction of the ventricle, such as is well known to occur in the frog and toad (cf. Figs. 114 and 115 and Figs. 108 and 109), but, on the contrary, have always found that the ventricular contractions are unaltered in strength if the rate of beat is unaltered (Fig. 114), or increased in strength according to the amount of slowing of the rate of beat caused by the stimulation of the nerve (Fig. 115); and MacWilliam¹ says that during the standstill due to vagus stimulation there is no diminution of excitability in its ventricle, as certainly occurs in the case of the frog. The same indifference of the ventricle to vagus stimulation was seen in the case of the eel by MacWilliam, of the crocodile and snake by me, of the terrapin and toad-fish by Wesley Mills;² in other words, in all the cases of Teleostei, Chelonia, and Reptilia which have been observed, the vagus does not in any way affect the ventricle. On the other hand, the vagus does affect the ventricle in the same way as the auricle—though to a less degree—in the frog and toad, in the newt according to MacWilliam, and in *Menobranchus* according to Wesley Mills,³ all instances which are included in Amphibia.

Further, in absolutely strict accordance with this absence of effect upon stimulation of the nerve in the neck, is the absence of inhibitory effect upon direct stimulation of the muscle.

Thus, as already mentioned, direct stimulation of the ventricle of the frog produces a local diastole which may last for some time, and is removable by atropine—produces, in fact, on the frog's ventricle an inhibitory effect which exactly corresponds with what I have described as the effect of direct stimulation of the suspended strip of the auricle of the tortoise. With, however, the suspended strip of the ventricle of the tortoise matters are very different. Here, just as in the case of the auricle, a series of blockings to the passage of the contraction are first got rid of, so that finally each of the single induction shocks causes a contraction which passes freely from one end of the strip to the other, but at no time does the passage of a weak interrupted current diminish the force of these contractions; even if the strip is beating spontaneously there is no evidence of any inhibition when the interrupted current is sent through.

A precisely similar negative result upon direct stimulation of the ventricle has been observed by me in the crocodile, and by MacWilliam in the eel.

Another somewhat unexpected coincidence is brought out by the comparison of ventricular muscle whose contractions are diminished by vagus stimulation, and ventricular muscle whose contractions are not so diminished; namely, that the staircase phenomenon obtains only in the former case and not in the latter.

This phenomenon of the staircase (*Treppe*) was discovered, as has been already mentioned, by Bowditch⁴ in the apex preparation of the frog's ventricle, and consists in this, that in the quiescent apex, through which a series of efficient single induction stimuli are sent, the first contraction is not the strongest, but the contractions increase in staircase fashion, until a certain maximum is reached at which the con-

¹ *Journ. Physiol.*, Cambridge and London, 1885, vol. vi. p. 224.

² *Ibid.*, vol. vi. p. 246; and vol. vii. p. 81.

³ *Ibid.*, 1886, vol. vii. p. 81.

⁴ *Op. cit.*

tractions remain steady for some time. MacWilliam¹ has been unable to confirm this observation of Bowditch when the ventricle of the eel or tortoise is used instead of that of the frog. In these cases he says there is no sign of any ascending staircase, the first contraction is as large as any of the others. I have seen the same thing in the strip of the tortoise ventricle; here it is true that the single induction shocks, when first sent into the strip, cause very small contractions, and gradually and more or less steadily the contractions increase in size, until they attain their maximum; this phenomenon, however, is clearly due to the gradual removal of the blocking points in the strip. When the strip has recovered, so that every contraction passes freely from end to end, then I have found that the first contraction after a pause, whether long or short, is as large as any of the subsequent contractions. It is very suggestive in this connection, that Bowditch² found that atropine removed this staircase effect in the frog's ventricle. The atropinised frog's ventricle, in fact, behaves in this respect, as in so many others, similarly to the non-atropinised ventricle of the tortoise, and this suggests that the phenomenon of the *Treppe* is due to the direct stimulation of inhibitory fibres in the frog's ventricle.

The investigation of the primary action of the vagus on the heart of cold-blooded animals brings out clearly two facts of great importance—

1. The inhibitory action is a direct one of nerve fibre upon muscle fibre, and affects all the properties of the muscle fibre in the same way—rhythmicity, excitability, conductivity, contraction-force, and tonicity.

2. The cold-blooded vertebrates are divisible into two sets, namely, those of the amphibian type, in which the ventricular muscle is affected in the same way as the auricular, but to a less degree, and those of the same type as Teleostei, Chelonia, and Reptilia, in which the inhibitory action of the vagus nerve appears to be confined to the auricles; at all events, no action is apparent on the ventricles.

This extraordinary and unexpected difference in the behaviour of the vagus nerve in these two groups leads at once to the idea that we are dealing here with a deep-seated morphological difference, and that the study of the physiology of the cardiac nerves may give very important help in the classification of the vertebrata; thus, if the birds have arisen from reptiles and the mammals from amphibia, we might expect to find that the vagus nerve does not affect the ventricle in the bird's heart, but does act upon the mammalian ventricle in the same way as upon that of the frog or toad. As far as the latter question is concerned, the experimental researches of MacWilliam³ point to the conclusion that the vagus does diminish the force of the ventricular as well as the auricular contractions in the various mammalia investigated (cat, dog, rabbit, rat, hedgehog, guinea-pig), and indeed that the nerve acts upon rhythm, excitability, contraction-force, etc., of the different parts of the heart, precisely in the same way as in the case of the amphibian; so that, as far as the heart of the mammal is concerned, the physiologist would agree that it is closely related to the amphibian. With respect to the heart of the bird, I have been unable to find any evidence;⁴ I cannot find that anyone has ever observed the effect of

¹ *Journ. Physiol.*, Cambridge and London, 1885, vol. vi. p. 212.

² *Op. cit.*

³ "Inhibition in the Mammalian Heart," *Journ. Physiol.*, Cambridge and London, 1888, vol. ix. p. 345.

⁴ Knoll, who has recently published a paper on the action of the vagus nerve in warm-blooded animals (*Arch. f. d. ges. Physiol.*, Bonn, Bd. xlvii. S. 595), describes some experiments on the hearts of pigeons as well as those on mammals. In this paper he points out that stimulation of the vagus nerve does diminish the strength of the contractions of the

the vagus upon the force of the ventricular contractions of the avian heart; it would undoubtedly be a very interesting subject of research. So also, in the case of Elasmobranchii, I cannot find anything definite; it does not appear to be known whether they behave like Amphibia or Teleosts. It would also be interesting to investigate the lung-breathing fishes, *Protopterus*, etc., which I should expect to behave like Amphibia.

It is perfectly conceivable, as Roy¹ has pointed out, that the strength of the auricular contractions is the most important factor in the beat of the heart, and that, therefore, it is not so necessary that the force of the ventricular contractions should be regulated to the same extent as the auricular; but still it is difficult to believe that in the evolution of the heart one part of its muscular structure was supplied with nerves, and not the other; we must, it seems to me, imagine that in the protovertebrate, the whole of the muscular tissue of the longitudinal venous sinuses was supplied with the inhibitory fibres, and that, as the different groups evolved themselves with the formation of auricles and ventricles, the inhibitory fibres still supplied all parts of the heart. It is possible that the difference in the behaviour of the ventricles in the two groups is due to a difference in the evolution of the striated muscular tissue of the ventricle, and that it still remains to be found out what change the inhibitory fibres do produce in the ventricular muscle of such an animal as the tortoise. It has certainly seemed to me difficult to believe in the absence of any diminution of tone in the muscular tissue of the ventricle upon stimulation of the vagus, when one sees the enormous increase in the volume of the whole heart when the nerve is stimulated. Still, on the other hand, it is not easy to understand how a nerve can produce a muscular relaxation without any accompanying diminution in the force of the contractions. We must wait for further investigations of the action of the cardiac nerves on the tortoise ventricle before it is possible to decide this question.

2. The action of the augmentor nerves.—The primary action of the augmentor nerves is in every respect exactly the opposite of that of the inhibitory. The evidence both in cold-blooded and warm-blooded animals shows that the rate of rhythm is increased, that the force of the contractions is increased, and that the conductivity is increased. Here, just as in the case of the inhibitory nerve, it is difficult to make any positive statement as to any increase in tonic contraction, apart, of course, from the diminished relaxation that of necessity accompanies an increased rate of contraction in a normally beating heart. Of these different phenomena I have already illustrated the alteration of the rate and force of the contractions in the case of the toad or frog, and it may be noticed that the augmentor nerve takes a very much longer time than the inhibitory nerve to reach its maximum effect, whether that effect consists of an alteration of rate or of contraction force; it is partly for this reason that, in the conjoint stimulation of the two nerves, the action of the inhibitory nerve is always most apparent at first, and that

ventricle in the mammalian heart, though to a less extent than those of the auricle. When a small dose of atropine is given, then it frequently occurs that the contractions of the ventricle are slightly larger during stimulation of the nerve, provided that such stimulation has caused some slowing of rate. He finds, therefore, that the mammalian ventricle behaves like the amphibian, but the atropinised ventricle behaves like the chelonian. In the case of the pigeon he states expressly, and illustrates his statement by tracings (Fig. 1, Taf. II., and Figs. 1 and 8, Taf. IV.), that the ventricle of its heart reacts normally without atropine to vagus stimulation in the same manner as the atropinised mammalian ventricle, *i.e.* its contractions are not diminished but increased in size if the rate is diminished; that, in fact, the avian ventricle behaves to vagus stimulation like the chelonian and reptilian and not like the amphibian ventricle.

¹ *Journ. Physiol.*, Cambridge and London, 1878, vol. i. p. 452.

of the augmentor most conspicuous later. I have chiefly studied the influence of the augmentor nerve upon conduction in the heart of the frog and toad, by means of the clamp in the auriculo-ventricular groove. When the clamp is tightened so that a partial block is caused, and the ventricle is responding to every second or more contraction of the auricle, then stimulation of the augmentor nerve forces the block, so that every contraction passes, even although the rate is increased by the stimulation. The same action upon the passage of a contraction wave over a block, as the result of stimulation of the augmentor nerve, has been described by MacWilliam for the eel, and by Bayliss and Starling¹ for the mammalian heart.

The position of the augmentor nerves seems clear. They belong, as already mentioned, to the same great group of visceral nerves as the vaso-constrictors; they increase the rhythmical power of that part of the heart which is initiating the rhythm; they increase the contraction force and conductivity of the cardiac muscle. They may distinctly be considered as the cardio-motor nerves, the difference between them and other motor nerves being due to the fact that they are motor to a rhythmical instead of a quiescent muscle. The question then arises, Can such a motor nerve cause a quiescent heart to beat? At first sight it would appear that the answer to this question must be in the affirmative, for as long ago as 1860, Schelske² asserted that the vagus, *i.e.* the conjoint vagus and augmentor nerves, could make the frog's heart beat again when it was reduced to standstill by raising the temperature. I myself have found that if the heart of the frog or toad be left till next day, it is often apparently quite motionless, and then stimulation of the conjoint vagus and augmentor nerves will make it beat again strongly. I found, as might be expected, first, that this effect was due to the augmentor fibres, and, secondly, that in reality the heart was not still. A powerful lens showed in every case the existence of exceedingly minute but regular contractions of the sinus and great veins, so that although the auricles and ventricle were absolutely motionless, the sinus contracted regularly. The standstill, in fact, was due to a block between sinus and auricles, just as in the ordinary case of a dying heart a block is first caused between auricles and ventricle, and then between auricles and sinus. The case, then, was not a case of motor action upon a quiescent heart, but a very striking example of the power of the augmentor nerve in removing a block to the passage of the contraction wave. Similarly, with regard to Schelske's experiment, the blocking power of heat upon the passage of the contraction from auricle to ventricle, and the removal of that block by stimulation of the augmentor fibres of the vagus nerve, is shown in my *Philosophical Transactions* paper, Fig. 17, Pl. LXIX. On the other hand, Löwit³ showed, in 1882, that when the heart of the frog had been brought to standstill by the application of muscarine, stimulation of the vagus nerve was able to cause such a quiescent heart to beat strongly. I myself⁴ have repeated his experiment, and found that here too it is the augmentor nerve which causes this effect, and apparently without any sign of beating in the sinus. I found, however, that a further dose of

¹ *Journ. Physiol.*, Cambridge and London, 1892, vol. xiii. p. 407.

² "Ueber die Veränderungen der Erregbarkeit durch die Wärme," Heidelberg, 1860, S. 20.

³ *Arch. f. d. ges. Physiol.*, Bonn, 1882, Bd. xxviii. S. 333.

⁴ "On the Action of Muscarine upon the Heart, etc.," *Journ. Physiol.*, Cambridge and London, 1887, vol. viii. p. 404.

muscarine prevented any such action of the nerve, and am therefore inclined to believe that in this case also the motor effect cannot be produced, unless some portion of the heart (in this case perhaps the large veins) is still beating.

Is it then possible to demonstrate any action of the augmentor nerve upon the quiescent muscular tissue of the heart? The evidence appears clearly to show that the augmentor fibres in the frog and toad supply the muscular fibres of all parts of the heart—sinus, auricles, and ventricle—and cause such changes in that tissue that the rhythmical tissue of the sinus beats more quickly and more strongly, and the contractions of the auricle and ventricle increase in force, while yet they are unable to produce any visible effect in any part of the heart which is quiescent. Can we by any means isolate the ventricle, and yet leave the augmentor nerves to the ventricle intact, so as to test their action on the quiescent ventricle? This can be done either by causing a block between sinus and auricles, by means of the application of muscarine to the sinus, or by clamping between auricles and ventricle. In both cases the ventricle remains still, and in both cases stimulation of the augmentor nerve is able to force the block, and thus produce a series of ventricular contractions. These contractions are increased in force, showing that the augmentor fibres to the ventricle are intact. Increase the muscarine very carefully, or slightly tighten the clamp, and it is then seen that the block cannot be forced, and so the ventricle still remains quiescent when the nerve is stimulated, and no visible effect is produced. However, upon testing this quiescent muscle by means of the galvanometer in the same way as already described in the case of the vagus nerve, a distinct variation in the muscle current was seen upon each stimulation of the nerve, of the opposite character to that seen upon vagus stimulation in the case of the tortoise auricle.¹ Give still more muscarine, or clamp still tighter, and then stimulation of the nerve is absolutely without effect, showing that the previous effect was due to a true nervous action.

This experiment shows that the augmentor nerve causes an electrical change in the muscular tissue, of the opposite kind to that caused by the inhibitory nerve, and it is worthy of note that the process to which this increase of negativity is due is like the corresponding positive change, a slow slight one, very different indeed from the rapid excessive process which initiates a contraction. The contrast between this slow motor effect of the augmentor nerve and the rapid movement of the galvanometer needle in the same direction when a contraction takes place, is most striking. The nature of the electrical change in the case of both nerves seems to me to point to the conclusion that the change which occurs in the quiescent muscle, upon stimulation of the inhibitory nerve, is of the nature of a relaxation or diminution of tone, while the change which occurs upon stimulation of the augmentor nerve is of the nature of an increase of tone. In neither case have I succeeded in actually measuring any difference in length of the muscle, coincidentally with the electrical change, so that the alteration of tone must be slight.

It seems to me that an alteration of tone in the two directions, due to an activity emanating from the ganglion cells of the two sets of nerves, is in accordance with the known facts of the function of the efferent vagrant ganglia, and the nerves emanating from them in other cases, *e.g.* the vasomotor and visceromotor ganglia and nerves.

The augmentor nerves, like the inhibitory, appear to affect the different parts of the heart to a different degree in different animals, and apparently

¹ *Journ. Physiol.*, Cambridge and London, 1887, vol. viii. p. 404, Pl. XIII.

the difference of effect is in the same direction as in the case of the inhibitory fibres. Thus we see in all animals the rhythmical fibres of the large veins and sinus are stirred up to increased rate of beat, and the fibres of the auricles are made to contract more vigorously, while in the amphibians the ventricular muscle is also most markedly influenced by the augmentor fibres which supply it. On the other hand, I am not at all clear whether any augmentor effect can be proved on the ventricle of the crocodile or tortoise; certainly, as far as my curves show, the effect is insignificant in comparison with the increase in the force of the auricular contractions, and I have grave doubts whether there is any true effect at all produced, whether in fact the ventricle of *Chelonia* and *Reptilia* is not as indifferent to stimulation of augmentor fibres as to stimulation of inhibitory fibres. In the case of these nerves, too, the mammalian heart behaves like the amphibian, according to the observations of Roy and Adami,¹ and of Bayliss and Starling.² The comparative physiology of the vertebrate heart requires further investigation, and would, I believe, yield results of very great value to the morphologist as well as to the physiologist.

3. The after-action of the inhibitory and augmentor nerves.—

From what has been said, we may conclude that the muscular tissue of the heart is supplied by two nerves of opposite action, the one of which, speaking broadly, causes a process of relaxation, or an atonic condition, and the other a tonic condition in the tissue. In order to try to understand the nature of these processes, we must investigate, not only the primary effects of stimulation of the nerves, but also their after-effects. Thus we consider that the action of an ordinary motor nerve upon muscle can be classed as katabolic, *i.e.* the metabolism caused is destructive in its character, not only because of the evidence given during the contraction, but also because of the subsequent exhaustion which follows a series of contractions.

What, then, are the after-effects of stimulation of the inhibitory and augmentor nerves respectively, and how far do they throw light on the meaning of inhibition?

In endeavouring to formulate any view of cardiac inhibition, there are, it seems to me, three possible methods of surveying the problem.

The first is the view which has been and is still so largely held, namely, that the inhibitory process takes place outside the muscular tissue, and can be explained either by Rosenthal's resistance theory, or some theory of interference of vibrations, similar to what is well known in the case of light. This theory is absolutely untenable, in view of the fact that the nerve acts directly on the muscle and diminishes its contractions. Of the other two possibilities, we see that such substances as lactic acid and carbonic acid cause a weakening of the contractions, and final stoppage in diastole, so that it is not impossible to imagine that changes detrimental in character to the activity of the tissue might produce the symptoms of inhibition. On the other hand, it is conceivable that a sudden increase in the anabolic process would manifest itself for the time being as a diminution of the katabolic process, and so bring about the diminished contraction and other inhibitory effects, although at the same time the net result would be an increase in that process.

According to the first view, inhibition, as far as the muscle is concerned, means cessation of external stimuli. According to the second, it means a process of exhaustion; according to the third, a beneficial process, the after-effects of which must be the opposite of exhaustion.

¹ *Op. cit.*, p. 244.

² *Op. cit.*, p. 413.

The most marked after-effect of the stimulation of the inhibitory nerve is its effect upon the conductivity of the tissue. When a block has been caused by a partial section of the auricle in the tortoise, so that only every second contraction passes the block, it is very common to see, as an after-effect of vagus stimulation, that every contraction passes, and with frequent vagus stimulation I have found that more and more tissue must be cut away, in order to keep the contractions blocked. Similarly, in the frog's heart, the clamp in the auriculo-ventricular groove requires to be screwed up tighter and tighter after a series of stimulations of the intracranial vagus, in order to cause a partial block. We see, in fact, just the reverse of what occurs in the dying heart, and also the reverse of what is seen after stimulation of augmentor fibres; for in the latter case I have noticed that after a series of stimulations of the augmentor nerve in the frog or toad, a partial block at the auriculo-ventricular junction, so that the ventricle responds to *every second* auricular contraction, is very apt to be produced, although with the clamp in the same position it responded to *every* contraction before the commencement of the series of stimulations. So, too, with respect to the force of the contractions, a series of stimulations of the augmentor nerve distinctly exhaust the muscular tissue of auricle and ventricle, so that it contracts more weakly than it would have done in the same time if no nerve had been stimulated. On the other hand, a series of stimulations of the intracranial vagus in the frog or toad keeps the heart up to a condition of vigorous contraction, which affords a very striking contrast to the condition of exhaustion of the heart which has been acted on by the augmentor nerve. So, too, after repeated stimulations of the augmentor nerve, not only does the heart beat weakly, but also these weak contractions cannot be augmented on stimulation of the nerve to any very great extent; under these circumstances I have frequently seen a decided improvement in the augmentor action, in consequence of the interpolation of two or three intracranial vagus stimulations. In fact, the evidence as to contraction-force and conductivity is distinctly to the effect that in each case the after-effect is in the opposite direction to the primary effect.

The after-effect upon rhythm is not so clear. My own experience is that, if I have been stimulating the augmentor nerve alone for a long time at intervals, the net result has been a quick rate of beat throughout the whole time; and if I have been stimulating in the same way the intracranial vagus alone, then, throughout, the heart has been beating slowly. I do not mean to assert that there is never any evidence of an increase of rate after each vagus stimulation, but simply that the exhaustion of the rhythmical tissue of the sinus, which is presumed to follow after repeated stimulations of the augmentor nerve, does not manifest itself in a marked slowing of the beat, any more than the presumed beneficial effect of a series of vagus stimulations manifests itself by a marked quickening of the beat. I do not feel clear how far it is possible to argue with respect to rate in the same way as with respect to force of contractions; an exhausted muscle must necessarily contract more weakly, but does it necessarily follow that an exhausted rhythmical muscle beats at a slower rate of rhythm?

The conclusion to which I came in 1881¹ was that the vagus nerve was the anabolic nerve of the heart, and that inhibition or relaxa-

¹ *Phil. Trans.*, London, vol. clxxiii. p. 1029.

tion of muscular tissue was a sign of anabolism in that tissue, just as contraction of the tissue is a sign of katabolism in that tissue. Subsequently, I have put forward the proposition that all muscular tissues are probably supplied with anabolic and katabolic nerves, the one causing relaxation of the tissue and diminution of its contractions, the other causing contraction of the tissue.

Such double nerve supply has been proved for very many muscular tissues, both unstriped and striped. Thus the muscles of the vascular system are supplied by vaso-dilator as well as vaso-constrictor nerves; the unstriped muscles of the bladder and other visceral muscles are supplied with two opposite kinds of nerves; among these the recent observations of Langley and Anderson¹ have shown a specially good example in the case of the retractor penis, supplied as it is with motor nerves from the lumbar region and inhibitory nerves from the sacral region; the adductor muscles of *Anodon* are supplied with two nerves of opposite function, according to Pawlow² and Heidenhain. And the most suggestive case of all, in connection with the question of the action of antagonistic striated muscles in vertebrates,—the adductor and abductor muscles of the claw of the crayfish are, according to Biedermann's researches, supplied with two nerves, of which the one is motor and the other inhibitory.

In close connection with this question of the meaning of relaxation of tone, when brought about by the action of an inhibitory nerve, is the meaning of the relaxation phenomenon, brought about in a tonically contracted muscle by the passage of a constant current through it. Such relaxation has been shown by Biedermann to occur in the snail's ventricle, when the ventricle has been thrown into a state of tonic contraction by too great a pressure within its cavity, in the tonically contracted muscle of *Anodon*, in the veratrinised sartorius, and has led him to the conclusion that such relaxation of muscle upon the passage of a constant current is evidence of assimilation.

This is, however, not the place to discuss the nature of the action of the constant current upon muscular tissue; it is sufficient to point out that the view of the action of the inhibitory nerves of the heart which I put forward in 1881, and which was subsequently in 1882 restated by Löwit³ in the terms of Hering's theory, is a view which is not opposed by the observations of Biedermann and others upon the phenomena of relaxation of muscle, brought about by the direct action of an electrical current.

It may, I think, fairly be said that this view, that the action of the vagus nerve is to promote the anabolic or assimilatory processes in the cardiac muscle, is steadily gaining ground; while the alternative view, that a special inhibitory nervous mechanism is situated in the heart, which causes inhibition by interference with motor impulses, is becoming more and more discredited. Such a view has been supposed to receive special support from the study of the action of various heart poisons, especially curari, nicotine, atropine, and muscarine.

With respect to these poisons, there is no evidence that they possess any selective power over one set of nerve fibres and nerve cells rather than another; the question is rather, do they act on the junction of the pre-ganglionic nerve fibre and the ganglion cell, or on the junction of the post-ganglionic nerve fibre and the muscle, or on the muscle itself?

The Action of Certain Poisons.—Nicotine, as already mentioned, acts in all probability on the junction of the pre-ganglionic fibre with the nerve cell.

¹ *Journ. Physiol.*, Cambridge and London, 1895, vol. xix. p. 71.

² *Arch. f. d. ges. Physiol.*, Bonn, 1885, Bd. xxxvii. S. 6.

³ *Ibid.*, Bd. xxix. S. 503.

The action of curari is upon the motor end-plate of the ordinary striated muscle, and takes the place of atropine in cases where the muscle becomes striated in character; thus in the bird's pupil, where the fibres are striped, curari not atropine causes dilatation. In the œsophagus of various mammals where the muscle is partly striped, partly unstriped, atropine prevents the action of the nerve on the unstriped, curari on the striped muscle; and, curiously enough, in the hearts of the snail, octopus, etc., according to Ransom's¹ observations, where the muscle is not only markedly striped, but also varies in strength of contraction according to the strength of stimulus, and can be tetanised, the action of the inhibitory nerve is not affected by atropine, but is put out of play by curari. In all these cases the curari in all probability acts on the endings of the nerve in the muscle. In the case of the heart of the frog and toad, and doubtless of other vertebrate hearts, the curari acts like nicotine on the junction of the pre-ganglionic fibre with the nerve cell, before it acts upon the junction of the post-ganglionic fibre with the muscle.

Atropine prevents the action of the motor nerves on the unstriped muscle of the œsophagus, of the iris, of the secretory nerves of the gland cells, whether sweat glands or salivary, of the inhibitory nerves of the heart of vertebrates, and from its local action it is clear that it paralyses the post-ganglionic fibres as well as the pre-ganglionic. In addition, it appears to act upon the muscle fibre itself.

The removal by atropine of Bowditch's "staircase" phenomenon, of the "local diastole" of Schiff, of the inhibitory action of the interrupted current on the strip from the tortoise auricle, are all to be explained by the action of the drug on the terminations of the post-ganglionic fibres in the muscle. On the other hand, Ransom² has shown that, in the case both of the cephalopod and of the snail, atropine must be classed with drugs, such as digitalin, antiaraine, etc., which produce an increased tonic contraction of the cardiac muscle. Romanes³ has shown the same thing with respect to the muscular tissue of the *Medusæ*, and I myself, in my investigations on the action of various drugs on the apex of the frog's ventricle,⁴ came to the conclusion that atropine acts in a much less degree but in the same direction as those drugs which increase the muscular contraction, and diminish relaxation.

The direct action of atropine upon the muscle-substance is rendered probable by its antagonising action to drugs which weaken muscular contraction by their direct action upon muscle.

This is especially seen in the case of such poisons as muscarine, which is apparently a muscle-poison, not a stimulant to inhibitory fibres or inhibitory mechanisms.

We see from the evidence brought forward by Luchsinger and his pupils,⁵ that a series of substances, such as potash salts, and the whole group of substances containing trimethyl-ammonium, to which muscarine belongs, all act in the same way upon the muscular tissue of the heart, namely, in the direction of weakening the contractions, and ultimately bringing the muscle into the condition of diastolic standstill; all behave, in fact, in the same manner as lactic acid, according to my observations. In opposition to this series of substances, we find another series which

⁴ *Journ. Physiol.*, Cambridge and London, 1880, vol. iii. p. 14.

⁵ Luchsinger and Am. Glauser, "Zur Kenntniss der Hemmungsmechanismen des Herzens," Inaug. Diss., Bern, 1884; Olga Sokolow, "Physiol. u. toxikolog. Studien am Herzen," Inaug. Diss., Bern, 1881.

act in the same way as sodium salts, namely, increase the strength and length of the contractions, and ultimately bring the apex or ventricle into a condition of systolic standstill. This series includes such poisons as antiarine, digitalin, veratrine, and, to a less degree, atropine.

Further, my own experiments have shown that, just as the alkaline sodium salt and the lactic acid solution can antagonise each other on the apex muscle, so also muscarine and digitalin¹ can antagonise each other; and Luchsinger and his pupil Amalie Glaue have shown that all the members of the muscarine group behave in the same way to atropine. The evidence, then, is strong that both atropine and muscarine act directly upon the muscular tissue of the heart in opposite directions. What the precise nature of these opposite actions is, whether the poisons form loose chemical combinations with the contractile tissue, as originally suggested by Langley and afterwards by Ringer and myself, or whether they act in some other way, is at present unknown.

The weakening effect of muscarine upon the muscular tissue is shown, not only by the diminution of the strength of the contractions and the relaxation of the tissue, but also by the diminution of the conductivity.

I know no more striking experiment to show the opposing action of muscarine and atropine, than is afforded by a strip from the auricle of the tortoise, which has been taught to respond vigorously and well to single induction shocks sent through a pair of electrodes applied to one end of the strip. With each induction shock a strong contraction occurs through the whole strip. Now, let a little muscarine solution drop over the strip; immediately the contraction is seen to consist of two parts—first, that of the small piece of muscle between the electrodes, and then, quickly following, the rest of the muscle; a little later, the pause between the contraction of the two parts of the muscle becomes very marked, and a partial block often occurs, so that only every second contraction of the piece between the electrodes is followed by a contraction of the rest of the strip, that contraction itself being weaker; finally, the block is complete, and the only part which contracts is the small piece between the electrodes. Now, apply a drop of atropine solution over the strip; like magic each contraction passes the block, and in a remarkably short time the whole strip contracts to every induction shock as strongly and rapidly as before. We see, in fact, in the strip a miniature representation of the action of the two poisons on the whole heart.

Again, the presence of the coronary nerve in the tortoise enables the question, whether muscarine applied to the sinus stimulates inhibitory mechanisms there, to be tested by means of the electrical changes which occur in the isolated quiescent auricular muscle, when the sinus and therefore the fibres of the coronary nerve are stimulated. I find² that, whereas a crystal of salt applied to the sinus will produce the same electrical variation as stimulation of the vagus nerve, muscarine applied to the sinus produces no effect whatever; there is not the slightest indication of any stimulating action.

It has been further argued by Kobert³ that, as a dose of muscarine, which will easily cause standstill when applied to the sinus, will not arrest the contractions of the isolated ventricle, therefore it acts

¹ Gaskell, *Journ. Physiol.*, Cambridge and London, 1880, vol. iii. p. 12, Pl. III.

² *Ibid.*, 1887, vol. viii. p. 404.

³ *Arch. f. exper. Path. u. Pharmacol.*, Leipzig, 1885, Bd. xx. S. 92.

in a special manner on the sinus. In accordance with this, he finds, and Pickering¹ confirms his observations, that muscarine is ineffective on the hearts of embryos when they first begin to beat. In other words, muscarine is asserted to be ineffective unless certain nerve cells, which are supposed to constitute an inhibitory centre, are present. Curiously enough, Pickering finds that under the same circumstances pilocarpine, which in other respects acts like muscarine, is effective at a time when muscarine is unable to produce standstill. It seems to me that we are dealing here only with a question of degree, and not with a question of fundamental difference of action. Some tissues are more resistant than others, and their resistance in the embryo differs from that in the adult.

Finally, Ransom's² experiments upon the heart of Cephalopods give very conclusive evidence upon this question, for he has shown, in the first place, that atropine does not paralyse the inhibitory nerve, though curari does; in the second place, that muscarine will produce standstill in this heart as in others, and yet that atropine will antagonise the action of muscarine. Clearly in this case the antagonistic action of atropine to muscarine cannot be explained by the supposition that muscarine stimulates inhibitory fibres.

Vulpian also asserts that muscarine will produce standstill in the snail's heart, and atropine removes that standstill.

We may, it seems to me, sum up the action of these poisons on the vertebrate heart in physiological amounts thus:—

Nicotine and curari break the connection of the pre-ganglionic fibre with the nerve cell.

Atropine acts on the muscular tissue to a slight extent tonically, breaks the connection between the post-ganglionic fibre and the muscle, and also the connection between the pre-ganglionic fibre and the nerve cell.

Muscarine, etc., act on the muscular tissue atonically.

Digitaline, etc., act on the muscular tissue tonically.

THE NUTRITION OF THE HEART.

The beating of the isolated ventricle or apex is dependent, not only on the pressure of the fluid in its cavity, but also upon the nature of that fluid, and a large number of observations have been made for the purpose of finding out what are the constituents which a fluid must contain in order to maintain good contractions of the cardiac muscle. The earlier experiments largely emanated from Ludwig's laboratory, under the guidance especially of Kronecker, and were started by Bowditch's³ discovery that delphine was able to make the isolated apex of the heart beat more or less rhythmically. This paper was followed in 1872 by that of Luciani,⁴ who showed not only that the frog's ventricle was able to beat when supplied with serum, but also that its contractions were not always regular like those of the intact heart, but during a portion of the time of action of the serum occurred in distinct groups, with pauses of varying lengths between the groups. Two distinct questions thereupon arose—(1) What are the constituents of serum which enable the ventricle to continue beating? and (2) what is the meaning of this periodicity?

¹ *Journ. Physiol.*, Cambridge and London, vol. xiv. p. 449.

² *Op. cit.*

³ *Op. cit.*

⁴ *Ber. d. k. Sächs. Gesellsch. d. Wissensch.*, Leipzig, 1873, S. 11.

With respect to the first question, the object of all investigators has been to remove the blood out of the ventricle or apex-preparation by means of a normal saline solution, and then when, in consequence of the washing out with the salt solution, the ventricle has ceased to beat, or is beating very weakly, to send in the fluid to be tested, and see whether the heart recovers its contractions. By the experiments of Merunowicz¹ in 1874, it was shown that the apex of the heart, when reduced to standstill by washing out with normal saline solution, could be made to beat again by sending through it a solution of the ashes of blood or serum; and among the different constituents in such ashes Merunowicz supposed that sodium carbonate was the most important, and that a solution of sodium carbonate and sodium chloride alone was able to resuscitate the motionless apex. Gaule,² following on Merunowicz and using Kronecker's perfusion cannula and the whole heart, proved that sodium hydrate was more efficient than sodium carbonate, and that when the heart no longer responded to the alkaline solution it could again be brought to renewed activity by sending through it for a second time the alkaline solution which had already passed through.

He attributed its efficiency over the simple alkaline salt solution to albuminous substances taken up from the heart; he came to the conclusion that amongst such substances peptones were especially efficient when added to the alkaline fluid. This conclusion of Gaule's was tested, and not confirmed, by Martius³ in Kronecker's laboratory. He found peptones absolutely useless, after the heart had been thoroughly washed out by an alkaline fluid; and came to the conclusion that the whole value of the alkaline solution was to remove the acid products of metabolism; and he and Kronecker came to the conclusion that the perfused fluid must contain serum albumin, and, further, that any fluid which maintained the cardiac contractions must contain this substance.

In a series of papers commencing in 1882,⁴ Ringer showed that a solution, containing sodium chloride, potassium chloride, and calcium chloride alone, would act as an efficient circulating fluid for the frog-ventricle, provided the salts in question were present in certain proportions. He found (as had been done by Merunowicz) that sodium chloride alone soon brings the heart to a standstill in diastole, but he further showed that the addition of a lime salt causes the beat to be prolonged by delaying the diastole, and eventually produces stillstand in systole.⁵ The potassium salt, on the other hand, when added to this mixture, antagonises the effect of the lime salt, and produces a normal beat. The solutions must be prepared with distilled water, since nearly all natural water contains an appreciable quantity of lime in solution.

The circulating fluid which Ringer eventually adopted is made as follows:—

A 0.6 per cent. solution of sodium chloride is saturated with calcium phosphate, and to each 100 c.c. of the mixture, 3 c.c. of a 1 per cent. solution of potassium chloride is added.

Howell and Cooke⁶ have lately shown that, if the heart is washed out with saline solution and Martius' fluid to exhaustion, and then supplied with Ringer's fluid, not only will it beat again, but they have seen such beating

last for thirty hours. According to Kronecker, this ought to be proof that Ringer's fluid contains serum albumin, especially in view of the statement of Martius, that from one and a half to two hours is sufficient to thoroughly exhaust the heart.

The great point of Ringer's work was the establishment of the importance of calcium salts for the contraction of the muscular tissue, and the recognition that a definite supply of sodium and potassium must also be contained in the circulating fluid; in fact, that the ideal circulating fluid must contain a variety of salts in right proportion. It does not at all follow that the fluid recommended by Ringer, although unquestionably effective, yet contains the salts in the absolutely best proportion. In fact, Howell and Cooke¹ removed the proteids from serum, and then found that the remaining solution of the salts in the serum was more efficacious than Ringer's solution. On the other hand, the proteids of the serum, after removal of the salts, were ineffective.

In view of this, the conclusions of White,² working with Kronecker, who, finding that serum would restore a heart after it had ceased contracting with perfusions of Ringer's fluid, supposed this action to be due to the proteid of the serum, are evidently not justified.

Another series of experiments by Heffter,³ Albanese,⁴ and Ohn,⁵ have led them to the conclusion, that a good circulating fluid must not only contain the right proportion of salts, but also must possess the same physical properties as blood with respect to viscosity, osmotic coefficient, etc. For this purpose they added gum arabic to Martius' solution, and assert that such a solution is as efficacious as serum in keeping up the contractions of the heart.

Howell and Cooke,⁶ and later, Locke,⁷ have pointed out that gum arabic is a combination of arabin with calcium and potassium salts, so that, in this case also, the salts, rather than the physical character of the fluid, are in all probability the important factors.

To sum up the evidence, the artificial circulating fluid which is most efficient in keeping the heart beating must contain the right proportion of sodium chloride, of a calcium salt, and of a potassium salt. The experiments so far do not prove that any special proteid is necessary in this mixture, and give no definite answer to the question whether the heart contracts at the expense of its own substance, or contracts only as long as a suitable proteid diet (according to Kronecker, serum albumin) is constantly supplied to it. Considering, however, the length of time it can be washed out with a fluid like Ringer's, and yet continue beating, it seems very unlikely that any serum albumin or other proteid can be still left in the capillary spaces, and therefore the probability is that the heart can continue to contract at the expense of its own substance upon an absolutely inorganic supply.

Luciani's groups.—The second question raised by Luciani's experiments is the question of the meaning of the secondary or periodic rhythm, observed by him when serum was sent through the ventricle. Subsequent experiments, especially by Langendorff,⁸ have endeavoured to determine the conditions necessary for the appearance of such groups as Luciani described; and the general opinion of physiologists at the present time is that the grouping does not appear unless a condition of asphyxia has been induced in the cardiac tissue. According to Langendorff, it is possible to obtain this periodic rhythmical contraction, not only in the ventricle, but also in the whole heart, by keeping a curarised frog under water for a sufficient length of time, so that, according to his observations, as well as those of Luciani and Rossbach on the isolated ventricle, this method of beating in groups, instead of with a normal

⁸ *Op. cit.*

regular rhythm, is due to some alteration in the rhythmical organ itself. In all these experiments the contractions of the ventricle alone are registered, the auricular contractions being only registered occasionally by the accident of their appearance on the ventricular curve. It is therefore not clear to my mind how far these groups of ventricular beats may be due to the passage of a series of contractions into the ventricle over a blocking-place, somewhere between the starting-place of the rhythm and the ventricular tissue.

Certainly I have occasionally obtained, by means of tightening the clamp in the auriculo-ventricular groove, a series of ventricular contractions which for a time were arranged in groups just like Luciani's groups, and Fano mentions the same thing as the effect of clamping. The separate ventricular contractions in these groups usually corresponded to every second contraction of the auricle, though occasionally a few contractions were able to respond to every auricular contraction, so giving curves resembling some of those figured in Langendorff's paper. In fact, during the group the conductivity of the tissue at the blocking point altered from that of a complete block to that of a partial block. Again, one of the most striking phenomena observed and recorded by me in my paper in the *Philosophical Transactions*, was the manner in which the vago-sympathetic nerve was able to cause a group of ventricular contractions, when, by means of heating or clamping, a complete block had been formed between auricle and ventricle. This group of contractions was most clearly dependent on the auricular contractions, being either all synchronous with those of the auricle, or mostly synchronous, with a few at the beginning or end of the group synchronous with every second auricular contraction. When we remember also that it is very difficult, without most careful investigation, to be sure that the sinus is not beating regularly when the heart is apparently still, that Luciani and Rossbach tied on to the cannula, not the ventricle alone, but the whole heart, and that it is astonishing how tightly it is necessary to screw up a clamp (or in their case to tie a ligature) between auricle and ventricle, so as to cause a block sufficiently complete to prevent the effect of the stimulation of the vago-sympathetic nerve, it is, I think, more probable than not that the so-called Luciani's groups, or periodic beating, owe their origin to a partial blocking of the contraction wave into the ventricle, and not to a peculiar periodicity of rhythm. Such an explanation is in complete harmony with the view that a condition of asphyxia is most favourable for the production of these groups, for such a condition is certain to produce a greater or less amount of blocking.

ANIMAL MECHANICS.¹

BY J. B. HAYCRAFT.

CONTENTS :—Introductory, p. 228—The Movements and Positions of the Body, p. 228—The Mechanism of Joints, p. 233—The Muscle as a Machine, p. 241—The Centre of Gravity of the Body, p. 257—Methods of Recording Movements of the Body, p. 264—Detailed Description of Special Movements, p. 267.

Introductory.—Animal mechanics is for the most part merely a special branch of ordinary mechanics, and the mechanical engineer would at once recognise that many of the problems to be solved are already discussed in textbooks of mechanics. Thus, the properties of the shoulder-joint are already known as soon as we recognise that it is a joint of three degrees of freedom, and of the nature of a ball-and-socket joint. But although we may understand the mechanical principles of the shoulder-joint, the movements which take place there are excessively difficult to follow. In the first place, the joint is in the living subject embedded in flesh, and we cannot be certain of its position in space; in the second place, we find in practice that a pure movement at the joint almost never occurs, but that it is accompanied by translations of the whole joint, due to movements of the shoulder-girdle. The study of the movements which actually take place at the joint is therefore a mechanical problem of the greatest complexity, and one which it is at present impossible to study with appropriate exactitude. This is typical of the movements of the limbs in general. There are other problems which a previous training in mechanics will not enable us to follow. For these we require a training in physiology, a study of the properties of muscles, and a knowledge of the action of the nervous system, the initiator and controller of our bodily movements. Our knowledge of the facts relative to muscular activity bearing upon locomotion is largely due to the investigations of the brothers Weber of Helmholtz, and A. Fick. The application of the study of mechanics to the human body is due chiefly to the brothers Weber, H. Meyer, and Marey, and recently, to the work of Braune and Fischer.

In attempting to epitomise these results we shall proceed synthetically, studying first the mechanical properties of the bones, joints, and muscles, and finally the whole body in its upright position and during progression.

THE MOVEMENTS AND POSITIONS OF THE BODY, DESCRIBED BY REFERENCE TO CO-ORDINATE PLANES OR AXES.

In their description of the position of parts of the body, anatomists have for long been accustomed to speak of these in their relationship with certain planes and axes. Thus, the liver is on the right-hand side of

¹ Professor Haycraft having been prevented by illness from seeing this article through the press, the proofs were submitted to Dr. René du Bois-Reymond, who has carefully revised them, and has supplied several additional paragraphs, which have been incorporated in the article.

the mesial plane of the body; a rotation of the head is described as taking place in a horizontal plane. By the use of co-ordinate planes and axes—a method extensively employed in mechanics—it is possible to express in exact terms and without ambiguity the position of any portion of the body in space, and to define its position relative to any other part. By this means we can exactly measure the extent and direction of a movement, say that which occurs at a joint, and determine what new position the limb has assumed as a result of that movement.

This method has been of late years so extensively used by those who are attempting to obtain more exact data in connection with animal mechanics, that it is necessary to master its principle at the outset, in order to understand the results at which they have arrived.

Let us, in the first case, confine our attention to space of two dimensions, and study the methods for determining the position of points which lie, or which change their position, in one plane. There are two methods, known as the method of rectangular, and the method of polar co-ordinates.

In the first of these we describe the position of any given point, by reference to two lines at right angles to each other. If, for example, we want to define the positions of a series of points in the upper limb, and to investigate their changes in position during the movement of that limb in a given

FIG. 119.—This figure represents the method of expressing the position of a point *p*—the centre of rotation of the elbow-joint—in reference to two co-ordinate axes (*xx* and *yy*).

plane, we choose two convenient reference lines. As the plumb-line is a definite direction in space, and readily determined by a thread and plummet, we take as one of our reference lines the plumb-line (*+y - y*) falling through the *centre* of rotation of the shoulder-joint. The other reference line must intersect this at right angles, and in the plane in which displacements are to be studied; this second line (*+x - x*) may itself pass through the shoulder-joint (Fig. 119), or, in many cases, may more conveniently form the ground-line.

If we draw the lines *pa*, *pb* at right angles to the reference lines, the position of the point *p* is defined without ambiguity, by saying that its ordinate is *-pa*, and its abscissa is *-pb*, which lengths we may express in centimetres.

In the method of polar co-ordinates we require to find the angle θ , which is usually denoted by θ . This is regarded as plus, if it be measured round the point o from a reference line in a direction the reverse of the movement of the hands of a watch, and minus if in the same direction. The radius vector op , denoted usually by r , must also be known; it is always taken as positive.¹

If we simply require to determine an angular displacement of a limb, we proceed as follows. A certain position of the limb, say the vertical, as in

FIG. 120.—This figure indicates the method of measuring the angular displacement of the arm from a primary vertical position (ab).

forearm upon the arm. One may readily, however, pass from one method of expressing the position to the other, for the angle $\psi = \psi$ and the angles ψ , ϕ , and χ are simply related to one another; for

$$\chi = \psi + \phi$$

If the angle ϕ be a rotation forwards, say of 30° , we may call this a negative rotation of 30° , and we must in that case term an extension at the shoulder backwards to ab'' as a rotation of $+30^\circ$.

So far we have limited our attention to the description of the positions or changes of position of points in space for two dimensions, but the shoulder-joint can move on more than one axis, and in more than one plane. In fact, to denote most of the changes of position of the limbs which are brought about by muscular contraction, and to denote completely the position in space occupied by various parts of the body, we have to deal with a problem in tridimensional space, and must refer these positions to three co-ordinate planes at right angles, to each other. In Fig. 121 these three planes are represented. The horizontal plane or floor is that through which the lines yy and xx pass. One vertical plane is that through which the lines yy and zz pass; the other vertical plane

¹ It is quite immaterial which direction is considered as plus and which as minus, so long as this is once settled and adhered to.

is that through which pass the lines zz and xx . The lines in the figure are each the lines of intersection of two planes; the point O is the point of intersection of the three planes. If now we wish to define the position of the point p in reference to these three co-ordinate planes, we can drop a line vertical to the horizontal plane, cutting it at a . pa is the distance of the point p from the horizontal plane xx and yy .

If, now, we draw a line ab perpendicular to the vertical plane zz and yy , this will give the distance of p from that plane. The distance bo gives finally the distance of p from the second vertical plane zz and xx . It is necessary further to notice the signs of pa , ab , and ob , which, in the case under consideration, are all positive. Were p below the floor, pa would be negative; for the movement of p around O would be in the direction of the hands of a watch. The method of describing the position of the body in reference to three co-ordinate planes has been greatly used by those who have studied the animal mechanisms, and by no one more elaborately than by Braune and Fischer.

In their investigation into the centre of gravity of the human body, they start with an erect position, in which the chief joints of the body, and the centres of gravity of the trunk and limbs, are all in one frontal plane. In Fig. 122, *B*, simplified from their original figure, this plane is vertical to the paper, and runs through the line zz . In Fig. 122, *A*, the plane is seen "from the front," and is mapped out in equal squares, giving distances along the line yy from the centre of the plane zz , these being reckoned as negative to the right-hand side, and positive to the left-hand side. Along this plane can also be measured distances from the ground plane in a vertical direction.

Cutting this plane through the line zz , and running in the mesial plane of the body, is the sagittal plane, seen from the left in Fig. 122, *B*. This is also divided into equal squares; and distances forwards from the axis zz of intersection of the two planes are counted as positive, while distances backwards are counted as negative, both passing in the direction xx of the figure.

FIG. 121.—Shows the method of determining the position of the point (p) in reference to three co-ordinate planes intersecting in the point O .

Co-ordinates on X, Y, and Z Planes.

Joint.	X.	Y.	Z.
Atlanto-occipital	0	0	152
Right hip	0	+8.5	87

In describing the position of any point of the body, say the atlanto-occipital joint, this will, by construction, be in the frontal plane, and therefore its deviation in the xx direction will be 0. As it is also in the mesial

plane, its deviation along the yy direction will also be nothing. It will be some distance, however, from the floor in a vertical direction; in the case of Braune and Fischer's subject, 152 cms. Again, let us take the centre of

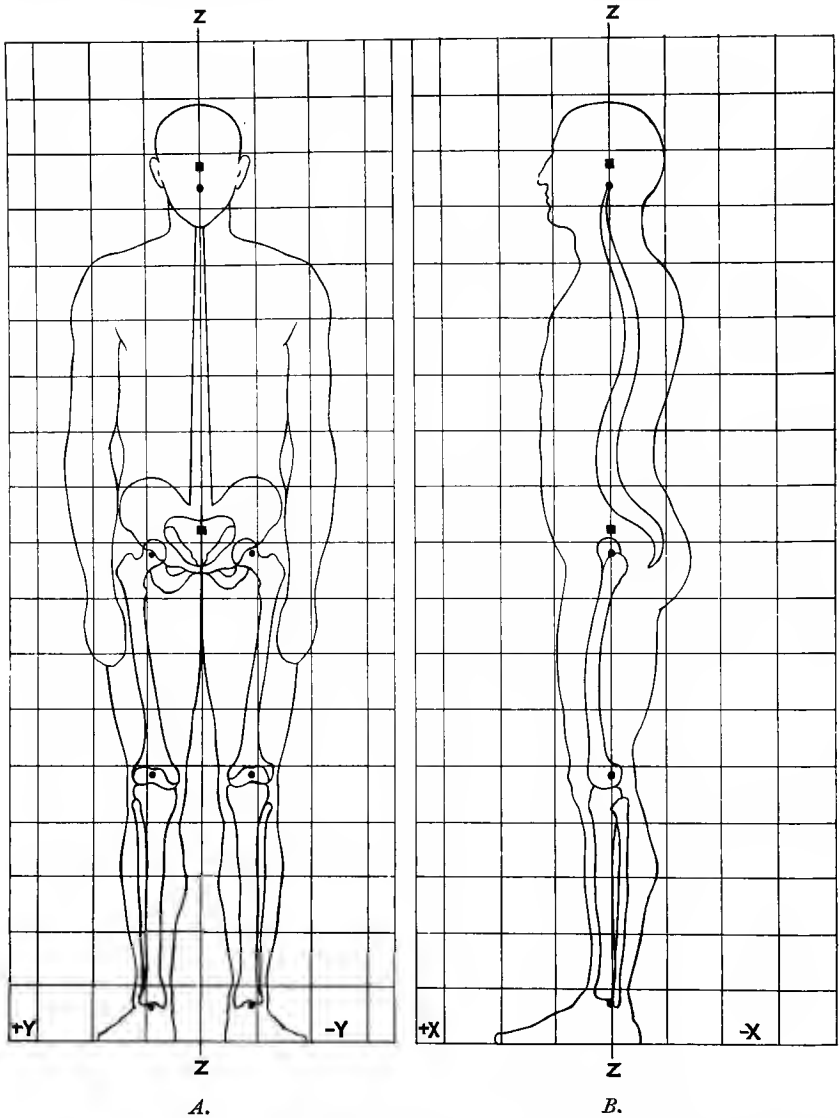

FIG. 122.—Showing the position of the centre of gravity of the whole body and of the head (■), and also the position of the centres of rotation of the chief joints (•) in reference to three co-ordinate planes.—Braune and Fischer.

rotation of the right hip. By construction this also will fall in the frontal plane, and its deviation in the zx direction will be nothing. It is not, however, in the mesial plane, lying in fact to its right. In the subject under discussion it is $+8.5$ c.c. on the yy direction. Its distance from the ground in a vertical direction is 87 cms.

The above being the relation of certain given parts of the body to the co-ordinate planes in the position or pose selected for study, any movement of the body will displace these points, which will again take up new positions in relation to these planes. Thus, on bending forwards, the right hip will move out of the frontal plane, and move in the *xx* direction, say to +12, and will occupy a lower position in the vertical direction, say 80 cms. from the ground.

When the whole body is translated forwards, as in walking or running, these planes must also be conceived of as being translated, one point of the body, at any rate, preserving its position in one of the co-ordinate planes.

If it be desired merely to describe a movement of a limb, the method of polar co-ordinates described at the head of p. 230 is more generally employed. If the movement take place in a plane, the position of this plane is noted with reference to three co-ordinate planes,—one sagittal, the other frontal, and the third horizontal,—all intersecting at the centre of rotation. The plane in which displacement occurs may also be defined by giving the direction of the axis of rotation (which is perpendicular to that plane) with regard to the three co-ordinate planes. Movements not in a plane are either described by resolving them into several movements in different planes, or by compounding the different axes of rotation in the way described on p. 236.

In addition to the movements hitherto spoken of, in which there is displacement of a limb, a different kind of movement can take place in some joints, *e.g.* the hip and shoulder-joint. The limb may remain practically stationary in space while revolving to a certain extent upon its own longitudinal axis. In this case the axis of rotation coincides with the longitudinal axis of the limb. There is no angular displacement of the limb itself, but the amount of longitudinal rotation can be measured by the angular displacement of an indicator-rod fixed to the limb perpendicularly to its axis. In the case of the lower limb, the tip of the toes will serve as such an indicator, pointing forward in the ordinary position, and nearly lateral in extreme outward longitudinal rotation of the leg.

Any actual movement not confined to a plane, as for instance waving the arm in a circle, or any movement in which rotation upon the longitudinal axis is combined with the angular displacement, cannot be accurately described by any definite number of rotations round fixed axes. Such movements are said to take place on shifting or instantaneous axes.

THE MECHANISM OF JOINTS.

From a mechanical standpoint we may, with A. Fick, divide joints into two classes. In the first class we may place joints, the bones of which have one fixed position of equilibrium, to which they return as soon as any displacing force is withdrawn. To this class belong the synchondroses, such as the vertebræ, united by white fibro-cartilage, and the amphiarthroses, such as the joints between the tarsal and carpal bones. The attachments of the bones to each other is here so firm that but little movement is possible, and that only by a displacement or deformation of the tissue of the joint, which thus suffers a strain, against which it reacts when released, and resumes its original condition of equilibrium.

In the second class are placed those joints which more especially concern us, such as the hinge and ball-and-socket joints. Here, the bones forming the joint may be placed in a great number of positions, in any one of which they can remain during muscular relaxation.

Joints belonging to the second class are formed by bones whose extremities are covered by a layer of articular cartilage, and they are enclosed in capsules and accessory ligaments of white fibrous tissue, sufficiently lax to permit of a more or less free play of action. Synovial fluid lubricates the joint and diminishes the friction between the articular ends. The friction between two surfaces is proportional to the pressures of these two surfaces—unless that pressure be very great. The friction is independent of the extent of the surfaces which touch one another. It is greatly influenced by the lubricating material, being, in the case of the joints, greatly diminished by the synovial fluid; and it is independent of the velocity of the movement. In the joints the coefficient of friction¹ (μ) is very small, and while movement between the surfaces is occurring, the coefficient of kinetic friction (K) is still less, so that practically it may always be regarded as nil.

The area of contact at articular surfaces.—It is generally believed that the articular surfaces are in close contact with each other, but it would appear that this is only the case when considerable pressure has been applied. König² was the first to show that the articular surfaces in a joint like the hip are not in contact in the dead subject; for in frozen sections, where the positions of parts are unaltered, a layer of frozen synovia is always found between them. König further showed that if the head of the femur be firmly wired to the acetabulum, the contact produced takes place over but a small area of the articular surfaces. If the pressure applied by König at all represented the pressures to which the joint is normally subject under the influence of muscular contraction and of the body weight, the joint would not conform in its movements to a true ball-and-socket joint, where there is extensive contact over two geometrically adapted surfaces. Its surfaces would, in consequence of this, slip or roll over each other.

Braune and Fischer³ doubt whether this pressure applied by König was sufficient, and they found much more extensive contact when the articular surfaces were pressed together by the help of screws. The action of the pressure is to mould the elastic cartilaginous surfaces upon each other, and to make them conform to pure geometrical figures. It is to be regretted that these experiments are but of a qualitative nature, the pressures applied not having been measured.

The forces which resist displacements of the articular surfaces.—The articular surfaces are bound together by the capsular and other ligaments of the joint, but these ligaments are only put upon the stretch when the surfaces are forcibly separated from each other or when the joint is bent. A certain separation of the surfaces can take place, therefore, without the intervention of these ligaments. This separation is, however, hindered by other forces which we have now to study. The muscles passing over a joint, and attached to the bones on either

¹ If a body press upon a plane surface with a pressure P , and a force F is required to move it along that surface, the coefficient of friction (generally written μ) is $\frac{F}{P}$.

² *Deutsche Ztschr. f. Chir.*, Leipzig, 1873, S. 256.

³ "Die Bewegungen des Kniegelenks," Leipzig, 1891.

side of it, exert more or less continuous pull upon the bones, jamming the articular surfaces together. This contraction has been estimated at about 20 kilos. in the case of the hip-joint, even during the resting condition of the limb, but will be a very considerable power when the muscles are voluntarily or reflexly contracted.

Edward Weber drew attention to the action of atmospheric pressure in keeping the articular surfaces in contact. He assumed that the joints, having closed cavities, cannot be enlarged, as they would be if the articular surfaces were separated, without the action of a force greater than that of the pressure of the atmosphere. In the case of a large joint like the hip, the atmospheric pressure would be such that a weight of about 20 kilos. would be capable of overcoming it, and of pulling the surfaces of the joint apart and rendering the joint-ligaments tense. These ligaments would, owing to their inextensible nature, be able to resist a weight of over 400 kilos. before complete rupture could take place. Weber divided all the muscles surrounding the hip-joint, leaving, however, the capsule of the joint intact. The weight of the limb was not sufficient to draw the articular surfaces apart. On opening the joint cavity, by boring a hole through the acetabulum, the head at once fell downwards. It is, however, doubtful whether the result of this experiment may be applied to any other than the hip-joint. A strain of 500 grms. put upon a metacarpo-phalangeal joint during muscular relaxation causes the articular surfaces to come apart, the space being filled by the surrounding substance closing in. For the living subject the articular cavity of the hip-joint may perhaps likewise be considered as being in partial communication with the outer pressure.

Ball-and-socket joints.—A spherical surface is produced by the rotation of a circle round any one of its diameters. If such a surface be received into a cup of the same, or of a slightly longer, radius of curvature, these two surfaces may be caused to move in relationship to each other. Putting on one side any "translation" of the cup-and-ball in space, and considering the cup as fixed—for example, when the arm or leg is raised from the shoulder or hip—we find that the centre of the spherical mass will remain fixed in space, and movements of the ball will take place around axes passing through the fixed point. This point is therefore termed the centre of rotation, and the axes are termed the axes of rotation. If, on the other hand, the ball be fixed in space, the socket may move upon it, as when the thigh or arm are fixed, and the trunk moves upon one of these fixed limbs. Here we have a centre and axis of rotation for the cup, but these do not lie within the substance of the cup. We must consider them as a point and line in space, the space occupied or partly occupied by the ball itself. In the body we may have simultaneous rotations of the ball and of the socket, as in many movements of the arm, where not only does the humerus rotate, but the shoulder-blade and glenoid cavity change their positions too. Confining our attention to the rotation of the ball, and remembering that the centre of rotation is a point fixed in space, any movement of the ball is equivalent to a rotation around a certain axis passing through the centre of rotation.

If the displacement of any two points in the sphere be known, neither of which is a point lying in the centre of rotation, nor in a line with it and

the other point, then we can determine not only the axis upon which the rotation took place, but also the position assumed by any other point resultant from the same displacement. In Fig. 123 let the points a and b be points upon the surface of a sphere with a large radius, and the points a' and b' the position which they occupy subsequent to a given movement.

FIG. 123.—Figure to show a method by which the axis of rotation of a ball-and-socket joint is determined, when the line ab is carried into the position of the line $a'b'$.

Join a and a' , b and b' by arcs of a great circle, and bisect each of these arcs. From the point of bisection draw lines perpendicular to aa' and bb' , meeting at the point o . The point o will have remained stationary during the rotation, and so will C , the centre of rotation, as well as every point on the line joining them. The line passing from the centre through o will therefore be the axis of rotation required. For join oa , ob , and oa' and ob' , then the triangles oab and $o'a'b'$ are equal and similar, hence the displacement of o is zero. The angle of rotation will be aoa' .

To find the position assumed by any other point p , during the displacement of the points ab to $a'b'$, perform the following construction (see Fig. 124).

Join pa and pb and ab to make the triangle pab . Join $a'b'$, and upon $a'b'$, the final position assumed by the line ab , erect

a triangle $a'p'b'$ equal and similar to abp . The point p' will be the position assumed by p at the end of the rotation.

Compounding axes of rotation.—If rotation occurs around two axes, one after the other, the same result may be obtained by a single rotation around a definite single axis. To find this single axis, adopt the following construction. In order that the line of the axis may be made to represent the direction of rotation, select that half of each axis which, if it runs through the length of the body of an imaginary observer, with his feet upon the centre of rotation, will place him in such a position that the direction of rotation will correspond to the direction of rotation of the hands of a watch.

FIG. 124.—Shows the method of finding the position assumed by the point p , when the line ab is rotated into the position $a'b'$.

Let the points O and O' represent the points at which these axes cut the surface of the sphere; join O and O' . If the rotation at O be equal to θ , measure off the angle $O'Ox$ equal to $\frac{\theta}{2}$ and in a direction opposite to the rotation around O . If the rotation around O' be equal to θ' , measure off the angle $OO'x$ equal to $\frac{\theta'}{2}$ and passing in the same direction. The position of the

point of intersection x will be unaffected by the double rotation, the centre of rotation will be at the same spot, and the line joining the centre of rotation with x , will be what is termed the resultant axis of rotation. For the rotation (θ) around the point O would carry the point x to the point x' , and the subsequent rotation around O' would bring it to the position x from which it started.

If the order of rotation be reversed, occurring first around O' and then

FIG. 125.—To illustrate the method of compounding axes of rotation.

around O , the resultant axis of rotation would pass through the point x' . Upon the other side of OO' draw the angles $O'Ox'$ equal to $O'Ox$, and $OO'x'$ equal to $OO'x$. The two triangles will be equal in every respect.

By constructions similar to those detailed above, the movements of any given solid in space can be exactly determined, provided the movements of three points (not in a straight line) of the solid be known. This axiom was applied by Braune and Fischer in their study of the movements at the knee. Since accuracy of observation depends on the distance traversed by the three points, rods of some length were fixed to the foot of the subject. The excursions of the tips of these rods, recorded by the photographic method described on p. 266, supplied the data for determining the movements of the knee-joint with accuracy. For most purposes simpler methods are sufficient.

In the case of the shoulder, as an example, we proceed as follows:—Attach to the outer surface of the arm, so as to run vertically and parallel with the axis of the limb, a light wooden rod bearing a small board 2 in. square, and marked out in equal squares. The board should centre somewhere over the spot at which the centre is supposed to lie. The arm is now allowed to swing pendulum-wise from side to side.

The observer now places himself with his eyes on a level with the joint, and holds a straight rod—a pencil—so that it is parallel with one of the horizontal lines on the board of equal squares (Fig. 126).

FIG. 126.—Shows the author's method of determining the centre of rotation of a joint. During the experiment the arm of the subject is allowed to swing backwards and forwards like a pendulum.

As the limb swings, the horizontal straight line on the board will be found to oscillate about a definite point in the line of the pencil, provided this line runs through the centre, and this point will therefore mark the position of the centre. If the horizontal line lies above or below the centre, it will, while the arm swings, alternately intersect the line of the pencil in two points. A line drawn vertically from a point bisecting the line joining these two points will pass through the centre, and this line may be drawn upon the skin. The observer should now hold his pencil parallel with a vertical line, and determine in the same way the position of the centre of the joint in an axis which is horizontal. The point of intersection of the two lines will mark the position of the centre of the joint. It is advisable in such an experiment to support the pencil, not by the hand, but by some kind of stand. In the case of a joint like the shoulder, the shoulder girdle should be steadied by an assistant, and the observer himself should move the arm backwards and forwards.

Special ball-and-socket joints.—In the shoulder-joint considerable movement can occur. In its ordinary position the humerus can rotate through an angle of 90° round its longitudinal axis. Round a sagittal axis the humerus can rotate through 120° , round a frontal axis through an angle of 170° . By an added movement of the whole shoulder the humerus may be moved through an angle of 170° round a sagittal axis, and through an angle of 190° round a frontal axis. With the combined movement of pronation and supination of the bones of the lower arm, the hand in all can be rotated through an angle of 280° .

In the case of the hip-joint we have a smaller range of movement, due in the first place to the capsular structure of the joint. This powerful and very inextensible structure consists of a capsule, strengthened by accessory ligaments, formed many of them by fascial sheaths of the surrounding muscles which are attached to it. The most important of these is the ileo-femoral ligament, which hinders eversion and too great extension of the limb. The actual movements of the limb at this joint are likewise hampered by the thick muscles of the hip, either by their passive resistance to pressure or by their extensibility. The femur can rotate through an angle of 45° round an axis running in the length of the limb. Around a sagittal axis rotation can take place through an angle of 80° , and round a frontal axis it can rotate through an angle of 140° .

The lower limb is not so movable upon the trunk as is the upper one, not only on account of the more limited movement of the hip, as compared with the shoulder-joint, but also because the acetabular surface occupies a fixed position on the trunk, whereas the glenoid cavity is itself movable.

Hinge-joints.—In these cases one articular surface forms a portion of a cylinder, and we may conceive it as having been generated by the rotation of a straight line around a central axis. This articular cylinder is received into another concave surface of similar shape. The surfaces are not always true cylinders, in fact more often grooved, or of a conical shape. In hinge-joints the capsular ligaments are characterised by greater strength at the sides, and are here termed the lateral ligaments of the joint. Rotation can occur around a single axis, every portion of the surface of the joint describing in its movements a portion of a circle. In these joints the axis is rarely at right angles with the long axis of the bones concerned; thus the trochlear surface and axis

of rotation of the ulna is set obliquely to the axis of the humerus, salient outwards at 105° , so that the forearm, when extended, forms an angle with the upper arm re-entrant outwards.¹

Many joints which we may, on superficial observation, regard as hinge-joints are really screw-joints; and we may now discuss the character of the surface of a screw, and the movements which such a surface can make. In moving the nut upon the surface of a screw, or, more simply still, in moving a small body up the thread of a screw, the movement of any particle can be resolved into rotation, and what is termed translation. The body or any portion of the surface of the nut will rotate around the cylindrical axis of the screw, and at the same time it will move in a direction parallel with the axis of this cylinder.

A screw is really an inclined plane rolled upon the surface of a cylinder, the hypotenuse forming a spiral or helix (see Fig. 127). The "pitch" of the screw is the vertical distance between two coils of the spiral, and the inclination of the screw is the angle *bac*.

The motion of the trochlea in the sigmoid cavity is that of a screw moving in a nut, the inclination of the screw is 8° , and in the 140° through which the elbow can pass the translation amounts to 2.5 mm. In most cases the right elbow is a right- and the left a left-handed screw.²

The screw character of a joint like the elbow may be demonstrated in the following manner. Clamp the humerus in such a position that the axis of rotation of the elbow-joint, whose ligamentous attachments are undisturbed, is vertical, the forearm being extended. Then stretch a thread horizontally between two retort stands, and get the eye in such a position that a marked spot on the coronoid process of the ulna is on a level with the thread. When the limb is flexed, the marked point moves round the axis of rotation, and is also displaced upwards or downwards over the thread towards the radial side of the limb.

The elbow-joint, as anatomically defined, contains two physiologically distinct articulations. The bones of the forearm together form a hinge-joint with the humerus, but the radius is also attached to the ulna by a similar joint, which allows it to rotate on its axis, its perfectly rounded head remaining in unchanged relation to the articular surface of the humerus. It may be remarked that in the radio-ulnar articulation the axis of rotation coincides with the longitudinal axis of the bone. In this respect the joint between radius and ulna, as well as that between atlas and dens epistrophei, represent a particular type of joint, rather to be compared to the pintles of a rudder than to the common form of hinge.

Radius and ulna being united at the wrist in nearly the same way,

FIG. 127.—This figure illustrates the fact that a screw is an inclined plane wrapped around the surface of a cylinder.

¹ Macalister, "A Text-Book of Human Anatomy," p. 144.

² Hultkrautz, "Das Ellenbogengelenk," Jena, 1892, S. 24.

the distal end of the radius can be swung around the comparatively immovable ulna. The head of the radius remaining stationary while the lower end moves in a circle round the distal end of the ulna, the shaft of the radius moves on the surface of a cone, of which the axis passes through the centre of the capitulum radii above and through the styloid process of the ulna below. This is the mechanism of the movements termed pronation and supination.

The movements at the knee-joint were carefully studied by the Webers.¹ According to these observations, movements occur in a sagittal plane (flexion and extension), through an angle of about 150°. The axis of rotation is, however, not a fixed axis, but shifts during the acts of extension and flexion. The articular surface of the tibia is almost horizontal, and upon it the condyles of the femur roll like the wheels of a carriage, rolling forwards during extension, and rolling backwards during flexion. But

this rolling is not a simple rolling in one plane, but it is combined with a rotation upon a vertical axis; the condyles moving in relation to the surface of the tibia, like the fore-wheels of a carriage as it turns a corner move on the ground.

Meyer,² like the Webers, in addition to that rotation which is bound up, as it were, with the act of flexion, recognises some rotation upon a vertical axis, which can be produced in the bent but not in the extended limb. Sappey³ described slight lateral movements of the joint.

FIG. 128.—To show the geometrical construction of a saddle-shaped joint.

Braune and Fischer,⁴ who have investigated in the living subject the movements of the knee in their relation to co-ordinate planes, agree in the main with the conclusions of Weber. Their most important additions appear to be the following. In respect of the rotation which accompanies and is bound up with the act of flexion, they find that, commencing with the extended position, and ending with that of complete flexion, there is at first, for about 20°, a rotation inwards. This amounts in all to 6°. Then follows a slighter rotation outwards, but as this lasts longer than the inward rotation that preceded it, it finally reaches 6° in the opposite direction, one effect counterbalancing the other.

Saddle joints and ellipsoidal joints.—We may conceive the saddle-shaped surface as generated in the following manner (Fig. 128).

Take the arc *ab* of a small circle, the centre of which is at *c*, and rotate it upon the axis *xw*, and it will produce the figure *abb'a'*.

¹ "Gehwerkzeuge," S. 170.

² "Statik und Mechanik des menschlichen Knochengerüsts," Leipzig, 1873, S. 357.

³ "Anatomie descriptive."

⁴ "Die Bewegungen des Kniegelenks," Leipzig, 1891.

The sides of this figure will possess a double curvature like a saddle, a curvature of a small circle in vertical, a curvature of a large circle in horizontal, direction. A saddle-shaped surface can glide on its counterpart to a certain extent around either of two axes (in the figure around an axis passing through cc or xx). Thus the surfaces may be brought to a multitude of new positions, by first rotating on one and then on the other axis. In this respect the saddle-joint lies between the hinge and ball-and-socket joint. Its freedom of movement is principally due to the absence of lateral ligaments. The trapezio-metacarpal joint is an example of a saddle-joint.

We may conceive an ellipsoidal joint as formed in the following manner. Take the arc ab of a circle whose centre is at c , and allow the arc to revolve around an axis xx on the same side of the arc as its centre, and the figure ($abb'a'$) will be formed. At the sides of this figure the surface resembles an ellipsoid, and will, like the saddle-joint, allow of rotation in two axes, namely, an axis passing through c and the axis xx . The first carpal joint is ellipsoidal.

R. du Bois Reymond,¹ says, "as a matter of practical experience, a certain movement of rotation is possible because the surfaces do not geometrically correspond, the stronger convexity not fitting the weaker concavity. A saddle-joint or ellipsoidal joint with rigid and perfectly adapted surfaces would not be capable of movement at all."

FIG. 129.—To illustrate the formation of an ellipsoidal joint.

THE MUSCLE AS A MACHINE.

The phenomena of muscular contraction are fully discussed in the portion of this work directed to the special physiology of muscle. We may, however, select for discussion a few of the points which have to be borne in mind, when studying the part these structures play in producing the movements of the trunk and limbs. When an unexcited muscle is stretched by a force, such as the weight of a limb, or other load, it elongates until a point is reached at which there is equilibrium. At this point the stress applied is equalled by the stress in the muscle acting in the contrary direction. While with most inorganic matter the elongation or distortion is proportional to the distorting force (*ut tensio scut vis*), in the case of the muscle it follows the formula $y^2 = ax^2 + bx$, where y is the elongation, x the weight, and a and b are constants.² The curve representing the elongation of a muscle when loaded with increasing weights is given in Fig. 130, and it will be seen that the muscle becomes less and less extensible as the weight increases. It is on this account that muscles are able to play an important rôle in the maintenance of equilibrium, quite apart from their action in shortening. They play the part of ligaments and prevent too free a movement of the body in undesirable directions. Thus, over-extension of the knee is in part prevented by

¹ *Arch. f. Physiol.*, Leipzig, 1895.

² Wertheim, *Ann. de chim.*, Paris, tomes xii. and xxi.

the over-extension of the muscles of the back of the thigh thereby induced, and the weight of the head which plumbs in front of the atlanto-occipital joint is partly supported by the mechanically stretched muscles at the back of the neck.

An ordinary stretched muscle is, from a histological point of view, a complex of muscular fibres and connective tissue, consisting for the most part of the inextensible white variety. It is on this account that they are able to resist over-extension, and it will be found that those muscles which are frequently called upon to do this, which have in fact to perform the part both of ligaments and muscles, have powerful tendinous prolongations passing through them. In some vertebrates this is very especially the case; for instance, in the horse, where the flexor metatarsi muscle is really a combination of a muscle and a check ligament. In this muscle there is a long tendon, which arises from the

FIG. 130.—Two curves are here represented; the upper one (*abcde*) is the extension of a tetanised muscle by 10, 20, 30, etc., grms. The lower curve (*a'b'c'd'e'*) represents the extension by the same weights of a muscle at rest. The two curves are seen to cross towards their lowest points, when the muscles are extended by weights a little over 50 grms.

anterior and inferior portion of the femur, and passes over the stifle (knee) down the front of the tibia and over the hock (ankle), and is inserted into the metatarsal bone. As this tendon passes over two joints, the knee and the ankle, when one of these is bent the other one is bent too, in purely a mechanical manner. This round inextensible cord receives the attachment of a strong band of muscular fibres springing from the tibia itself, and is directly pulled upon by the

force of its muscular contraction.

When a muscle with parallel fibres contracts and lifts a load, each muscular fibre bears its fraction of the load, so that if the load be w and the number of fibres n , each fibre raises a load of $\frac{w}{n}$. It follows that the load which can be lifted will vary with the number of fibres, and therefore with the sectional area of the gross muscle. When the fibres are not parallel but obliquely set, as in the gastrocnemius, we have a greatly extended transverse area of muscular fibres, which act therefore very powerfully, though, on account of their short length, they can exercise their pull through but a comparatively short distance.

If a weight be attached to a muscle, and if that muscle be stimulated to contract, it will exert a pull or force upon the weight, the mass of which will then be acted upon in opposite directions by two forces, that of gravity and the muscular force. The absolute muscular force may be measured, after Weber, by so adjusting the mass of the load, that the muscle on passing into activity neither lifts the load nor is itself

elongated. In this case the force of the muscle exactly balances gravity, and may be measured by it. We may say that the force of a particular muscle per square centimetre of its cross-section is a weight of 3 kilos. If we wish to express this in units of force, or dynes, we must multiply the grammes or units of the mass, namely 3000, by 981, the acceleration due to gravity.

$$\text{Force} = \text{mass} \times \text{acceleration.}$$

In this case force = $3000 \times 981 = 2,943,000$ dynes.

The dynamometer may be used with advantage to gauge absolute muscular force. It is a spring in some form or another, whose distortions under the action of gravity have been previously ascertained, as by suspending weights from it and recording its elongations. If the spring be now pulled upon by a muscle, and elongated an inch, an elongation previously produced by gravity acting upon a mass of 3 kilos. suspended from it, we conclude that the force of the muscle is equal to 3 kilos., or 2,943,000 dynes.

The absolute muscular force is not the same for the muscles of all animals. Thus Rosenthal¹ found that per square centimetre of cross section the gastrocnemii of a frog can just raise 3 kilos., while in warm-blooded animals the same sectional area will raise about twice as much.² It is probable that the muscular force is not the same for all muscles of the body, and it is subject to physiological and pathological variation in one and the same muscle. Exercise is said to increase it, and the greater power of the right arm over the left is sometimes instanced as an example of this increase. It is, however, to be borne in mind that the girth of an exercised muscle, *e.g.* that of the right arm, increases, so that in this case it is not clear that per unit area the muscular force is increased. Disuse and degenerative changes greatly diminish the muscular force, and fatigue operates in a similar direction.

It had long been known that many of the lower animals, insects for instance, are, for their size, remarkably strong.³ Thus, while a horse can barely drag its own weight, many insects can drag a weight over sixty times their body-weight. But the comparison between the force of the pull of different animals, when this is expressed in terms of the body-weight, yields no data by which we may compare their absolute muscular forces. The reason of this is, that whereas in ascending a scale of size the body-weight increases as the cube, the cross-section of the muscles, on which the absolute force depends, increases only as the square. If, then, the absolute muscle force be the same throughout the whole animal kingdom, the larger animal would be able to lift or drag a smaller proportion of his body-weight than the smaller one; indeed, the insect who can drag sixty times its own body-weight may have muscles which are, per cross-section, weaker than those of a horse which cannot drag its body-weight.

When a muscle is stretched to or beyond its full physiological length,⁴ it is able to exert more power in raising a weight; its absolute force is greater. As it shortens, its force becomes less and less.⁵ This is clear from Fig. 130, in which is represented the curve of extension of a contracted muscle, the abscissæ being weights applied, and the

¹ *Compt. rend. Acad. d. sc.*, Paris, 1867, tome lxiv. p. 1143.

⁴ The full physiological length is the greatest length it ever assumes during life.

⁵ Schwann, Müller's "Handbuch d. Phys.," 1837, Bd. ii. S. 59.

ordinates the shortening which follows upon the application of a uniform stimulus. Let us consider the position of the muscle at the three points *a*, *b*, and *c*. At *a* the muscle is loaded with 10 grms., and it is raised to a considerable height; the muscle is short. Its strain balances the stress of the 10 grms., and more than 10 grms. would elongate it. At *b* it is loaded with 20 grms., and at *c* with 30 grms. In each case there is equilibrium between the muscular force and that of gravity, and we notice that this muscular force is smaller when the muscle is shorter.

A simple method of demonstrating this fact is the following. Stand upright in front of a table, bend one knee backwards so that the toes touch the ground. Load the foot as by the weight of a child sitting in front of the heel. If the child is of the right weight, you can just lift it by trying to bend the knee still more. Now, bend the body forward on the table so as to flex the thigh upon the trunk, and the child can be raised with ease. In the latter case the flexor muscles of the knee are nearly at their full physiological length, and their absolute force is greater.

The amount of shortening during contraction.—When the muscle contracts under the action of a given stimulus, it will shorten and raise a weight to a height that will bear a certain ratio to its length. Two similar muscles fastened tandem-wise to a weight will, on contracting, raise it to twice that height. This distance will bear the same ratio to their combined lengths, and with the same results these two muscles might be replaced by one muscle of the length of the two together; and we may say, therefore, that the shortening of a muscle is proportional to its length. This accounts for the fact that the extensive movements of the fingers are not brought about by muscles situated in the hand, but are produced by longer muscles lying in the forearm.

By the same muscle, and with the same stimulus or effort, the lift diminishes as the load increases.

In Fig. 130 the abscissæ represent the weights attached, and the ordinates, lengths of muscles. The lower curve represents a muscle at rest when loaded with 0, 10, 20, etc., grms., and the upper curve represents the positions assumed by the same point of the tetanised muscle when loaded in a similar manner. It will be observed that the lift (*aa'*) of the unloaded muscle is greater than when the muscle is loaded with 10 grms. (*bb'*), and so on. Weber believed that the curves ultimately cross, as represented in the figure. According to this observer, on loading the muscle, with say 50 grms., and then stimulating it, it lengthens instead of shortening. This is denied by more recent observers, such as Fick.¹

While Weber described a muscle as shortening 70 per cent. of its length, when unweighted, more recent observers incline to put the shortening at 20 to 30 per cent. of its length.

Shortening of individual muscles.—In order to investigate upon the skeleton the possible shortening of an individual muscle, during a movement of a limb, the following plan may be adopted. A hook is driven into the exact place of insertion of the muscle to be investigated. A staple is driven into the position of origin of the same muscle. A piece of twine attached to the hook is passed through the staple and tied to a weight, by means of which it is kept taut. The limb is placed

¹ "Untersuch. ueber Muskularbeit," Basel, 1867.

in such a position that the weight is pulled up towards the staple as far as it will go. The length of the thread from hook to staple gives the length of the muscle at its fullest physiological extension. The weight is then allowed to pull the hook towards the staple, and the distance in this case gives the length of the muscle in complete physiological contraction. The difference between these two lengths is equal to the shortening which takes place during contraction.

The terms full physiological extension and full physiological contraction have been used to indicate that the measurements relate to the extensions and contractions which can actually take place in the living body. An excised muscle can of course be extended beyond the point to which it is stretched, when it is physiologically extended within the body. In the same way, an excised muscle can contract to a shorter length than it ever reaches during life. A muscle *in situ* is in fact always stretched to a certain degree; thus when we flex the shoulder, rotate it inwards, bend the elbow, and supinate the hand, the points of attachments and origin of the biceps muscle are as close together as they will come. The muscle can, however, in this position be made to contract by an effort of the will, and this contraction can be felt by the other hand.

Weber¹ was the first to investigate the amount of shortening which takes place during the contraction of the individual muscles of the body.

The following table gives some of the measurements of E. Fick² :—

Name of Muscle.	Position of Humerus when Muscle maximally contracted.	Position of Humerus when Muscle maximally extended.	Amount of Contraction.
Coraco-brachialis .	Flexed, adducted, and rotated inwards.	Extended, abducted, and rotated outwards.	76 mm.
Long-head biceps .	Flexed and rotated inwards.	Extended, abducted, and rotated outwards.	40 mm.

Work done by a contracting muscle.—When a force acts upon a body and moves it, that force is said to perform work, which work is measured by the product of the force into the space traversed in the direction of the force—

$$W = F \times S.$$

When a muscle contracts, its force is capable of lifting a body against gravity, and, as has already been shown, the muscular force is measured as against that of gravity itself. If a muscle contracts and lifts a unit of mass, 1 gm., the force employed in dynes is

$$1 \times 981 \text{ (the acceleration due to gravity).}$$

If the gramme be lifted through unit of space (1 cm.), the work

¹ Ber. d. k. Sächs. Gesellsch. d. Wissensch., Math.-Phys. Cl., 1851.

² E. Fick, Verhandl. d. phys.-med. Gesellsch. in Würzburg, N. F., Bd. xi. S. 349.

done = $F(1 \times 981) \times S(1) = 981$ ergs, or units of work, in absolute measure.

The pull of gravity on the unit of mass is often taken to represent the unit of force, and in these gravitation units—

$$W = M \times S.$$

Thus, if 10 lb. be lifted 10 ft., we have the work of 100 foot-lbs. If 10 grms. be lifted 10 cms., we have 100 grm.-cms. of work.

While the force exerted by a muscle depends upon its cross-section and not upon its length, the work done will be proportioned not only to the cross-section but also to the length, inasmuch as the space through

which the force acts is one of the determinants of the work done, and the work done will therefore bear a proportion to the whole mass of the muscle. Many of the muscles of the body, such as the long head of the biceps, pass over two joints; and one advantage of its length is the fact that the work done by such a muscle is greater than can be accomplished by a shorter one of the same girth. The mass which a given muscle has to lift modifies in an important manner the amount of work which it will perform. As the muscle is gradually

FIG. 131.—Represents the curves of a resting and contracting muscle, when loaded with 0, 10, 20, etc. grms. On loading a muscle with 10 grms. and stimulating it, the weight will be raised from c to d , and the work done will be represented by the area $abcd$. The areas $QRST$ and $XYRQ$ are other areas representing work done (see text).

loaded, the distance through which the loads are raised diminishes, as we have already seen; but the product of this diminished space and the increased weight becomes greater and greater. After a time a maximum is reached, and after this the work done falls gradually to zero, at which point $S = O$.

We may represent the work done by an area. Thus, if in Fig. 131 the muscle lifts a weight of 10 grms. through 10 mm., the muscle performs 100 grm.-mm. of work, which is represented by the area $abcd$.

The work may be increased, as Fick has shown,¹ by any mechanical device which diminishes the load while a muscle is contracting. It will be understood by consulting Fig. 131, that, on loading the muscle with 40 grms., it

¹ Hermann's "Handbuch," Bd. i. S. 241.

will contract on stimulation, and lift the load from T to Q. In so doing it will perform work represented by the area QRST. If, however, when the muscle has contracted to Q, a fraction of the load be removed, it will lift the rest and perform more work. If, for instance, 5 grms. be removed, it will lift the remaining 35 grms. to X, and do an additional amount of work represented by the area XYRQ. If this be continued, it will finally contract to O, and perform its maximum work represented by the area OSTQ. This area may be measured and compared with the parallelogram *abcd* either by using a planimeter, or by cutting out corresponding areas in a piece of cardboard and weighing them, or by plotting out on squared paper. Many muscles in the body encounter, during the course of their contraction, less and less opposing force, and approximate in some degree to the ideal case represented above. The reason for this will be understood when the movements around the joints are studied, for then it will be seen that, according to the position of the limbs, the force of muscular contraction is very frequently opposed to a diminishing resistance (see p. 253).

From the definition of the term "work," as given above, a peculiar difficulty arises in discussing animal mechanics. It would seem from it that, when a muscle remains contracted and supporting a weight, it does no mechanical work while this is going on. "Work" being the product of a force into a space, there can be no "work" done when no space is traversed. But the muscle after a time becomes exhausted, and it is found to contain products of chemical action. This shows conclusively that work is actually being done, though it does not appear as external work, and cannot be gauged by the ordinary mechanical standard.

The rapidity of muscular contractions.—When a muscle contracts it does so with a certain rapidity, shortening for a certain distance in a certain interval of time. A survey of animal movements shows us that these differ greatly in their velocity, from the slow movements of the muscular walls of the stomach to the rapid movements of the insect's wing. We find that there are, in nature at least, three ways by which increased velocity of movement may be obtained. In the first case, the muscular fibres themselves acquire the faculty of moving more quickly and imparting a greater velocity to the hard tissue to which they are attached. This change is associated with a marked structural alteration—they become striped. Thus the muscular tissue of molluscs in general is unstriped; but certain species, together with more active contraction, have acquired striped muscular tissue.

In the second case, the muscle is attached nearer to the fixed point of a lever on which it acts. Thus, while the biceps, attached to the radius near the elbow-joint, moves its point of attachment with but a small velocity, the hand at some distance from the elbow moves comparatively rapidly through space.

But there is a third method, by which a greatly increased velocity may be obtained, a method almost entirely overlooked by physiological investigators, although it has not escaped the observation of A. Fick. Helmholtz¹ has shown that the full force of muscular contraction takes some time to develop. The muscle, as it were, gets up steam, so that a movement is made, not at full steam pressure, but begins as soon as the absolute muscular force just overbalances the resistance. It follows from this that if the point of attachment of the muscle be fixed in space, for, say, a second after the muscle has begun to contract (but not to shorten), and if it be then let go, the muscle will have developed a

¹ *Arch. f. Anat., Physiol. u. wissenschaft. Med.*, 1850, S. 276; and 1852, S. 199.

greater force, and the attachment of the muscle will be pulled at a much greater velocity.

In Fig. 132 are two tracings from the gastrocnemius muscle of a frog. The muscle was weighted with 5 grms., and, where a tetanising

FIG. 132.—Reduced tracings taken from the frog's gastrocnemius muscle by the pendulum myograph. In *a* a tetanic current was suddenly passed through the muscle. In *b* the muscle was prevented from contracting until the current had operated for a short time. The upright broken lines mark the position of the path of the lever on a stationary plate. In *a* the point of the lever is raised to *A'* in about $\frac{1}{100}$ of a second, giving a velocity of about 6 in. per second. In *b* the point of the lever was raised to the same height (*B'*) while the plate travelled the distance *BB'*, or in about $\frac{1}{200}$ of a second, giving a velocity of about 100 in. per second.

current was passed through it, it raised the point of the lever from the ground line up to *A'*, corresponding to a shortening of the muscle of about .4 cm. This took place while the plate was travelling from

A to *A'*, a period of about $\frac{8}{100}$ of a second, giving a velocity of about 5 cms. per second. In the case of tracing *b*, the lever was held for a short time after the tetanising current had passed through the muscle, and then it was suddenly released. It will be noted that the point of the lever attached to it has moved upwards to the same distance, namely, to *B'*, but that it has done so while the recording surface travelled from *B* to *B'*, which event occupied $\frac{1}{200}$ of a second only, giving a velocity of about 80 cms. per second, a velocity sixteen times as great as in the first case.

FIG. 133.—Reduced tracings taken of the movements of the human fingertip with the pendulum myograph. Curve *a* represents the path of a sudden voluntary flexure. Curve *b*, the path described by the same finger, fixed during the first part of contraction, and then suddenly released. The broken lines sloping upwards are the paths of the finger with a stationary plate. In *a* the finger is raised to *A'* (about an inch) during the time that the plate has travelled from *A* to *A'*, or in about $\frac{3}{100}$ of a second; its mean velocity is therefore about 33 in. per second. In *b* a movement of the same height has occurred while the plate has been travelling from *B* to *B'*, or in about $\frac{1}{100}$ second. Its velocity is therefore about 150 in. per second, or about five times that of *a*.

In Fig. 133 a tracing is made by a style attached to the finger. During the movement of the plate the finger is voluntarily bent as quickly as possible. The style moved from the ground line to *A'* during the time the plate travelled from *A* to *A'*—in about $\frac{1}{30}$ second. The second curve represents the path of

We have all found out empirically the fact that the above experiment illustrates, and when we wish to impart great velocity, we check the movement during the initial stages of the muscular contraction. Thus, when we wish to project a pellet of paper with considerable velocity, we place it on the tip of the thumb, press the nail of the middle finger into the soft skin of the thumb and behind the pellet; then we forcibly extend the middle finger, but do not at once release it.

contraction of the finger, supported during the initial stage of the contraction, and then suddenly released—snapped, in fact. The same movement is made while the plate travels from B to B' in about one-fourth of the time.

Amongst many lower animals this "hold and let go" method of increasing velocity characterises their most important movements. The elater (click-beetle, *Springkäfer*), when he falls upon his back is unable to right himself in the manner usual with insects, on account of the shortness of his legs. He bends his prothorax backwards, and hooks a spine into a depression of his mesothorax. He then contracts his extensor muscles, suddenly lets go, and springs many inches into the air.

FIG. 134.—Drawn from an instantaneous photograph of cheese maggots. Some are curling round to fix the tail to the head. The upper one has already done this, is straining to extend itself, and is just about to unfix itself and jump into the air.

The cheese maggot bends its

body round and inserts a hook attached to its tail into a grooved plate, like a file, near its head. It then contracts its straightening muscles, the hook is released suddenly from the file, and the maggot is projected with great velocity many times its own length. (Fig. 134).

FIG. 135.—The letter *g* marks the position of the common centre of gravity of the hand and lower arm, the letter *r* the position at which the lower is supported by the upper arm, and *m* the position at which the triceps muscle is attached. The arrows represent the forces acting at these positions.

Moments.—Let us suppose that the upper arm and trunk are fixed in space, the upper arm being raised, and that the lower arm and hand are fixed together so as to form a single rigid body free to move at the elbow-joint upon the upper arm (Fig. 135). The centre of gravity of the lower arm and hand (the weight of which is w) is at the point g , and the line of action of gravity will be in the direction of the downwardly pointing arrow. The triceps will exert a force pulling in the direction of the arrow descending from m . The point r is a point through which passes the axis of rotation of the lower upon the upper arm.

If the two forces m and w are balancing each other, and if we then shift the force w nearer to the hand, it will overcome the force m , and the limb will sink. Shift it towards r , and it will itself be overcome by m , and the limb will rise. This "value" of a force is termed the "moment" of the force, and is measured by the product of the force, and by the distance of its line of application from the point considered

(in this case r). If the distance gr be five times as great as the distance rm , and if the force w be 5 lb., and the force m 25 lb.,

the moments of the two forces are equal, and there is rest or equilibrium.

$$gr \text{ (5 units of length)} \times 5 = mr \text{ (1 unit of length)} \times 25.$$

Thus the smaller force acting on the longer arm balances the greater force acting on the shorter one. From its situation near the joint the force of the muscular contraction of the triceps needs to be very great, in comparison with the force of gravity pulling down the limb. This muscle may be taken as typical of those of the body generally, and when we push, or pull, or lift, the force of muscular exertion is often many times as great as the force against which it is opposed.

If in Fig. 136 the horizontal line grm represent the rigid lower arm, we may represent the forces acting upon it by straight lines, which can represent these forces, not only in the direction in which they act, but, as in the figure, their lengths may be made to correspond with the *magnitudes* of the forces. The consideration of these balanced forces is one of statics, but when equilibrium is disturbed by the moments on one or the other side being increased or diminished, a movement of rotation around the point r will occur, and we enter the region of kinetics.

If we suppose that the force at m (the contraction of the triceps) be increased, rotation of the limb will take place, and after a certain interval of time it will have assumed the position $g'r'm'$. In the performance of this movement g will have travelled five times the distance that m has travelled, and in an opposite direction,

FIG. 136.—Represents the rotation of a rod gm to the position $g'm'$ around a fulcrum at r .

so that if the force of contraction of the triceps at m has to be just a little more than five times as great as the force of gravity acting at g , the point g will be lifted five times as far as the point m will be lowered. What is lost in power is therefore gained in amount of movement, so that an extensive motion of the hand occurs when the muscles acting at the elbow-joint shorten to but a slight extent.

When we take into account the element of time, we learn that the velocity of the point g will be five times as great as that of the point m . Movements of g to g' and m to m' take place in the same interval of time, and $V = \frac{s}{t}$.

The aforesaid muscles may, on account of the distance of the hand from the elbow-joint, cause the hand, as in the act of throwing a ball, to move with considerable velocity.

Although the hand carrying a weight may be moved through a great space and with a great velocity, there is no more work done by the arm than is put into it by the muscle. A lever or other machine does not make work; it only performs work in such ways as may be desired and arranged for. This is affirmed in general principles by the law of the conservation of energy, and may readily be shown from Fig. 136.

The muscular contraction of the triceps lowers the point m to m' , with a force of 25 lb. The work is therefore $25 \times mm'$. Although, as the result of this contraction, the point g is raised to g' through a space five times

as great, the product (= the work done) remains the same, for the force applied at g is only one-fifth of that at m .

Action and reaction.—Returning once more to Fig. 136, it will be evident that unless the point r be fixed in space, the weight of the limb acting at g and the force of the contracting triceps will carry the upper arm bodily downwards. This they tend actually to do with a force which acts upon the upturned articular surface of the humerus. This action produces (Newton's third law) an equal reaction in the opposite direction, which reaction, if equilibrium be established, must exactly counterbalance the two forces acting at g and at m .

In the case of most muscular actions we have to consider three forces—that of gravity, that of muscular force, and that of the reaction at a joint. It is by investigating the movements around a joint that we can solve many problems of movement; thus, given the force of gravity and its moment, and given the distance of the point of application of the muscular force from the centre of rotation of the joint, we can calculate the muscular force necessary to counterbalance that of gravity acting upon the limb, or any weight supported by the limb.

Lever.—Although the term has not yet been used, it is evident that the bones fall under the definition of a lever. This is defined as a rigid bar, with a fixed point around which it can rotate, which is acted upon by two or more forces, and the reaction of the fixed point called a fulcrum.

The raising of the body by the action of the calf muscles.—In his well-known article in Wagner's *Händwörterbuch*, Bd. iii. S. 88, entitled "Muskelbewegung," Edward Weber describes the foot as a lever of the second order. When we stand upon the ground, and then raise the body on the toes, the fulcrum, according to Weber, is situated at the ball of the foot, the weight of the body falls vertically on the position of the ankle-joint, and the muscular pull is at the point of insertion of the tendo Achillis in the heel. Weber therefore supposed the forces and movements to be related as follows:—If M = the muscular pull and W the weight of the body (see Fig. 137), $M \times ac = W \times ba$, overlooking the fact that the shortening of the calf muscle is the real measure for the movement of the point of insertion, whatever space that point may travel through at the same time from other causes.

Knorz¹ and Henke² rectified this error and gave the true formula, $M \times bc = W \times ba$.

Richard Ewald³ explains the matter in the following way:—If a man were to stand on his head and support on his toes another

FIG. 137.—To illustrate Weber's theory of the movements around the ankle-joint. a marks the centre of rotation of the ball of the great toe; b that of the ankle-joint; and c the point of attachment of the calf muscles.

¹ "Ein Beitrag zur Bestimmung der absoluten Muskelkraft," Marburg, 1865.

² *Ztschr. f. rat. Med.*, Leipzig u. Heidelberg, 1865, Bd. xxiv.

³ *Arch. f. d. ges. Physiol.*, Bonn, 1894, Bd. lix. S. 251; and 1896, Bd. lxxiv. S. 53.

man of his own weight, then his ankle-joints would be fulcra fixed in space, and would be situated in the middle points of the levers; the feet would be levers of the first order, or two-armed levers. If now he were to stand on his own feet, and raise himself on his own toes,

FIG. 138.—Diagram to illustrate the method of calculating movements around the ankle-joint. Letters as before.

he would be doing just the same mechanical act as before; therefore the foot is a lever of the first order.

L. Hermann,¹ who has constructed a most ingenious model to illustrate the mechanism of the ankle-joint, discusses with Ewald at some length the question, as to whether the foot is a lever of the second order, as Weber thought, or a lever of the first order, as Ewald maintains. The question is, how-

ever, merely one of words and definitions.

Fischer² has given the subject as a general problem an exact and comprehensive study. It is evident that the same reasoning will apply to many different movements, as for instance raising the body by extending the arms on parallel bars.

Forces acting obliquely upon a bone.

—So far, we have studied forces such as those of gravity or muscular contraction, acting in a direction at right angles to the bone, and in calculating their moments we have measured the distance along the bone from their point of action to the fixed point. We cannot do this if they act obliquely, the moments being in this case calculated from the nearest distance from the fixed point to the line of direction of the force. This nearest distance will be that of a straight line passing from the fixed point, and falling vertically upon the line of direction of the forces. Thus, in Fig. 139, gravity $\times gr$ will give the moments on one side of r , and muscular action $\times rm$ will give the moments upon the other side. The moments of the muscle thus varying with position, it is evident that when trying to overcome a constant resistance a flexor muscle exerts

FIG. 139.—Diagram to represent the method of calculating movements when the forces are oblique to the axes of the body on which they act.

least traction when the limb is fully extended, but that the moment will increase as flexion takes place. If the moment of the resisting force does not, as is the case with gravity, augment in the same proportion, it will therefore become less, compared to the moment of the muscular force, and the muscle will do its work under the most favourable conditions, *i.e.*

¹ *Arch. f. d. ges. Physiol.*, Bonn, Bd. lxii.

² *Arch. f. Anat. u. Entwicklungsgesch.*, Leipzig, 1895, S. 101.

diminishing resistance. It must be borne in mind that the direction of traction may be greatly modified by the tuberosities over which the tendon may pass before insertion. A calculation of the moments at the ankle-joint will serve to illustrate the important principle alluded to above. The calculation is only true for the position at which the calculation is made, and the reason is that the moments vary with every change in position.

Knorz¹ and Henke² pointed out that before the heel is raised the body is instinctively thrown forwards, so that the centre of gravity falls over the base of the toes on which the body rests, before the heel actually leaves the ground. As Bedart³ pointed out, it is on this account that when we stand with our toes touching a vertical wall it is impossible to rise on the toes (Fig. 140). When in this position we lean forwards against the wall, the centre of gravity plumbs over a point midway between the ankle and the base of the toes, the wall prevents the experimenter from leaning forward enough to throw the centre plumb over the toes. He has therefore no support for his body and cannot raise it.

FIG. 140.—In *a* the tip of the toes, the front of the chest, and the chin are in the same vertical plane. In *b* the individual rises on his toes, and in so doing the body moves forwards into the position indicated. Were a wall to occupy the position of the vertical line, this action would be impossible.

FIG. 141.—Diagram to represent the moments around the ankle-joint (*b*) resting on the ground, and when it is raised to the position *b'*. *a* marks the centre of the ball of the great toe, and *c* and *c'* the point of insertion of the calf muscle.

Thus, when we raise ourselves higher and higher on the toes, the centre of gravity shifts slightly forwards towards the tips of the toes. One can assure oneself of this fact by standing in front of the door, with the toes about 2 in. from the door. If one can just raise the heel, say half an inch, and keep it in that position without falling backwards, it will be found impossible to raise the body to its full height. This can, however, readily be done on standing back, say half an inch. Still more important is the fact that

¹ "Ein Beitrag zur Bestimmung der absoluten Muskelkraft," Marburg, 1865.

² *Ztschr. f. rat. Med.*, Leipzig u. Heidelberg, 1865, Bd. xiv.

³ *Compt. rend. Soc. de biol.*, Paris, 1892.

when we raise the body on the toes, the heel end of the lever becomes relatively longer as compared with the toe end, so that the muscular pull required becomes less and less. Fig. 141 illustrates this in the case of a boy's foot. With the foot upon the ground the distance ab is to bc as 4 to 1.4. On raising the heel somewhat more than 2 in.—see dotted line—the relations are altered, ab' being to $b'c'$ as 2.8 to 2. It is true that it is very tiring to stand with the body raised high on the toes, but it is probable that this is due to the fact that the calf muscles are shortened, and their pull in consequence greatly diminished.

The resolution of moments into their components.—The moment of a force is, as appears from the construction given, smaller than the force itself. The reason is that a part of the force spends itself by exerting pressure on the joint. Thus in a muscle acting obliquely on a bone there are two component forces to be considered, one acting in the direction of the bone and producing pressure on the joint, the other acting perpendicularly to the first, and producing rotation. The lines representing the component forces form one half of what is termed the parallelogram of forces.

FIG. 142.

So far we have studied the action of a muscle lying in the plane of movement of the bone upon which it acts. If we are dealing with a joint under constraint, which can, like the elbow-joint, move in one plane only, we have to consider the action of muscles like the pronator radii teres, which are oblique to that plane. If, as in Fig. 142, we represent in force and direction the action of the muscle by the straight line ab , we can resolve this force by the parallelogram of forces into two, one of which ac lies in the plane in which movement can actually take place, and the other at right angles to it. The length of ac will represent the force of the muscle acting so as to produce the movement. The moments of flexion will be the

force in this direction, multiplied by the perpendicular distance between the point of rotation and the line of action of the force. The rest of the force will be spent in pressure and lateral strain on the joint.

When we are dealing with the action of a muscle upon an unconstrained joint, like that of the shoulder, the direction of the resulting movement will be determined by the direction of the muscle itself. If we take that plane which passes through the centre of rotation of the joint, the point of insertion, and the point of origin of the muscle (or the line of action of the muscle), then its contraction will cause a rotation around an axis normal to that plane, and passing through the centre of rotation. We may further, by means of three co-ordinate planes, determine the position of these points and the position of the centre of rotation, and then calculate by trigonometrical methods the position of this axis, and the new positions assumed by the limb, resultant upon the muscular contraction.

It is customary to describe the action of muscles in relationship to three co-ordinate planes. Thus, a portion of the deltoid is described as abducting the humerus, slightly flexing it, and rotating it inwards. In other words, abduction may be taken as a plus rotation on the frontal plane, and about a horizontal sagittal axis; flexion, a plus rotation along a sagittal plane about

a frontal and horizontal axis; and rotation inwardly, as a plus movement in a horizontal plane and about a vertical axis. If we represent the muscle by a line, the length of which represents in force and direction the action of the muscle, we may resolve these into forces acting in three directions by the ordinary parallelepipedon of forces. Thus, in Fig. 143, if a represents the insertion, and b the origin of the muscle, and the line ab represents the action of the muscle in force and direction, we can resolve ab into forces acting along axes intersecting at the point a . The lines ad , ae , and ac will represent the three components in three planes, at right angles to each other.

In practice we may proceed as follows:—

The bone from which the muscle arises is fixed in space by a clamp. The limb is then brought into the position at which the action of the muscle is to be studied. A cord is then attached to the bone at the point of insertion of the muscle, and the cord passes through an eye at the point of its origin, and to the end of this is attached a weight to keep it taut. By this means the distance from the point of insertion to the point of origin of the muscle may be measured along the cord, which can be graduated for that purpose. If the muscle is a pure flexor, when the limb is flexed it will be found that the points are at their nearest possible approximation. If it be mainly an adductor, and a flexor to but a slight extent, then movement in the direction x (flexion) will but slightly approximate the points; while movement through the same angle in the direction y (adduction) will produce a relatively greater approximation. The components are, therefore, found by moving the bone through a small angle, say 10° , in each of the co-ordinate planes, and reckoning the shortening of the cord which occurs in each case.

FIG. 143.—The resolution of the force of contraction of a muscle, represented by the line ab , into three forces acting in three co-ordinate planes, namely, into ac along zz , ad along xx , and ae along yy .

The double action of a muscle at both insertion and origin.—So far we have, for the sake of simplicity, considered the point of origin of a muscle as being fixed in space and not free to move. The latter is sometimes the case, as when the upper arm is fixed by muscles from the shoulder, and then the forearm is moved upon it. But, in the great majority of cases, both the points of origin and of insertion are more or less free, and move as a result of the muscular pull applied to them. If a muscle passes directly between its point of origin and insertion, and if it contracts with a force F , this acts equally upon the point of origin and of insertion. Even if the muscle by its tendon passes round a corner, the extensors of the thigh over the knee, or the long head of the biceps over the shoulder-joint, the same still holds good,

for a force is transmitted without diminution by a perfectly flexible cord passing over a perfectly smooth surface, and the tendon may, for all practical purposes, be considered as perfectly flexible, and the surface over which it passes as perfectly smooth.

A muscle like the brachialis, which passes from the anterior surface of the humerus, and is inserted into the coronoid process of the ulna, not only exerts a force upon the ulna, but exerts an equal and opposite force upon the humerus from which it springs. If the humerus be free to move at the shoulder-joint, this force may cause a rotation of the humerus as well as a rotation of the ulna at the elbow-joint. Fischer,¹ who has investigated this subject with great care, studied chiefly the actions of the brachialis muscle and the triceps. He made a mechanical model of the arm, corresponding to it not only in gross

FIG. 144.—*A* represents the action of the triceps upon the humerus and ulna. As the ulna is extended the humerus flexes. *B* represents the action of the brachialis which flexes the ulna, and at the same time extends the humerus. In both *A* and *B* the black figures represent the bones before the muscles have contracted.—After Fischer.

weight, but in the position of the centres of gravity of both the upper and lower arm, and likewise in the general distribution of mass in the direction of its length. The muscle was represented by an elastic band, fastened in the position of the muscle, and balanced by the tension of a string. On burning this string the elastic band shortened, and when it represented the brachialis muscle it bent the model at the elbow, and also extended the shoulder backwards. The model was free to rotate on a vertical pivot at the shoulder, the whole moving on a glass plate in the horizontal plane, to avoid the effect of gravity.

When the band represented the triceps it extended the elbow, and at the same time flexed forward the humerus (Fig. 144).

Stimulation of these muscles in the living body by faradic currents gave similar results.

It appears, therefore, that a muscle which only passes over one joint does yet effect movements on neighbouring joints, and this as a rule in an opposite direction; thus a flexion at the elbow causes extension at the shoulder; and extension at the elbow causes flexion at the shoulder.

Muscles which pass over two joints.—While certain muscles, such as those which move the jaws—the deltoid, the brachialis anticus, etc.—pass over but one joint in their course from origin to insertion, many muscles, especially those of the limbs, pass over two joints, or even more. Thus the long head of the biceps passes over both the shoulder-

¹ Fischer, "Beitr. zu einer Muskeldynamik," Leipzig, 1895, S. 56-197.

and elbow-joints; the hamstring muscles inserted into the bones of the lower leg arise from the pelvis and pass over both the hip- and knee-joints. There are certain advantages gained from this construction of the body, one of these being that, as the amount of shortening of a muscle is in proportion to its length, a greater amount of shortening is obtained from the long muscles under consideration. As Fick¹ has pointed out, we are able by this arrangement to move two joints by means of one muscle, and thus there is an economy in the amount of muscular substance required. Thus, in order to perform the same amount of work in extending the hip- and bending the knee-joint by muscles passing over one joint alone, it would be necessary to have two sets of muscles, each set equal to the combined masses of the hamstring muscles. Not only, then, is the amount of movement of a limb considerably increased, but the amount of work which can be performed, say by bending the knee, is very greatly increased by this arrangement.

THE CENTRE OF GRAVITY OF THE BODY.

Johannes Alphonsus Borellus² and the brothers Wilhelm and Eduard Weber,³ taking for granted that the centre of gravity lies in the middle line of the body, determined its distance from the sole of the foot, but failed to determine its position in the antero-posterior plane. They placed a man flat on his back upon a board, and balanced the board see-saw wise upon a wedge. The centre is situated roughly between the pubes and buttocks, and is farther from the sole of the foot than from the crown of the head. If the whole height of a man be taken as 100, the distance of the centre of gravity from the ground will, in the erect position, be 57 per cent. of the total height. This result was verified by Harless⁴ and Meyer,⁵ whose measurements vary within the limits of 3 per cent. This is, however, to be expected, for no two individuals possess the same build—a man with muscular arms and shoulders will have his centre of gravity relatively high, another man with strong legs and sloping shoulders will have his centre of gravity relatively low.

Meyer further determined the position of the centre of gravity in the antero-posterior plane by the following method. A man standing at "attention" bent forwards so that the weight of the body fell upon the front of the feet; a line plumb to this point passed through his centre of gravity. He then extended his limbs at the ankle-joint until he nearly fell backwards over his heels; the line plumb to his heels passed through the centre of gravity, which lay in the point of intersection of these two lines. Meyer found the centre to lie in the body or canal of the second sacral vertebra.

Recently Braune and Fischer⁶ have ascertained the position of the centre of gravity. They proceeded as follows:—A "subject" placed flat on the back upon a board was frozen in this position. The frozen

⁶ "Abhandl. d. math.-phys. Cl. d. k. sächs. Gesellsch. d. Wissensch.," Bd. xv.

body was then pierced by steel "spits," placed in three axes at right angles to each other. From these spits the body was in turn suspended, and inasmuch as the centre of gravity must in each case be in the plane vertical to the axis of suspension, it could be readily fixed by finding the point of intersection on these three planes. Having found the centre of gravity for the whole body, the head and limbs were removed from the trunk, and their centres of gravity determined by the same method.

In a typical subject, to which special reference is made, the centre of gravity for the whole body was 4.5 cms. above the axis joining the centres of the heads of the two femora, and on a level with the upper border of the third sacral vertebra. The centre of gravity of the head was plumb above the atlanto-occipital joint, and those of the limbs almost exactly in the line joining the neighbouring joints; thus, the centre of gravity of the arm and thigh lay in the lines joining the centres of the heads of the humerus and femur with the middle point of the axis of the elbow- and ankle-joint. The centre of gravity of the torso lay in the line joining the atlanto-occipital joint to the centre of the line joining the centres of the humeral heads.

The centres of gravity of the different portions of the body lying in the lines joining the principal joints, it was possible to arrange a skeleton of a subject similar in build to the frozen subject, so that the axes of all the joints were in the same frontal plane. In this case, were the skeleton clothed with flesh, the centres of gravity would fall in this plane. The skeleton was photographed from the front and profile, and the centres of gravity, the positions of which were calculated from the observations made upon the frozen subject, were indicated, together with the joints on two co-ordinate planes, one in a frontal and the other in a sagittal direction. These planes were mapped out in equal squares of 1 mm., and the position of any point, say the centre of gravity of a limb, could be indicated as a plus or minus distance from the line of intersection of these planes in both a frontal and in a sagittal direction, together with a distance along the line of intersection. Thus the centre of gravity of the whole body falling in the frontal plane would give the deviation O along the sagittal plane; those for the head and trunk lying in the lines of intersection would show deviation O for both the frontal and sagittal plane, while the centres for the arms and legs, lying as they do to the side, would give a deviation in the frontal plane of $\pm x$ cms (see Fig. 122).

The next step taken by Braune and Fischer was to utilise the services of a soldier of nearly the same proportions as the cadaver used. The positions of his joint-axes were indicated on the surface of the body, and he stood in such a manner that these joint-axes plumbed one over the other; and, by inference from the dead subject, his centre of gravity and those of his limbs lay in the same frontal plane. This was termed the normal position (*Normalstellung*). A profile photograph was then obtained, on which was projected a millimetre network of equal squares, from which plus and minus deviations from the line of intersection of the frontal and sagittal planes could be measured on the sagittal plane. When the soldier assumed the military position (German), or a position of ease, the joints and centres of gravity occupied new positions, moving forwards or backwards, downwards or upwards, on the sagittal plane. Photographs were taken of the soldier in these new positions; and the new positions of his centres of gravity of limbs, trunk, head, etc., measured on the co-ordinate planes. From these data the position of the centre of gravity of the whole body was calculated, by the

method of finding the resultant of two or more parallel forces due to the action of gravity on the centres of the limbs.

One cannot read the work of these authors without the greatest admiration for the care with which they have tried to settle an important problem, but it is very doubtful if the mathematical calculations they have so rigorously used can be applied with advantage to the case in point. To apply data supplied from a corpse stretched upon its back, and subject before freezing to the distortions of gravity acting in the front to back direction, to a somewhat similar living man standing upright and subject to the distortion of gravity acting in a vertical direction, is not a basis upon which we can hope, with further work, however careful and exact, to obtain accurate results.

As will presently be shown, the determination of the position of the centre of gravity is of importance in determining the position of stable and unstable equilibrium. It is here a matter of chief interest to find out whether the centre plumbs in front or behind the hip- and knee- and ankle-joints; to determine, in fact, its position in the sagittal plane. This can easily be determined by an apparatus, contrived by Dr. W. Sheen and myself, which is so simple and easily manipulated that it can be used by the physician as a clinical instrument. It consists of a box, on which the patient stands upon both feet (Fig. 145). The board

ab , on which one foot rests, is provided below with a steel runner like that of a skate. The runner is supported at each end in a slot of metal. The oblique front view of the apparatus is seen in the lower part of Fig. 145. Below the runner is a strong steel rod, and by introducing between the rod and the runner the bent lever, the runner can be prised up at any point in its length. If the patient be standing with his centre of gravity falling over the middle of the foot, and if we prise up the runner in front, the front part will be raised, the runner resting on the lever and the back slot. On prising the runner behind the ankle, the back part will be raised, for the centre is in front. On prising the runner nearer and nearer the plumb-line through the centre

FIG. 145.—Apparatus for determining the centre of gravity. Above, the upper view of the box is shown. ab is the board on which one foot rests, and which is tilted by the lever l . Below is shown an oblique view of the same. r is the rod on which the lever l rests, and x the runner carrying the board ab . The indices at either end of the board ab show which end is raised.

of gravity alternately behind and in front of it, we shall gradually reach the plumb-line and carry the runner balanced on the lever. It is quite easy to determine this to within $\cdot 3$ cm. By arranging a plumb-line to fall through this point, as in Fig. 146, we can determine by photography the relation between the centre of gravity and the centres of rotation of the joints previously determined.

Braune and Fischer, as we have seen, give as the *Normal-stellung* that erect posture in which all the axes of rotation of the joints lie in the same frontal plane. In this position the centre of gravity of the body is found by them to fall in the same plane. This we failed to verify, though the deviation from the plane is not a great one. In the case of a well-built soldier (Fig. 148), the centre of gravity was 1.5 cms. in front of it. While in the individual of normal build there is not that strict relationship between the position of the centre of gravity and the joints which Braune and Fischer maintain, it is certain that in many abnormal figures, and with women in pregnancy, the centre of gravity must lie well away from the plane containing these joints when they are placed in what is called the *Normal-stellung*.

FIG. 146.—The posture is arranged that the dots indicating the centres of rotation of the principal joints fall in the same vertical plane, which is indicated by the vertical line. The posture is a very constrained one, and the centre of gravity of the body falls in this individual slightly in front of that plane.

The erect position.—The brothers Weber assumed that the erect position was maintained without or nearly without muscular exertion. They found reasons for believing that every part of the body might be sustained by the tension of ligaments. As long as the centre of rotation of the knee is in front of the line between hip and ankle-joint, the body weight pressing on the hip-joint will cause the leg to be bent at the knee. But if extension of the knee be carried so far that the centre of rotation falls behind the line mentioned, the body weight will only tend to produce over-extension, and the knee will be kept rigid by its powerful check ligaments. In the same way the body may easily bend forward on the hip-joints if its centre of gravity plumbs before these joints, but if it plumbs behind, the pelvis and spine can only rotate backwards until the check ligaments of the hip come into play. The head was believed by

Weber to be exactly balanced on the atlas in its normal position. Thus the whole body would be sustained in the erect position without intervention of muscles, provided it were poised in equilibrium on the ankle-joints.

Now, according to the brothers Weber, the centre of gravity plumbs behind the hip, in front of the knee, and above the ankle-joint, when the body is standing in the position of greatest ease. For this reason muscular effort is only required to establish and retain the position described. Meyer agrees in the main with the Webers, except that he states that the centre plumbs in front of the ankle-joint, thus calling upon the extended calf muscles to contribute towards the support of the body. Meyer, moreover, places the centre of gravity of the head

a little in front of the atlanto-occipital joint, so that the head is largely supported without muscular exertion by the stretching of the muscles and ligaments at the back of the neck. These views were still further modified by Henke.¹

The fact that the thigh may be rotated considerably farther backwards from its position in standing, shows that the backward rotation of the pelvis is not at its maximum, the ligaments therefore are not taut. Braune and Fischer place the centre of rotation of the knee before the line between hip and ankle-joint, and thus prove the necessity of muscular exertion to maintain extension of the knee. The fact adduced as counter-evidence, namely, that when the knees are straight the extensor muscles of the thigh are perfectly flaccid, as tested by the patella, which can be moved from side to side without resistance, is not a valid argument, as extension of the knee in the upright

FIG. 147.—The position of the centre of gravity is indicated by a dot in each of the postures *a*, *b*, and *c*. In *a* and *c* it lies outside the body altogether.

position can doubtless be enforced by the muscles at the back of the leg. The increase of metabolism during standing upright, and its variations with varying positions, offer proof of considerable muscular exertion.

According to Braune and Fischer, who corroborate the results obtained by Parow,¹ the centre of gravity plumbs in the line joining the hip-joints—in the *Normal-stellung*, and but very slightly behind it in the *bequeme-haltung*, and very slightly in front of it in the position of attention.

These somewhat conflicting views are no doubt due to the difficulty in defining what is the erect position. As a matter of fact, there are many erect postures more or less comfortable, and the centre of gravity may be made to plumb either in front of, above, or behind either the hip, the knee, or the ankle. The erect position of the brothers Weber

¹ "Anatomie u. Mechanik der Gelenke," Leipzig u. Heidelberg, 1863, S. 215.

² *Virchow's Archiv*, Bd. xxxi.

probably did not correspond to that described by Meyer and termed by him *militärisch*, and this again certainly does not correspond with the *bequeme-haltung* of Braune and Fischer.

In Fig. 147 three figures of a man are represented (*a*) bending backwards, (*b*) standing erect, and (*c*) bending forwards. In *a* and *c* the centre of gravity actually falls outside the body, and it will readily be understood how the slightest movement in *b*, either forwards or backwards, will shift the position of the centre in relation to the joints.

The following points may be readily ascertained by the aid of the apparatus for ascertaining the position of the centre of gravity mentioned on p. 259. Where the centre plumbs over the ankle-joint, or lies behind it, the body is held uncomfortably erect, and there is a feeling that it would easily be caused to fall backwards. In the most comfortable position the centre plumbs in front of the ankle, but when it is caused to fall over, or nearly over, the ball of the great toe, as in the position of attention, there is a feeling of strain, and the posture cannot be maintained long without great discomfort. On this account soldiers are not kept long at attention by officers of experience; indeed, it is very doubtful whether this position should be retained at all, for it is questionable whether a smart appearance, and the gaining of half a second in commencing to march, compensate for the waste of considerable muscular activity.

FIG. 148.—A soldier in the erect posture. The black vertical line plumbs with centre of gravity. The centres of rotation of ankle, knee, and hip fall behind this plumb-line.

There is no erect posture of the body which can be long maintained without exhaustion.¹ If we are called upon to stand for some length of time, we instinctively change our posture from time to time, throwing the strain first on one set of muscles and ligaments and then upon another. The position of the centre of gravity changes with any deformation of the figure. Thus, a protuberant belly, either caused by pregnancy or by excessive development of fat, causes the centre to move forwards, so that the obese or pregnant person has to hold his or her head and shoulders well back, in order that it may plumb within the area of ground covered by the feet. A burden on the back, on the contrary, causes the centre common to the burden and the individual carrying it, to move backwards, so that the bearer

has to bend forwards in order that the centre may fall plumb with the feet.

Viewing the body as a rigid body, we shall find that its stability will depend upon its height and the area of its underpropping (see Fig. 149). If we imagine a force (push) acting through the centre of gravity in the direction of the line *ac*, it will, if great enough, cause the body to fall over the toes at the point *f*. In so doing, it will overcome the force of gravity acting downwards at the distance *fd*.

The question is really one of the moment around the point *f*. At the instant the overturning is just about to commence, the moments around *f* will

¹ In the horse, the weight of the animal is largely supported by what are termed "check ligaments," found both in the fore- and hind-legs. The animal can on this account remain standing for a considerable time without fatigue, and can sleep in the standing position (F. Smith).

be equal. The moments are found by drawing the shortest line fb from f to the direction of the force ac , and the line fd to the direction along which gravity acts. Then $bf \times \text{push} = fd \times \text{weight of body}$.

FIG. 149.—To show the effect of a push acting in the direction of the arrow ac in overturning the body, which is viewed as a rigid body resting on the feet.

If the push be greater than $\frac{fd}{bf} \times \text{weight of body}$, then the body will be pushed over.

It also follows that the longer fd is, the greater must be the push in order that overturning may take place; indeed, we may say that the larger the area of underpropping the more stable is the body. In the erect position at attention the area of underpropping is as 1 in Fig. 150, and coincides with the area covered by the feet, together with the area between them. Under ordinary circumstances we stand with the feet somewhat apart as in 2, when the area of underpropping is increased. When we wish to resist a push from the sides, we stand as in 3; and when, as in fencing or boxing, we wish to resist a push from the front, we stand as in 4.

Strictly speaking, the body not being a rigid mass, there can be no question of stable or even unstable equilibrium. In fact a living subject is constantly in motion, even when trying hard to stand "motionless." Vierordt¹ by a simple recording method obtained tracings of the swaying movements of persons standing upright. Leitersdorffer² proved by this

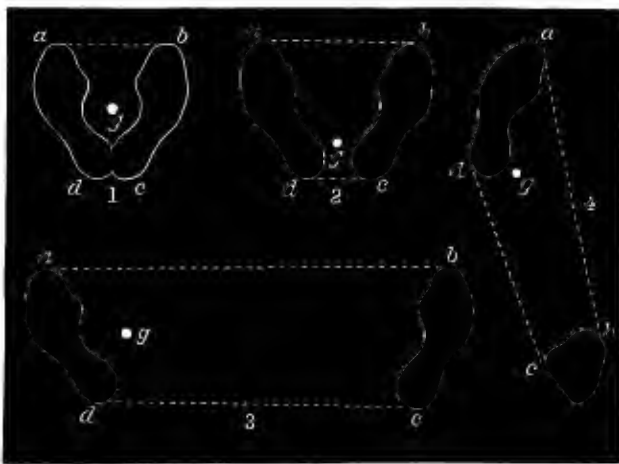

FIG. 150.—Shows the area of underpropping and the plumb of the centre of gravity (g).—(1) At attention. (2) In an erect and easy attitude. (3) When resisting a force applied from the left. (4) When resisting a force applied from the front, as in boxing.

method the influence of the area of underpropping and the difference between trained and untrained subjects.

METHODS OF RECORDING THE MOVEMENTS OF WALKING
AND RUNNING.

The Webers¹ studied the actions of walking and running, on a track of measured length. By means of a watch they could determine the period of any given pace; for, knowing the space traversed, the time taken to traverse it, and the number of paces indicated by the foot-prints, the mean duration and length of a step could easily be calculated. Further, they were able by this means to determine the relationship between the length of the step and its duration, and arrived at conclusions which will presently be alluded to.

FIG. 151.—Shoe for indicating when a man's foot comes in contact with the ground; * transmitting tube effects a communication between the air-chamber and the chronographic tambour.—After Marey.

By observation they established the fact that, in walking, the trunk and centre of gravity sink to a lower level than obtains in the erect position, and they found, moreover, that this sinking is greater the longer the stride.

Chronographic methods.—M. Marey, who has rendered such signal service to the physiologist by inventing useful methods for recording the movements of the heart, the blood vessels, and the muscles of the body, has also been the pioneer in inventing chronographic methods for recording such movements of the whole body as those of walking, running, swimming, etc.² These methods do not yield very full information, but they give useful data as the exact times during which the several limbs remain in contact with the ground.

The apparatus for recording the "paces" of a man is as follows:—A pair of shoes are constructed (Fig. 151), with thick india-rubber soles, within each of which is a hollow cavity, communicating by a long tube with a Marey's writing tambour. The two tambours are arranged to record in vertical series upon a revolving drum, which is carried in the hand (Fig. 152). When a foot touches the ground, a wave of pressure travels to the corresponding writing-lever, which is caused to trace an ascending curve upon the cylinder.

FIG. 152.—Pedestrian furnished with special shoes and carrying a chronographic apparatus.—After Marey.

The paces of the horse have naturally called forth much observation, and

¹ Wilhelm and Ednard Weber, "Mechanik der menschlichen Gehwerkzeuge," Göttingen, 1836. Recently republished in vol. iv. of Wilhelm Weber's "Gesammelte Werke."

² *Ann. d. sc. nat.*, Zoologie, Paris, 1872. His work recently epitomised in "Le mouvement," English transl. by Pritchard, 1895.

for their study a similar piece of apparatus has been used by Marey (Fig. 153). Indiarubber bags, stuffed with hair, are fixed in the hollow of the hoof, communicating, by means of a long indiarubber tube, each with a writing-lever. The rider (Fig. 154) carries a revolving drum, with the four writing-levers arranged in vertical series. The tracings obtained from a man running are shown in Fig. 155. The continuous curve is that of the right foot, while the discontinuous curve is that of the left. The upper curve represents the oscillations of the centre of gravity. In both cases, descent of the lever is due to pressure of the foot upon the ground. Ascent is due to the sole of the foot leaving the ground. Marey usually represents his results directly obtained by means of the above curves in the notation seen on the lower part of this figure and in figure 156. The method of its derivation from the curves will readily be understood by reference to figure 155.

Vierordt modified Marey's method, using electrical recorders instead of air recorders. In other experiments, tiny outflow pipes from a reservoir of coloured fluid, carried on the shoulders of the runner or walker, were attached at various points, such as the hip, knee, shoulder, etc. From these outflow pipes a continuous flow spurted upon a piece of paper, fixed vertically by the side of the person under observation, and thus recorded the movements which were taking place.

Chronophotographic method.—This method is a modern one, dating from the year 1878, when Janssen took a series of photographs of the planet Venus while it was traversing the sun's disc, and suggested a similar method for the investigation of animal locomotion. It has since been used with remarkable success by Muybridge, Marey, Anschütz, Braune, and Fischer.

Muybridge, in studying the movements of the horse, caused that animal to run in front of a white screen along a track across which were stretched a series of wires, each one of which formed

FIG. 154.—The chronographic apparatus for recording the paces of a horse.—After Marey.

part of the circuit of an electro-magnet, which closed the shutter of a photographic camera. When the horse broke the wires, one by one, a shutter was released each time, and the horse was photographed.¹

¹ "The Horse in Motion, as shown by Instantaneous Photography," London, 1882. See also Londe, "La photo. inéd.," Paris, 1893.

FIG. 153.—Special apparatus for recording the contacts of a horse's feet with the ground; a transmitting tube effects a communication between the air-chamber and the chronographic tambour.—After Marey.

Marey, using but one camera, provided with a rotating series of diaphragms, obtained a series of exposures—ten a second, each lasting $\frac{1}{500}$ second—upon his single plate. In photographing a man running, he caused him to pass in front of a black background, consisting of an enormous box, blackened on the inside, and opening towards the camera, and protected from the direct influence of the sun's rays. He thus obtained a series of photographs, say at intervals of $\frac{1}{10}$ second. When, however, he dealt with slow

FIG. 155.—Marey's curves obtained from a man running; *o*, oscillations of the centre of gravity; *a*, curve described by pressure of right foot; *g*, the same of left foot.

parts during each phase of even a slow motion.

A second method consisted in using a sensitive plate, or preferably a roll of sensitised gelatin, which travelled at a known rate, and was at intervals, say, of $\frac{1}{12}$ of a second, brought to a standstill. At each moment, during which the plate became stationary, the shutter of the camera was automatically opened and a photograph taken. In order to keep the camera pointed at the moving object—a bird, for instance—the camera was reduced as much as possible in size, sighted like a gun, and moved after the bird by the observer.

W. Braune and Fischer¹ used a modification of Marey's method. The person under observation was clothed in black, and upon important parts of the head and limbs a series of eleven Geissler's tubes were attached. They were filled with nitrogen, and connected with the secondary coil of a Ruhmkorff's machine. In the primary coil was placed an interrupter, which caused a current to pass through the tubes at regular intervals of $\frac{1}{25}$ of a second. The experiment was conducted in a dark room, and the periodic flashes of the Geissler's tubes were photographed. Nitrogen was placed within the tubes, because its light is especially rich in chemically active rays. The most important advance made by these observers was the exact record of their results in relationship to co-ordinate planes. The observed person's movements were recorded by cameras placed

¹ "Der Gang des Menschen," Leipzig, 1895.

on either side, with their optical axis perpendicular to the plane of his path, and at the same time his movements were photographed from the front or from behind. By this means, and by the help of networks of equal squares, these observers were able to record photographically the movements of any part—say the shoulder—in all three dimensions of space, a result not hitherto satisfactorily achieved.

DETAILED DESCRIPTION OF MOVEMENTS.

Walking.—On level ground one foot leaves the ground as the other reaches it. On walking uphill or in carrying a weight the advancing foot does not leave the ground until its companion has become firmly planted (Fig. 156,¹ and ²).

In studying the details of the movement we may consult Fig. 158.

This is obtained chronophotographically from a man clothed in black, with white stripes in the axis of the limbs (see above). It agrees remarkably with the results more recently

FIG. 157.—Chronophotographic method of recording bodily progression. The axes of rotation of the joints and axes of the limbs are represented in white on a dark background. These are photographed during progression.—After Marey.

FIG. 158.—Chronophotograph of a man's movements when walking. Read from left to right.—After Marey.

obtained by Braune and Fischer,¹ but differs somewhat from the older observations obtained by less exact methods.

Examining the figure representing the movement of one side of

¹ *Op. cit.*, Leipzig, 1895, plate x.

the body, we notice that the trunk oscillates upwards and downwards on a vertical plane. A crest occurs about the middle of the period during which the limb rests upon the ground. There is another crest which occurs while the leg is off the ground, and this coincides with the middle of the period during which the *other* leg—not represented in the figure—is in contact with the ground.

If we study the position of the limb just before it leaves the ground, it will be noted that the limb is fully extended and forms the hypotenuse of a right-angled triangle, whose vertical side falls from the hip-joint to the ground. The trunk is now falling, and in order that the leg may be brought forward free of the ground, it is bent by muscular exertion and reaches its maximum of bending. It then extends until the heel reaches the ground and the limb is once more straight. While the foot remains upon the ground, and while the hip is still advancing, the knee is once more bent, but to a slighter extent. The limbs are straight, therefore, at the moment when they reach and leave the ground; they are bent at all other times.

Running.—In the case of running, the body remains suspended for a

FIG. 159.—Chronograph of the movements of a man's leg in running. Read from right to left.—After Marey.

moment in the air (see Fig. 156, ³ and ⁴), that is to say, one limb leaves the ground a little before the other leg reaches it. On examining Marey's chronophotographic figure (Fig. 159) representing a running man, it will be noticed that although the limbs are never quite extended, as in walking, yet the greatest extension is at the time the foot reaches, and then again at the time it leaves, the ground.

In running, the length of the stride may be greater than in walking, and the frequency of stride may also be greater. On this account it is often stated that a man can run three times as fast as he can walk. This is undoubtedly an error, as the running and walking "records" conclusively show. While the record for the mile run is 4 minutes 18 seconds, the record for the mile walked is 6 minutes 36 seconds¹. Even if we calculate for running on the running pace for 100 yds. (10 seconds), this gives for the mile run 2 minutes 56 seconds.

Relationship between duration and length of stride.—According to the brothers Weber,² there is in walking a relationship between the

¹ Amateur records up to 1895.

² "Mechanik der Gehwerkzeuge."

duration of a stride¹ and its length, the longer strides being taken in the shorter periods of time.

The Webers also investigated this relationship in the case of a running man, and found that the duration of the stride suffered but slight variations, and that in consequence differences of velocity are due chiefly to differences in the length of stride.

Marey investigated this matter by somewhat improved methods, and found that, as the number of steps was increased in walking from 40 to 75, the length of the stride was increased, too, but that in still quicker walking the length diminished very considerably.

In the face of this conflicting evidence, it is difficult to believe in any necessary relationship between the length of a stride and its duration. Indeed, without any scientific appliances at all, we can convince ourselves that the step can voluntarily be lengthened and shortened at will within very wide limits, without changing the duration of the pace. It is very questionable whether we can accept either the Webers' or Marey's results as true, except for the particular experiments which they carried out. For instance, in Marey's experiments, the subjects of experiment were required to walk in time with the sound of a bell struck at regular intervals. Knowing the distance traversed, and the time which this took, the mean length of the stride could be calculated. The men—they were soldiers—when they had to walk to a quicker time would instinctively lengthen the pace, the object of quick time being to get over ground, and this they were able to do up to a certain limit. We may indeed walk or run in many fashions, and even the Webers recognised that the time relationship between length and duration of pace was not the same in "*Sprunglauf*" as in "*Eillauf*." Nevertheless, there is probably for each individual a walking and running pace of certain duration involving the least expenditure of energy. The step is quicker in short than in tall persons, and the reason for this will be apparent on perusal of the next section.

Pendulum movements of the limb.—The Webers² taught that, in walking or running, the forward movement of a limb, from the moment at which it is lifted from the ground to the moment it reaches it again, is a pendulum-swing, due not to the action of muscles but of gravity itself. This view is generally held to be true, and some writers such as A. Fick³ consider that the swings of a hanging thigh are merely damped by the surrounding muscles, which alter the amplitude but not the period of the swing: they would deny the aid of muscles altogether.

The evidence in favour of this theory is as follows:—The lower limb hanging lax and allowed to swing has a period of 0.692 seconds. In walking or running, half a swing is executed by each limb during the period of a single pace, and a whole swing during the period of two paces. This is true especially in the case of rapid running, when the feet touch the ground and remain at rest for a very short period of time. Now two such paces are accomplished in 0.664 seconds, rather less, in fact, than the time taken by the swing of a lax leg. This somewhat shorter duration is accounted for, by those who advocate the pendulum theory, by the fact that in running the leg is flexed, and that on this account the period of its swing would be diminished. Again, it is maintained by the followers of the Webers that by the pendulum theory alone can the fact be explained that the longer the stride the shorter is the period

¹ The length of a stride is the distance, say, between the point of the toe of one foot as it leaves the ground, and the point of the other foot when it, in its turn, leaves the ground.

² "*Mechanik der Gehwerkzeuge*."

³ Hermann's "*Handbuch*," Bd. ii. Th. 1, S. 330, 331.

taken. Moreover, it is a well known and undoubted fact that people with short legs walk in quicker time than those with long ones, when they assume a natural pace, as free as possible from muscular exertion.

The investigations of Marey just quoted have, however, shown that there is no necessary relationship between the length and the duration of the stride.

Mechanical forces operative during progression.—In walking and running there are certain forces which have to be so equilibrated that the pace is neither increased nor diminished, and that the body retains its elevated position from the ground. There is, in the first place, the weight of the whole mass of the body tending to seek its lowest level. Secondly, there is the resistance of the air, which will vary with the velocity of progression, and the extent of surface presented by the body, etc.; and, thirdly, the reaction of the ground upon which progression is performed. As against these forces we have the muscular force of the body which tends to straighten the legs, raise the centre of gravity, and give it the necessary forward velocity.

FIG. 160. — The upward thrust of the leg is represented by the arrow *ca*. From *c*, the centre of gravity, the line *cb* represents the force of gravity. By completing the parallelogram *cadb*, we obtain the line *cd* which represents the displacement of *c* that will actually take place.

During forward progression, it is certain that the centre of gravity is constantly and rhythmically changing its position, as the body itself is mobile, and rhythmically changes its shape. The centre, which always lies approximately in the median sagittal plane of the body, is moved in space on a horizontal plane, not only forwards but from side to side. This side-to-side movement is due to the shifting of the body in the direction of the leg on which it for the moment rests. Marey, by photographing from the front a bright spot over the pubes, showed this side-to-side movement of the body; and the same can experimentally be shown by walking towards two vertical threads placed in a line with one eye, one thread under these conditions appears alternately on each side of the other. These movements are slight, and are usually disregarded in discussing the mechanism of locomotion. In relation to other parts of the body, it is certain that the centre of gravity shifts its position during progression, coming forwards in the mesial plane

when the body is bent, and probably moves rhythmically to some slight extent as the limbs swing. These movements also we must discard as being relatively unimportant, and we must view the centre of gravity as fixed in the body, and in the median plane just above and somewhat in front of the middle of the line joining the centre of rotation of the hip-joints. The chief movements in space of this centre—which we may fix by the movements in space of the hip-joint—are a movement forwards and a movement up and down.¹ Marey's chronophotographic figure (Fig. 158) shows that the hip and shoulder, and therefore the centre of gravity, as well as moving forwards, are displaced upwards and downwards several centimetres during each stride. The moment at which the leg

¹ During walking the mean position of the centre is nearer the ground than it is in the erect position. It is still lower during the act of running.

on the left-hand side of the figure leaves the ground, the push of the leg would be in the direction of the arrow *ca* (Fig. 160). If the line *ca* represents the push of the leg in amount and direction, and the line *cb* the force of gravity, by completing the parallelogram we obtain the actual displacement of the centre *cd*, which would take place under the influence of these two forces. The push of the leg under discussion and gravity combined would cause the body to be projected forwards and downwards, but for the fact that at this very time the other leg touches the ground in the extended position, and prevents this downward displacement of the body. The momentum of the body, therefore, carries it forward, and it swings forward on the second leg, which is like the travelling radius describing the arc of a circle. Thus the centre of gravity is raised upon the extended leg, and then falls, until raised again, when the first foot next reaches the ground.

The resistance of the air is not a very considerable force, but its rate of increase is in proportion to the square of the rate of progression.

FIG. 161.—To illustrate the surface of body exposed to the resistance of air (*a*) in bicycling, (*b*) in running, (*c*) in walking. The centroid is indicated by a white spot.

This resistance is met by the changes in the posture of the body which invariably accompany progression. During the act of rapid walking or running the body is bent forward, so that a diminished surface is presented in the direction of movement. In bicycling, the racer also bends down upon his handles, presenting a diminished surface in the direction of resistance. Fig. 161 is constructed from three photographs taken at equal distances from the same individual bicycling (*a*), running (*b*), and walking (*c*), the areas being respectively 100, 73, and 72.¹

Not only does the act of bending forward diminish the surface

¹ The areas were calculated by projecting the photographs upon pieces of cardboard, outlining the figures, cutting them out and weighing them. The centre of the surface (centroid) was found in the usual way, by suspending each of them from two different points and finding the point of intersection of the plumb-lines of these points.

exposed to the resistance of the air, but it is a necessary action, which must occur if equilibrium is to be established without the aid of excessive muscular exertion. This will be readily understood on reference to Fig. 162.

In the erect position the centre of gravity of the body is approximately above the centre of rotation of the hip, and it is steadied upon the hip by the aid of muscular effort. Were the body to progress forwards in the erect position, and encounter the resistance of the air, it would be toppled backwards, unless for muscular adjustments. In point of fact, we instinctively lean forwards, so that the centre of gravity is well in front of the hip-joint, as in B (Fig. 162). If, as in the figure, we consider the centre of the vertical surface exposed to the resistance of the air (the centroid) as corresponding with the centre of gravity, we may consider the line bc as representing in force and direction the resistance of the wind. Its moments around h , the centre of rotation of the hip, will be bc multiplied by the shortest distance between h and the direction of bc , namely, hb . Now the centre of gravity must, in order that equilibrium

FIG. 162.—In A, the erect position, the centre of gravity (c) plumbs above hip h . B represents the body of a man running, the resistance of the wind is represented by the line bc , and (c) the centre of gravity plumbs in front of the hip-joint (h).

be established, move forwards, until its moments are equal, until the force of gravity multiplied by hc' is equal to the resistance of the air multiplied by hb . In more rapid progression, resistance of the air increases as the square, and, in consequence, the movement forward of the centre of gravity must be much greater.

The reaction of the ground upon which progression is made is the last of the external forces acting upon the body which we need discuss. Were the ground perfectly smooth, a condition which is not reached by the smoothest ice, we should be unable to progress, for a perfectly smooth surface has a reaction in the vertical direction only, and the feet would at once slip backwards. On smooth ice progression is difficult, because of the large amount of slipping which takes place, but on an ordinary floor there is sufficient roughness to give a grip to the foot.

When the foot is about to leave the ground, pushing the body forwards, the thrust or reaction of the ground will be in the direction of the arrow (Fig. 163, ab). If ab represents this reaction in force and direction, we may resolve it by the parallelogram of forces into a vertical force (ac) and a horizontal force (ad). The vertical force is that which

FIG. 163.—The thrust of the ground represented by the arrow ab may be resolved into a vertical component ac and a horizontal component ad . This latter is the force which will prevent the leg from slipping backwards.

balances the vertical weight of the body through the leg, and the horizontal force (*ad*) balances the backward slipping of the foot which would otherwise occur.

The forces which we have now considered may be termed external; and in contradistinction to these are the internal forces of the body, the friction occurring at the joints, the tension of ligaments, tendons, and over-stretched muscles; and, over and above all these, the force of muscular contraction. In all forms of progression muscular contraction is that which opposes the external forces which act upon the body.

THE MUSCULAR AND NERVOUS MECHANISM OF THE RESPIRATORY MOVEMENTS.

By E. H. STARLING.

THE MECHANICAL CONDITIONS OF RESPIRATION.

SINCE the lungs are contained in a closed cavity, their outer surface being in direct contact with the inner wall of the thorax, it is evident that any changes in the capacity of the thorax must lead to corresponding changes in the volume of the lung. In inspiration, the cavity of the thorax is enlarged in all directions, in consequence of the action of certain muscles. The lungs must therefore expand to take up the increased space in the thorax, and air is drawn into them. The existence of the pleural cavity insures the uniform expansion of the lung, even although some parts of the thoracic wall move more freely than others. The inspiratory enlargement of the lungs not only acts against gravity in raising the ribs, but also stores up potential energy in consequence of a stretching of the rib cartilages and of the elastic lungs. As soon, therefore, as the muscles relax, these forces—gravity and elastic reaction of thoracic wall and pulmonary tissue—come into play, bringing the thorax back to its original size, and thus causing an expulsion of air from the lungs—an expiration. On the other hand, the cavity of the thorax can be diminished below that corresponding to its position of rest by contraction of certain expiratory muscles. In this case, relaxation of the muscles would be followed by a return to the normal size of the thorax, and therefore by an inspiration. It is evident, therefore, that respiration might be carried out in one of two ways—by an active inspiratory effort, followed by a passive respiration due to elastic reaction; or an active expiratory effort, followed by an elastic inspiratory reaction. We find that in all mammalia the former mode of breathing is the normal one, inspiration being due to the contraction of muscles, whereas expiration is largely passive.

In order that the lungs may follow accurately the changes in capacity of the bony cage in which they are enclosed, it is necessary that they should be highly elastic organs; and we know that the greater part of their framework is made up of a meshwork of elastic fibres. In consequence of this elasticity, the distension of the lungs will require the expenditure of a certain amount of energy, which, as soon as the distending force is removed, will become active and cause collapse of the lungs. In the new-born child, before it has breathed, the lungs are collapsed and airless, and their tendency to contract further is nil. As soon as the first breath has been taken, the cavity of the thorax becomes permanently larger than the volume of the contracted lung, so that, during the whole of life, the lung is in a condition of distension, its collapse being prevented by the resistance of the thoracic wall. This tendency of the lungs to collapse can be shown by piercing the thoracic wall of an animal. As soon as this occurs, the pressures on the outer and inner walls of the lung vesicles become identical; the lung collapses, and air rushes in through the hole in the pleura to take the place formerly occupied by the distended lung.

When this experiment is performed on the dead body, the expulsion of air from the lungs is never complete, owing to the fact that the smaller bronchioles collapse and prevent the total emptying of the alveoli by the elastic contraction of the alveolar wall. The elastic reaction of the wall is however not complete until the alveoli are empty. This only happens when in the living animal the inspiratory force or pull of the thoracic wall is prevented from acting on a portion of the lung, in consequence of the accumulation of fluid in the pleural cavity or obstruction of a bronchus; in this event the part of the lung that is thrown out of action becomes airless. The air that could not be forced through the bronchioles has been absorbed by the blood circulating through the pulmonary capillaries.

Since the lungs are in a continual state of tension, they must exert a pull on the thoracic wall and also on all the other structures contained in the thoracic cavity. Hence there is a negative pressure in the pleural cavity. This negative pressure is increased when the volume of the lungs is enlarged, as in a condition of inspiration, and diminished during expiration, but with normal lungs it could only be abolished by a shrinking of the thoracic walls until they enclose a cavity no larger than the atelectatic lung. This negative pressure naturally affects all the other organs enclosed in the thoracic cavity, and therefore exercises an important influence on the flow of blood into and from the heart, as well as on the lymph flow (cf. vol. i. p. 300).

Inspiration.—The inspiratory increase in the thoracic cavity which takes place in all three diameters, is effected by two processes,—the elevation of the ribs and the descent of the diaphragm. The articulation of the ribs to the spinal column behind and to the sternum in front allows of a double movement of these bones. Thus, when they are raised, they revolve about an axis passing through the heads of two corresponding ribs, so that the front part of the rib is raised, the angle between rib and costal cartilage straightened out, and the sternum pushed forwards and upwards. At the same time, a slight rotation of the rib occurs, and its outer surface, which in a condition of rest was directed somewhat downwards, is thus caused to look outwards. Moreover, since the transverse diameter of the thorax increases from

the first to the ninth ribs, an elevation of the ribs, by bringing, say, the ninth rib into the position previously occupied by the eighth rib, must cause an increase in the transverse diameter of the thorax at this point. This increase in transverse diameter would be attended by a corresponding shortening of the vertical diameter of the thorax, but this shortening is more than counteracted by the fixation of the lower ribs and the descent of the diaphragm. In the relaxed condition, the diaphragm, in consequence of the pressure of the abdominal viscera and elastic reaction of the abdominal muscles, is pressed upwards into the thorax, presenting a convex surface to this cavity. Moreover, the circumferential parts of the diaphragm come into close apposition with the lower portion of the thoracic wall, the two layers of parietal pleura being in contact. When the muscular fibres of the diaphragm contract, two events occur, first, a lowering of the diaphragm; and,

second, a flattening of its circumference, which is thus drawn away from the chest wall, the space left being filled by the descent of the lung. Of these two results of the diaphragmatic contraction, the second is by far the most important in ordinary respiration. It may be shown that, under these conditions, the central tendon of the diaphragm is practically motionless. As soon, however, as the respiration becomes laboured, there is an actual movement downwards of the central tendon.

FIG. 164.—Diagrammatic representation of position of diaphragm during expiration (I), normal inspiration (II), and forced inspiration (III).

It will be seen that the projecting end of the sound only moves with respiration when the animal is rendered dyspnoic in any manner. The difference in the changes between the shape in the diaphragmatic floor of the thorax in normal and laboured respiration is shown diagrammatically in Fig. 164.

In consequence of the attachments of the diaphragm to the six lower ribs, contraction of the diaphragm will tend to pull the ends of the upper three of these downwards and inwards, of the lower three upwards and inwards. Under normal circumstances, this tendency is counteracted by the simultaneous expansion of the rib-cage effected by the inspiratory muscles, and the fixation of the lower ribs by the serratus posticus inferior, quadratus lumborum, and the lower portions of the sacro-lumbalis. In cases of paralysis of the muscles which receive their innervation from the cord below the origin of the phrenic nerves, and much more frequently in children where the ribs are wanting in rigidity, the contraction of the diaphragm may cause a well-marked depression, running downwards and outwards on each side in front of the chest, corre-

sponding to the costal origins of this muscle. This groove is frequently seen in rickety children, where the softness of the bones has been combined with respiratory troubles.

The contraction of the diaphragm may also cause a widening of the lower part of the thorax, since in its descent it presses upon the abdominal viscera, so distending the abdomen and pushing out the lower ribs.

The elevation of the ribs in respiration is carried out by means of the contraction of a number of muscles, of which the external intercostals are usually regarded as the most important. Other muscles involved in the act are the scalenus anticus, the serratus posticus superior, and the levatores costarum. Whereas these muscles raise the upper ribs towards the spinal column and fix it in this elevated position, the external intercostals raise all the ribs with the exception of the first, each intercostal acting from its attachment to the rib above as a fixed point.

The functions of the external and internal intercostal muscles have been the subject of considerable discussion ever since Hamberger¹ put forward his views concerning these muscles, and the question cannot even yet be regarded as finally decided.

In discussing the action of the intercostal muscles, we must distinguish three portions—

1. The external intercostal muscles, which run from one rib to the next rib below in an oblique direction, forwards and downwards. They extend from the levatores costarum behind to the rib cartilages in front.

2. The internal intercostal muscles, which extend from the angles of the ribs behind to the rib cartilages in front. The fibres are directed downwards and backwards, and are somewhat shorter and less oblique than those of the external intercostals.

3. The muscoli intercartilaginei, which are generally regarded by anatomists as part of the internal intercostals, their fibres being directed, like those of the latter, downwards and outwards.

With regard to the actions of the external muscles, most physiologists² have accepted the view put forward by Hamberger, that they are inspiratory in function, and that their action is to raise the ribs. Hamberger founded his theory on the following geometrical considerations. If in the Fig. 165 ac and bd represent two ribs, which can rotate in a vertical direction about two points a and b , and cd represent the sternum, then $abcd$ represents a parallelogram, of which only one side ab is fixed. The line ef corresponds in direction to a fibre of the external intercostal muscles. The force with which this fibre tends to move the two ribs may be represented by the lines he and gf . Of these he represents the force acting at the point e , and tending to depress the rib ac , while fg represents the force acting at f , and tending to raise the rib bd . Since the component acting in an upward

FIG. 165.

¹ "De Respirationis mechanismo" (quoted from Rosenthal, Hermann's "Handbuch," Bd. iv. S. 189).

² Hutchinson, Todd's "Cyclopædia," London, 1852, vol. iv. p. 1043; Volkmann, *Ztschr. f. Anat. u. Entwicklgs.*, Leipzig, Bd. ii. S. 159 (quoted from Rosenthal); Newell Martin, *Journ. Physiol.*, Cambridge and London, 1879, vol. ii. p. 24.

direction works on a longer lever arm than the force tending to depress the rib, the total result of the contraction of the muscle must be to raise the lower rib and with it the upper rib.

Hamberger showed, moreover, that an elevation of the ribs must be associated with a widening of the thorax. Thus, in Fig. 166, it is evident that the distance from *b* to the vertical line *gf* is greater than the distance from the point *b* to the vertical line *cd*, i.e., that in the inspiratory condition, the distance between sternum and spine, that is to say, the antero-posterior diameter of the thorax, is increased. Again, since *bh* is smaller than *ba*, the elevation of the ribs is attended with a widening of the intercostal spaces. It is also obvious that *al* is shorter than *ak*; in other words, the contracted condition of the muscular fibres corresponds with a raised condition of the ribs.

FIG. 166.

Analogous reasoning applied to the internal intercostal muscles shows that these, so far as they lie between the bony ribs, must be expiratory in function and tend to depress the ribs. The intercartilaginous portions, on the other hand, although they continue the general direction of the internal intercostal muscles, yet bear a different relation to their attachments, i.e. the cartilages, since these are directed upwards and inwards. As will be seen from Fig. 167, the action of these fibres on the rib cartilages appears to resemble the action of the external intercostals on the bony ribs, namely, to raise the cartilages and to flatten out the angle between them and the bony ribs. They must, therefore, it is argued, be inspiratory in function.

The views of Hamberger as to the action of the external intercostal muscles have been confirmed by physiological experiment. Newell Martin and Hartwell¹ recorded the contraction of a segment of the internal intercostal muscles after they had been separated from the rest of the body by dividing the ribs and intercostal spaces on each side of the muscle, leaving only the intercostal artery and the nerve supply to the internal intercostal intact. They found that these muscles acted alternately with the diaphragm, and were therefore expiratory. On the other hand, the segment of the muscles between the costal cartilages acted synchronously with the rest of the internal intercostals, and were therefore also expiratory. Since this result with regard to the intercartilaginous muscles is difficult to understand from a mechanical point of view, it has been put to the test of a further experimental investigation by Masoin

FIG. 167.—*ac, he*, two ribs with their cartilages *cd, ef*. *kl*, a fibre of the external intercostal. *hg*, a fibre of the intercartilaginous muscles. The tendency of these two muscles acting together to depress the angle *c*, is counteracted by the next set of muscles *k'l'*, *h'g'*, which act at a greater mechanical advantage, and so tend to raise the point *c*.

¹ *Journ. Physiol.*, Cambridge and London, 1879, vol. ii. p. 24.

and R. du Bois-Reymond,¹ who, while accepting Martin and Hartwell's view with regard to the intercostals between the bones, show conclusively that the intercartilaginous muscles contract synchronously with the diaphragm, and are therefore, as Hamberger thought, inspiratory. The method they employed was practically identical with that devised by Martin. In normal respiration, the contraction of these muscles was not noticeable; it only became evident in laboured respiration.² After apnoea has been produced, the intercartilaginous muscles begin to contract later than the diaphragm. Division of the phrenic nerve has no influence on their contractions.

Expiration.—The diminution of the thoracic cavity which gives rise to expiration is under normal conditions not associated with the active contraction of any muscles. As the inspiratory muscles relax, the lung, in virtue of its elasticity, tends to contract and drag the chest wall with it. Moreover, the ribs which have been raised against gravity and the elastic resistance of the rib cartilages, return to their previous condition, while the slack diaphragm is pushed up into the chest by the retraction of the abdominal walls pressing upon the abdominal viscera.

Laboured respiration.—In forced inspiration, such as occurs when there is any obstruction to the entrance of air into the lungs, or if the aeration of the blood be prevented in any way, in addition to a more powerful action of the muscles already mentioned, the aid of other muscles is called in. In order to secure an inspiratory action of these accessory muscles, a fixed attachment must be provided by the elevation and support of the head, shoulder, and arm. The chief of these accessory muscles are the sterno-mastoid, the pectoralis minor, the lower part of the pectoralis major, and the lower slips of the serratus magnus.

The chief muscles concerned in forced expiration are those forming the abdominal wall. These press on the contents of the abdomen and pull down the sternum and ribs, thus diminishing the cavity of the thorax in all directions. They are assisted in the depression of the lower ribs by the serratus posticus inferior and portions of the sacro-lumbalis. In the strong expiratory convulsions of asphyxia, an enormous number of muscles come into play, and every muscle which can depress the ribs or press on the abdominal viscera, or afford a fixed point for muscles having these actions, is forcibly contracted.

Accessory respiratory movements.—Besides the movements of the thorax which bring about changes in the capacity of this cavity, and so serve to draw air into, or expel air from, the lungs, certain other movements are connected with the respiratory act, known as accessory or concomitant respiratory movements. These have no influence on the size of the thoracic cavity, but serve simply to facilitate the entrance and exit of air to and from the lungs. Many of them are wanting in normal respiration, and are only seen when the breathing becomes laboured from any cause.

1. *Movements of the larynx.*—Even in quiet respiration there is a movement of the larynx up and down, the upward movement corresponding to expiration. The depression of the larynx during inspiration is due partly to contraction of the sterno-hyoid and sterno-thyroid muscles,

¹ *Arch. f. Physiol.*, Leipzig, 1896, S. 85.

² Weidenfeld, *Sitzungsb. d. k. Akad. d. Wissensch.*, Wien, 1894 (3), Bd. ciii., had personally come to the conclusion, from his experiments, that the intercostals take no part in the respiratory movements.

partly to the drawing down of the lungs and trachea, in consequence of the deepening of the thoracic cavity. The elevation during expiration is due chiefly to the recovery of the lungs, partly to the contraction of the thyro-hyoid muscles.

2. *Movements of the vocal cords.*—During quiet breathing the rima glottidis is moderately open, and shows but slight movements. If, however, deep inspirations be made, the glottis is widely dilated with each inspiration, by means of contraction of the posterior crico-arytenoid muscles. Even in quiet breathing, however, the muscles of the larynx must be in a certain state of activity, since in total paralysis of all the muscles the position of the glottis differs from that in the normal individual. In the former case the vocal cords are placed rather obliquely, so that their upper surface looks outwards and their lower inwards. The effect of paralysis is to make the rima into a valve-shaped opening, which may close by the apposition of the two cords if any sudden inspiratory effort be made. There will, however, be no impediment to expiration.

3. *Movements of alæ nasi.*—During each inspiration the nostril is dilated by the action of the dilatator naris, contracting again during expiration. This contraction is chiefly due to the elastic reaction of the nasal cartilages, but may be assisted by the action of the compressor naris (*m. nasalis*). The movements of the alæ nasi are more evident in children than in adults, and become especially well marked in the former when there is any obstruction to the entry of air into the lungs.

Other accessory muscles of respiration are those which fix the head, shoulder, spinal column, etc., and which only come into play during laboured respiration.

Different types of respiratory movements.—The amount to which each diameter of the thorax is altered with respiration differs, not only according to the depth of the respiratory movements, but also with the sex.¹

Thus in man, ordinary quiet respiration is effected almost entirely by contraction of the diaphragm, so that the chief external sign is a pushing out of the abdominal wall and the lower ribs. In woman, on the other hand, inspiration is mainly carried out by means of the thorax, so that the abdomen recedes with inspiration.² In laboured respiration these differences almost disappear, the breathing being mainly thoracic in both cases, and the abdomen recedes with each inspiration. Mosso³ has shown that during sleep the respiration in the male sex is also chiefly thoracic.

Movements of the lungs.—Since the lungs in inspiration expand all over, while the increase in the thoracic cavity is more marked in certain diameters (especially the vertical), it follows that there must be a movement of the lung with regard to the thoracic wall as it expands. This movement of the lungs occurs in two directions from two fixed points, being in the vertical direction from the apex towards the base of the chest, and from the attachment of the lungs to the bronchi towards the front and sides of the chest, and is rendered possible, as already mentioned, by the existence of the pleural cavity.

¹ Cf. Hutchinson, *loc. cit.*

² It is stated that the difference is mainly produced by the habit of wearing stays, and that in women who have never adopted this habit, the ordinary respiration is abdominal (Wilberforce Smith, *Brit. Med. Journ.*, London, 1890, vol. ii. p. 843).

³ *Arch. f. Physiol.*, Leipzig, 1878, S. 441.

Hence, as the chest expands from the expiratory to the inspiratory position, the lower border of the lungs moves from the level of the sixth or seventh rib to that of the eleventh. There is, moreover, a movement of the anterior margins of the lungs forward, consequent on the lateral expansion of these organs. On this account the area of cardiac dulness is markedly decreased, or even abolished, during a deep inspiration.

On applying the ear to the chest of a healthy individual, a delicate rustling sound is heard with each inspiration. This sound is known as the "vesicular murmur," and is supposed to be due to the entry of air into the alveoli. Expiration is either noiseless or is accompanied by a much fainter murmur of the same character, which only lasts during the first third of the expiration. If we auscultate over the trachea or bronchi, a sound is heard which is quite distinct in character from the vesicular murmur, and is known as "bronchial breathing." It is a loud blowing murmur, resembling the sound produced by approximating the root of the tongue to the soft palate and expiring, as in pronouncing the Greek letter χ . It differs from the vesicular murmur, moreover, in that the expiratory part is as loud as or louder than the inspiratory. It is probably generated in the larynx, since complete division of the trachea below the glottis abolishes the sound.

Respiratory rhythm.—In normal conditions each inspiration is followed immediately by an expiration, which is succeeded by a slight pause before the next inspiratory movement takes place. The inspiration is generally shorter than the expiration, the time occupied by the two phases being in the proportion 10 to 12. The pause between two respirations lasts about one-third to one-fifth of the total time between the beginning of one inspiration and the next.

Both the frequency of respiration and the amount of air respired vary within wide limits in different individuals, and under various conditions; these are fully discussed in the article on the "Chemistry of Respiration" in Vol. I.

Pressure in the lungs and pleural cavities.—We have already seen that, even in conditions of expiration, the lungs are still in a stretched condition, and therefore exert a pull on the thoracic walls, until they are allowed to collapse by puncture of the wall. The amount of this elastic force has been measured by connecting a mercurial manometer with the trachea in the dead body, and then puncturing the thorax. Measured in this way it amounts to between 2 and 5 mm. Hg. According to Donders,¹ however, this is less than the actual pressure in the living body, owing to a loss of elasticity by the lungs. Donders calculated the elastic pull of the lungs in the expiratory condition as about 7.5 mm. Hg. After an ordinary inspiration this is increased to 9 mm., and after the deepest possible inspiration to about 30 mm. It is evident that these figures also represent the negative pressure in the thoracic cavity under the same conditions.

During ordinary respiratory movements there are slight changes of pressure in the alveoli and tracheal air. In inspiration the pressure in the trachea is from -2 to -3 mm. Hg, in expiration about $+2$ mm. Hg. By connecting the closed trachea or air passages with a manometer, we may measure the total possible force exerted by the respiratory muscles in drawing air in or expelling air from the lungs. These

¹ *Ztschr. f. rat. Med.*, 1853, N. F., Bd. iii. (quoted from Rosenthal, *loc. cit.*).

pressures amount to from -30 to -74 mm. Hg in inspiration, and to from about +62 to +100 mm. Hg in expiration (Donders).

Methods of registering the respiratory movements.—The methods of registration can be divided into four classes—

1. In the first class the expansion and contraction of the thorax are recorded. To this end Marey devised his *pneumograph*, which consists of a cylinder with elastic ends, the interior of which is connected with a recording tambour. A strap or cord attached to the membrane, closing the two ends of the cylinder, is passed round the chest. As the thorax expands, the membrane at each end of the cylinder is drawn out. The rarefaction of the air in the cylinder thus produced is transmitted to the tambour and causes a fall of the lever.

Burdon Sanderson's *stethometer* consists of a rigid rectangular framework, formed of two bars joined by a cross piece. The distance between the bars can be adjusted to fit the antero-posterior diameter of the subject under investigation. The free ends of the bars are provided, one with an ivory button which rests on the spine of a vertebra, the other with a tambour, the knob of which presses against the sternum. An increase in the antero-posterior diameter of the chest presses on the button of the tambour, and the movement thus produced is transmitted by a rubber tube to another recording tambour.

2. Another method is to record in animals the movements of the column of air which enters and leaves the lungs at each respiration. One method of doing this is to attach a T-piece to the tracheal cannula, one limb of the T being left open, while the other is attached to a large vessel of air, which is also connected with a Marey's tambour. When it is desired to record the movements the free end of the T-piece is clamped, so that the animal now breathes in and out of the receiver, and the consequent changes of pressure in this vessel are transmitted to the Marey's tambour and recorded. This method suffers from the drawback that the air in the receiver soon becomes vitiated, so that the breathing is altered, and it is necessary to interrupt the observation in order to renew the air.

Gad¹ has used a modification of this method in nearly all his researches. This observer's *pneumatograph*, which is substituted for the Marey's tambour employed in the method just described, is a light open box of mica, which is counterpoised so as to rest face downwards in a vessel of water. To the bottom of the box is attached a lever, the movements of which can be recorded on a blackened surface. The interior of the box is connected with a large air chamber into which the animal breathes. Each inspiration causes a sucking of air out of the box into the air chamber, so that the pneumatograph sinks in the water, whereas each expiration will increase the volume of air, and so cause a rise of the pneumatograph with its lever.

3. Since each respiratory movement causes a change in the intrathoracic pressure, it is evident that a record of these variations may be used as evidence of the respiratory movements. These variations may be studied by introducing a cannula connected with a manometer or tambour into the pleural cavity, or by introducing an elastic sound connected with a registering tambour through the mouth into the œsophagus. The latter method has been used especially by Rosenthal.²

4. Since the diaphragm is in the higher animals the most important inspiratory muscle, and in rabbits is practically the only active muscle in quiet respiration, it is obviously of advantage to record its movements directly. Many methods for recording the contractions of the diaphragm have been devised.

¹ *Arch. f. Physiol.*, Leipzig, 1879, S. 181.

² Hermann's "Handbuch," Bd. iv. Th. 2, S. 163-286.

In one method an elastic bag is inserted through an opening in the abdominal wall, between liver and diaphragm. The elastic bag is connected by a tube with a recording tambour. Each descent of the diaphragm in inspiration presses on the bag, and the increased pressure transmitted to the recording tambour can be recorded as a respiratory movement.

Kronecker's *phrenograph*¹ consists of a lever, one broad spoon-shaped end of which is inserted between the liver and diaphragm, while the other end is connected by threads running on pulleys to a writing lever. Rosenthal's *phrenograph* differs from the preceding in that the movement is transmitted by air to a tambour instead of by means of threads.

5. All these methods, however, suffer from the defect that, although they directly or indirectly give a fairly correct record of the movements of the respiratory apparatus, they are unable to discriminate between passive and active movements. Thus, if the lungs be artificially distended, there will be a descent of the diaphragm and a movement of the phrenograph lever, just as if the inspiration were brought about by an active contraction of the muscle. In dealing with the innervation of respiration, we shall see that it is very important to be able to study the effect of artificial inflation or collapse of the lungs on the activity of the respiratory muscles; and such information can be only very imperfectly afforded by any of the graphic methods already described. The method which best meets these difficulties is that

FIG. 168.—Normal tracing of diaphragm-slips of rabbit.—(Head's method.)

devised by Head.² This observer has shown that in the rabbit the anterior part of the diaphragm, which is connected to the ensiform cartilage, is so disposed that it may be isolated as two parallel slips from the rest of the muscle without injury to the blood- or nerve-supply. These slips may be clamped at the tendinous end, and the contractions recorded by a lever attached by a thread to the other end, which is cut free from the cartilage. It is then found that the slips contract synchronously with the rest of the diaphragm, and their contractions (Fig. 168) may be taken as a sample of the contraction of the whole diaphragm, while they are but little affected by any passive movements which may be imparted to the thoracic wall. The results arrived at by this method will be described later on.

THE NERVOUS MECHANISM OF RESPIRATION.

We have seen that each act of inspiration involves the contraction of a number of muscles, which are added to whenever the need for greater respiratory interchanges occurs. Expiration also, although normally effected by the passive retraction of the stretched lungs and costal wall, yet, with the smallest additional call on the respiratory apparatus, involves the co-ordinated actions of a number of other muscles. These co-ordinated rhythmical contractions must be initiated in the central nervous system, and we have in this section to discuss

¹ v. Marekwald, "The Movements of Respiration," translated by Haig, London, 1888, p. 9.

² *Journ. Physiol.*, Cambridge and London, 1889, vol. x. pp. 1 and 279.

the seat and mode of the activities of the central nervous system which determine the respiratory movements.

The respiratory muscles receive their nerve supply from various parts of the cerebro-spinal axis. Thus the muscles moving the *alæ nasi* are innervated from the seventh nerve; the muscles opening the glottis, from the accessory part of the vagus; the diaphragm, from the cervical cord by the fourth and fifth cervical nerves; and the intercostal muscles, from the whole of the dorsal cord. From what we know of the anatomy of the cord, we may affirm almost certainly that the motor fibres going to the inspiratory muscles are derived from cells in the grey matter of the anterior cornua of the cord, or from the corresponding part of the grey matter in the medulla oblongata. All these cells represent, therefore, centres for the innervation of the inspiratory muscles, and any contraction of these muscles can only be brought about during life through the intermediation of these cells. Under normal conditions, the motor cells of the cord are excited to activity by the impression on them of nervous impulses derived from sensory fibres which have entered the cord by the sensory roots, or from fibres originating in cells situated in the higher parts of the nervous system, *e.g.* pyramidal tract fibres.

The normal performance of the respiratory movements is dependent, then, upon a rhythmic and co-ordinate activity of a number of cells extended over a considerable length of the medulla oblongata and spinal cord. The question we have to discuss is the manner in which the activities of these cells are roused and co-ordinated. Are they so constituted that their normal metabolism leads to rhythmic automatic discharges, or is their activity excited by changes in the blood passing to them or by afferent impulses arriving from the periphery? Is the co-ordination of their activities dependent on intercentral communications between the motor cells at various levels of the cord, or are they harmonised in obedience to impulses proceeding to them from higher parts of the central nervous system? In the latter case, can we by experiment localise any part of the nervous system which carries out this function of origination and co-ordination, and so plays the part of a respiratory centre?

The first attempts to answer these questions by systematic experiments were made by Legallois.¹ His investigations were amplified and confirmed by Flourens.² These experiments were as follows:—If the spinal cord be divided on a level with the seventh cervical nerve, respiration continues, but is carried out solely by means of diaphragmatic contractions, the chest walls remaining motionless or being moved passively by the contractions of the diaphragm. If the spinal cord be divided at the third cervical nerve (*i.e.* above the origin of the phrenic nerves), the respiratory movements of the thorax either cease entirely, or are confined to spasmodic elevations of its upper part, induced by contractions of the sterno-mastoid and trapezius muscles. The animal therefore dies of asphyxia if artificial respiration be not resorted to. Respiratory movements, although not effectual in aerating the lungs, are still to be observed in the laryngeal muscles, and in the muscles of the face. These experiments seem to indicate that the spinal centres

¹ "Œuvres complètes," Paris, 1824, tome i.

² "Recherches expérimentales sur les propriétés et fonctions du système nerveux," 2me édition, Paris, 1842; *Compt. rend. Acad. d. sc.*, Paris, 1858, tome xlvii. p. 803.

of the respiratory nerves are unable, of their own initiative, to carry out rhythmic respiratory movements, but are subsidiary to the action of a co-ordinating centre situated somewhere above the lower end of the medulla oblongata.

If, on the other hand, a section be made through the upper part of the medulla oblongata, separating this and the spinal cord from the higher parts of the brain, respiration is absolutely unaffected. It is evident, therefore, that the respiratory centre, or the part of the central nervous system which originates and co-ordinates the respiratory movements, is situated in the medulla oblongata, somewhere between its lower part and the striæ acusticæ. A number of attempts have been made to localise the situation of the respiratory centre more exactly. From the time of Flourens it has been recognised to be bilateral, as is proved by the fact that bisection of the medulla oblongata by an antero-posterior incision in the middle line does not alter in any way the rhythm of respiration. According to Flourens¹ the respiratory centre is represented by a circumscribed spot just below the apex of the calamus scriptorius, of the size of a pin's head. This spot was designated by its discoverer the *nœud vital*, and according to him, its destruction causes total cessation on the side on which it was destroyed, or, if the lesion be bilateral, an instant and permanent cessation of the respiratory movements on both sides, and consequently the death of the animal.

In 1873, careful experiments were carried out by Gierke² in Heidenhain's laboratory, in order, if possible, to determine the cells or groups of cells contained in Flourens' centre. Gierke was unable to localise the respiratory centre in any special group of cells, and found that the grey matter lying in the situation of Flourens' centre might be destroyed to a considerable extent, without causing a cessation of the respiratory movements. The only part of the medulla oblongata which, according to him, seemed to be essential for the carrying out of these movements, was a longitudinal bundle of white fibres on each side of the median line. This bundle, which was termed the "respiratory bundle" by Krause, and is generally known as the *funiculus solitarius*, is situated

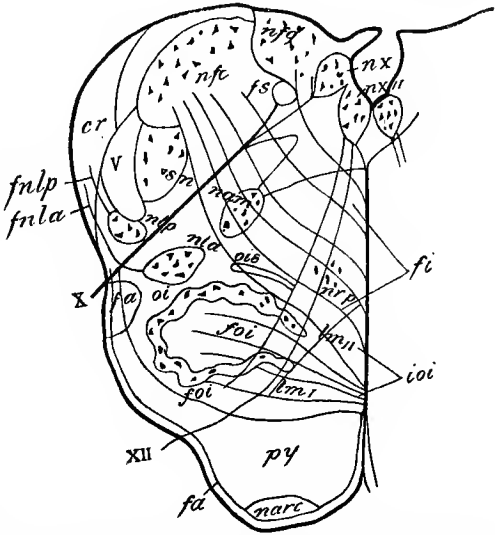

FIG. 169.—Diagrammatic section of medulla oblongata below middle of olivary body, to show region of respiratory centre. *na*, nucleus of tenth nerve; *X*, root of tenth nerve; *navi*, nucleus of twelfth nerve; *fs*, funiculus solitarius; *fa*, arcuate fibres; *nam*, nucleus ambiguus; *cr*, restiform body; *py*, pyramidal tract; *V*, ascending root of fifth nerve; *nlp*, nucleus lateralis; *nfc*, nucleus of funiculus cuneatus; *nfg*, nucleus of funiculus gracilis.—After Bechterew.

outside and below the nucleus of the pneumogastric and glosso-pharyngeal nerves. It is surrounded by gelatinous grey matter with many small nerve cells. "Its fibres appear to lose themselves among the cells of the enclosing grey matter, and this and the bundle gradually disappear when traced towards the spinal cord. Traced upwards, they pass out with the bundles of nerve-roots which go to form the vagus and glosso-pharyngeal."¹

Mislawsky,² who experimented on cats, concluded that the respiratory centre was to be found, not in Gierke's bundle, but in two cell groups lying in the *formatio reticularis* on each side of the median raphe internal to the roots of the hypoglossal nuclei. The latest attempts to localise the centre have been made by Gad and Marinesco.³ In order to destroy the medulla oblongata bit by bit, these observers used minute hot glass beads, the destructive action of which could be accurately localised. In this way they claim to have burnt away the whole of the medulla oblongata corresponding to the situations laid down by Flourens, Gierke, and Mislawsky for the respiratory centre, without altering the respiratory movements. They themselves locate the centre in the cells of the *formatio reticularis*, and consider that it occupies an extensive area in this formation on each side of the middle line; it certainly cannot be restricted to a part the size of a pin's head, as was supposed by Flourens.

Although the evidence in favour of the localisation of the respiratory centre in the medulla oblongata is apparently so convincing, certain observers have denied altogether the adequacy of the experiments adduced in its support. Thus Brown-Séguard,⁴ in 1860, showed that, if young animals were kept alive by artificial respiration for some time after the division of the cord below the medulla oblongata, on ceasing the artificial respiration co-ordinated movements of thorax and diaphragm might still for a time be observed. He considered therefore that the centre of respiration was not confined to a circumscribed area in the medulla oblongata, but extended throughout the spinal cord. The effects on respiration which follow section of the cord below the medulla oblongata, he ascribed to inhibition of these spinal centres consequent on the lesion acting as a stimulus, and compared the result to the phenomena accompanying shock. Twenty years later this idea was warmly taken up by Langendorff,⁵ who carried out a number of experiments similar to those of Brown-Séguard, in order to prove the independent automatism of the spinal centres. Wertheimer⁶ also pointed out that if an adult animal (dog) were kept alive by means of artificial respiration for some hours after section of the cervical cord, rhythmic respiratory movements of the thorax take place as soon as the artificial respiration is discontinued; he states that in one case a dog survived the cessation of artificial respiration about three-quarters of an hour, respiration all this time being carried out by the spinal centres. These experiments have been repeated by a number of other observers, who, while confirming to a certain extent the previous results, were unable to attribute to them the same importance. As I have already pointed out, the cells from

which the nerve fibres to the respiratory muscles arise can, like the motor cells of other parts of the cord, be affected by impulses reaching them along various paths. We may conclude that their normal activity in respiration is determined by impulses reaching them from the medulla oblongata. But they can also be affected along other tracts derived ultimately from the posterior roots, either at the same or at a higher or lower level of the cord. We know that the spinal cord, separated from the upper parts of the central nervous system, under the influence of asphyxia or strychnine, gives rise to spasmodic motor discharges, which have a tendency to take on a more or less rhythmic character. These rhythmic discharges affect the limbs as well as the muscles of the trunk, and it is evident that, if we were tracing the movements of the thorax or diaphragm, they might resemble the effect produced by normal respiratory movements. But, strictly speaking, we cannot locate respiratory centres in the cord, since this property of rhythmic discharge, in consequence of asphyxia or strychnine, is shared by all the motor cells or centres of the cord, and is not limited to those supplying the respiratory muscles. As a matter of fact the pseudo-respiratory movements observed under these conditions are extremely inadequate for the renewal of air in the lungs, and one often obtains simultaneous spasms of inspiratory and expiratory muscles. So long, therefore, as an animal is warm-blooded, they are of very little use for the maintenance of life. In Wertheimer's experiments, in consequence of the prolonged ventilation of the lungs, the animal had become practically cold-blooded, and under these circumstances it is not wonderful that it should have survived cessation of artificial respiration for forty-five minutes. In an anæsthetized and curarised animal, after a long experiment in which the animal has had time to get cold, the heart may go on beating for half an hour or more after artificial respiration has been discontinued.

Moreover, Porter¹ has shown that such a lesion as dividing the medulla oblongata below the respiratory centre does not produce an appreciable amount of shock, *i.e.*, does not affect injuriously the subordinated activities of these spinal respiratory centres. Thus, if the bulb be hemisected below the respiratory centre, the respiratory movements of the diaphragm at once cease on that side. This result, according to Brown-Séquard or Langendorff, would be due to shock or inhibition of the diaphragm centre in the cord. If now the phrenic nerve be divided on the other side, the diaphragm on the side of the hemisection at once commences to contract, the impulses coming from the other side of the medulla oblongata having crossed from one side of the spinal cord to the other by means of commissural fibres situated at the level of origin of the phrenic nerves. This immediate result shows that the diaphragmatic centre in the cord was previously inactive, not in consequence of inhibition due to the hemisection, but because the impulses from the respiratory centre in the medulla oblongata on the same side had been cut off by the hemisection.

We may conclude, therefore, that for the normal performance and co-ordination of the respiratory movements, the integrity of certain parts of the medulla oblongata situated on each side of the median line is necessary, and we are therefore justified in giving to these parts the name of respiratory centre.

¹ *Journ. Physiol.*, Cambridge and London, 1895, vol. xvii. p. 455.

Since each inspiration is followed by an expiration, which, though passive during quiet breathing, may and frequently does involve the co-ordinated activity of a number of muscles, we might, from a purely physiological point of view, divide the respiratory centre into two parts, one always active and presiding over inspiration, the other only active when a special call is made on the respiratory mechanism and presiding over expiration. Nevertheless we have no experimental evidence of any anatomical separation between these two centres. Localised stimulation applied to the medulla oblongata may call forth inspiration or expiration according to the condition of the centre and the phase of respiration at which the stimulus is applied; inspiration, however, predominates in most cases over expiration. No point of the respiratory centre has been found as to which we can say with certainty that we shall obtain only expiration or only inspiration as the result of the stimulus. We do not know, therefore, whether some groups of cells originate or transmit inspiratory and others expiratory impulses, or whether both sets of muscles are innervated from the same cell-groups.

We have now to inquire into the nature of the activity by virtue of which this centre is able to excite rhythmic co-ordinated movements of the respiratory muscles. This inquiry involves two distinct questions—

1. How is the activity of the centre aroused? Is it aroused by stimuli arriving at the centre from the periphery along afferent nerves, or by changes occurring in the cells of the centre itself, the results of their normal metabolism, or by changes in the fluids—lymph and blood—surrounding the cells?

2. What is the cause of the natural rhythm of this activity?

In deciding the first point, *i.e.* whether the activity is automatic or reflex, we must attempt to study the behaviour of the centre when separated as much as possible from the influence of all afferent impulses. Rach,¹ who was the first to make this attempt, came to the conclusion that the respiratory centre separated from all afferent impulses was unable to originate any movements. His experiment consisted in dividing the cord below the fifth cervical nerve, and the medulla oblongata above the striæ acusticæ, and then cutting both vagi and all the posterior roots of the upper cervical nerves. Subsequent repetition of Rach's experiment by Rosenthal and Marckwald² failed to confirm these results. We may consider here shortly the effects on the respiratory movements of the various operative procedures employed in this experiment.

Section of the lower part of the cervical cord in the rabbit leaves the diaphragmatic movements practically unaltered, since in this animal the chief part of inspiration is carried out by the diaphragm. The section through the upper part of the medulla oblongata, separating the respiratory centre from the higher parts of the brain, is equally without effect on the depth and rhythm of the respiratory movements. A great change is observed, however, if the vagi are subsequently divided under these conditions. The first effect is a long inspiratory spasm of the diaphragm, which may last as long as a minute. Its relaxation then follows, to be succeeded again by another inspiratory spasm many times exceeding in duration the ordinary respiratory contraction of the

¹ "Inaug. Diss.," Königsberg, 1863.

² "The Movements of Respiration," translated by Haig, London, 1888.

diaphragm. The animal thus continues to breathe by a series of prolonged inspiratory spasms. The centre continues to discharge rhythmically, but its activity is not adequate to the normal aeration of the blood, and the spasms get gradually slower and slower, until the animal finally dies of asphyxia. According to Rosenthal, these imperfect respiratory movements are not altered further by dividing all the posterior roots of the upper cervical nerves, and he concludes, therefore, that the isolated respiratory centre is capable of an automatic rhythmic activity apart from the influence of afferent impulses.

It must be remembered, in attempting to draw conclusions from this experiment, that it is necessarily an imperfect one, since afferent impulses must be ascending to the centre in consequence of stimulation of the cut ends of the nerves as they lie in the wound, and the animal cannot be kept alive sufficiently long for the irritating effects of the section to pass off. These impulses are constant and not rhythmic in character, so that the only certain conclusion to be drawn from the experiment is that the centre is able to convert constant into rhythmic discharges. We do not know certainly whether the centre separated from all afferent impulses would discharge at all. H. E. Hering,¹ who has investigated the activity of the spinal cord in the frog after division of all the posterior roots, has concluded that in this case the motor centres are unable to discharge, even under the influence of strychnine, when removed from all peripheral stimuli, and it is possible that, were we able to perform a similar experiment on the respiratory centre of mammals, we should meet with like results.

If we conclude with Rosenthal that the activity of the centre is automatic, we must seek to find out what are, apart from afferent impulses, the local changes in or around the nerve cells by which this activity is evoked. Among the environments of the cell the most important factor in evoking this activity is the condition of the blood circulating through the blood vessels of the part. It has long been known that the activity of the centre is intimately dependent on the condition of the blood, and is especially excited by increased venosity of the blood and allayed by improved arterialisation. Every hindrance to the free renewal of the blood-gases in the lungs calls forth increased respiratory movements, which, if the obstacle be not removed, may involve almost every muscle in the body; this condition is known as *dyspnœa*. On the other hand, free renewal of the gases in the blood leads to a condition in which the respiratory movements are rendered shallower or even abolished. This condition, which is known as *apnœa*, is, as we shall see later, most readily produced by reflexes from the lungs, but may also, in the absence of these impulses, be brought about by free aeration of the blood (see p. 301).

Ever since *dyspnœa* has been the subject of scientific investigation, the question has been much discussed whether the excitant is to be sought in the increased amount of carbon dioxide, or in the diminished quantity of oxygen in the blood. Opinions at first were divided on this point; J. Müller² and, in his earlier work, Rosenthal,³ considering the deficiency of oxygen as the stimulus, while Traube⁴ and Thiry⁵ ascribed

¹ *Arch. f. d. ges. Physiol.*, Bonn, 1893, Bd. liv. S. 614.

the activity of the centre to the larger quantity of carbon dioxide. It was later on shown by Pfüger and Dohmen¹ that either of these two moments—increased carbon dioxide or diminished oxygen—might serve as a respiratory stimulus. These authors controlled their results by analyses of the blood.

Where dyspnoea followed inhalation of hydrogen or nitrogen, they found that the blood only differed from normal blood in containing less oxygen. On the other hand, when the animals were made to breathe mixtures of carbon dioxide and oxygen, the blood contained a normal amount of oxygen, but an excess of carbon dioxide. In both these cases dyspnoea was produced, although in the one instance deficiency of oxygen, and in the other excess of carbon dioxide, were the only deviations from the normal. It is in the first stages alone that the results of these two experiments are similar. If the inhalation of the abnormal gaseous mixtures be continued, it is found that deprivation of oxygen leads to ever-increasing dyspnoea, and finally general convulsions, the animal dying of asphyxia. When, on the other hand, the animal breathes a mixture of carbon dioxide and oxygen, the respiration, which is deepened and slightly quickened at first, undergoes very little further alteration. The animal can continue to breathe the mixture for a considerable time without apparent ill effects; then respirations gradually become slower, the animal passes into a deep sleep, and finally dies without convulsions, as under the influence of a narcotic poison.

Bernstein² attempted to show that carbon dioxide dyspnoea differed from that produced by absence of oxygen, in the fact that carbon dioxide chiefly augmented expiration, while absence of oxygen increased inspiration. More careful experiments by Gad³ have proved that this is not the case, but that in each instance the dyspnoea is mainly inspiratory.

Some physiologists have found a difficulty in conceiving how the *absence* of a substance (oxygen) could act as a stimulus. It has therefore been suggested that the exciting agent was probably represented by such "reducing substances" as have been described by Schmidt⁴ and Pfüger⁵ as occurring in the blood of asphyxiated animals.

According to the theory of Pfüger, metabolic changes are constantly occurring in living cells, including nerve cells, leading to the formation of molecules, or groups of molecules, with a high affinity for oxygen. It is these intracellular reducing substances which combine in the first instance with the oxygen leaving the vessels, or are able to tear away the oxygen from such substances as methylene blue, as in Ehrlich's experiments.⁶ It is possible that these bodies, when they meet with insufficient oxygen for their saturation, act as excitants on the nerve cells; so that the normal activity of these cells is maintained by a condition of auto-stimulation, the stimulus being supplied by their own products of metabolism. On the other hand, when oxygen is supplied in excess, the affinities of the reducing substances are satisfied. No

excitation, therefore, takes place, and a condition of apnœa (*apnœa vera*) is produced.

Whatever explanation we choose to adopt of the exact mode in which the excitation is brought about, there can be no doubt that the absence of oxygen, or rather the need of the centre for oxygen, is a very considerable factor in determining its activity. We have hitherto only considered the cases in which this need was increased or diminished by altering the amount of oxygen supplied to the centre. But we may also alter it by increasing or diminishing the metabolic activity of the centre itself, by heating or cooling the medulla oblongata. Thus Fick¹ and Goldstein² surrounded the exposed carotid arteries of a dog with a vessel with hollow walls, between which hot or cold water could be passed, so changing the temperature of the blood flowing to the medulla oblongata. They found that in each case the respiratory rhythm underwent marked alterations. If the blood is warmed above its normal temperature, so increasing the rapidity of the metabolic changes in the centre, the respirations become much quicker and shallower (*tachypnœa*, Gad); whereas, when the metabolic changes are depressed by lowering the temperature of the blood, the movements become much slower. The latter result may also be produced, as Fredericq³ pointed out, by direct application of pieces of ice to the exposed medulla oblongata,—a further proof of the fact that the respiratory impulses are originated there, and not in the cord, since we cannot imagine that the application of cold should act as an *excitant* of inhibitory impulses.

There are thus two kinds of stimuli which may act on the respiratory centre in the medulla oblongata, and provoke its activity. The stimulus derived from the blood is, under normal conditions of respiration, constant. The stimulus derived from the afferent nerves is subject to rhythmical variation, and, as we shall see later, this variation is of considerable importance for the maintenance of the normal respiratory rhythm. The centre can, however, go on discharging rhythmically in the absence of any rhythmic afferent stimulation. We have therefore to discuss how the centre is able to respond to a constant stimulus with a rhythmic discharge.

The simplest explanation of this process, if explanation it can be called, is to say that it is a property of the nerve cells as of the muscle cells of the heart to respond to a constant stimulus by a series of rhythmic discharges. Many physiologists, especially Pflüger, have attempted to form a conception of the intra-molecular processes which lead to this transformation. Pflüger⁴ considers that the molecular processes in a living cell may be divided into two sets—those which tend to produce a discharge of energy, and those which tend to prevent a discharge. In more modern terms, we might speak of these two processes as katabolic or dissimilative, and as anabolic or assimilative. In a condition of rest, these processes balance one another exactly. The effect of applying a stimulus to the cell is to increase the metabolic processes. In order that these excitatory processes may prevail against the inhibitory, it is necessary that they should attain a certain superiority above the latter. As soon as this condition is reached, the excitatory processes break

¹ *Arch. f. d. ges. Physiol.*, Bonn, 1872, Bd. v. S. 88.

² *Verhandl. d. phys.-med. Gesellsch. in Würzburg*, 1872, N. F., Bd. ii.

³ *Arch. f. Physiol.*, Leipzig, 1883, Suppl., S. 51.

⁴ "Untersuch. ueber d. Physiol. des Elektrotonus," Berlin, 1879.

through the resistance of the inhibitory, and an explosive discharge is the result. After the discharge the inhibitory processes are in the ascendant, and the stimulus from without has to continue acting for a further length of time before the excitation can gather fresh strength to break again through the resistance.

This conception, in default of a better, has played a great part in the speculations of physiologists on the nature of inhibition and the production of rhythmic activity. It suffers, however, as was pointed out by Gad, from the drawback that the molecular processes have to be considered as endowed with inertia. Otherwise, as soon as the excitatory were in excess of the inhibitory processes, there would be a leaking discharge, and a constant stimulus would cause a constant activity. We shall have occasion to discuss further applications of this theory later on when dealing with the nature of the action of the vagus on the respiratory centre. I have already mentioned the opinion held by some physiologists, that the respiratory centre, if separated altogether from afferent stimuli, would be unable to originate any respiratory movements. How, under this hypothesis, could we explain the action of oxygen-hunger on the respiratory centre? It is evident that the results of deprivation of oxygen might be equally well explained by assuming that its action was similar to that of strychnine, only differing from this drug in its more pronounced specific effect on the medullary centres. Like strychnine, asphyxia may cause convulsions of spinal origin after separation of the spinal cord from the medulla oblongata. Whether we consider that the activity of the respiratory centre is inaugurated by afferent stimuli, or by the molecular life of the cells themselves, it is evident that a lowering of the resistance to the passage of the impulses from the cells in all directions will lead first to an increase in the respiratory movements, as in dyspnoea, and later on to the general convulsions of asphyxia.

We may conclude that respiration is dependent on the integrity of a part of the central nervous system situated in the medulla oblongata, and which is therefore termed the respiratory centre. This centre is so arranged that it can respond to constant stimulation by intermittent rhythmic discharges. Under normal conditions this constant stimulation may be afforded by—

1. The sum of afferent impulses arriving at the centre.

2. The venosity of the circulating blood.

3. The normal metabolic changes in the nerve cells. These two latter factors may probably be classed together as the oxygen-hunger of the cells.

The influence of afferent nerves on respiration.—I have already mentioned the fact that, on cutting off the centre as far as possible from all afferent impulses, the respiratory movements, though rhythmic, differ widely from the normal. They consist of a series of spasms, recurring at ever-increasing intervals, which are inadequate for the maintenance of life. This fact shows that, for the normal performance of the respiratory functions, the arrival of afferent impulses at the centre is necessary, and we have now to consider the paths of these afferent impulses and the nature of the influence they exert on the centre.

Action of the vagus on respiration.—Of all the sensory nerves in the body, the vagi are the only ones whose section produces a marked and permanent change in the respiratory rhythm. These, therefore, have

been looked upon, and rightly, as the most important for the carrying out of normal respiratory movements, since they must convey, during the whole of life, impulses which affect and regulate these movements. We have, therefore, to discuss the nature of the influence exerted by the vagi on the respiratory centre and the mode in which these impulses are initiated.

As in all other cases, where we wish to study the functions of a nerve trunk or nerve centre, our experiments can be divided into two main classes: Those in which the normal function is abolished by section or extirpation, and those in which this function is initiated or exaggerated by artificial stimulation.

The earlier experiments of this nature were inconclusive, conflicting results having been obtained by different observers. It is to Rosenthal¹ that we owe the first accurate investigation of the subject, with a clearly defined hypothesis of the normal working of the vagus and respiratory centre founded on experiment. This observer showed in the first place that the constant effect of section of both vagi was to make the respiratory movements deeper and less frequent. The amount of air taken in during a given time was, however, unaltered, the increase in depth of the respirations exactly counteracting the slower rhythm. Before Rosenthal's time, the effect of electrical excitation of the central end of one vagus was found to produce sometimes expiration, sometimes inspiration. Rosenthal showed that the trunk of the vagus contains two definite sets of fibres. Excitation of one set produces reflex contraction of the inspiratory muscles, especially of the diaphragm, while stimulation of the second set produces relaxation of the diaphragm, and might therefore be looked upon as inhibitory of inspiration. The first set of fibres is, according to Rosenthal, distributed solely to the lungs, so that inspiration or a tetanic spasm of the diaphragm is an invariable sequence of excitation of the nerve in the lower part of the neck. If the exciting current be weak, the result may be not inspiratory spasm, but simply a quickening of the respiratory rhythm to that which obtained before the section of the vagi. On the other hand, a purely expiratory effect is produced by stimulating the central end of the superior laryngeal nerve, and Rosenthal ascribed the occasional expiratory effects, observed by his predecessors on stimulation of the vagus in the lower part of the neck, to an escape of current to the superior laryngeal nerves. As a result of his investigations, Rosenthal founded a theory of the normal working of the respiratory centre in the medulla oblongata, based to some extent on a hypothesis conceived about twelve years earlier by Ludwig and Hoffa² to account for the action of the vagus on the heart. These observers, on recording the contractions of the mammalian heart by a lever resting on the surface of the exposed ventricle, found that, during stimulation of the vagus, the heart beats, though less frequent, appeared much more powerful, and they concluded that the total amount of work performed in any given time by the heart muscle was the same under all circumstances, the only result of the vagus stimulation being to increase the resistance to the motor discharge, so that the tendency to discharge had to rise to a

¹ "Die Athembewegungen, u. ihre Beziehung zum Nervus vagus," Berlin, 1865. See also the section on the respiratory movements by the same author in Hermann's "Handbuch," Bd. iv. (2) S. 165.

² *Ztschr. f. rat. Med.*, 1850, Bd. ix. S. 129.

greater extent before it could be effective. Although this hypothesis was shown to be untenable by Coats,¹ working under Ludwig's guidance, Rosenthal made use of a very similar conception to explain the activity of the respiratory centre. I have already mentioned that (according to Rosenthal) the cause of the respiratory rhythm is to be sought in the existence of a resistance to the passage of impulses from the centre to the inspiratory muscles. The centre itself is kept in a condition of constant stimulation, in consequence of the unsaturated condition of the blood circulating through it. So long as the normal conditions for the conveying of oxygen to the blood are maintained, the activity—and total work done by the centre—could be regarded as constant, an increase of the resistance to discharge serving only to make each discharge more forcible, but the interval between consecutive discharges longer. In the normal animal this resistance is diminished by tonic influences ascending both vagi from the lungs. If both vagi be cut, these influences are abolished, with the result of an increased resistance to discharge of the centre. We thus get the familiar picture of slow deep inspirations following section of both vagi. Stimulation of the central end of the vagus fibres coming from the lungs diminishes this resistance, so that the respiration may be quickened, or, if the resistance be entirely

To be read from left to right.

FIG. 170.—Effect of closing trachea at height of inspiratory period. The trachea was suddenly closed at + and again opened at O.—Head.

abolished, there may be a continuous flow of energy from the respiratory centre to the inspiratory muscles, so producing a tetanic spasm of the diaphragm. Stimulation of the superior laryngeal has the reverse effect. It increases the resistance to discharge, so that inspiration is abolished. If stimulation be prolonged, the store of energy in the respiratory centre rises to such an extent that, being unable to burst through the normal resistance to inspiratory impulses, it escapes through the resistance between it and the expiratory muscles, thus producing an active expiration.

A complete revolution in our idea of the relationship of the vagus to the respiratory movements was effected by the experiments of Hering and Breuer² in 1868. These observers considered that, in order to arrive at some idea of the normal functions of the vagus, it was important to employ a stimulus for these nerves resembling as far as possible the normal stimulus. Proceeding on the assumption that the normal stimulus for the vagus was to be sought in the alternate distension and contraction of the lungs, they attempted to exaggerate these influences by closing the trachea at the end sometimes of an expiratory, sometimes of an inspiratory movement. They found that, if the trachea

¹ *Arch. a. d. physiol. Anst. zu Leipzig*, 1869.

² *Sitzungsb. d. k. Akad. d. Wissensch.*, Wien, 1868, Bd. lviii. S. 909.

be closed at the end of an inspiration, the result is an immediate relaxation of the diaphragm, and the expiration thus produced is enormously prolonged (Fig. 170). In those cases where tonic contraction of the diaphragm was present during the expiratory period, the muscle continues to relax, and its fibres finally reach a condition of complete elongation. After a varying interval, the pause is broken by an inspiratory contraction considerably stronger than the normal inspirations. The elongation which follows is again complete and a second long pause follows, which is, however, shorter than the one which preceded it, though longer than the normal pauses. If the tracheal cannula be now opened, the respiratory movements become very rapid.

If, on the other hand, the trachea is closed during the expiratory pause, the breathing suffers the converse change. The pause, during which the trachea is closed, lasts the usual time, and is followed by an inspiratory contraction of the normal rapidity. But when the inspiration has reached the normal strength, instead of ceasing abruptly, it goes on increasing until the curve reaches a point far above the crests of the normal inspiratory contractions (Fig. 171). Thus closure of the trachea in the expiratory phase of respiration causes an increase in the strength and duration of the inspiratory contractions.

FIG. 171.—Effect on respiratory movements of closing the trachea during the expiratory pause. The trachea was closed at + and opened at o.—Head.

Still more marked results were produced by inflating the lungs, or by allowing them to collapse entirely by making an opening in the thoracic wall. The effect of blowing up the lungs was invariably to cut short an inspiratory movement which might be proceeding, and to cause a long expiratory pause. On allowing the lungs to collapse, a strong inspiratory spasm of the diaphragm was produced, which lasted in the rabbit from eight to ten seconds, giving place to gradually increasing oscillations of the diaphragm, and finally, with the onset of dyspnoea, to complete relaxations of the diaphragm between the spasmodic inspirations.

Here we have evidently the mechanism for an automatic regulation (*Selbststeuerung*) of the respiration, each expansion of the lungs in inspiration tending to stop the inspiratory movement which caused it, and so bring on the following expiration. The collapse of the lungs during expiration would, on the other hand, send inspiratory impulses up the vagi, which would excite again the activity of the inspiratory centres. We see at once that the influence of the vagi must therefore be to quicken the respiratory movements, and, by cutting them short, to make them shallower, so that the results of cutting both vagi, by withdrawing these quickening impulses, must be a slowing and deepening of the respirations.

Subsequent investigations, while confirming the account given by Hering and Breuer of their experiments, have introduced certain modifications into their interpretation of them. It is curious to note that, whereas Rosenthal regarded the lung fibres of the vagus as purely inspiratory in function, the researches since the publication of Hering and Breuer's paper have tended more and more to exalt the expiratory functions of these fibres, some authors going so far as to deny the existence in the vagus of any fibres whose function it normally is to promote inspiration.

Of these investigations, the most important are those carried out by H. Head¹ in Hering's laboratory, since they not only embrace a number of experiments of the most varied kind on the functions of the vagi, but they also represent the only series of researches in which the method of experiment was free from objection and really adapted to the object in view. In order to record the respiratory movements, all other investigators have used the depression of the diaphragm, the elevation of the ribs, or the movements of the air in the lungs. These methods are obviously inapplicable when we wish to study the normal mode of stimulation, *i.e.* distension or collapse of the lungs, since these events cause a passive movement of the recording lever which it is difficult to dissociate from the active movement caused by the contraction of the inspiratory muscles. In Head's method, as has been already described, the activity of the respiratory centre is gauged by recording the contractions of an isolated slip of the diaphragm, which is practically unaffected by passive movements of the chest wall. In the succeeding account the results of Head's experiments will be mainly followed.

1. The normal respiratory movements.—Each inspiratory contraction of the diaphragm, as sampled by the isolated slip, begins rapidly, but soon becomes slower, though the lever is still rising when the contraction suddenly ceases. The first part of the expiratory relaxation is extremely rapid, but the fall of the lever generally gets slower towards the end of the relaxation. The writing point then traces a horizontal line, representing the complete elongation of the muscular slip (Fig. 168). In the rabbit the expiration is in most cases entirely passive. Where an active expiratory movement takes place, it begins gradually towards the end of the expiratory pause, and increases until it is suddenly broken in upon by the rapid inspiratory contraction of the diaphragm, which is accompanied by a complete relaxation of the expiratory muscles. Very often, when the breathing is rapid, the respiratory pause may be entirely wanting, and in such cases it is often found that the lever does not quite descend to the base line between each inspiratory contraction, so that each contraction starts, as it were, from the summit of a tonic contraction of the diaphragm. The existence of this tonus may be easily shown by dividing the phrenic nerves, when the lever at once sinks to the base line of total relaxation.

2. Effects of division of the vagi.—Division of the vagi has been performed by every physiologist who has investigated the innervation of respiration, but with varying results. The typical effect, as described by Rosenthal, I have already described. In many cases, however, the issue may be quite different. The breathing may become irregular, and accompanied with restlessness of the animal, while in other cases division may be followed by long expiratory pauses. Now, in all instances where the nerves are divided by section or ligature and

¹ *Journ. Physiol.*, Cambridge and London, 1889, vol. x. pp. 1-70, and pp. 279-290.

allowed to fall back into the wound, the effects of division of the conducting tracts may be complicated by the occurrence of excitation in consequence of closure of the demarcation current at the surface of the cut nerve. In order, therefore, to observe the effects of pure division, it is better to use the method adopted by Gad,¹ of freezing the nerve. Gad has shown that, when the conductivity of an afferent nerve is abolished in this way, no effective stimulation, so far as can be judged from the reflexes, is produced, although, if a motor nerve be treated in the same way, fibrillar twitchings of the muscle supplied by the nerve are observed. In addition to this method, Head made use of another devised by Biedermann, for extinguishing the conductivity of the nerve. The vagus is placed in a tube of indiarubber, so constructed that ether vapour can be passed over it without affecting the atmosphere which the animal breathes. In a few seconds the nerve is completely anaesthetised and incapable of conducting impulses. On removing the ether vapour, by blowing air through the tube, the nerve completely recovers its conducting power, and this process can be repeated several times without any apparent injury to the nerve.

Since the results of dividing one vagus in this manner are very transitory, and resemble in a smaller degree those due to division of both nerves, we may

pass at once to the effect of the latter proceeding. It is found invariably that removal of the influence which the vagi normally exert on the breathing leads to an increase in the force and duration of the inspiratory contractions, the first contraction which follows the division far exceeding in extent both the previous and the subsequent contractions. Division of the vagi affects the duration rather than the height of each contraction of the diaphragm. The expiratory relaxations are as a rule incomplete, so that the base line of the curve is raised, *i.e.* the diaphragm is in a state of tonic contraction (Fig. 172). In course of time the inspiratory tonus gradually diminishes and the expiratory pause is more pronounced, so that finally the breathing assumes the type which has already been described as typical after section of both vagi. If the animal be deeply narcotised or in a bad condition, or if there be any dyspnoea, the prolonged

FIG. 172.—Effects on respiratory movements of dividing (freezing) first one, and then the other vagus. *a, a*, control curve, showing passive movements of the chest wall; *b, b*, curve taken by a tambour, showing changes in pressure in a bottle of air connected with the trachea; *c, c*, myogram of diaphragmatic slip; *d*, time-marking in seconds.—Head.

initial contraction and the subsequent tonic contraction of the diaphragm are absent; the respirations become at once deeper and less frequent, each inspiration being followed by an expiratory pause which may be accompanied with active contraction of the expiratory muscles.

3. **Effects produced by increasing the duration or intensity of the normal action of the vagi.**—The results of increasing the duration of the normal vagal stimulation by closing the trachea at the end of inspiration or of expiration, as observed by Hering and Breuer, have been already described. The effects of increasing the extent of the stimulation by artificial inflation or collapse of the lungs were also studied by these observers. Since, however, certain new facts were brought to light by Head's experiments, some further mention of them is necessary.

If the lungs be gently inflated, the first result is an immediate cessation of the rhythmic inspiratory contractions, so that a pause is produced which may last fifteen to twenty seconds, but is always, sooner or later, broken by an inspiratory contraction. If any tonic contraction of the diaphragm were previously present, the lever, after its first rapid fall to the ordinary expiratory position, continues to sink slowly until, if the pause last long enough, the muscles attain complete relaxation.

If the inflation is carried out too violently, an inspiration may

FIG. 173.—The right vagus has been divided, and the curve shows the effect produced by complete collapse of the left lung. The left pleural cavity was opened at +, and the resulting tonic contraction of the diaphragm lasted twenty-five seconds (only the beginning and end of the pause are shown).—Head.

precede the expiratory pause, due probably to the stimulation of nerves in the body wall,—since it may be produced even after division of the vagi.

I have already mentioned that collapse of the lungs produces a prolonged contraction of the diaphragm. Since the further course of the experiment is complicated by the onset of dyspnoea, we may only perforate one pleura. In this case, since the resulting inspiratory dilatation of the sound lung tends to inhibit the inspiratory movement which produces it, the vagus nerve must be divided previously on the sound side. If, as is usually the case, each lung is supplied only by the vagus nerve of its own side, the result of the unilateral collapse is to cause a quick contraction of the diaphragm, which may continue in this condition for over twenty seconds. The first incomplete expiratory elongations then appear, but it is many minutes before the respiratory movements in any way approach the normal type. Finally, the breathing assumes a form different from the normal in the strength of the inspirations and the presence of a certain amount of inspiratory tone, very similar to that resulting from division of both vagi (Fig. 173).

A similar result (inspiratory spasm and increased inspiratory tone) may be produced by momentary suction applied to the tracheal tube.

Mechanical apnoea.—The increased inspiratory activity following

collapse of the lung or a momentary suction of air out of the air tubes, as well as the diminished activity caused by inflation or by closing the trachea at the end of inspiration, outlast the events which give rise to them by a considerable time. Thus, a momentary suction will give rise to an increased tone of the diaphragm which lasts for four or five seconds, or during the five or six respirations following the suction. These after-effects are designated by Head the "*positive after-action*."

Now this observer, in confirmation of observations by Gad, has

FIG. 174.—Effects of positive ventilation with air on respiratory movements. (The upper line shows the *passive* movements of the sternum, the middle line the strokes of the pump, and the lower line the respiratory movements of the slip of diaphragm.)—Head.

shown that, by repeating the stimulation at sufficiently short intervals, we may have a summation of the effects (the positive after-action), so that finally there is a standstill of respiration in a condition of expiration, or of continuous inspiration, or in a position halfway between the two. In order to carry out the series of rhythmic inflations or suction, Head employed a double-action pump devised by Hering. When the whole pump is in action the first stroke pumps a certain quantity of air or gas into the lungs, and the next stroke removes exactly the same quantity. By connecting one-half only of the pump with the trachea, it is possible to produce only periodic inflations (*positive ventilation*), while by using only the other half the ventilation consists simply of periodic suction (*negative ventilation*), the lungs in each case tending to return to the previous condition between the strokes of the pump, in virtue of the elasticity of the chest wall.

When positive ventilation is employed (Fig. 173), every inflation not only produces an expiratory pause during the time that it lasts, but this depressing influence on the inspiratory activity of the centre continues even after the lungs have returned to their normal volume. Hence the subsequent contractions suffer from the inhibition, and the inspiratory movements get smaller and smaller with every stroke of the pump, until they entirely disappear, the pause continuing for a time even after the ventilation is stopped; this condition is *expiratory apnœa*.

FIG. 175.—Effects of negative ventilation on respiratory movements.—Head.

On using negative ventilation the respiration is modified in a very different manner. Each suction causes a strong inspiratory contraction, which ceases as soon as the suction stops, but leaves behind it a condition of raised inspiratory activity, evidenced by the imperfect relaxation of the diaphragm. As the suction is repeated, the augmentor effects on the inspiratory activity are summated; the relaxation of the diaphragm between each stroke becomes less and less, until finally there is a cessation of movements of the diaphragm, which remains in a state of tonic or tetanic contraction, far exceeding in height any normal inspiration (*inspiratory apnoea*).

FIG. 176.—Diagrammatic representation of effects of different kinds of ventilation. *a*, normal breathing; *b*, apnoea with positive ventilation; *c*, apnoea with negative ventilation; *d*, apnoea with compound ventilation.—Head.

Compound ventilation produces an apnoea intermediate between the other two forms, the inspiratory contractions and expiratory elongations becoming smaller until they finally disappear; and the lever traces a line of varying height, according to the relative value of the two stimuli (alternate inflation and suction).

Rosenthal ascribed the apnoea produced by positive ventilation (*i.e.* by artificial respiration as ordinarily practised) to the excessive aeration of the blood thereby induced; whereas we have just seen that the causation of the apnoea can be adequately accounted for by the periodically recurring excitations of the inhibitory fibres of the vagus, consequent on the repeated inflations of the lungs.

A cogent objection to Rosenthal's interpretation is to be found in the fact, that the arterial blood is normally so nearly saturated with oxygen that increased ventilation can cause very little increase in the amount of oxygen carried by the blood. Moreover, it has been shown that towards the end of an apnoeic pause, before the respiratory movements have recommenced, the blood becomes of a venous hue on both

FIG. 177.—Apnoeic pause, caused by positive ventilation with hydrogen.—Head.

sides of the heart. The oxygenation of the blood is in fact less than in a normal animal. The most striking proof, however, that the apnoea is determined solely by recurring stimulation of the vagus fibres, is afforded by the fact that a distinct apnoeic pause can be produced by positive or compound ventilation with some inert gas, such as hydrogen or nitrogen, which is powerless to support life (see Fig. 177).

It might be thought from these experiments that it would be

impossible to produce apnoea after section of both vagi, and Knoll stated that such was the case. As a matter of fact, however, although difficult shortly after section of the vagi, it is not impossible to produce an apnoëic pause by ventilation with air. The ease with which this effect is produced increases with the length of time that the vagi have been divided.

How is the production of apnoea under these conditions to be explained? Head ascribes its production to the fact that, after section of the vagi, the aeration of the blood is not efficiently carried out, and the blood gradually gets more and more venous. In consequence of its lowered nutrition, the respiratory centre becomes adapted to this dyspnoëic condition of the blood. If active ventilation be now carried out, the blood, being normally aerated, is over-oxygenated with reference to the condition of the centre, so that in this case the causation of the apnoea is the same as that imagined by Rosenthal for the apnoea in animals with intact vagi.

As might be expected, it is impossible, after division of the vagi, to cause apnoea by ventilation with hydrogen or nitrogen. The fact that it is possible, even after section of the vagi, to produce an apnoëic pause by means of artificial respiration, was first established by Miescher,¹ who therefore distinguished *apnoea vera* or chemical apnoea, due to (relative) over-oxygenation of the centre, from *apnoea vagi* or mechanical apnoea, due to the inhibitory effects of repeated distension of the lungs.

Where does the summation of the stimuli which cause the apnoëic pause take place? Gad, who was the first to explain the apnoea as due to the summation of certain stimuli, believed that the summation takes place in the peripheral end-organs of the vagi. Head has shown, however, that if the vagi be divided at the beginning of the apnoëic pause, this pause, instead of being cut off, is much more pronounced than under normal conditions, showing conclusively that the summation of stimuli must take place in the centre itself rather than in the vagal terminations.

Effects of artificial stimulation of the central end of the divided vagus nerve.—Rosenthal pointed out that electrical stimulation (by induction currents) of the central end of the vagus in the neck causes an increase in the inspiratory rhythm, and with stronger currents an actual tetanus of the inspiratory muscles. He ascribed all expiratory effects to the escape of current into the superior laryngeal nerves. Since then it has been shown by numerous observers that the constant effect of the weakest current which can cause any change at all in the respiratory movements is inhibitory. The pauses between the inspiratory contractions become longer than usual, and the inspirations are generally less powerful. Exactly the same effect is produced when the divided nerve is stimulated by its own demarcation current, or when a constant current is passed through it in an ascending direction (Langendorff and Oldag).² The statement of these observers, that on opening the current, or on closing the current in a descending direction, an inspiratory effect is produced, has been contested by later authors, e.g. Lewandowsky.³ With the ordinary induction currents this primary expiratory effect is difficult to obtain with certainty, since a very slight

¹ *Arch. f. Physiol.*, Leipzig, 1885, S. 355.

² *Arch. f. d. ges. Physiol.*, Bonn, Bd. lviii, S. 201; cf. also Boruttan, *ibid.*, Bd. lxi, S. 39.

³ *Arch. f. Physiol.*, Leipzig, 1896, S. 195.

increase in the strength of the current produces the inspiratory effects described by Rosenthal. The inspiratory tetanus in the latter case is brought about chiefly by a decrease in the completeness of the expiratory relaxation of the diaphragm, which finally enters into a state of tonic contraction. A further increase in the strength of the exciting current leads to active expiratory contractions (possibly due to escape of current to the superior laryngeal nerves?).

Negative after-action.—Head has described an important after-effect of changes in the volume of the lung on the respiratory centre, under the term "negative after-action." The nature of this effect may be best explained by two or three illustrations.

If the lungs be inflated for a short time, the return of these organs to their normal volume is often followed by a slow inspiratory contraction of great duration but of comparatively small strength, and the elongation after the next two or three inspirations is incomplete. Here the positive effect of the inflation is an abolition of inspiratory tone. The negative after-effect is increased inspiratory tone.

FIG. 178.—Respiratory tracing showing negative after-effect. The left vagus was stimulated electrically with currents just insufficient to cause Rosenthal's 'tetanus.' The period of stimulation is marked by the rise of the line above the seconds time-tracing. During this time both lungs were inflated for a period marked by the rise of the tracheal manometer curve (dotted line). This inflation caused instant elongation of the inspiratory muscles. As soon as the lungs were allowed to return to their normal volume, the muscles again contracted under the influence of the vagal stimulation, and fell into a condition of complete tonic contraction.—Head.

During the normal breathing of a rabbit, with partial pneumothorax on one side, the diaphragm is in a condition of slight tonic contraction. If we wait until the tone has disappeared and then inflate the lungs, we notice, on the resumption of the movements after the arrest immediately following the inflation, that the tone has reappeared. It disappears again after a little time, but can be again recalled by another inflation.

If the central end of the divided vagus on one side be stimulated by means of an interrupted current, it is possible so to graduate the strength of the current that it is just insufficient to cause a complete 'tetanus' of the diaphragm. If the lungs be now inflated, the diaphragm at once elongates. As soon, however, as the lungs return to the normal volume, the diaphragm contracts powerfully and completely, the stimulus which was previously ineffectual being now able to evoke a complete tetanus, since it is reinforced by the negative after-action due to the inflation (Fig. 178).

What light do these observations throw on the functions of the vagus in normal respiration?

We have seen that the immediate effect of section of both vagi is to

cause the appearance of an inspiratory tone and to lengthen the individual inspiratory contractions. This effect is still more marked if the division of the vagi be carried out after the medulla oblongata has been separated from the upper parts of the brain by a section through the striæ acusticæ. In this latter case the inspiration which follows division of the second vagus may last from forty-five seconds to one and a-half minutes. At the end of this time there is a quick complete relaxation of the diaphragm, followed by a slow expiratory contraction of the abdominal muscles. When this active expiration has reached a considerable height, the abdominal muscles suddenly relax, and the inspiratory muscles contract violently, producing a second prolonged inspiratory spasm. Gad¹ pointed out that these effects indicate that the impulses previously ascending the vagi were inhibitory in character, rather than inspiratory, as was supposed by Rosenthal. Whereas Hering and Breuer had imagined that the vagus is traversed alternately by expiratory and inspiratory impulses, Gad concluded that the only impulses travelling up the vagi are expiratory or inhibitory in nature. These impulses are excited by the condition of distension of the lung, and are therefore present even at the end of a normal expiration, being only abolished by total collapse of the lung.

It is evident that we can explain the results of distension or collapse of the lungs just as well on this hypothesis as on that of Hering and Breuer. When the lungs are forcibly distended, the normal inhibitory influence of the vagus is increased, and an expiratory pause is the result. Sudden collapse of the lungs causes a diminution in the normal inhibitory stimuli, and therefore increased inspiratory activity.

Head, though agreeing with Gad in thinking that the collapse of the lung in normal quiet expiration acts only by a removal of inhibitory stimuli, does not accept his view that the only impulses travelling up the vagi are inhibitory. If this were the case, sudden collapse of both lungs should be exactly equivalent to section of both vagi; whereas Head, using a more perfect method of investigation than Gad, has shown that the results of collapse are far more pronounced than those of simple section of the vagi. Moreover, it is difficult to understand the summation of effects produced by negative ventilation on the assumption that each suction merely causes a diminution of previously existing stimuli.

Assuming that the inhibitory impulses which ascend the vagi are the more important under normal conditions of respiration, how can we explain the quickening effect of these stimuli? In endeavouring to answer this question, it must be remembered that every stimulus, whether produced by inflation or collapse, is followed by a positive and a negative after-reaction. After the division of the vagi, the breathing finally acquires the type characterised by long powerful inspirations, separated by complete expiratory pauses. If now we could suddenly reinstate the vagi, it is evident that in the very next inspiration, before the movement could be completed, the dilatation of the lungs would send an inhibitory impulse up to the centre, checking the inspiratory movement and causing a subsequent pause (positive after-action). As soon as this positive after-action was sufficiently diminished, a second

¹ *Arch. f. Physiol.*, Leipzig, 1880, S. 1; *ibid.*, 1881, S. 538.

inspiration would occur, which would be again cut short before it had reached its full height. Not only, however, will the height of the contractions be diminished by this automatic governing arrangement, but each inhibitory impulse ascending the vagi will have a negative after-action, tending to increase the vitality or inspiratory activity of the centre. The effect of this increased inspiratory activity will be to diminish the pauses between the different inspirations, so that finally we get a condition in which the breathing remains rhythmic, but the inspiratory contractions are smaller and more frequent than before the reinstatement of the vagi. Moreover, the centre is in a condition of increased vitality, and able to respond with much greater promptitude to any inspiratory stimulus. The vagi thus act like the governor of a steam-engine in economising the labour expended, and in preventing the centre from wearing itself out by excessive exertion. When these nerves have been divided, the centre finally settles down into a condition of "spendthrift activity," regulated only by the impulses from the centres in the higher parts of the brain, and we have already seen that, even with their aid, the aeration of the blood, the object of the respiratory mechanism, becomes more and more ineffectually carried out.

Of the other views with regard to the nature of vagus action, I need only mention those of S. J. Meltzer.¹ This author, after showing that in all animals excitation by means of strong currents of the central end of the divided vagus produces expiration, followed after the cessation of the stimulus by a strong inspiratory movement, concludes that the vagus contains two classes of fibres,—the inspiratory and the inhibitory or expiratory fibres. These differ in the time relations of their response to stimuli, resembling in this particular the accelerator and inhibitory cardiac nerves. When they are both stimulated together, the primary effect is therefore expiration, the more lasting effect inspiration. He imagines that the inspiratory expansion of the lungs excites both sets of fibres simultaneously. During the excitation, the inhibitory effects predominate over the inspiratory, so that the first result is a stoppage of inspiration with relaxation of the inspiratory muscles. The expiratory collapse which follows removes the stimulus, and therefore the more lasting after-effect of the excitation, namely, that due to the inspiratory fibres, can make itself felt, and we get a new inspiration.

The influence of other afferent nerves on respiration.—Although there are hardly any afferent nerves in the body, stimulation of which may not cause some change in the respiratory rhythm, yet in no case can we regard their influence on respiration as equivalent to that of the vagus, since their division is without effect on the respiratory rhythm.

Superior laryngeal nerve.—As was first shown by Rosenthal, stimulation of the central end of this nerve has a nearly pure expiratory effect. Stimulation with a weak current causes an instant cessation of inspiration and an expiratory pause. Stronger stimulation may evoke strong contractions of the expiratory muscles. Besides this effect on the respiratory rhythm, excitation of the superior laryngeal also affects the swallowing centre in the medulla, and so gives rise to elevation of the larynx, followed by peristaltic contractions of the œsophagus. As was pointed out by Steiner² and by Meltzer,³ the first phase of each act of deglutition is accompanied by a short twitch of the diaphragm. A tracing of the diaphragm during stimulation of this nerve shows

¹ *Arch. f. physiol.*, Leipzig, 1892, S. 340.

² *Ibid.*, 1883, S. 57.

³ *Ibid.*, 1883, S. 209.

therefore a series of small elevations rising from the base line corresponding to the condition of relaxation.

Inferior laryngeal nerve.—Excitation of this nerve is frequently attended by inhibition of inspiration, with sometimes active expiratory movements.

Glosso-pharyngeal nerve.—Kronecker and Meltzer,¹ in studying the mechanism of deglutition, found that the small inspiration mentioned above, which accompanies the first phase of this act, is followed by a period during which respiration is entirely inhibited. This result they ascribed to an irradiation from the centre of deglutition to the respiratory centre. Marckwald² has shown, however, that the pause is originated reflexly by means of the glosso-pharyngeal nerve. If this nerve be cut and its central end stimulated, after a latent period of half to one second, an absolute stoppage of respiration takes place. This stoppage differs from that produced by any other nerve, in that the muscles remain in the condition in which they were when the stimulation began to act, whether during inspiration, expiration, or midway between the two conditions. This cessation of respiration lasts for about the time occupied by the two or three preceding respirations. Respiration then recommences, even though stimulation be continued, with an inspiration which starts from the position at which the diaphragm was arrested at the beginning of stimulation.

Other sensory nerves.—Gentle stimulation of most sensory nerves causes quickening and increase in the inspiratory movements; with a stimulation strong enough to evoke signs of pain, the animal becomes restless, and the breathing is mainly of the active expiratory type. The application of gentle stimuli to the stomach or abdominal viscera, or to the splanchnic nerves, is, however, invariably expiratory, and displays itself either as an increase in the expiratory pauses, or more often as a strong contraction of the expiratory muscles.

A pure expiratory reflex may also be brought about by gentle stimulation of the nasal mucous membrane of the rabbit, as by application of chloroform vapour. A similar expiratory pause is caused in many animals by dipping the nose into water, or even by plunging the lower half of the body into water (*Tauchreflex*). The temperature of the water is of no influence on the results of the experiment. Fredericq³ has shown that a specially long expiratory pause may be produced in a diving animal, such as the duck, by allowing a stream of water to flow on its beak. The teleological importance of these reflex cessations of respiration, which have been classed together by Miescher-Rusch⁴ as *apnœa spuria*, is obvious.

Influence of the higher parts of the brain on the respiratory centre.—We have seen that a complete section of the bulb above the respiratory centre is without influence on the respiratory rate, the centre with the help of the vagi being quite sufficient to carry out the normal respiratory rhythm. If, however, the vagi have been previously divided, the severance of the paths from the higher parts of the brain has an enormous influence. The previous rhythmic respiratory movements are practically abolished, and give place to a series of prolonged inspiratory spasms, which are separated by long pauses during which

¹ *Arch. f. Physiol.*, Leipzig, 1888, Suppl.

² "Movements of Respiration," 1888, p. 88.

³ *Arch. f. Physiol.*, Leipzig, 1893, Suppl., S. 65.

⁴ *Ibid.*, 1885, S. 355.

the inspiratory muscles are completely relaxed. Towards the end of the pause, active contraction of the expiratory muscles takes place. These spasms are inadequate for the proper aeration of the blood. As the blood gets more venous, the spasms become less and less frequent, and the animal, at the end of an hour or so, dies of asphyxia. We must conclude from these results that, in default of the normal vagus stimulation, the activity of the respiratory centre can be regulated and controlled to a large extent by vicarious influences from the higher parts of the brain. In searching for the origin of these impulses, we naturally think first of the afferent nerves which enter the cerebro-spinal centres above the medulla oblongata, especially since we know that respiration may be altered in an inspiratory or expiratory direction by excitation of the olfactory, optic, auditory, and fifth nerves. A total division of these nerves would be probably impracticable. Loëwy¹ has shown that bilateral section of the fifth nerves at their exit from the pons does not alter the respiratory rhythm after division of both vagi. Attempts have therefore been made to localise the origin of these impulses—first, by carrying out the extirpation of the brain in successive stages from above downwards; and, secondly, by observing the effects of stimulation of certain parts of the higher portions of the brain.

By the first method it has been determined that, after division of both vagi, no further alteration takes place in the breathing until the section has been carried through the level of the anterior corpora quadrigemina.

By the second method, certain localised areas of the brain have been found to give, on excitation, definite changes in the respiratory rhythm. Thus mechanical, thermal, or electrical stimulation of the inner wall of the optic thalamus on each side (Budge, Christiani) causes either a standstill of the diaphragm in an inspiratory condition, or increases the rhythm and depth of the inspiratory movements. On the other hand, an expiratory centre has been described by Christiani² in the substance of the anterior corpora quadrigemina close to the aqueductus Sylvii, and an inspiratory centre by Martin and Booker³ midway between the anterior and posterior corpora quadrigemina. It would seem that a section has to pass through or behind these two last-named centres, in order to produce the effects already described of cutting off the higher centres from the medulla oblongata after division of the vagi.

Spencer⁴ obtained slowing and arrest of respiration by faradic stimulation of the cortex just outside the olfactory lobe in front of the point where the tract joins the temporo-sphenoidal lobe, and increased action on stimulating a spot on the convex surface of the cortex within the motor area. Excitation of the junction of the olfactory bulb and tract, as well as of the uncinatè gyrus, produced super-inspiratory *clonus*, while super-inspiratory *tonus* was obtained on stimulating the descending motor tract.

The experimental facts at our command are not adequate at present to permit of our arriving at any definite conclusions as to the nature or mode of origin of the vicarious impulses which reach the medulla oblongata from these centres. We have, however, no reason to suppose

that they are active during normal respiration, for which the integrity of the medullary centre and vagi is all that is necessary.

Asphyxia.—This condition is brought about by all circumstances which hinder the normal respiratory changes of the blood passing to the medullary centres. It may therefore be caused by any agency which prevents the respiratory movements as well as by obstructing the trachea, or by opening both pleural cavities, so that the respiratory movements no longer dilate the lungs. Asphyxia may be brought about by cutting off the blood supply to the medulla oblongata, either by ligature of all the vessels going to the brain, as in the Kussmaul-Tenner experiments,¹ or by producing universal anæmia by a large hæmorrhage. So far as the respiratory movements are concerned, the phenomena of asphyxia may be divided into three stages.

In the first stage, the respiratory movements are increased in rhythm and amplitude. This stage is sometimes known as *hyperpnœa*. If any tonic contraction of the diaphragm had been previously present, this disappears at the onset of dyspnœa, the relaxation of the diaphragm at the end of each inspiration being complete.

In the second stage (*dyspnœa*) the expiration becomes active, and gradually the expiratory movements become increased out of all proportion to the inspiratory, so that finally respiration is made up of a series of prolonged expiratory convulsions, separated by short inspirations. In these forcible expirations nearly every muscle of the body may be involved.

At the end of the second minute after ligature of the trachea (if this mode of producing asphyxia has been adopted), the expiratory convulsions cease almost suddenly, and give way to slow deep inspirations. With each inspiratory spasm, the animal stretches itself out, and opens its mouth widely, as if gasping for breath. The whole stage is one of exhaustion; the pupils are widely dilated, and the animal is perfectly insensitive, being unaffected by the strongest sensory stimulation. The pauses between each inspiration become longer and longer and each inspiration shallower, till, at the end of four or five minutes, "with extended limbs and straightened trunk, with the head thrown back, the mouth widely open, the face drawn and the nostrils dilated, the last breath is taken."²

The effects of deprivation of oxygen upon the circulation are different in the different stages of asphyxia, and naturally vary according to the mode by which asphyxia is produced. If by occlusion of the trachea, the variations in intrathoracic pressure which are brought about by the dyspnœic movements of the chest are enormous, and produce corresponding effects upon the arterial and venous pressures. In addition to this, and whatever be the method by which asphyxia is caused, the venous blood circulating in the medulla oblongata stimulates both the vasomotor and the cardio-inhibitory centres, so that the arterioles are contracted and the heart-beat slowed. The effect of the vaso-constriction is, however, greater than that of cardio-inhibition, and the blood pressure markedly rises. There are also usually produced very well-marked Traube-Hering curves, indicating a rhythmic action of the vasomotor centre. These changes go on during the first and second stages of asphyxia, but after this the heart muscle, over-strained by the raised peripheral resistance and inadequately supplied with

¹ "On Epileptiform Convulsions from Hæmorrhage," by Kussmaul and Tenner, *New Syd. Soc. Translation*, London, 1859.

² M. Foster, "Text-book of Physiology," 6th edition, p. 640.

oxygen, begins to fail. Each beat becomes more and more feeble, the quantity of residual blood left in the cavities at the end of systole increasing at each beat, until finally the heart is enormously dilated, and each contraction is marked only by a feeble flutter of the cardiac walls. In consequence of this heart failure, the pressure sinks steadily until circulation is at an end and the pressure is the same all over the vascular system (about 10 mm. Hg). A vigorous animal, with well-marked vasomotor reaction, will die of heart failure, before any relaxation of the vessels has taken place. This is shown by the fact that if artificial respiration be suddenly employed, when the blood pressure is approaching its lowest point, the access of oxygen benefits the heart earlier than the vasomotor centre, and the pressure may rise to a point even higher than that reached during the primary asphyxial rise.

Failure of the circulation, however, gradually impairs the activity of the medullary centres, as is shown by the gradual decline in arterial and venous pressures after all circulation has ceased (in consequence of increased capacity of vascular system).

At the end of asphyxia, therefore, all cavities of the heart are distended with blood, the distension being most pronounced in the cavities with thin walls, *i.e.* auricles and right ventricle. The difference thus occasioned between right and left ventricles is generally increased after rigor mortis has set in, and it is supposed that the post-mortem contraction of the left ventricle expels the contents of that cavity, so that it may be found almost empty unless examined immediately after death.

MODIFIED RESPIRATORY MOVEMENTS.

Coughing.—This consists in the first place of a deep inspiration, followed by closure of the glottis. This is succeeded by a sudden powerful expiratory effort, with total relaxation of the inspiratory muscles. The air is forced suddenly through the resistance offered by the glottis, and the blast of air thus produced serves to expel through the upper air-passages and mouth any foreign body lodged in the larynx. Coughing is usually excited by stimulation of the terminations of the superior laryngeal nerve in the mucous membrane of the larynx. But it may also be due to stimulation of certain of the vagus endings in the lungs, or of the nerves supplied to the pleura.

Sneezing is very allied in its general characters to coughing. In each case an inspiration is followed by a powerful expiratory effort. In sneezing, the resistance to the outburst of air seems to be afforded in the first place by the approximation of the dorsum of the tongue to the soft palate, so that the first part of the expired air passes through the nasal passages. The greater part of the air is, however, expelled through the mouth. Sneezing is usually excited reflexly by stimulation of the nasal branch of the fifth nerve; when it is produced by sudden exposure to a bright light, the afferent impulses probably travel up the optic nerve.

In **laughing** and **crying**, a deep inspiration is followed by a series of short spasmodic expirations. The glottis is freely open during the whole time, and the vocal cords being tense, are thrown into vibration, so occasioning the characteristic sounds of the two actions. The chief difference between the two actions is in the accompanying facial expressions.

Yawning consists of a deep inspiration accompanied by a wide opening of the mouth and of the glottis, often attended by movements of the arms.

Cheyne-Stokes respiration.—A special modification of the respiratory rhythm, known under the above title, occurs in certain pathological cases. In this form the activity of the respiratory centre becomes periodic. Thus the respirations gradually decrease in amplitude until they cease altogether. After a pause of greater or less duration, a feeble inspiration ensues, to be succeeded by a somewhat stronger one, and the inspirations gradually return to, or somewhat above, their normal height, to then undergo a diminution as before. Mosso¹ has shown that, even in the normal state, a certain periodicity during respiration may be observed during sleep. Well-marked Cheyne-Stokes breathing has often been observed in cases where there was increased cerebral pressure or deficient blood supply to the brain. Langendorff² discovered that a similar condition might be produced in frogs by ligature of the aorta, or by cutting out the heart, or by poisoning with muscarin. In the latter case, the phenomenon could not be abolished by subsequent administration of atropin. In animals a periodic respiration has sometimes been observed when a section between the brain and the medulla oblongata has been carried out too low, so as to affect the respiratory centre injuriously. Although we can assume with a high degree of probability that the cause of the Cheyne-Stokes phenomenon is to be sought in a morbid condition of the respiratory centre, we are not yet in a position to form a definite conclusion as to the exact changes involved in this condition.

THE INNERVATION AND ACTION OF THE BRONCHIAL MUSCLE FIBRES.³

A contraction of the smooth muscle fibres which surround the large and smaller air tubes must have several effects, namely—(1) A constriction of the bronchi or bronchioles. (2) A diminution of the air space of the lungs, and therefore, in the absence of compensatory changes in blood contents, of the volume of the whole lung. (3) An increased resistance to the passage of the air into and out of the alveoli.

From the time when Longet,⁴ from direct observation of the bronchioles, concluded that the vagus nerve carried motor fibres to the bronchial muscle, the subject has been investigated by a number of physiologists. Although in some cases purely negative results were obtained, the accuracy of Longet's statement must be accepted as beyond doubt. Among those who obtained evidence of bronchial constriction by various methods, more or less imperfect, may be mentioned Schiff,⁵ Paul Bert,⁶ Gerlach,⁷ MacGillavry,⁸ Roy and Brown,⁹

Sandmann,¹ F. Franck,² Riegel and Edinger,³ Einthoven and Th. Beer. Einthoven made use of two methods, both based on the increased resistance to the passage of air through the bronchioles which would be occasioned by contraction of the bronchial muscles. In the first method, artificial respiration was carried out, a constant volume of air being blown in and sucked out at each respiration. Any diminution in the calibre of the bronchioles must increase the resistance to the incoming current, and so cause a rise of pressure in the tracheal tube. Instead of recording the variations of pressure throughout the whole of each stroke of the pump, an arrangement was made use of, by means of which the mercurial manometer was connected with the trachea only for a brief space of time, during one part of the inspiratory phase. The lever recording the excursions of the mercury in the manometer recorded therefore an almost unbroken line during the experiment. Any increased

FIG. 179.—Tracings of blood pressure (middle curve) and of intratracheal pressure (upper curve), taken by Einthoven's "differential manometer." Between Q & Q' the peripheral end of one vagus was stimulated. Time marking=seconds.

resistance to the current of air raised the pressure during the whole inspiration, and therefore during the moment at which the manometer was put into connection with the tracheal tube. A rise of the lever was thus produced, which continued with each stroke of the pump, until the level of the mercury corresponded with the true pressure obtaining at the moment of connection, during constriction

of the bronchioles. Einthoven calls this arrangement a "differential manometer," since its principle is the same as that of Bernstein's differential rheotome.

In the second method, artificial respiration at a constant pressure is made use of. Any change in the bronchioles will in this case affect the volume of air entering the lungs at each stroke of the pump, and can be measured by recording the passive respiratory movements of the chest wall or diaphragm. In both cases the animal must be curarised, so as to abolish spontaneous respiratory movements.

The influence of stimulation of the peripheral end of the vagus.—If in a curarised animal the peripheral end of either vagus be stimulated, the effect is invariably a constriction of the bronchioles. This is rendered evident by a rise of the manometer lever, if Einthoven's first method of observation be adopted (Fig. 179); or by a diminution of the respiratory movements of the thoracic wall, if the second method be

¹ *Arch. f. Physiol.*, Leipzig, 1890, S. 252.

² *Arch. de physiol. norm. et path.*, Paris, 1889, tome i. p. 538.

³ *Ztschr. f. klin. Med.*, Berlin, Bd. v. S. 413.

employed (Fig. 180); the effect is increased within limits, by increasing the duration of the stimulus. The latent period which elapses between the beginning of the excitation and the commencement of the bronchomotor effect, lies between 1.0 and 1.5 seconds.

It might be thought that this bronchial spasm was directly caused by the fall of blood pressure, due to the action of the vagus on the heart. It is not possible to exclude this explanation by administration of atropin, since this drug paralyses completely the bronchomotor fibres of the vagus. Einthoven has shown, however, that there is no proportionality between the effect on the heart and the amount of bronchial constriction, and that, in fact, a well-marked and typical bronchial constriction may be brought about by vagal stimulation, even after the death of the animal and consequent cessation of the blood flow.

Tonic action of the vagus.

—In the dog there is, as a rule, very slight evidence of a tonic influence of the vagus on the bronchial muscle. Section of both vagi either does not alter the respiratory curve (Einthoven's method), or lowers it by 2 to 10 mm. water. It is, however, in all cases, easy to bring about a vagus tonus by allowing the animal to inhale air containing an excess (3 or 4 per cent.) of CO_2 . As the CO_2 tension in the blood rises, the bronchi constrict slowly. This constriction is at once cut short by dividing both vagi. It is not due to commencing asphyxia (oxygen hunger), since it is not produced by allowing the animal to inhale pure nitrogen.

Chauveau¹ states that in the horse the vesicular murmur disappears after section of the vagi. This fact would tend to point to a marked tonic action of the vagi on the bronchial muscles in this animal.

When present the vagus tonus may present slight slow rhythmical oscillations, and may sometimes be inhibited by stimulation of the central end of a sensory nerve such as the sciatic. In one case, Einthoven observed a reflex broncho-constriction on stimulating the central end of the sciatic in a curarised dog. There seems to be no satisfactory evidence for assuming the existence of broncho-dilator fibres in the vagus.

The effects of bronchial constriction; Asthma.—Under the influence of vagal stimulation or of CO_2 , the pressure necessary to drive the normal amount of air into the lungs may be raised in the dog from 125 to 300 mm. H_2O .

We should therefore expect that, in cases where bronchial constriction is present, there would be difficulty both in inspiration and expiration. There

FIG. 180.—Diminution of respiratory excursions produced by spasm of bronchial muscle (artificial respiration at constant pressure). A' = thoracic wall, A'' = diaphragm. Vagus stimulated between P and P' .—Einthoven.

¹ Quoted by Einthoven, *loc. cit.*, S. 373.

is, however, a difference in the mechanical conditions of the bronchi during the two phases of a respiratory movement. Normally the elastic structure of the lungs is drawing upon the bronchial wall, tending to maintain it patent, and so opposing the action of the bronchial muscle. During inspiration this expanding force is increased, so that in the presence of bronchial constriction the access of air is rendered the easier, the more powerful the contraction of the inspiratory muscles. In expiration all parts of the lung collapse, drawing with them the chest wall; the pull of the lung tissue on the bronchial wall is lessened, but is still present. If, however, the expiratory muscles contract vigorously, the intrapleural pressure becomes positive, and the pull of the lung tissue on the bronchial walls is changed into a pressure tending to obliterate their lumen, and so impede the outflow of air.

It is evident, therefore, that in the presence of a spasmodic contraction of the bronchial muscles the inspiration will be forcible and rapid, but all contractions of muscles must be avoided, so far as possible, during expiration, which must be left to the elastic reaction of the lungs, and becomes slow and prolonged. Moreover, it will be of advantage to keep the lung as nearly as possible in the inspiratory position, so as to reinforce the elastic forces which dilate the bronchioles and aid expiration. We thus get the typical breathing which occurs in man in cases of spasm of the bronchial muscles, known as *asthma nervosum*. This type of breathing is often described as being marked by *expiratory dyspnoea*. This description is, however, erroneous. The muscles which in these cases are contracted to their uttermost, are the inspiratory muscles; the expiratory muscles, such as the abdominal, will be found to be quite flaccid even during expiration.

THE MUSCULAR AND NERVOUS MECHANISMS OF THE DIGESTIVE TRACT.

BY E. H. STARLING.

CONTENTS :—Mastication, p. 313—Sucking, p. 314—Deglutition, p. 314—Movements of the Stomach, p. 321—Vomiting, p. 324—Movements of the Intestines, p. 326—Defæcation, p. 335.

MASTICATION.

IN order to prepare the solid food-stuffs for the action of the digestive juices in the alimentary canal, they are reduced to a fine state of subdivision in the mouth by the process of mastication. In this act the incisors divide the lump of food into smaller portions, which are then ground up between the molar teeth. The necessary movements for these processes are carried out by the muscles acting on the lower jaw, the temporo-maxillary articulation allowing of elevation and depression of the lower jaw, as well as forward, backward, and side-to-side movements. This dental triturating apparatus would be of no avail without some means of keeping it constantly supplied with fresh particles of food. The renewal of the food between the teeth is carried out by movements of the tongue and cheeks. Bilateral paralysis, sensory or motor, of the tongue, renders mastication almost impossible. Paralysis of the cheek (buccinator) on one side causes the food to collect and form a pouch outside the molar teeth. In such cases, the patient assists mastication by emptying the pouch with his finger.

With regard to the muscles involved in the various movements by which mastication is performed, the lower jaw is raised by the action of the masseter, temporal, and internal pterygoid muscles. Depression of the lower jaw is largely passive, but is also aided by the digastric and, to a slighter extent, by the mylohyoid and geniohyoid muscles. The grinding movements of the jaw—sidewards, forwards, and backwards—are carried out by contractions of the external pterygoid muscles of the two sides in varying degree.

Of the muscles affecting the tongue, the genioglossus and transverse fibres move this organ forwards, while the hyoglossi, palato- and styloglossi cause retraction. Movement from one side to the other is effected by contraction of the longitudinal muscular fibres. Contraction of the hyoglossi alone will make the upper surface of the tongue convex from side to side; contraction of the genioglossi will make it concave.

The act of mastication is a voluntary one, but, like most other co-ordinated muscular actions, is dependent for its guidance on sense impressions. The sensory nerve involved is the fifth. The efferent

impulses travel by the motor root of the fifth cranial nerve to the elevators of the jaw and the mylohyoid, along the seventh nerve to the digastric and muscles of the lips and cheek, and along the hypoglossal nerve to the muscles of the tongue.

SUCKING.

During the first year of life, before the development of the teeth, the child is dependent for its sustenance on liquid food, which it obtains under normal circumstances from the breast of the mother. In this act the lips enclose the nipple, adherence being assisted by the existence of a special membranous projection of the front part of the gums of both jaws. During suction, the respiration goes on through the nose without check. Normally the dorsum of the tongue lies against the hard palate, but, according to Donders,¹ at the back part it is separated from the soft palate by a small space. Owing to the weight of the jaw, there is a negative pressure in this space of 2–4 mm. Whether such a space is present under ordinary conditions or not, it is certain that the jaw is maintained in its position, not by muscular effort, but by the pressure of the air; so that, if a tube from a manometer be passed between the tongue and the palate, the manometer shows a slight negative pressure corresponding to the weight of the jaw. If, therefore, the nipple of the breast or feeding-bottle be passed between the tongue and palate, there will be a tendency for the fluid to flow into this space. During active sucking the space is enlarged and the negative pressure increased by means of movements of the tongue, this organ being retracted and also hollowed out on its upper surface by means of the genioglossi and palatoglossi.

DEGLUTITION.

Muscular mechanisms.—Since the time of Magendie, physiologists have been accustomed to divide the act of swallowing into three stages.

In the first stage, the bolus of food is carried past the anterior pillars of the fauces; the second stage comprises the period during which the food is conveyed through the pharynx, past the openings of the nasal cavities and larynx; and during the third stage it is passed through the lower part of the pharynx and down the œsophagus. Since, however, there is no pause between these various stages, but the muscular movements involved follow one another continuously, it is better to consider the act of deglutition as one process.

The food, when sufficiently masticated, is collected as a bolus on the dorsum of the tongue by the movements of this organ. A pause then occurs in the process of mastication, a slight movement of the diaphragm usually takes place ("respiration of swallowing"), and a sudden elevation of the tongue occurs, which travels from the apex to the base, so squeezing the bolus backwards past the isthmus faucium. At this moment the bolus has arrived at a part of the pharynx which is common to the functions of respiration and deglutition. It has therefore to be conveyed quickly past the openings of the air passages into the pharynx,

¹ *Arch. f. d. ges. Physiol.* Bonn, 1875, Bd. x. S. 91.

and means must be taken to prevent any of the food escaping into the air passages. We have therefore to consider the means whereby—
 (1) The bolus is propelled downwards into the grasp of the constrictors;
 (2) the nasal passages are closed; (3) the larynx is guarded.

1. The chief factor in the propulsion of the bolus through the back of the pharynx is the contraction of the mylohyoid muscle, which presses the tongue against the palate and pushes it backwards. In this action it may be aided by the contraction of the styloglossus and palatoglossus muscles, which pull the base of the tongue suddenly backwards. These muscles, moreover, especially the palatoglossi, serve to close the isthmus faucium, thus preventing any return of the food towards the mouth.

2. The shutting off of the naso-pharyngeal cavity is a somewhat complicated act. As soon as, or even before, the bolus touches the soft palate, this structure is raised and put on the stretch by a simultaneous contraction of the levator palati and palato-pharyngeus muscles on each side. At the same time the contraction of the last-named muscles, which form the posterior pillars of the fauces, approximates and straightens the edges of these two structures, and raises to a certain extent the upper part of the pharynx. The soft palate, which has thus been raised, comes in contact with an elevation on the posterior wall of the pharynx, an elevation due to the contraction of fibres of the superior constrictor of the pharynx. The uvula, which is also raised slightly by the azygos uvulæ, lies between and fills up the opening between the straightened posterior pillars of the fauces. The soft palate is thus formed into a tense sloping roof, which guides the bolus down the pharynx.

3. More important still is the shutting off of the lower air-passages from the pharynx. The contraction of the mylohyoid muscles, which accompanies the first act of deglutition, can be seen to be followed almost immediately (at an interval of 0·07 seconds) by an elevation of the larynx. Observations on animals and on men in whom the parts involved have been extensively exposed by operation, have shown that this elevation of the larynx is accompanied by a closure of the glottis as well as of the superior opening of the larynx. That this latter is important is shown by the fact that the mucous membrane of the vestibule of the larynx is extremely irritable, so that any particle of food falling on it will cause a spasmodic cough. It has generally been supposed to be carried out by a movement of the dorsum of the tongue backwards, effected by the stylo- and palato-glossal muscles. In consequence of this movement, combined with contraction of the muscular fibres in the aryteno-epiglottidean folds, the expanded portion of the epiglottis has been supposed to be folded like a lid over the opening of the larynx, thus furnishing a sloping floor for the passage of the food. But observations by Anderson Stuart¹ have shown that this bending over of the epiglottis probably does not occur, that the epiglottis remains erect, and that the food passes not over its upper (anterior) but over its lower (posterior) surface; the anterior resting against the root of the tongue. Magendie and Schiff had already pointed out that extirpation of the epiglottis caused very little disturbance to an animal, which could swallow both solids and fluids as well after the operation as before.

The laryngeal opening is bounded in front by the epiglottis, behind by the tips of the arytenoid cartilages, and at the sides by the aryteno-

¹ *Proc. Roy. Soc. London*, 1891, vol. 1. p. 323.

epiglottidean folds, in which are contained the two small cartilages of Santorini and Wrisberg. During normal respiration this cavity is widely open, and the arytenoids lie against the posterior wall of the pharynx. When deglutition takes place, the arytenoid cartilages leave the posterior wall of the pharynx, are rotated and moved inwards and forwards, with their internal faces in contact. In consequence of this movement of the hinder boundaries of the laryngeal opening forwards, this opening assumes the form of a triradiate fissure, the vertical limb being short, while the transverse limb is rounded, owing to the pulling inwards of the margins of the epiglottis. Round the central point of the triradiate fissure three prominences are to be observed, namely, the cushion of the epiglottis, and on each side of this the cartilages of Wrisberg. Thus, according to Stuart, closure of the larynx is effected chiefly by the pulling of the posterior boundaries of its orifice forwards, and not, as often described, by the movement of its anterior boundary, the epiglottis, backwards.

The muscles which are actively involved in this closure are the external thyro-arytenoid and arytenoid, and the ary-epiglottidean and the lateral crico-arytenoid muscles. The external thyro-arytenoid muscle, which runs from the thyroid cartilage in front to the outer surface of the arytenoid cartilage behind, pulls the latter forcibly forwards and rotates it inwards. It is therefore, with the arytenoideus muscle, the chief factor in the closure of the larynx. The function of the ary-epiglottidean muscles is to make tense the folds of mucous membrane which bound the entrance on each side. The lateral crico-arytenoids aid the thyro-arytenoids by pulling the bases of the arytenoid cartilages forwards and rotating them inwards.

By the action of these muscles, both the true and false vocal cords are approximated. This closure of the glottis is not, however, essential for the carrying out of deglutition. Longet showed that swallowing was performed without passage of food into the windpipe, even if the vocal cords were held apart by passing a pair of forceps up between them from an opening in the trachea.

The approximation of the posterior to the anterior boundary of the laryngeal opening is only rendered possible by the elevation of the whole larynx under the hyoid bone, which is chiefly effected by the thyro-hyoid muscles. Hence the act of deglutition is rendered impossible by fixation of the larynx.

Thus the openings into the posterior nares and into the larynx being both closed, and the entrance from the pharynx into the œsophagus widened by the pulling forward of the arytenoid cartilages and the contraction of the palato- and stylo-pharyngeus muscles, the bolus is shot rapidly past these openings into the region of the middle and inferior constrictors of the pharynx. If it is large, it is seized by these muscles and thrust down into the œsophagus by the successive contraction of their fibres from above downwards. With a smaller bolus, however, or when liquids are swallowed, the movement of the back part of the tongue is sufficient to propel the substance past the constrictors and through the œsophagus to its lower end, or even through the cardiac orifice into the stomach, as shown by Kronecker and Meltzer.¹ In such cases, the rapid passage of the bolus is followed by a contraction of the constrictors and by a peristaltic contraction of the œsophagus, which

¹ *Arch. f. Physiol.*, Leipzig, 1880, S. 446; and 1883, Suppl., S. 328.

serve merely to drive any particles of food that may be still adherent to the walls of the tube, down into the stomach (Figs. 181-184).

This view, which was first put forward by Kronecker and Falck,¹ is supported by the fact that in cases where corrosive fluids have been swallowed, the œsophagus has been attacked only at three points, where it is narrowed, and not along its whole length, as would be the case if the fluid were propelled gradually down the tube by the peristaltic contraction of its walls.

The authors showed, further, that the act of swallowing causes an elevation of pressure of 20 cms. water in the œsophagus, and regard this elevation of pressure, due (chiefly) to the contraction of the mylohyoid muscles, as the active force in the onward propulsion of the food.

The movement of the bolus through the fauces and pharynx is carried out entirely by striated muscles. In the œsophagus the bolus, if too large to be shot through the lax tube, is carried down more slowly by the peristaltic contraction of its walls. These walls, in the cervical part

of the œsophagus, are composed of striated muscle. In the upper

FIG. 181.

FIG. 182.

FIG. 183.

FIGS. 181-183.—Curves obtained during swallowing by placing two rubber balloons, one (the upper curve) in the pharynx, the other (the lower curve) in the œsophagus. In Fig. 181 the second balloon was 4 cms.; in Fig. 182, 12 cms.; and in Fig. 183, 16 cms. from the upper end of the œsophagus. In each curve it will be noticed that the excursion of the upper lever (due to passage of the swallowed fluid and the consequent rise of pressure), and then, after an interval of time varying with the distance of the second from the first balloon, by another rise of the œsophageal lever due to the contraction of the wall of that tube, *i. e.* to the advancing peristaltic waves.—Kronecker and Meltzer.

¹ *Arch. f. Physiol.*, Leipzig, 1880, S. 296, 446.

part of the thorax, striated and unstriated muscular fibres are associated together, while the lower part consists entirely of unstriated muscle. Corresponding to these differences in structure, Kronecker and Meltzer have found differences in the duration and rapidity of propagation of the contraction wave in each part. Thus, in the first section (cervical) of the œsophagus, which is about 6 cms. long, the contraction wave lasts 2.0 to 2.5 seconds. From the beginning of this contraction to the commencement of the contraction of the second part, an interval of 1.8 seconds elapses. The contraction of the second part, which is about 10 cms. long, lasts 6 to 7 seconds. The contraction of the third part, the length of which these observers could not determine accurately, lasts about 9 to 10 seconds, and commences 3 seconds after that of the second part. Each of these parts seems to contract almost simultaneously throughout its whole length. Kronecker and Meltzer¹ consider that in all probability the contraction travels from one end of the section to the other, but that the rapidity of propagation of the wave was too rapid to be accurately determined by the means at their disposal.

When a second act of deglutition succeeds the first within a sufficiently short interval, the nervous changes which originate the

FIG. 184.—Curve obtained by placing a balloon in the œsophagus 12 cms. from its upper end. In this case it is seen that a series of swallowing movements is only followed by *one* contraction, showing that the œsophageal walls are inhibited during the passage of the swallowed fluid.—Kronecker and Meltzer.

pharyngeal movements of the second act, or rather the second act itself, causes a reflex inhibition of the œsophagus-contraction, which would otherwise follow the first act. The œsophagus thus remains in a lax condition, and allows of the free rapid shooting of the food downwards until the movements of deglutition have come to an end, when the peristaltic contraction of the œsophagus occurs and sweeps all remaining adherent particles of food into the stomach.

Under normal circumstances the circular fibres of the lower end of the œsophagus, which form a ring round the cardiac orifice of the stomach, are in a state of tonic contraction, in order to prevent the regurgitation of food from the stomach. When one mouthful of food or liquid is swallowed, it may be either squirted directly through the opening into the stomach, or it may remain at the lower end of the œsophagus until the following peristaltic wave forces it through the orifice. When several acts of deglutition succeed one another, the cardiac sphincter seems to share in the inhibition of the œsophageal walls, so that it offers no resistance to the direct propulsion of food from the mouth into the stomach.

¹ *Arch. f. Physiol.*, Leipzig, 1883, Suppl., S. 328.

The following table is intended to show the time relations of the contractions of the chief muscles engaged in deglutition, as determined by Kronecker and Meltzer, and by Marekwald:—

Time from Commencement.	Interval.	Muscle Movement.	Duration of Contraction.
...	Mylohyoid.	0·6 seconds.
... ..	·03 seconds.	Respiration of swallowing. ¹
... ..	·07 ,,	Elevation of larynx.	0·8 ,,
·3 seconds	·2 ,,	Constrictors of pharynx.	1·0 to 2·0 seconds.
... ..	·9 ,,	First section of œsophagus.	2·0 to 2·5 ,,
3·0 ,,	1·8 ,,	Second section of œsophagus.	6·0 to 7·0 ,,
6·0 ,,	3·0 ,,	Third section of œsophagus.	About 10 ,,

¹ See p. 314.

Thus a bolus of food, if carried down entirely by the peristaltic contractions of the gullet, reaches the stomach six seconds after leaving the mouth. As a rule, on auscultating over the lower end of the œsophagus, two sounds are heard to follow one swallowing action. The first sound is coincident with the passage of the bolus, and occurs immediately after this has left the mouth. A second sound is then heard about six seconds later, as the peristaltic contraction reaches the cardiac orifice and forces through it food particles and bubbles of air which had adhered to the walls of the tube during the passage of the bolus.

The process of deglutition has been lately studied by Cannon and Moser¹ in unanæsthetised animals, by the use of the Röntgen rays, using liquid or semiliquid food, to which the opaque subnitrate of bismuth had been added. For a solid bolus bismuth was administered in gelatin capsules. These observers find that the rapid injection or squirting of the food, by the action of the mylohyoids, only occurs in man and the horse, and then only in the case of liquid food. With semiliquid or solid food the greater part of the act is carried out by the peristaltic contractions of the œsophagus in all the animals investigated (fowl, cat, dog, horse, and man). Thus in the dog the total time for the descent of a bolus is from four to five seconds. The food is always propelled rapidly in the upper œsophagus and moves more slowly below. This rapid movement is frequently continued further with liquid food. No distinct pause was observed when the movement of the bolus changed from the rapid to the slower rate.

The nervous mechanism of deglutition.—Although swallowing can be started by the will, and is therefore to that extent voluntary, as a whole it is a reflex act, and cannot take place unless some stimulus be applied to the fauces. When we swallow voluntarily we supply the necessary initial stimulus, either by touching the fauces with the tongue

¹ *Am. Journ. Physiol.*, Boston, 1898, vol. i. p. 435.

itself, or by forcing a certain amount of saliva into the fauces. The afferent impulses for this reflex act travel by branches of the second division of the fifth, and by the glosso-pharyngeal nerve and the pharyngeal branches of the superior laryngeal nerve. By excitation of the latter nerve, it is possible to evoke either a single act or a whole series of acts of deglutition.

The centre of deglutition lies in the medulla oblongata, in the neighbourhood of the nucleus of the vagus nerve. According to Marckwald,¹ it can be destroyed without injuring the adjacent respiratory centre. After such destruction, stimulation of the superior laryngeal nerve causes total relaxation of the diaphragm, unaccompanied by the small twitches (respirations of swallowing) which accompany or precede the normal acts of deglutition.

The efferent impulses from the centre pass by the hypoglossal nerve to the muscles of the tongue, by the fifth to the mylohyoid muscle, by the glosso-pharyngeal, the pharyngeal branches of the vagus, the fifth, and the spinal accessory nerves, to the muscles of the fauces and pharynx. The closure of the larynx is effected by impulses which travel through the superior and inferior laryngeal branches of the vagus.

The distribution of nerves to the œsophagus varies in different animals. In man the upper part of the œsophagus receives branches from the recurrent laryngeals, the lower part from the pulmonary and œsophageal plexuses of the vagus. In the rabbit and also in the guinea-pig some of the fibres to the upper portion of the œsophagus run in a distinct nerve, which rises from the trunk of the vagus and passes upward to its destination.² In the horse and dog the innervation of the lower segment of the œsophagus resembles that in man. Most of the fibres to the upper segment are derived, however, from a small branch of the pharyngeal nerve, which travels alongside of the œsophagus down into the chest, sending numerous branches into the muscular wall on its way.

The effects of section of the œsophageal nerves vary in the different segments of this tube. Whereas the upper part becomes permanently relaxed, the lower segment, including the cardiac sphincter, enters into a condition of tonic contraction, which may last several days. These results suggest that, although the contraction of the œsophagus resembles in many particulars the autochthonous, peristaltic contractions of other muscular tubes, such as the intestine and ureter, it will probably differ from these in being dependent on nervous influences from outside. As a matter of fact, Mosso³ has shown that the propagation of contraction down the œsophagus is a reflex act, and requires the integrity of the nervous connections of the œsophagus with the centre of deglutition. If the œsophagus be ligatured or cut across, waves of contraction, originated from the pharynx, pass across the lesion from one separated end to the other, as before. On the other hand, section of the nerves going to the œsophagus abolishes its peristaltic contractions. The peristaltic contraction of the œsophagus, therefore, like that of the pharynx, is a reflex started from the stimula-

³ *Untersuch. z. Naturl. d. Mensch. u. d. Thiere*, 1876, Bd. xi. S. 331.

tion of the palate and fauces. It is interesting to note that it can only be inaugurated in this way, and that stimulation applied to the mucous surface of the œsophageal tube is without effect and produces no contraction.

There is an important interdependence between the functions of respiration and deglutition. The small inspiratory movement depends on intra-bulbar connections between the two centres.¹ More important, however, is the inhibition of respiration which occurs during swallowing. Without this inhibition, food particles might be drawn by the ingoing current of air into the bronchi and lungs, and would there set up inflammation. This inhibition of respiration is a reflex act, and is carried out by the intermediation of the glosso-pharyngeal nerve. As has been already mentioned, in dealing with the respiratory movements,² excitation of the central end of the glosso-pharyngeal nerve at once causes a cessation of respiration, in whatever phase it may happen to be. This cessation lasts for five or six seconds, *i.e.* a sufficient length of time for a whole series of acts of deglutition. Respiration then recommences, and the inhibition cannot be prolonged by continuing the stimulation of the glosso-pharyngeal nerve.

MOVEMENTS OF THE STOMACH.

The movements of the stomach have a twofold purpose. In the first place, they serve to churn up the ingesta with the gastric juice, and, in the second place, to propel the semi-digested chyme onwards into the duodenum and intestines.

The muscular coat of the stomach consists of three layers—an outer longitudinal layer, continuous with the longitudinal fibres of the œsophagus; a middle or circular; and an inner incomplete layer of oblique fibres, passing from the left of the cardiac orifice, and merging at the pyloric end in the middle or circular coat.

The pyloric part of the stomach is divided by a special thickening of the circular fibres, the “transverse band”³ or “sphincter antri pylorici,”⁴ into two parts, the *antrum*, between the band and the pylorus, and the pre-antral portion or middle region of the stomach.

If the stomach be examined in a fasting animal, care being taken to avoid stimulation by cooling or drying on exposure to the air, it will be found to be in a state of rest in slight tonic contraction. Owing to this contraction, the cavity of the stomach is small, the walls are fallen together, and the mucous membrane, which cannot retract with the muscular coat, is thrown into rugæ. When food is taken, the walls of the stomach relax in proportion to the distension of its cavity, each act of swallowing being, moreover, accompanied by a special dilatation of the cardiac orifice, carried out mainly by the radiating longitudinal fibres in the outer muscular coat. Shortly after the taking of food irregular contractions of the gastric wall begin, and these become more active as digestion advances. According to Beaumont’s observations on Alexis St. Martin,⁵ these movements are of such a character as to pro-

⁵ Beaumont, *op. cit.*

duce a movement of the gastric contents, from the cardia along the greater curvature to the pylorus, and then back again along the lesser curvature. These movements, together with subsidiary currents which are set up, effect a thorough mixing of food and gastric juice. After a time, which depends on the nature of the food taken, the stomach movements acquire more of the characters of a peristaltic contraction. We may observe a deep groove, produced by the contraction of the circular muscles of the stomach, midway between pylorus and cardia (the "transverse band"). This groove or constriction travels down towards the pylorus, so tending to heap up the food, and to press it against the pyloric opening. Finally, on the arrival of one of these waves at the pylorus, a partial relaxation of this opening is brought about, partly by inhibition of the circular sphincter pylori, partly by contraction of the longitudinal muscular fibres. In consequence, the fluid portion of the food in contact with the opening is pressed through this opening into the duodenum. At the beginning of digestion only fluids can pass from stomach into duodenum. As digestion advances, the propulsive contractions of the stomach, especially at its pyloric end, become more and more marked, and the relaxation of the pyloric sphincter more complete, so that, towards the end of digestion, undigested pieces of food can be forced through, and the stomach may empty itself entirely.

The description of the stomach movements given by Hofmeister and Schütz, is very similar to that of Beaumont. These observers studied the movements of the excised stomach, placed in a warm moist chamber. They describe a typical movement as consisting of two phases. At first a constriction of the circular fibres starts near the cardia and passes towards the pylorus, gradually increasing in strength until it reaches the region in front of the antrum ("preantral constriction"). The transverse band now contracts highly, while the preantral constriction is relaxing, shutting off the antrum from the rest of the stomach, and this is followed by a general contraction of the muscles of the antrum.

Cannon,¹ who has investigated the movements by observing the stomach after administration of bismuth, by means of the Röntgen rays, has shown that the movements observed by Beaumont and the two last-mentioned physiologists were hardly physiological, and were produced by the abnormal character of the irritant (thermometer tube in Beaumont's case), or other abnormal conditions of the stomach.

According to Cannon (whose results confirm those of Rossbach,² obtained by direct observation of the exposed viscus in dogs), movements of the stomach commence a few minutes after taking food, and consist of slight constrictions, which appear near the middle of the stomach, and course slowly towards the pyloric end. As digestion goes on, the antrum elongates, and the contractions grow stronger, but do not entirely divide the cavity until the stomach is nearly empty. A wave takes about 30 seconds (in the cat) to move from the middle of the stomach to the pylorus. The waves recur regularly at intervals of 10 seconds, so that when one wave is beginning several others are running in order before it, causing the stomach to be bulged out between rings of constriction. The fundus during this time acts as a reservoir for the food, and merely squeezes its contents gradually into the pyloric part. Since no churning movements take place in the fundus, salivary digestion can go on in this region for a considerable time, before it is stopped by the acid gastric juice.

¹ *Am. Journ. Physiol.*, Boston, 1898, vol. i. p. 359.

² *Deutsches Arch. f. klin. Med.*, Leipzig, 1896, Bd. xlvi. S. 296.

The pylorus does not open at the approach of every wave, but only at irregular intervals. The arrival of a hard morsel inhibits the opening of the sphincter, and thus interferes with the passage of the already digested food. Thus the motor functions of the stomach, which result in the mixing, trituration, and expulsion of the food, are carried out almost entirely by the pyloric half of the stomach.

von Mering¹ has shown that when fluids alone are taken by the mouth, their first discharge into the duodenum may occur within ten minutes after the time at which they reach the stomach, and the stomach may completely empty itself within twenty to twenty-five minutes after the taking of fluid. This observer also pointed out that a state of repletion of the small intestines reflexly slows the evacuation of the stomach. The same effect may be produced by psychical excitement.

With regard to the causation of the gastric movements we know very little. The stomach can be separated from all its nervous connections, and indeed cut out of the body, without abolishing the contractions. These, therefore, must have their origin in the walls of the stomach itself. A number of small ganglia are to be found in the walls of this organ, and have been regarded as local centres for the production and co-ordination of the contractions.² It is more probable, however, that here, as in the heart, the contraction wave is originated and propagated in the muscular tissue itself. That the stimulus to contraction is not in the main afforded by the distension of the stomach, is shown by the fact that the movements become more vigorous as digestion proceeds, and as the stomach empties more of its contents into the duodenum. It has been thought, therefore, that the chief exciting cause of the movements is the acidity of the gastric contents, which increases steadily with the progress of digestion.

Although contractions of the stomach can be produced locally, this local reaction is aided by reflex impulses carried out through the intermediation of the central nervous system. The stomach is supplied with nerves from two sources, namely, from the vagi, and from the dorsal region of the spinal cord through the sympathetic chain and splanchnics. The exact nature of the impulses carried by these nerves cannot yet be regarded as finally settled. All observers, however, agree in describing the vagus as a motor nerve for the stomach. According to S. Mayer,³ the results of exciting the peripheral end of the vagus in the neck may be one of three—(1) A contraction of the cardiac end, which gradually advances towards the pylorus; (2) the groove present in the region of the transverse band deepens, and similar constrictions appear in other parts of the stomach; (3) the whole muscular wall enters into a state of tonic contraction, which comes on slowly and lasts a considerable time.

More or less similar results have been obtained by Longet,⁴ Goltz,⁵ v. Braam Houckgeest,⁶ Openchowski,⁷ Morat,⁸ and others. According to v. Braam Houckgeest and Morat, the motor effects are obtained more

certainly and promptly if the animal be in state of digestion, or if the splanchnic nerves be previously divided.

Langley¹ has recently shown that the vagus conveys both motor and inhibitory impulses to the stomach. If curari be given, stimulation of the vagus causes, as a rule, *contraction* of the œsophagus and cardiac end of the stomach. After administration of atropin, stimulation of the vagus causes *relaxation* of the cardiac end, followed, on cessation of the stimulus, by a strong contraction. At the pyloric opening, the general result of vagal stimulation is contraction, though occasionally dilatation of the orifice may be observed.

According to Schiff, motor fibres also reach the stomach from the sympathetic chain, by way of the splanchnics. Morat also observed one case in which the rhythmical contractions of the stomach (and intestine) were augmented on stimulation of the splanchnics. As a rule, however, excitation of these nerves caused diminution of the tonus, as well as of the rhythmic contractions of the stomach.

The movements of the stomach, however excited, may be inhibited reflexly by stimulation of the central end of the vagus, or indeed of any sensory nerve. Cannon noticed that any mental disturbance (anger, pain) of the cats under investigation, at once checked contractions of the stomach, which had been induced by feeding the animal.

According to Head,² the sensory fibres to the stomach in man probably run in the sixth, seventh, eighth, and ninth dorsal nerve-roots, the cardiac end being especially associated with the sixth and seventh, and the pyloric end with the ninth roots.

Vomiting.—Under normal circumstances, the contractions of the stomach wall are directed solely to the mixing of the food with the gastric juice, and to the furtherance of the passage of chyme into the duodenum. If, however, irritating substances have been taken or the stomach over-distended, it is important that this organ should have some means of ridding itself of its contents, and this is mainly accomplished by the contraction of the abdominal muscles and diaphragm pressing against it. Vomiting is usually excited by the direct contact of irritants with the gastric mucous membrane, but it may be also caused by reflex irritation from other parts of the body, and especially of the alimentary tract, as is the case with the vomiting caused by acute intestinal obstruction. It may also occur in the colic produced by the passage of a renal or biliary calculus, or from inflammation of the peritoneum or any of the abdominal viscera. Besides this reflex causation, vomiting may be brought about directly by events occurring in the central nervous system. Thus it may be excited by emotions or smells, and is a very frequent symptom of diseases of the brain, such as tumour and inflammation. Sea-sickness, although complex in origin, is probably chiefly determined by reflex stimulation originating in the semicircular canals.

Vomiting is generally preceded by a feeling of nausea, which is accompanied by copious salivation. The saliva which is swallowed carries down with it a quantity of air, which distends the stomach and may assist in the subsequent dilatation of the cardiac orifice. Retching movements then occur. These consist essentially in deep inspiratory efforts, attended with closure of the glottis. Since no air can be drawn

¹ *Journ. Physiol.*, Cambridge and London, 1898, vol. xxiii. p. 407.

² *Brain*, London, 1893, vol. xvi. p. 66.

into the lungs, the contraction of the diaphragm drags in the lower ribs and presses on the stomach, and at the same time air is drawn into the pharynx and into the œsophagus. After a few ineffectual efforts of this description, a sudden, violent expiratory contraction of the abdominal muscles takes place, accompanied by a contraction of the diaphragm. The stomach is thus compressed between the abdominal muscles and diaphragm. Immediately before this effort the cardiac orifice of the stomach is brought close up to the opening in the diaphragm by a contraction of the longitudinal fibres at the lower end of the œsophagus, and is dilated by the contraction of these fibres and the relaxation of its sphincter. Thus a way is opened for the escape of the contents of the stomach, and these are pressed out by the contraction of the abdominal muscles, and to some extent by that of the muscular wall of the stomach itself, and are ejected forcibly up the œsophagus and out through the mouth. At the same time the soft palate is raised, and the posterior pillars of the fauces approximated, so as to shut off, though in many cases ineffectually, the passage through the nose. A strong expiratory effort is made immediately after the passage of the gastric contents, in order to prevent any remnants of the vomit passing into the larynx.

If the movements of the stomach be observed, either by opening the abdomen (Openchowski), or by means of the Röntgen rays (Cannon) after the administration of apomorphine, the first change noticed is an extreme relaxation of the cardiac end. Then a deep constriction starts about 3 cms. below the cardia, and, growing in strength, moves towards the pylorus. On reaching the transverse band, this contracts tightly, and a wave of contraction passes over the antrum. This is followed by ten or twelve other waves, and then the firm contraction at the beginning of the antrum divides the stomach into two parts, one tightly contracted, and the other, the fundus, relaxed and flaccid. A sudden contraction of the diaphragm and abdominal muscles, accompanied by the opening of the cardiac orifice, now forces the gastric contents into and through the œsophagus.

During vomiting there is generally a discharge of bile from the gall bladder into the duodenum. A little of this may be pressed through the closed pyloric orifice, so that, after the emptying of the stomach, the later efforts of vomiting may bring up a little bile-stained mucus.

It was long a subject of discussion whether the contraction of the stomach or that of the abdominal wall was the more essential factor in the act of vomiting. Magendie¹ thought he had decided the question when he pointed out that vomiting might be produced by the injection of tartar emetic into the blood, even after the stomach had been replaced by a bladder. It was shown subsequently, however, that this was only true if the bladder were tied into the lower end of the œsophagus. If the cardiac orifice be left intact, and merely the greater part of the stomach replaced by the bladder, vomiting cannot be brought about.² This fact proves that there are two necessary factors in vomiting, namely, active dilatation of the cardiac orifice and compression of the stomach. So far as the latter event is concerned, it is probable that Magendie was correct, since, in a curarised animal, it is impossible to

¹ "Mémoire sur le vomissement," Paris, 1813. Cited by S. Mayer.

² Tanbini Omodei, *Ann. univ. di med. e chir.*, Milano, 1824, (S. Mayer); Schiff, *Untersuch. z. Naturl. d. Mensch. u. d. Thiere*, 1867, Bd. x. S. 353.

excite vomiting, though, after paralysis of the abdominal muscles alone, the expulsion of the gastric contents can be still brought about by the agency of the diaphragm. The intrinsic contraction of the stomach itself, though unable to empty this organ, as in vomiting, can cause the escape of gas or of small quantities of food or of fluid, as occurs in pyrosis, or water-brash.

Since vomiting involves the co-ordinated activity of a number of muscles, voluntary as well as involuntary, it is evident that the proper carrying out of this process must depend on the integrity of the central nervous system. Vomiting is generally said to occur through the agency of a vomiting centre in the medulla oblongata. This has been thought to be closely related in situation to the respiratory centre;¹ and it is probable that, like the latter, it is intimately related to the central connections of the afferent and efferent fibres of the vagus.

Vomiting can be excited reflexly in many ways. The most usual stimulus is one affecting the stomach. Both in this case, and in all other cases when the exciting cause is some affection of the abdominal viscera, the afferent impulses are probably carried by the vagi. Vomiting can also be excited reflexly through the olfactory, the fifth and glosso-pharyngeal, or the auditory nerve, or directly from the higher parts of the brain. The efferent channels of the act are:—The vagus, to stomach, cardiac sphincter, œsophagus, larynx; through chorda tympani, and probably tympanic branch of glosso-pharyngeal to salivary glands; through phrenics and various spinal nerves to respiratory muscles.

Emetics, or substances which excite vomiting, may act either reflexly from the stomach (*e.g.* mustard and water), or directly on the centre (apomorphin), or in both ways, as in the case of tartar emetic.

MOVEMENTS OF THE INTESTINES.

After the chyme has arrived in the duodenum, it has to be carried slowly from one end of the intestine to the other, in order that the digestive juices poured into different parts of the gut may have time to complete their action on the food-stuffs, and that all assimilable constituents may be absorbed. Thus only the indigestible portions of food, together with a certain amount of epithelial *débris* and mucus, arrive at the lower end, to be extruded in the act of defæcation.

The investigation of the mechanism of intestinal movements is beset with many difficulties, so that we still find a considerable divergence among various authors of repute, even as to the character of the movements which are the subject of investigation.

The following are the chief factors which contribute to this divergence of results, and which must be taken into account in working on the intestinal movements, namely, the varying reactions of the intestines in different animals, the disturbing action of drugs and anæsthetics, but, above all, the fact that each segment of the intestines is subject to augmentor and inhibitory influences, partly originating in other portions of the gut and transmitted along the walls of the intestine, partly

¹ Grimm, *Arch. f. d. ges. Physiol.*, Bonn, 1871, Bd. iv. S. 205. The identity has been contested by Harnack on pharmacological grounds; *Arch. f. exper. Path. u. Pharmacol.*, Leipzig, 1874, Bd. ii. S. 154.

originating in the intestine or elsewhere and transmitted reflexly through the central nervous system.

As is well known, the muscular wall of the small intestine consists of two layers of unstriated muscular fibres separated by a thin layer of connective tissue, in which is embedded a rich plexus of ganglion cells and non-medullated nerve fibres, known as Auerbach's plexus. Fine fibres from this plexus form networks round the individual fibres of the two layers. These layers are separated from the mucous membrane by the submucosa, a tough, fibrous membrane which, according to Mall,¹ determines the limit of distension of the intestine. The two muscular coats are so closely bound together, that it is difficult, by inspection, to determine whether any given change of form of the intestine is caused by a relaxation of one coat or by a contraction of the other coat. It is possible, however, to record the contractions of the two coats independently; when it is found that they nearly always contract simultaneously, the function of the longitudinal coat being to aid the contraction of the circular, and not to assist in the relaxation of the intestine.

The contraction of the longitudinal or circular coats may be conveniently registered by means of the enterograph (Fig. 185).

In a brass plate *aa*, two steel needles, *b* and *c*, are fixed in a slot; *b* can be shifted nearer to or farther from *c* by loosening its fixing screw; *c* is

FIG. 185.

prolonged through the slot, and revolves as a lever round the axis *dd*. The upper end *c'* is fastened by a thread to the disc on the rubber of the tambour *e*, which communicates by a tube *f*, with a piston recorder. The lower ends of *b* and *c* are pierced with holes. Through these holes pass fine threads, which are carried by a needle through the outer layers of the intestinal wall, and fastened. The muscle fibres running from *b* to *c* can only contract by pulling *c* towards *b*. This causes a movement of the upper end of *c* in the opposite direction, and a consequent pull on the membrane of the tambour, which is registered by the piston recorder. The distance of *e* from *c'* and the tension on the muscle fibres between *b* and *c* can be regulated by means of the screw *x*, or roughly by moving the tambour in the slot *z*.

The contractions of the circular coat alone can be registered by introducing an indiarubber bulla, which is slightly distended with air or water, into the interior of the intestine through an opening in the free border, and connecting

¹ *Johns Hopkins Hosp. Rep.*, Baltimore, 1896, vol. i. p. 37.

the bulla with a recording tambour. Those of the longitudinal coat alone can be registered by an ingenious contrivance devised by New,¹ consisting of two glass tubes sliding the one within the other, so arranged that contractions of the longitudinal coat diminish the common cavity and raise the lever of a recording tambour, while contractions of the circular coat are unable to affect it.

Nature of the intestinal movements.—In order to avoid the disturbing effects of drying and cooling on the intestines, it is best to open the abdomen under a bath of warm normal saline (von Braam Houckgeest).² The appearance of the intestines will vary according to the state of the animal. If it has not received food for two or three days, the intestines will be seen to be anæmic, motionless, and in a state of tonic contraction. After food, however, the intestines are hyperæmic, relaxed (*i.e.* thicker and shorter), and the various loops present the swaying movements which were described by Ludwig³ as *Pendelbewegungen*. Very much the same appearance will be observed also in

fasting animals, if both splanchnic nerves have been previously divided (Fig. 186).

FIG. 186.—Rhythmical contractions of circular coat of small intestine. A rubber balloon distended with air was placed in lumen of gut, and connected with a piston recorder. Time marking=six-second intervals. Contraction causes upward movement of lever.

1. The swaying movements have been generally regarded as occasioned by contractions of the longitudinal muscles, since the translatory movements of the loops are more apparent than the changes in their calibre. If, however, we record the movements of the intestine by connecting its interior to a piston recorder, or by inserting a small balloon, which is connected with a tambour, into the lumen of the gut, we find

in most cases that the wall is undergoing a series of rhythmical contractions, repeated regularly ten to thirteen times in the minute, so that each individual contraction lasts from $5\frac{1}{2}$ to 6 seconds. This intestinal rhythm is remarkably independent of external conditions, although the amplitude of the contractions may be augmented or diminished. Thus, distension of the intestine or of a rubber capsule in its interior causes increased height of contraction, or may evoke contractions, if these were previously absent. The contractions are better marked in a fed animal, or when the intestines are hyperæmic. They may be diminished or abolished by shutting off the arterial blood supply to the intestines. They are propagated rapidly down the intestine (2 to 5 cms. per second), but may originate at any point of the gut, so that an exact determination of their rate of propagation is very difficult. They are as well marked in isolated loops as in those which retain their functional continuity with the rest of the intestine. Both coats of the intestine act together in these contractions. In the normal intestine these waves

¹ "Proc. Physiol. Soc.," March 18, 1899, *Journ. Physiol.*, Cambridge and London, vol. xxiv.

² *Arch. f. d. ges. Physiol.*, Bonn, 1872, Bd. vi. S. 266.

³ "Lehrbuch d. Physiologie," Aufl. 2, Bd. ii. S. 615.

nearly always travel from above downwards. After paralysis of the local nervous mechanism (Auerbach's plexus) by nicotin or cocain, the waves are still present in undiminished force, but now travel indifferently in either direction. They therefore originate in the muscle fibres, and probably are transmitted from one muscle cell to the next, *i.e.* the contractions are *myogenic* and *myodromic*.

The post-mortem "vermicular" contraction described by Engelmann in the rabbit is probably merely an exaggerated wave of the type just described, since it may be excited by local stimulation, and travels equally well in either direction at a rate of 3 to 4 cms. per second.

Mall, however, would place this form of contraction in a class by itself, and distinguishes, therefore, three types of contraction, namely, pendular or rhythmic, vermicular, and peristaltic.

2. True physiological peristalsis is a slow process. According to Cash,¹ it takes in the cat about an hour and a half to travel from one end of the intestine to the other. On observing the intestines in an animal, after division of the splanchnic nerves, such waves of constriction may be seen passing slowly down the gut, or, if absent, may be excited by mechanical stimulation. They may be studied by introducing a bolus of wax, or cotton-wool and vaseline, into the intestine at some point. Almost immediately it will be noticed that the segment of intestine just above the bolus enters into a strong tonic contraction. At the same time the intestine for a considerable length below the bolus is inhibited and relaxed, as may be shown by recording the contractions of either muscular coat by means of the enterograph. In consequence of this contraction above and relaxation below, the bolus moves onwards down the intestine, followed up and driven by the advancing ring of constriction. If the intestine be less irritable, the introduction of the bolus may cause merely an augmentation of the rhythmic contractions of the segment above, and the inhibition below may be only slightly marked. In this case the movement of the bolus still occurs, but is incomparably slower than under the conditions just described. It may be quickened if we increase the stimulus due to the presence of the bolus by pinching the gut at this point, each pinch being followed by a temporary inhibition of the gut below, and a corresponding acceleration of the movement of the bolus. The progression of the bolus down the intestine depends, therefore, on two events, which are excited by the mere presence of the bolus, namely, augmentation of contraction above, and inhibition of contraction below, the bolus. This double effect is the characteristic response of the intestine to local stimulation. If we record the contractions at any point of the gut, it will be found that a pinch applied from 1 inch to 12 inches above the recorded spot gives an instant inhibition of the rhythmic contractions; whereas a pinch applied from $\frac{1}{2}$ inch to 3 inches below produces, after a varying latent period, an augmentation of the contractions.

It is evident that the true peristaltic contraction is a co-ordinated reflex, carried out by the local nervous centres in the wall of the gut. By means of the injection of nicotin or the local application of cocain, we can paralyse the nerve centres, leaving the muscle fibres intact. We then find that, although the rhythmic contractions are even better

¹ *Proc. Roy. Soc. London*, vols. xl. and xli.

marked than before, running as waves up or down the gut with a rapidity of 2-4 cms. per second, they are totally unaffected by the application of a strong stimulus to the intestine, either above or below the segment which is under observation. Since the double effect of local stimulation, augmentation above and inhibition below, is wanting, the power of the intestine to move its contents in any definite direction is also gone. A bolus placed in any part of the paralysed loop remains absolutely motionless.

Nothnagel¹ pointed out that the application of a crystal of sodium chloride to the outer surface of the intestine causes in the rabbit and cat a ring of constriction, not at the stimulated point, but immediately above it. He rightly refers this effect to the stimulation of Auerbach's plexus, and contrasts it with that produced by potassium salts, which excite the muscle fibres directly, and therefore cause a ring of constriction at the stimulated spot. This observer also noticed the inhibition in front of an advancing wave of constriction, which we have shown to be of so great importance for the normal progress of the intestinal contents.

The fact that the true peristalsis, dependent on the activity of the local nerve centres, is only propagated in one direction, is well illustrated by an experiment carried out by Mall. If a segment of intestine be separated from the rest, and then resected in its former position, the functions of the bowel are carried out in a perfectly normal fashion. If, however, the resected loop be turned round, and connected with the cut ends of the remaining intestine, so that its previously lower end is connected with the upper part of the intestine, and its upper end is directed towards the rectum, the animal dies after a time of intestinal obstruction, due to the accumulation of indigestible material in the gut above the resected loop. These experiments show that the propulsive movements of any part of the intestine always occur in one direction.

We have, therefore, in the normal animal to take into account only two kinds of movement. The effect of the pendulum movement is to thoroughly mix the contents of the intestine and bring them in intimate contact with the mucous membrane of the wall. If an animal be fed with pills containing bismuth subnitrate, and observed under the Röntgen rays, it will be seen that the opaque pills move continually to and fro in the lumen of the intestine, their actual progress towards the colon being very small in comparison with the distance traversed (Grützner).² If the contents of the bowel are fluid, the mixing effects due to the pendulum movements may predominate to such an extent over the progression due to peristalsis, that foreign substances introduced with large enemata into the rectum may travel up past the ileo-cæcal valve into the small intestine, or in rare cases may even enter the stomach. Such a phenomenon has often been regarded as a proof of the existence of anti-peristalsis in the normal gut, but is probably sufficiently accounted for by the factors I have already mentioned.

Conditions of intestinal activity—Circulation.—The activity of the intestines may be modified or called into play by a number of local conditions. Chief among these are to be reckoned changes in the circulation. According to some observers, local anæmia, induced by

¹ "Physiologie u. Pathologie des Darmes," Berlin, 1884.

² *Arch. f. d. ges. Physiol.*, Bonn, 1898, Bd. lxxi. S. 492.

obstruction of the aorta, causes or strengthens the intestinal contractions (Schiff).¹ Nasse,² Mayer and v. Basch³ state that obstruction of the aorta arrests the movements for a time, but they return afterwards with increased vigour. Most observers (Betz,⁴ v. Braam Houckgeest,⁵ Mall), however, agree that anæmia inhibits all the movements of the intestines, a view which I can confirm. If the rhythmical contractions of the small intestines in the dog be recorded by the insertion of a small balloon communicating with a piston recorder, obstruction of the aorta in the chest causes an almost immediate cessation of the movements, which lasts as long as the obstruction is continued (up to 15 minutes). During this time the lever sinks slowly, *i.e.*, there is a gradual diminution of intestinal tonus. If, now, the blood be let in, the intestines contract immediately, once or twice, then pause, and then recommence their rhythmic movements, the contractions often increasing in force for a couple of minutes. This recommencement is associated with a considerable diminution in the diastolic volume of the intestines, *i.e.* increased tonus. Mall points out that ligation of the superior mesenteric artery causes strong contractions. In this case the determining cause appears to be, not the ischæmia, but the hæmorrhagic infarction which is produced by the ligation, so that the ultimate effect resembles in some extent that produced by venous obstruction.

It is probable that the varying statements on this subject depend on the frequent coincidence of anæmia and local asphyxia. The excitatory effect of the circulation of venous blood through the intestines has been frequently pointed out (Engelmann, v. Basch, etc.). In general asphyxia, one may indeed observe a preliminary inhibition of intestinal movements, but this is due to the splanchnic excitation, and consequent anæmia. I must confess, however, that I have often missed altogether an excitatory effect of asphyxia on the intestinal movements, and have only observed it in rabbits.

Influence of the nervous system on intestinal movements.—

The intestines receive a rich nerve supply from the spinal cord, by way of the sympathetic chain, great and small splanchnics (from first three lumbar ganglia), and solar and mesenteric plexuses. They also receive fibres from the vagus through the communicating branches from the anterior and posterior gastric plexuses to the solar plexus.

Vagus.—A number of authors have described the vagus as the motor nerves of the intestines. Thus stimulation of the vagus in the neck has been said to evoke active contractions of both stomach and intestines (Budge,⁶ Ludwig and Kupffer,⁷ Engelmann⁸). According to v. Braam Houckgeest,⁹ the vagus has no direct action on the intestines, the contractions being simply propagated from the stomach. Mayer¹⁰ states, however, that he has observed movements of the small and large intestines on stimulation of the vagus, even after ligation of the duodenum. There is no doubt that, in a number of cases, stimulation

¹⁰ Hermann's "Handbuch," Bd. v. (2).

of the vagus has no apparent effect on the intestines. Bunch¹ only observed an effect (inhibition) once in a large number of experiments, and hence denied that the vagus is to be regarded as a motor nerve. Jacobi² states that in the rabbit (after a few days' starvation) stimulation of the vagus is without effect, unless the splanchnics or the fibres which run from the suprarenals to the solar plexus be divided, and hence regards these fibres and the vagi as mutually antagonistic. In rabbits he describes the intestinal fibres as conveyed chiefly in one vagus, either right or left, while the other sends fibres chiefly to the stomach. These discordant results are due to the influence of various disturbing factors, among which may be mentioned the influence of anæsthetics and the exposure and handling of the intestines, with the circulatory changes thereby induced. More important than these, however, are the inhibitory influences to which every part of the intestine is subject, either originating in the higher parts of the gut, and travelling down the

FIG. 187.—Curves obtained by balloon method, to show effects of exciting peripheral end of right vagus. Upper curve=intestinal contractions, second curve=arterial blood pressure, third curve=excitation marker, lowest curve=time marking in six-second intervals. During the period shown on the excitation marker, the vagus was excited with strong induced currents (tenth excitation).

intestinal wall, or started by any sensory stimulation of the gut itself, and transmitted reflexly through the spinal cord. It is necessary, therefore, to cut out such influences as much as possible, by dividing both splanchnics and by avoiding any lesion of the intestine above the observed point, such as a ligature, which might set up descending inhibitory impulses. If these precautions are observed, stimulation of the vagus in the neck, after paralysis of the cardio-inhibitory fibres by means of atropin, will always produce an effect upon the intestinal movements; the effect, which may be little marked at first, but increases with each succeeding stimulation, is twofold—(1) An inhibition with very short latent period (less than one second), leading to the dropping of one or two beats, and (2) an augmentation of the rhythmic contractions, which gradually develops after the lapse of 10 to 30 seconds, and lasts for some length of time after the cessation of the stimulus. The

¹ *Journ. Physiol.*, Cambridge and London, 1897, vol. xxii. p. 357. (This contains an excellent summary of previous work on intestinal innervation, with full references.)

² *Arch. f. exper. Path. u. Pharmacol.*, Leipzig, 1892, Bd. xxix. S. 171.

vagus effect may come on simultaneously at all points of the small intestine, and is not abolished by ligaturing the second part of the duodenum or the upper part of the jejunum. The vagus fibres must therefore reach the intestine at all points, and do not run down from the stomach or duodenum between the two coats. The effects are better marked in those portions of the intestine which are already excited by the presence of a bolus or of a balloon for the purpose of recording the movements.

We must conclude, therefore, that the vagus contains two sets of fibres to the muscular coat of the intestine—one set inhibitory, with a very small latent period; the other set augmentor or motor, with a very long latent period. The action of the latter can be easily prevented by the presence of inhibitory influences acting on the intestine at any point.

Sympathetic.—The main sympathetic supply reaches the intestines by means of the splanchnic nerves. Pflüger¹ was the first to show

FIG. 188.—Curve showing inhibitory effect on contractions of small intestine, of stimulating peripheral end of right splanchnic nerve. The middle line shows the duration of stimulation. Time marking=six-second intervals. Balloon method.

that the stimulation of these nerves inhibits the intestinal movements. This observation has been confirmed by almost every subsequent observer, though there has been considerable discussion as to the exact mode in which the inhibitory action is brought about. It has been already pointed out that anæmia of the intestines checks the movements, and S. Mayer and v. Basch² ascribed the inhibitory action of the splanchnics to their vaso-constrictor influence on the intestines. According to v. Braam Houckgeest, this view is negatived by the following experiment. The intestines of a rabbit are exposed to the air until they become reddened by vasomotor paralysis. Stimulation of the splanchnics now has no effect on the blood vessels. The movements of the intestines, however, are inhibited, as in a normal animal. Jacobi states that the intestinal inhibitory fibres of the splanchnics take a

¹ "Ueber d. Hemmungsnervensystem f. d. peristaltischen Bewegungen d. Gedärme," Berlin, 1857.

² *Sitzungsb. d. k. Akad. d. Wissensch., math.-naturw. Cl.*, Wien, 1870, Bd. lxii., Abth. 2, S. 811.

different course from the vasomotor fibres, and that section of the nerves running from the suprarenals to the solar plexus annuls the inhibitory action of the splanchnics without affecting their vaso-constrictor effect.

Besides these inhibitory effects, various observers have recorded a motor effect on stimulating the splanchnics (Schiff, Ludwig and Kupffer, Bechterew and Mislawsky, Bunch). The last-named observer has given graphic records of intestinal movements, in which stimulation of the splanchnics caused in some animals augmentation, in others inhibition, of intestinal tone, and in some cases primary augmentation followed by inhibition; and concludes that nerve fibres of opposed function run in the splanchnics, and that the result obtained is due to the preponderating influence of one or other kind in the particular animal employed. I have myself never obtained any other effect than inhibition on excitation of these nerves.

In 1885, Ehrmann¹ put forward the view, that the intestines conformed to v. Basch's idea of "crossed innervation," and that the splanchnics were motor for the longitudinal but inhibitory for the circular coat. Courtade and Guyon,² on the other hand, found that the splanchnics produced contraction of the circular and inhibition of the longitudinal coat. Their method of recording the movements of the two coats does not appear to offer any criterion for distinguishing active from passive movements of the intestinal wall. These authors find that when the intestines are in an abnormal condition, Ehrmann's results may be obtained, and conclude, therefore, that the splanchnics contain motor and inhibitory fibres for both layers of muscle.

Observations by Bayliss and myself³ lend no support to the theory of crossed innervation in either of its versions. Recording the contractions of each coat by means of two enterographs, placed at right angles to one another, we have found that both coats contract synchronously, and that the contractions of both are inhibited on stimulating the peripheral end of either splanchnic nerve. So far as concerns the vagus, although the initial inhibitory effect is produced equally on both coats, the subsequent augmentation is confined almost entirely to the circular coat.

Bechterew and Mislawsky⁴ and Bunch have investigated the spinal nerve-roots which contribute fibres through the sympathetic to the intestines. According to Bunch, the nerve fibres pass to the splanchnic from the anterior roots, from the sixth thoracic to the second, third, fourth, or fifth, lumbar nerves, and have one cell station on their course (in the ganglia of the solar plexus).

Central and reflex influences.—According to Bechterew and Mislawsky, stimulation of the sigmoid convolution in dogs, or of the posterior corpora quadrigemina, influences the intestinal contractions; these being inhibited or augmented according to the exact localisation of the stimulus. Hence they locate "centres for intestinal movements" in these parts of the brain. Somewhat similar results were obtained by Bochefontaine,⁵ and by Pal and Bergrün.⁶

It is probable that the intestinal movements, like those of the stomach, may be inhibited or reinforced under the influence of

¹ *Med. Jahrb.*, Wien, 1885.

² *Arch. de physiol. norm. et path.*, Paris, 1897, tome ix.

³ *Journ. Physiol.*, Cambridge and London, 1899, vol. xxiv.

⁴ *Arch. f. Physiol.*, Leipzig, 1889, Suppl. S. 254.

⁶ *Med. Jahrb.*, Wien, 1888, Bd. viii. (quoted by Mislawsky).

emotions. They are certainly checked reflexly by painful stimulation of sensory nerves, especially if the stimulus affect the abdominal viscera. If the splanchnic nerves be intact, the application of an interrupted current to any point in the intestines causes a ring of constriction at the excited spot, with a simultaneous reflex inhibition of the spontaneous contractions, and tonus of all other parts of the small intestine. This inhibitory effect is almost abolished by section of both larger splanchnic nerves.

The innervation of the alimentary canal in the frog.—It has been stated by Steinach and Wiener,¹ that the alimentary canal of the frog receives its motor innervation chiefly from the *posterior* roots of the spinal nerves. The following table shows the distribution of these nerves to the various parts of the canal, according to these observers:—

Œsophagus . . .	Vagus, third and fourth posterior roots.
Stomach . . .	fourth and fifth (and sixth) posterior roots.
Anterior half of small intestine . . .	„ fifth and sixth . . .
Posterior half of small intestine . . .	„ sixth and seventh . . .
Rectum . . .	„ seventh and eighth . . .
	„ „ „ anterior roots. „

Stimulation of the anterior roots of all these nerves (with the exception of the seventh and eighth) had no effect on the intestines. Somewhat similar results had already been obtained by Waters,² without, however, distinguishing between the anterior and posterior roots. The following represents the results obtained by this observer:—

Fourth spinal nerve . . .	Contraction and vaso-constriction in œsophagus.
Fifth „ . . .	„ „ „ „ „ stomach.
Sixth „ . . .	Feeble „ contractions „ of intestines; vaso-constriction in the upper part of intestines.
Seventh „ . . .	Vaso-constriction in lower two-thirds of intestine; occasional peristalsis.
Eighth „ . . .	Vaso-constriction in rectum.

A repetition of these experiments by Horton Smith³ under Langley's directions failed to confirm them. Horton Smith regards the vagus as the sole motor nerve for the œsophagus, stomach, small intestine, and upper part of the large intestine, while the lower part of the large intestine and the rectum are supplied by the *anterior* roots of the ninth and tenth spinal nerves. The matter cannot be regarded as definitely settled.

DEFÆCATION.

As the products of digestion pass down the colon they lose their fluid consistence, in consequence of the absorption of water. The mass thus formed is carried down by the peristaltic contractions of the colon towards, and tends to accumulate in, the sigmoid flexure. That it is not driven down at once into the rectum is due largely to the fact that the contractions which start at the ileo-cæcal valve become less powerful on their way down the intestine, and do not as a rule affect the rectum. In healthy subjects, except just before defæcation, the rectum is empty, and the presence of fæces in this part of the bowel at once gives rise to discomfort, and to a desire to defæcate.

¹ *Arch. f. d. ges. Physiol.*, Bonn, 1895, Bd. lx.

² *Journ. Physiol.*, Cambridge and London, 1885, vol. vi.

³ *Ibid.*, 1897, vol. xxi. p. 101.

When the fæces have reached the rectum, the passing is still kept in check by the tonic contraction of the two sphincters of the anus, the internal sphincter composed of involuntary and the external sphincter of voluntary muscle. When the contents of the rectum are fluid, or when they are forced against the sphincters by strong peristaltic contractions of the lower bowel, the action of the sphincters may be voluntarily reinforced by active contraction of the levator ani muscles, which raise and compress the lower segment of the rectum or anal canal.

Defæcation is normally started by a voluntary act, although it may take place involuntarily, as is shown by the fact that it may occur in a dog whose spinal cord has been divided in the mid-dorsal region (Goltz).

The steps of normal defæcation are as follows:—The glottis being closed, a forcible expiratory contraction of the abdominal muscles takes place. The perineal muscles being relaxed at the same time, the lower part of the rectum is straightened, and a portion of the contents of the sigmoid flexure is forced down into the lower part of the rectum. The presence of a foreign body in this part of the rectum irritates the mucous membrane and excites reflexly the rest of the act. Strong peristaltic contractions take place along the whole of the descending colon, sigmoid flexure, and rectum, while both sphincters are relaxed, thus forcing out the contents of the bowel. The last section of the rectum at the close of the act is emptied by a forcible contraction of the levator ani and the other perineal muscles.

The carrying out of this reflex act is dependent on the integrity of a certain part of the lumbar spinal cord. If this centre be destroyed, the tonic contraction of the sphincter muscles disappears. Budge¹ found that stimulation of the spinal cord in the rabbit, at the level of the fourth lumbar vertebra, caused contraction of the rectum. He considered this portion of the cord to be a centre for the rectum, bladder, and vasa deferentia, and named it therefore the genito-spinal centre. His view that motor fibres left this centre to run to the rectum by the sacral nerves was confirmed later by Masius.² Nasse³ showed that, in addition to this supply from the sacral nerves, the rectum receives fibres from the lumbar nerves through the sympathetic chain and mesenteric plexus.

The nerve supply to the pelvic viscera has been recently the subject of careful investigation by Langley and Anderson.⁴ These authors come to the following conclusions with regard to the descending colon, rectum, and anus.

These parts of the alimentary canal receive fibres from two sources: an upper supply in the rabbit from the second, third, fourth, and fifth lumbar nerves; in the cat from the second, third, and fourth lumbar; and a lower supply from third and fourth sacral nerves in the rabbit, with some fibres either from the second sacral or first coccygeal nerve; and in the cat from the second and third sacral nerves, and sometimes also from the first sacral.

³ "Beitr. z. Physiol. der Darmbewegung," Leipzig, 1866 (quoted by Langley and Anderson).

⁴ *Journ. Physiol.*, Cambridge and London, 1895, vol. xviii. p. 67; 1895, vol. xix. p. 71; and 1896, vol. xx. p. 371.

The upper set of fibres pass into the lumbar sympathetic chain, and thence in the mesentery to the inferior mesenteric ganglia, and so by the colonic and hypogastric nerves to the rectum. They are connected with nerve cells chiefly in the inferior mesenteric ganglia, and supply the descending colon, rectum, and internal sphincter. A few fibres pass along the sympathetic chain to the sacral ganglia, and thence by the grey rami of the ganglia to the sacral nerves; in these they follow the somatic branches of the sacral nerves, and end chiefly in the unstriated muscles of the skin round the anus.

The lower set of fibres run in the pelvic nerves, or *nervi erigentes*. They pass into the hypogastric plexus, and have ganglion cells either as they pass the side of the rectum, or more peripherally.

The object or use of this double nerve supply to the rectum is difficult to ascertain. It is natural to imagine that these two sets of nerve fibres should be antagonistic to one another, as is the case with other organs, such as the heart, which are supplied with nerves from two sources. Fellner, working in v. Basch's laboratory, has indeed come to the conclusion that the theory of "crossed innervation," put forward by the latter, also applies to the rectum. According to this theory, when a muscular tube containing circular and longitudinal fibres in its walls, is supplied with two sets of nerve fibres, one set of nerves will be inhibitory for the longitudinal and motor for the circular muscles, while the other nerves will be motor for the longitudinal and inhibitory for the circular muscles. Fellner,¹ as the result of experiments on the dog, concluded that the sacral nerves are motor for the longitudinal muscles of the rectum, including the recto-coccygeal muscle, and inhibitory for the circular muscles, whereas the fibres which run from the hypogastric nerves cause contraction of the circular fibres and relaxation of the longitudinal. We have already seen that this theory is inadmissible for the intestine, and Langley and Anderson, while not denying the possible accuracy of Fellner's experiments, so far as the rectum of the dog is concerned, have shown that they do not apply to other animals. In rabbits and cats they find that the fibres from the lumbar nerves may cause either inhibition or contraction of either muscular coat. The usual result was inhibition of both coats of the rectum, which might be preceded or followed by a slight contraction. On the internal sphincter the effects were again variable, though here also inhibition predominated.

Excitation of the sacral nerves produced much more marked results than did that of the hypogastric nerves. In most cases a strong contraction of the recto-coccygeal muscle and of the longitudinal fibres of the rectum was accompanied by marked relaxation and dilatation of the internal sphincter. Strong peristaltic contractions were also set up in the lower part of the bowel, so that stimulation of these nerves gave rise to defæcation. Here, therefore, both kinds of fibres were caused to contract in the upper part of the rectum. In a few cases the relaxation of the internal sphincter was replaced or succeeded by a contraction of this muscle.

The voluntary external sphincter and levator ani are also supplied from the sacral nerves; in man, from the fourth sacral.

¹ *Med. Jahrb.*, Wien, 1883, S. 571, and *Arch. f. d. ges. Physiol.*, Bonn, 1893, Bd. lvi. S. 542. The tracings given in the latter paper do not, however, by any means support Fellner's contentions.

MUSCULAR MECHANISMS OF THE URINARY TRACT.

BY ERNEST H. STARLING.

CONTENTS :—MOVEMENTS OF THE URETERS, p. 338—MOVEMENTS OF THE BLADDER, p. 339—Muscular Tissue of Bladder and Urethra, p. 339—Mechanism of Closure of Bladder, p. 340—Intravesical Tension, p. 341—Nerve Supply of the Bladder, p. 342—Mechanism of Micturition, p. 344—Voluntary Control of Micturition, p. 345.

MOVEMENTS OF THE URETERS.

THE urine, which is secreted continuously, though at varying rates, passes to the bladder through the ureters, partly in consequence of the pressure at which it is secreted, partly in consequence of peristaltic contractions of these tubes.

These contractions begin at the upper end of the ureters, and travel down to the bladder, but do not affect the musculature of the latter. Although, by artificial stimulation, contraction waves may be started at any point in the ureter, from which they will then travel upwards as well as downwards, under normal conditions the contractions always take place from above downwards, no spontaneous antiperistaltic waves having ever been observed. The contraction waves, according to Engelmann,¹ travel at about 20 to 30 mm. in the second, and are repeated at the rate of about three in the minute.

If the ureter is divided about its middle, the upper half still continues to present rhythmic waves of peristalsis. The lower half often begins to contract on its own account, but its rhythm now no longer coincides with that of the upper half.

The contractions seem to be initiated by the muscular tissue of the walls of the ureter. Although (in man) the ureter receives fibres from the mesenteric, spermatic, and hypogastric plexuses, and contains a few ganglion cells, the middle third of the ureter is, according to Engelmann, free from nervous elements, and yet contracts rhythmically when isolated from the other segments. According to Dogiel,² Maier,³ and Protopopow,⁴ however, ganglion cells may be found in all parts of the ureter, although more abundant at the two ends. The contractions are altered to a certain extent by distension of the ureter, yet they are largely independent of the urinary flow, and occur almost as frequently in animals which have been deprived of water, as when the urinary flow is excessive in consequence of administration of large amounts of fluid.

Contractions of the ureter can be excited by stimulation of the

⁴ *Arch. f. d. ges. Physiol.*, Bonn, 1897, Bd. lxxvi. S. 1.

splanchnic nerve of the same side. They are said to cease permanently shortly after ligature of the upper end of the ureter, in consequence of the severance of the nerve fibres. They may occur, however, in the isolated ureter. That this tube is well supplied with sensory fibres is evidenced by the severe pain of renal colic, which occurs on the impaction of a calculus in the ureter.

The reflux of urine from the bladder into the ureters is prevented by the oblique manner in which these enter the bladder, a sort of valvular opening being thus formed.

MOVEMENTS OF THE BLADDER.

The urine, which is constantly trickling down the ureters, accumulates in the bladder, whence it is expelled at intervals by the contraction of the muscular wall of this viscus. The act of micturition is in the young child purely reflex and dependent on the tension in the bladder. With advancing age, however, the individual acquires more or less voluntary control over the reflex act. It will be convenient to first consider the purely reflex act of micturition.

Muscular tissue of bladder and urethra.—The muscular wall of the bladder is generally described as being composed of three layers—an outer longitudinal, a middle circular, and an inner longitudinal or oblique coat. The division between these coats is, however, by no means well marked, and, as Griffiths has shown,¹ bundles which are longitudinal may become circular or oblique, and bundles of different coats may be continuous with one another. The longitudinal fibres are best marked in the middle of the anterior and posterior surfaces of the bladder. These coats are practically continuous in the female with a similar series of coats forming the muscular wall of the urethra. In the male, according to Griffiths, the bundles are gradually lost in the connective tissue of the neck of the bladder, and are not inserted into any special part, such as the capsule of the prostate gland. On the lateral surfaces of the bladder, the oblique and transverse fibres are most apparent. The bundles of muscular tissue on the two sides of the bladder are continuous. The longitudinal fibres of the bladder, with or without the transverse fibres, are often described as the *detrusor urinae*.

The apparent necessity for some muscle which by its contraction would close the vesico-urethral orifice, has led many anatomists to ascribe an internal sphincter muscle, formed by a thickening of the circular coats of the bladder at its junction with the urethra. An account of this internal sphincter was given by Charles Bell,² and has been repeated in other works on anatomy. Careful dissection, however, fails to show any thickening of muscle around the commencement of the urethra, sufficient to constitute a sphincter. The absence of such a sphincter has been especially emphasised by Griffiths, and can be easily verified by dissection. There are, however, round the urethra, collections of unstriated and striated muscle, which by their contraction close this canal, and check the urinary flow. Thus the first part of the urethra is surrounded by a muscular coat, consisting of inner longitudinal fibres and an outer thicker circular layer, continuous with the inner and middle layer of the bladder. There is also a sheet of striped muscle, which surrounds the greater part of the urethra, and in the male extends from the level of the entrance of the vasa deferentia into the urethra, to within a couple of inches of the urinary meatus. In man, the first part of this muscle is represented by a few trans-

¹ *Journ. Anat. and Physiol.*, London, 1894, vol. xxv. p. 540.

² "Anatomy of the Human Body," 6th edition, 1826, vol. iii. p. 390.

verse fibres on the ventral surface of the lower half of the prostate gland, and is here known as the *external sphincter* of Henle. Round the membranous part of the urethra the sheet is termed the constrictor urethræ, and round the penile portion forms the *accelerator urinæ*. In the dog we find a similar collection of striated muscle fibres round the small portion of the urethra which intervenes between the prostatic and membranous parts. This is designated *Wilson's muscle*.

Mechanism of closure of the bladder.—The mechanism of closure of the bladder has been the subject of much discussion. The retention of urine has been variously ascribed to the elastic resistance of the tissues at the neck of the bladder, or to the contraction of the internal sphincter or of the external sphincter (striated muscle) of Henle. Rosenthal's¹ view, that the closure was due to the elasticity of the sphincter, which had to be forcibly overcome by the contraction of the detrusor in micturition, was discredited by the statement of Heidenhain and Colberg,² that the bladder is able to hold fluid at a much greater pressure in the living than in the dead subject. These authors found that the intravesical pressure necessary to overcome the resistance of the sphincter amounted to between 21 and 33 cms. of water in the living rabbit, and to between 2·5 and 7·5 cms. of water in the dead rabbit. In the dog, the bladder in the dead animal is able to hold fluid at a pressure of 18 to 20 cms. of water, whereas in the living animal the pressure may reach 100 cms. before the contents of the bladder begin to trickle through the urethra. If the lumbar spinal cord be destroyed, the difference in favour of the living animal is abolished, showing that it depends on the existence of a tonic contraction under the influence of this part of the cord. Griffiths has pointed out that there is no such striking difference between the pressure necessary to open the urethra and force out urine in living and dead animals. In the latter case, however, if the urethra has once been forced open by raising the pressure in the bladder, it remains more or less patent, so that on subsequent occasions a flow of urine is obtained at a low pressure. This author finds that the resistance to the escape of urine, which in the male dog varies from 16 to 20 in. of water, remains the same after division of the pelvic nerves, of the hypogastric nerves, or even of the spinal cord in the dorso-lumbar region.

There can be no doubt that the greater part of the resistance to the outflow of urine is occasioned at the urethro-vesical orifice, only a small part being offered by the urethra itself. Thus, in surgical operations, the urethra may be incised up to the neck of the bladder without any escape of urine, and in the cat³ the urethra between the neck of the bladder and the prostate gland may be divided completely without any of the urine escaping. Reyfisch has excised the prostate in dogs without producing any incontinence. Moreover, if the intravesical pressure necessary to cause a flow of urine be determined, by connecting the interior of the bladder through a tube in the ureter with a reservoir of fluid (a catheter having previously been placed in the urethra), it is found that this pressure remains the same, whatever may be the situation of the catheter. It is not until the catheter is actually pushed into the

¹ "De tono cum musculorum, tum eo imprimis, qui sphincterum tonus vocatur," Diss., Königsberg, 1857.

² *Arch. f. Anat., Physiol. u. wissenschaft. Med.*, Berlin, 1858, S. 437.

³ Griffiths, *loc. cit.*

bladder that there is any fall of the pressure at which urine escapes. These facts show that the resistance to the outflow of urine is situated at the neck of the bladder, and must be due either to a tonic contraction of circular fibres at this point, or to the elastic retraction of this orifice, aided, perhaps, by the apposition of the mucous surfaces along the whole length of the urethra, and the tendency of the weight of the contained urine in the relaxed bladder to press the two walls of the urethra together. Griffiths concludes that this resistance is in the main physical, from the fact that it remains the same after death (on the first occasion tried) as during life.¹

Intravesical tension.—In the empty bladder the wall of this organ is contracted, so that the cavity is obliterated. The pressure in the empty bladder can be regarded as practically zero. As urine is gradually secreted, the tension in the bladder rises. Since, however, the wall of the bladder is normally in a condition of greater or less contraction, it follows that the rise in internal pressure of the bladder is not proportional to the increased amount of fluid in its cavity. If the tonus of the bladder wall is well marked, the intravesical pressure may be raised to a considerable extent by the injection of only a small amount of fluid. On the other hand, the bladder is able to accommodate large quantities of fluid without any corresponding rise in pressure, in consequence of a relaxation of the tonic contraction of its muscular wall. The amount of fluid which the bladder is able to accommodate depends largely on the rate at which the fluid enters the bladder. Thus, in man, the state of tension of the bladder wall which is associated with a desire to micturate, equals about 15 cms. water. This state of tension is attained by the injection of about 150 c.c. of fluid, although, when the bladder is allowed to fill naturally with urine secreted slowly by the kidneys, an intravesical pressure of 15 cms. corresponds to about 250 c.c. of urine.² When, on account of a continued accession of urine, the tension reaches a certain height, slow rhythmical contractions of the bladder wall begin, weak at first, but growing gradually stronger, with increasing distension. Thus in the bladder, as in most other hollow viscera, the effect of tension on the sheet of unstriated muscle forming the wall of the organ is twofold.

1. A relaxation (not a stretching), accommodating the capacity of the viscus to the incoming fluid.

2. An excitatory effect, bringing about rhythmic contractions of the wall, the extent and strength of the contractions being directly proportional to the intravisceral tension (*i.e.* to the *stretching* of the muscle fibres).

Both these effects seem to be independent of the nervous system, and may be observed in most hollow viscera after separation from all nervous connections with the body, and must therefore be dependent on local nervous mechanisms or on fundamental properties of the muscle fibres themselves.

Each rhythmic contraction of the bladder lasts on an average from

¹ This experiment of Griffiths does not put a muscular tonic action absolutely out of court. The retractor penis muscle in the dog retains its irritability and contractility for two or three days after the death of the animal, and would, when the body had cooled down, be in a strongly contracted condition. It seems possible, therefore, that the unstriated muscle at the neck of the bladder might similarly be in a state of tonic contraction one or even two days after death.

² Genouville, *Arch. de physiol. norm. et path.*, Paris, 1894, tome vi.

40 to 60 seconds, that is to say, the bladder rhythm is similar to the spleen rhythm, first described by Roy.¹

Since the mere accumulation of urine in the bladder increases the intravesical tension and brings about rhythmic contractions, increasing in force with growing distension, it would appear theoretically possible that at a given distension a contraction might raise the pressure high enough to overcome the resistance at the neck of the bladder, and cause expulsion of the urine. According to v. Zeissl, this actually does occur. This observer has found that micturition may be accomplished normally in a dog after section of all the nerves to the bladder.² As a rule, however, this evacuation will be only partial, the escape of urine being checked as soon as the intravesical pressure falls below a certain point. Thus, so-called incontinence of urine, which is met with in various affections of the spinal cord, is invariably an overflow of urine from a full bladder.

It is evident, then, that for the normal carrying out of micturition we require one or both of the following events:—

1. A strong contraction of the muscular wall, continued until the bladder is emptied.

2. A relaxation of the "sphincter" at the neck of the bladder.

For either or both of these events to occur, the local mechanisms of the bladder must be reinforced by impulses from the central nervous system.

Nerve-supply of the bladder.—We have now to inquire into the nature and paths of the impulses which reach the bladder. The walls of this organ are supplied with nerve fibres, which run to the neck of the bladder from the hypogastric plexus. This plexus consists of nerve fibres and small collections of ganglion cells lying in the loose connective tissue on both sides of the middle part of the rectum. Some ganglion cells are also found in the course of the fibres in the walls of the bladder itself. The hypogastric plexus receives its fibres from two sources—from the sacral nerves, and from the inferior mesenteric ganglion.³ The branches from the sacral nerves which run to the plexus are two or, more rarely, three in number, and are derived in the cat from the second and third sacral nerves. They are known as the *nervi erigentes* or pelvic nerve (Langley), and run straight to the plexus without passing through the sympathetic chain. The fibres from the inferior mesenteric ganglion to the plexus run in the hypogastric nerves, two grey nerve-trunks which pass downwards on each side of the rectum to take part in the formation of the plexus near the neck of the bladder. The inferior mesenteric ganglion consists of four small ganglia connected by fine fibres, lying round the origin of the inferior mesenteric artery. This ganglion receives three nerves from the lumbar sympathetic chain, and sends branches down along the inferior mesenteric artery, and two fine branches upwards to the superior mesenteric ganglion, and so to the solar plexus. The fibres which reach the inferior mesenteric ganglion from the sympathetic chain are derived from the third, fourth, and fifth lumbar nerve-roots

¹ A tracing of these contractions is given by Sherrington, *Journ. Physiol.*, Cambridge and London, 1892, vol. xiii. pl. xxii. fig. 10.

² *Wien. klin. Wchnschr.*, 1896.

³ Nawrocki and Scabitschewsky, *Arch. f. d. ges. Physiol.*, Bonn, 1897, Bd. xlviii. S. 335.

(in the cat). They are connected, as Langley and Anderson¹ have shown by means of the nicotin method, with cells in the inferior mesenteric ganglion, and make no connection with the cells in the ganglia of the lumbar sympathetic chain. In the monkey, according to Sherrington,² these nerves are derived from the second, third, and fourth lumbar in most cases, rarely from the third, fourth, and fifth.

FIG. 188A.—Diagram of the nerve supply to the bladder and colon in the cat (Langley and Anderson, *Journ. Physiol.*, Cambridge and London, 1896, vol. xx. p. 372.

With regard to the functions of these two sets of nerves, almost all observers agree that they convey motor impulses to the bladder. On exciting the lumbar nerve-roots or the mesenteric branches to the ganglion, a weak bilateral contraction of the bladder is obtained—a

¹ *Journ. Physiol.*, Cambridge and London, 1895, vol. xix. p. 71; 1896, vol. xix. p. 372; 1896, vol. xx. p. 372.

² *Ibid.*, 1892, vol. xiii. p. 678.

contraction which is unable to overcome the resistance of the sphincter and to give rise to micturition. The bilateral character of the contraction is due to the fact that certain of the fibres cross in the inferior mesenteric ganglion, so that the lumbar nerves of one side send fibres to both sides of the bladder. Stimulation of one hypogastric nerve may produce a contraction which is more or less unilateral. Stimulation of the sacral nerve-roots or of the *nervi erigentes* gives rise to a strong contraction of the bladder, which is unilateral if the nerves of only one side be stimulated, and which generally causes an expulsion of urine, *i.e.* an active micturition. Stimulation of the branches of the hypogastric plexus causes contraction of the bladder wall, limited to the area of distribution of the excited filaments (Griffiths).

Under some circumstances, it seems that stimulation of the upper set of nerve fibres may cause a relaxation of the bladder,¹ or may hasten the process of relaxation, after a contraction has been excited by stimulation of the pelvic nerves. According to von Zeissl,² the hypogastric nerves are the physiological antagonists of the sacral nerves. If fluid be forced into the bladder by means of a cannula in one ureter, at such a pressure that it is just able to overcome the resistance of the sphincter and trickle through the urethra, stimulation of the hypogastric nerves will at once stop the flow by reinforcing the contraction of the sphincter. On the other hand, if the fundus of the bladder be opened and tied round a glass tube connected with a pressure-bottle, and the latter be so arranged that the fluid is just unable to overcome the resistance of the sphincter, then stimulation of the *nervi erigentes* will cause a relaxation of the sphincter, and a flow of fluid through the urethra. In this case, the fundus being opened, any contraction of the muscular wall of the bladder is ineffectual to raise the pressure in the bladder, so that the result can only be ascribed to the relaxation of the sphincter. The accumulation of urine in the bladder would therefore be effected through the intermediation of the upper set of fibres, while the evacuation would be brought about by stimulation of the sacral fibres. Langley objects to these experiments, that the results obtained by von Zeissl on stimulating the hypogastric nerve might be due to a longitudinal contraction of the basal portion of the bladder drawing the urethra forwards, whereas a strong contraction, such as that produced by stimulating the *nervus erigens*, even if it involved the urethra, would tend to widen the urethral orifice, and so give the apparent effect of relaxation of the sphincter. I am of opinion that von Zeissl's results are due to a fallacious method of experiment. I have been unable to confirm him as to the inhibitory influence of the pelvic nerve on the "sphincter vesicæ." If his experiments be repeated, it will be found that even when the fundus is connected by a fairly wide tube with a reservoir, the sudden contraction of the bladder wall, on stimulation of the pelvic nerve, causes a considerable rise of pressure in the bladder. The expulsion of urine is caused by this rise of pressure, and not by any relaxation of the sphincter. If a tube one inch in diameter be tied into the fundus, and fluid poured into the tube until it just drops from the urethra, stimulation of the pelvic nerve does not alter the rate of

¹ Griffiths, *Journ. Anat. and Physiol.*, London, 1894, vol. xxv. p. 540; and 1895, vol. xxvi. pp. 60 and 225.

² *Arch. f. d. ges. Physiol.*, Bonn, 1893, Bd. liii. S. 560.

flow, the free escape from the bladder through the wide tube having prevented any rise of intravesical tension. Von Zeissl performed his work in von Basch's laboratory, and looks upon his experiments as confirmatory of the theory of crossed innervation already put forward by von Basch. He regards the hypogastric nerve as motor for the circular, and inhibitory for the longitudinal (detrusor) fibres of the bladder, the *nervi erigentes* having the reverse effect. Courtade and Guyon¹ also conclude that the pelvic nerve is motor for the longitudinal, the hypogastric for the circular fibres. I have already mentioned, however, that there is, according to Griffiths, no demarcation to be made out between circular and longitudinal or oblique fibres, all being apparently continuous with one another.

The nerve centre which presides over the tonus and contraction of the bladder is situated in the lumbar spinal cord. If this centre and its connections be intact, micturition may be carried out normally, even after section of the cord in the dorsal region. The centre can be excited reflexly by stimulation of almost any sensory nerve, such as the sciatic or the fifth nerve.² In many cases where, in consequence of obstruction to the passage of impulses from the higher parts of the central nervous system, micturition is delayed, this act may be excited by the application of cold or hot sponges to the perineum, and it is well known that almost any irritation of the pelvic organs in children may give rise to reflex involuntary micturition.

The mechanism of micturition.—It is evident that the reflex act of micturition is originated by afferent impulses ascending to the centre in the lumbo-sacral cord, and started either by the increasing tension of the bladder wall (most probably), or by stimulation of the urethra. According to Goltz,³ Kuss,⁴ and Finger,⁵ with increasing tension the rhythmic contractions increase in force until one of them is sufficient to overcome the resistance of the sphincter and to drive a little urine into the urethra. The stimulus of this urine in the urethra starts the whole reflex chain of events leading to micturition. The sphincter, by the intermediation of the spinal centre, is inhibited. At the same time, the longitudinal and circular fibres of the bladder wall contract, thus emptying the bladder. The evacuation may be aided by an associated contraction of the abdominal muscles. At the end of the act, the last drops are expelled from the urethra by rhythmical contractions of the perineal muscles, especially the *accelerator urinæ* and *levator ani*. There is no doubt that in this act the contraction of the 'detrusor' (*i.e.* of the whole bladder wall) is the most important factor in bringing about the expulsion of the urine. Without the co-operation of the bladder wall, the strongest contraction of the abdominal muscles is inadequate to empty the bladder. It is much more uncertain what part, if any, in the process, is played by the structures at the neck of the bladder. Nearly all authorities lay a great stress on the importance of a dilatation of the sphincter, either by the direct action of the detrusor (longitudinal) fibres (Kohlrausch,⁶ and Henle), or by an inhibition of the

⁶ "Zur Anat. u. Physiol. der Beckenorgane," Leipzig, 1854, S. 14.

circular fibres at the neck of the bladder. The main events in reflex micturition may be summarised as follows:—

1. Accumulation of urine.
2. Slow rise of intravesical pressure (to 15 cms. water).
3. Rhythmical contractions of bladder, increasing in force with increasing tension.
4. Afferent impulses ascending from bladder to lumbo-sacral cord.
5. Reflex discharge of impulses by hypogastric and pelvic nerves, causing contraction of the whole bladder wall, and a rise of intravesical tension to 20 or 30 cms. water.
6. The resistance at the neck of the bladder is overcome, the beginning of the urethra is straightened out, and the adhesion of the walls of the empty tube overcome.
7. Discharge of urine and emptying of bladder.
8. Contraction of the unstriated and striated muscles surrounding the urethra and emptying this canal.

At 5 there will be in nearly all cases a reinforcing contraction of the abdominal muscles.

Voluntary control of micturition.—In the adult, the processes of retention and evacuation of urine are modified and controlled by voluntary effort. The normal action of the sphincter mechanism may be aided by the contraction of the perineal muscles, which keep the urethra closed. The reflex process of micturition may be set in motion by the contraction of the abdominal muscles, by which the pressure in the bladder is increased and the resistance to the passage of urine into the urethra overcome. It is possible, too, that the individual has a certain extent of voluntary power over the unstriated muscles of the bladder, and that the contraction of the muscular wall may be augmented by impulses proceeding from the cortex to the micturition centre in the bladder cord. In this case, the initiation of the act would be analogous to that in which micturition is caused by stimulation of some sensory nerve, since in both cases the centre in the lumbar cord must first be influenced by the stimulus.

This view is favoured by the fact that contraction of the detrusor urinæ can be evoked by stimulation of the crura cerebri, or of the medulla oblongata or anterior columns of the cord (Budge,¹ Mosso²), and that this effect may be observed even after exclusion of contraction of the abdominal muscles by opening the abdomen or by the administration of curari. Bechterew and Mislawsky³ obtained contraction of the bladder on stimulating the sigmoid gyrus in dogs.

The series of striated muscles which surround the urethra are under the control of the will, so that micturition can be stopped at any time by their forcible contraction. According to some authors, however, there is direct voluntary control over the unstriated fibres at the neck of the bladder, the so-called "internal sphincter," which, as I have already mentioned, does not exist as a distinct muscle. According to Reyfisch,⁴ the "internal sphincter" may be inhibited or set into contraction directly by voluntary impulses.

Thus, if a catheter be pushed up the human urethra until its opening lies in the prostatic part of the urethra just outside the bladder, no urine flows, unless micturition be inaugurated voluntarily by the person experimented on. When micturition is proceeding, the flow can be instantly checked at the will of the person experimented on. Reyfisch considers that the voluntary muscles surrounding the urethra are in this case powerless to stop the stream, since the closure of the canal is prevented by the presence of the rigid catheter. He concludes, then, that the stoppage can only be accounted for by a voluntary contraction of the internal sphincter. It seems to me, however, possible that a lifting up of the base of the bladder and the prostate by the anterior fibres of the levator ani might be responsible for the sudden stoppage in the urinary flow observed in Reyfisch's experiments.

THE MUSCULAR MECHANISMS OF THE GENERATIVE APPARATUS.

BY ERNEST H. STARLING.

CONTENTS :—Erection, p. 347—Nervous Mechanism, p. 348—Retractor Penis, p. 349
—Parturition, p. 349—Nervous Mechanism, p. 351.

THE act of impregnation consists in the introduction of spermatozoa into the female genital tract, where they may come in contact with and fertilise the ovum, which has been discharged from the ovary by a bursting of the Graafian follicle. We have therefore to describe the changes in the generative organs in both sexes, which accompany this act, and the means by which these changes are brought about.

Erection.—The mechanism by which the erection of the penis is brought about is twofold. The most important factor, as was shown by Eckhard¹ and Loven,² is an active dilatation of the vessels of the penis, especially of the medium and smaller sized arteries. This is shown by the fact that, if the penis be cut across, venous blood merely trickles away from the cut surface, whereas, if erection be excited, the flow of blood from the cut surface is increased eight to ten times, and the blood becomes bright arterial in colour. That this vaso-dilatation is the most important factor in erection, is shown by the fact that it is possible to excite erection in an animal, in whom the second factor has been abolished by paralyzing the muscles by the injection of curare.

The second factor is the contraction of the ischio-cavernosus or erector penis muscle, certain fibres of which pass over the dorsal vein of the penis, and compress this vessel when they contract. Although this mechanism undoubtedly assists in the production of erection, yet it is unable by itself to cause erection, since ligature of the veins coming from the penis is unable to do so.

Before or at the beginning of coitus, analogous erectile changes occur in the female organs, leading to erection of the clitoris and of the other erectile structures of the vulva. The friction between the glans and the wall of the vagina causes a reflex discharge of motor impulses in both female and male. In the male, the muscle in the walls of the vasa deferentia and vesiculæ seminales enters into peristaltic contractions, thus forcing the contents of these receptacles into the urethra. The semen is pressed along the urethra by rhythmical contractions of the bulbo- and ischio-cavernosi muscles, which empty this canal from behind forwards. At the same time it seems probable that movements take place coincidentally in the uterus, consisting in a change in the

¹ *Beitr. z. Anat. u. Physiol. (Eckhard)*, Giessen, 1863, Bd. iii, S. 125.

² *Arch. a. d. physiol. Anst. zu Leipzig*, 1866.

position of this organ, so that its axis more nearly coincides with that of the vagina, and, according to observations on animals, in an active antiperistaltic contraction of uterus and Fallopian tubes, by which the semen becomes forwarded towards the ovaries. Some such movement as this seems necessary to explain the fact that the fertilisation of the ovum takes place, as a rule, in the Fallopian tubes, and may take place on the surface of the ovaries or in the abdominal cavity.

Nervous mechanism.—Although, in both sexes, coitus is attended by a high degree of psychological excitement, yet it is essentially a reflex act, and can be carried out when all impulses from the higher centres are cut off by section of the cord in the dorsal region. The centre presiding over the act is situated in the lumbar spinal cord; and we have now to consider the paths, afferent and efferent, which are concerned in the various phases of the act.

The first accurate information on these points was furnished by the discovery by Eckhard¹ of the function of the *nervi erigentes*. Since this time, the nerves to the generative organs have been the subject of investigation by Gaskell,² Morat,³ Sherrington⁴ and Langley and Anderson.⁵ I shall follow the very full account given by the two last-named observers.

The external generative organs, like the bladder, are supplied from two sets of nerve fibres—from the lumbar nerves through the sympathetic, and from the sacral nerves. The fibres from the lumbar nerves arise in the cat from the second, third, and fourth, or the third, fourth, and fifth lumbar nerve-roots, and in the dog from the thirteenth thoracic, and the first to the fourth lumbar roots. They run in the white rami communicantes to the sympathetic chain, whence they may take two paths.

(a) The great majority of the fibres run down the sympathetic chain to the sacral ganglia, whence fibres are given off in the grey rami communicantes to the sacral nerves; their further course is by the pudic nerves, none running in the *nervi erigentes*.

(b) A few fibres go by the hypogastric nerves to the pelvic plexus.

Excitation of these fibres causes strong contraction of the arteries of the penis, and of the unstriated muscles of the tunica dartos of the scrotum. In animals which possess a retractor penis muscle, excitation of the lumbar nerves causes strong contraction of the muscle.

The fibres from the sacral nerve can be divided into two classes—visceral and somatic. The visceral branches run in the pelvic nerves, or *nervi erigentes*. Stimulation of these fibres produces active dilatation of the arteries of the penis or vulva, and also inhibition of the unstriated muscle or body of the penis, the retractor muscle of the penis, when present, and of the vulva muscles. The somatic branches supply motor nerves to the ischio- and bulbo-cavernosi, as well as the constrictor urethræ. In the female, they supply the analogous muscles, namely, the erector clitoridis (ischio-cavernosus), and the sphincter vaginae (bulbo-cavernosus). Both these sets of fibres are therefore involved in the erection of the generative organs which accompanies coitus.

⁴ *Journ. Physiol.*, Cambridge and London, 1892, vol. xiii. p. 675.

⁵ *Ibid.*, 1895, vol. xix. p. 85.

The internal organs, *i.e.* the uterus and vagina in the female, and vasa deferentia, seminal vesicles, and uterus masculinus in the male, differ from the external organs in receiving no efferent nerve fibres from the sacral nerves, as has been pointed out by Langley and Anderson. They are supplied with fibres which pass out through the anterior roots of the third, fourth, and fifth lumbar nerves (in the rabbit and cat), and run through the sympathetic to the inferior mesenteric ganglia, whence they proceed by the hypogastric nerves. On stimulating these fibres, two effects are produced on the uterus and vagina, namely, a contraction of the small arteries, leading to pallor of the organs, and a strong contraction of the muscular coats. In the vagina, the contraction can usually be seen to start from one end and spread to the other. The whole then remains for a time in a state of powerful tonic contraction, which affects both longitudinal as well as circular muscles. In the male, stimulation of these nerves excites strong contraction of the whole musculature of the vasa deferentia and seminal vesicles, which may be strong enough to cause emission of semen from the penis. Here again both sets of muscular fibres are involved. These effects on the uterus and seminal vesicles are not abolished by injection of atropine.

The course of the sensory fibres from the generative organs to the lumbo-sacral cord has not yet been fully made out, but it seems probable that it corresponds to the course taken by the efferent fibres.

An accessory genital muscle, the *retractor penis*, which is found in the dog, cat, horse, donkey, hedgehog (not in the rabbit or man), presents considerable physiological interest. It was first described by Eckhard as the *Afterruthenband*, and consists of a thin band of longitudinally arranged unstriated muscle (15 to 20 cms. long in a spaniel weighing about 15 kilos.),¹ which is inserted at the attachment of the prepuce, and is continued backwards in a sheath of connective tissue to the bulb, when it divides into two slips which pass on either side of the anus. A few striated fibres are found in the back part of this muscle, derived from the external sphincter of the anus and the bulbo-cavernosus muscles.

This muscle is extremely sensitive to changes of temperature, and is at the same time very tenacious of life. Thus it may be cut out of the body and kept in serum or blood, in a cool place, for two days. At the end of this time it will, on warming, relax, and enter into spontaneous rhythmic contractions. At about 40° C. the muscle is quite flaccid. On cooling slightly (to 35°) it will shorten, and at the same time may enter into slow rhythmic contractions. If cooled to 15° C. the muscle will contract to about a quarter of its previous length. The same shortening may be produced on exciting the muscle with strong interrupted currents.

The muscle is innervated from two sources, the two nerves having antagonistic actions. The *motor* fibres to the muscle are derived from the lumbar sympathetic (*i.e.* the upper set of nerve roots), and run to the muscle in the internal pudic nerve. The pelvic nerves, on the other hand, carry inhibitory impulses to the muscle, thus enabling the concomitant vascular dilatation to take effect in producing erection of the penis.

Parturition.—During pregnancy, marked changes take place in all the generative organs, the most important and striking being those affecting the uterus. This organ undergoes an enormous hypertrophy involving all its tissues, so that, whereas in a virgin the uterus is about

¹ Langley and Anderson, *loc. cit.*, p. 88.

6.5 cms. long, at the end of pregnancy it is 35 cms. in length by 24 cms. in width, and is twenty-four times as heavy as the unimpregnated uterus. This growth is mainly due to the hypertrophy of the muscular tissues, the larger muscular cells being increased seven- to eleven-fold in length, and two- to five-fold in breadth. Moreover, a number of fresh muscle cells are developed, apparently from cells which have the character of embryonic muscle cells. At the same time there is a marked growth in the mucous membrane which forms the decidua, and in all the connective tissue structures of the uterus, including blood vessels and lymphatics.

Along with the growth of the ovum, the uterus increases in size and becomes more distended, its irritability becoming greater, so that it is easily excited to contract. The stimulus may be supplied from adjacent abdominal organs, from the brain—as by emotions, or by direct excitation of the internal surface of the uterus, in consequence of movements of the foetus. In many cases no antecedent stimulus can be discovered, and the automatic contraction of the uterus seems to be analogous to that which occurs in the distended bladder. These contractions ordinarily give rise to no sensations, and are only felt when they are augmented in consequence of reflex stimulation. During the greater part of pregnancy they have little or no effect on the contents of the uterus. During the last weeks or days of pregnancy, however, these contractions, which have now become more marked, have a distinct physiological effect. Not only do they, by pressing on the foetus, cause it, in most instances, to assume a suitable position for its subsequent expulsion, but, affecting the whole body of the uterus, including the longitudinal muscular fibres surrounding its neck, they assist the general enlargement of the organ in dilating the internal os, so that the upper part of the cervix is obliterated and drawn up into the body of the uterus some little time before labour has commenced.

With these changes in the uterus are associated changes in the round ligaments and in the vagina and vulva. The muscular fibres of the round ligaments become much hypertrophied and lengthened, and these structures can therefore aid appreciably the uterine contractions in the subsequent expulsion of the foetus. The vaginal walls become thickened and of looser texture, so as to afford less resistance to distension during the passage of the foetal head.

Considerable discussion has taken place as to the cause for the onset of the processes comprised under the heading of labour or parturition, at a nearly constant period of two hundred and seventy-two days after conception. Most of the explanations which have been suggested, such as the great irritability of the uterus at the termination of pregnancy, the loosening of the foetal membranes, the return of the menstrual congestion after ten months, thrombosis of the placental sinuses, simply replace one question by another. According to Spiegelberg, the phenomena accompanying the birth of twins, which are often born at a considerable interval from each other, the onset of contractions of the uterus at the right time in normal as well as in extra-uterine foetation, the fact that the extra-uterine foetus dies when it has become mature, all go to show that the reason why labour occurs at a definite time must be sought for in foetal rather than in uterine changes. This author suggests that some substances which had previously been used up by the foetus gradually accumulate in the maternal

blood as the fœtus becomes mature, and provoke, by their direct action on the uterus or spinal cord, the uterine contractions which give rise to labour.

Actual parturition is in man generally divided into two stages. In the first stage, the contractions are confined to the uterus, and chiefly act in dilating the os uteri. In this dilatation two factors are involved, namely, the active dilatation brought about by the contraction of the longitudinal muscular fibres which form the chief constituent of the lower part of the uterine wall; and, in the second place, a passive dilatation by the pressure of the fetal bag of membranes, which is filled with amniotic fluid, and forced down as a fluid wedge into the os by the contractions of the uterine fundus.

The uterine contractions are essentially rhythmical, being feeble at first, and increasing gradually in intensity to a maximum which endures a certain time, and then gradually subsides. The frequency and duration of the contractions increase as labour advances.

As soon as the os is fully dilated and the fœtal head has entered the pelvis, the contractions change in character, being much more prolonged and frequent, and attended by more or less voluntary contractions of the abdominal muscles. This action of the abdominal muscles is associated with fixation of the diaphragm and closure of the glottis, so that pressure is brought to bear on the whole contents of the abdomen, including the uterus. No expelling force can be ascribed to the vagina, since it is too greatly stretched by the advancing fœtus.

In this way the fœtus is gradually thrust through the pelvic canal, dilating the soft parts which impede its progress, and is finally expelled through the vulva, the head being born first. The membranes generally rupture towards the end of the first stage of parturition.

A third stage of labour is generally described. This consists in a renewal of uterine contractions about twenty to thirty minutes after the birth of the child, and results in the expulsion of the placenta and fœtal membranes.

Nervous mechanism.—We possess little experimental knowledge of the nervous mechanism of parturition. The most important observation on this point is the already quoted experiment by Goltz,¹ in which this physiologist observed the normal performance of menstruation (heat), impregnation, and parturition in a bitch whose spinal cord had been completely divided in the dorsal region during the previous year. On the other hand, destruction of the lumbar cord completely abolishes the normal uterine contractions of parturition, so that this act must be regarded as essentially reflex, presided over by a controlling 'centre' in the grey matter of the lumbar cord.

The activity of the centre can be inhibited or augmented by impulses arriving at it from the peripheral parts of the body, as by the stimulation of sensory nerves, or from the brain, as under the influence of emotions. The nerve paths from the centre to the uterus have been already described in the previous section.

THE MECHANICAL, THERMAL, AND ELECTRICAL PROPERTIES OF STRIPED MUSCLE.

BY J. BURDON SANDERSON.

CONTENTS.—THE MECHANICAL RESPONSE—Response to Successive Excitations, p. 353—Response to Single Stimulus, p. 358—Influence of Mechanical Conditions on Excitatory Process, p. 363—Muscular Tonus, p. 377—Genesis of Tetanus, p. 378—Summation of Stimuli, p. 380—Period of Latency, p. 381—Rate of Propagation, p. 383—Conduction of Slow Waves, p. 384—EXHAUSTION AND DEATH OF MUSCLE—Fatigue, p. 385—Causes of Exhaustion, p. 389—Death of Muscle, p. 390—Rigor Mortis, p. 390—NATURE OF PROCESS CONCERNED IN MUSCULAR CONTRACTION, p. 393—PRODUCTION OF HEAT DURING CONTRACTION, p. 397—ELECTRICAL PROPERTIES OF MUSCLE—In the Unexcited State, p. 407—Current of Injury, p. 411—Electromotive Phenomena of Excited Muscle, p. 413—Electrical Response to a Single Stimulus, p. 414—Electrical Response to a Series of Stimuli, p. 422—DIRECT ACTION OF VOLTAIC CURRENT ON MUSCLES—Polarisation of Muscle, p. 426—Polar Effects during and after Passage of Current, p. 429—Polar Excitation, p. 431—Secondary Excitation, p. 436—Polarising Action of Currents of Brief Duration, p. 438—CARDIAC MUSCLE—The Mechanical Response, p. 439—The Electrical Response, p. 443.

THE function of a muscle is to contribute to the accomplishment of bodily movements, or to the performance of external work, by changing its form in obedience to influences received by it from the central nervous system.

These influences are comprised under the general term "stimuli." The characteristic of a stimulus is that it evokes the specific function of an excitable organ; and the characteristic of an excitable organ is that its function is a response to stimulation. Muscle is the type of such an organ. According to the mode of observation employed, the phenomena of muscular function which present themselves to the observer are chemical, mechanical, thermal, or electrical. The present article comprises the last three of these four classes.¹

I.—THE MECHANICAL RESPONSE.

In the examination of the mechanical changes which follow excitation, we may begin either with the mechanical effect of a single momentary excitation, or by comparing the mechanical properties of a muscle when in a *state of excitation* with those which it possesses when at rest. For two reasons the latter course is preferable. One reason is that the natural action of a muscle consists in its passing from the unexcited into the excited state, under the influence of a stimulus which acts con-

¹The chemical changes which accompany the activity of muscle are dealt with in vol. i. The phenomena of muscular contraction which require the aid of the microscope for their observation are described in works on histology, and are therefore omitted here.

tinuously; the other, that the response to a single stimulation consists of two processes or stages, in one of which it enters into the state of activity, in the other returns to that of rest. The interference of these two states involves complications which do not present themselves in a muscle which is continuously excited.

Mechanical response to a succession of instantaneous stimuli—Tetanus.—A state of excitation comparable to voluntary contraction can be produced for the purpose of investigation, by subjecting a muscle to the action of a succession of instantaneous stimuli of sufficient frequency. The response to excitation of this kind is technically called tetanus.¹ In using this term, it should be carefully borne in mind that there are other forms of continuous contraction which are not evoked by repeated stimuli; and it is by no means certain that voluntary contraction is not of the number.

The methods of producing tetanus will be discussed more fully in a subsequent section. For our present purpose it is sufficient to say that the tetanic state (the state of excitatory shortening) can be produced either directly or indirectly, *i.e.* by subjecting either the muscle itself (direct method) or its nerve (indirect method) to a succession of stimuli. For the purpose now in view it is essential that the stimulations should be not only frequent, but of uniform efficiency; and to insure this, they must be of such strength as to make the muscle contract to the utmost.

The characteristic phenomena of tetanus can be best observed in a muscle which is excited directly by induction currents in alternately opposite directions, of which the frequency is from 30 to 100 per second. It is assumed in what follows that this method is employed.

For experiments relating to the mechanical response to stimulation, the muscle preparation which has been used by preference is that of the pair of internal thigh muscles of the frog—the *gracilis* and *semimembranosus*. These are easily recognised by the tendinous inscription with which each is provided. They take their origin from the ischio-pubic symphysis and run nearly parallel to each other, to be inserted into the inner aspect of the head of the tibia-fibula. The preparation is made by cutting through the two heads on each side and removing with each the two muscles in question, together with the ischio-pubic ridge from which they spring. The advantage of this preparation (hereafter referred to as the “double adductor preparation”) is that each of the muscles consists of fibres all of which run in the same direction. It is a further advantage that when prepared as above described the two groups act for all practical purposes as one muscle, the length of which, if they are used lengthwise, may be, in a good-sized frog, as much as 3 in. (Fig. 189).

The phenomena which present themselves when a muscle is *completely* and *continuously* excited, differ according to the mechanical conditions under which it is placed. If before and during excitation its opposite attachments are so fixed that they cannot be brought nearer together by the effort of the muscle to contract, the excitation is said to occur under *isometric* conditions. If, on the other hand, one end of the muscle is left free, so that it can shorten on excitation, and in

¹The fact that continuous contraction can be produced by repeated stimulation was known to Volta (1792). The word “tetanise” was introduced into physiology by Matteucci (1838). “Tetanus” is now defined in most text-books as the effect of rapidly repeated stimulation (see Hermaun’s “Handbuch,” Bd. i. S. 41). du Bois Reymond, who first used this method for investigating muscular contraction, did not limit the meaning of the word to the result of this kind of stimulation.

so doing lift a weight which is attached to it, the excitation is said to take place under *isotonic* conditions.

In the former case the form of the muscle remains nearly the same as it was before it was stimulated, although, owing to a certain amount of internal displacement, consequent on unequal contraction of different parts, it is not precisely the same.¹ The muscle which was before relaxed now becomes tense. It thus acquires properties resembling those of a spiral steel spring of which the ends are attached to two fixed points, at a distance from each other which considerably exceeds the length of the spring when left to itself.

FIG. 189.—The double adductor preparation. *sm*, *s'm'*, semimembranosus; *g g'*, gracilis of right and left legs respectively of a *Rana esculenta*; *i.p.r.*, ischiopubic ridge; *t, t'*, head of tibia-fibula of right and left side respectively.

According to the simplest theory of muscular contraction, the work done by a muscle in passing from the relaxed to the contracted state, and thereby lifting a weight, is equal to the work done by the same weight on the same muscle in extending it from its length when so shortened to its length when relaxed. Experiment, however, shows that it is only under exceptional conditions that this equality is realised. It is on these conditions, therefore, that the efficiency of muscular action depends. For, just as a stretched spring cannot do more external work when released than was required to stretch it, but may do less, so a loaded muscle, when excited, lifts its load with an efficiency which may equal but cannot exceed that which would be exercised on the excited muscle by the load in extending it to the same length. The relation between the two quantities, *i.e.* between the amount of work done *on* the excited muscle in extending it, and the amount of external work which can be done *by* the same muscle in lifting a weight or overcoming a resistance, has been investigated experimentally under a variety of conditions by Fick, who embodied the results in a small book on the physiology of muscle some seventeen years ago.² As it is of great importance that the subject should be treated experimentally, I propose to begin the discussion of it by giving an account of a form of experiment in which the amount of actual work done is equal to that estimated.

The amount of work which must be done on an excited muscle in order to stretch it to its "natural" length when not excited, is, as in the case of a spiral spring or an indiarubber band, the product obtained by multiplying half the increment of length by the weight which is required to extend it. With regard to muscle, this statement is not absolutely exact; for when an excited muscle is stretched, it does not

¹ See Blix, *Skandin. Arch. f. Physiol.*, Leipzig, Bd. vi. S. 245.

² Fick, "Mechanische Arbeit und Wärme-entwicklung bei der Muskelthätigkeit," Leipzig, 1882.

lengthen in exact accordance with Hooke's law, *i.e.* the successive increments of length which are produced by equal increments of load are not perfectly equal. In other words, it is not perfectly elastic. It is, however, so nearly elastic that the statement above given is sufficiently correct.

In all experiments the external work actually done is represented by the lifting of a weight, and estimated in gramme-millimetres by multiplying the weight by the height to which it is lifted; but the amount so measured varies according to the mechanical conditions under which the effort is made. In order to obtain the most favourable result, these must be such as to enable the muscle, throughout the period during which it is being excited, to act to the best advantage. Now, in a muscle excited under isotonic conditions, the stress rapidly diminishes as the muscle shortens. If, for example, it shortens from its natural length when unexcited to its natural length in tetanus, the tension diminishes *pari passu* with the length, from a considerable amount to zero. If the load is nearly as much as it can lift at the beginning of the effort, there will be a slight initial shortening followed by a long period during which at first no work is being done by it, but afterwards "negative" work is being done on it. If the load is very small, the muscle will at once nearly complete its contraction, but will thereby do little work; for, though the lift is great, the load is too small to yield a considerable product. If the original load is reduced to half, the result of the first part of the effort will be much

FIG. 190.—Cosine lever, combined with writing lever and tension recorder. *HH'*, steel writing lever, 32 cms. long, rotating on the axle *A*, which bears two pulleys, of 4 and 8 mm. diameter respectively, from one of which a scale-pan *L* is suspended. *M'*, the muscle preparation, fixed at *z*; its free end, *k*, being attached by a fine wire to one arm of the writing lever at a distance half-way between the axis and the writing point *s'*, *i.e.* 8 cms. from *A*. *DD'*, wires from the secondary coil of an inductorium. To the extremity of the other arm of the writing lever, at *H'*, *i.e.* 16 cms. from *A*, one bar of the cosine lever is connected by a long thread, the whole length of which (about 60 cms.) is not shown in the figure. *M*, the movable block on this bar to which the thread is attached. *C*, axle of the cosine lever, fixed to a stand, so that the two brass cross-bars shall be in the same vertical plane as the lever, *HH'*. *L*, sliding weight of 200 grms. on the second cross-bar. *S*, scale-pan for additional weights. *AA'*, stops on the stand for preventing the weight *L* from acting on the muscle before and after the experiment respectively. *hh'*, bamboo tension-recording lever, with its fixed axle *a* bearing a small pulley, only 1 mm. in diameter, round which is strung a pliable but inextensible thread, ending in a brass hook *c*, by means of which it can be attached to a pin *d* on the length-recording lever *HH'*, at the same point at which the free end of the muscle is attached, and readily detached. *ff'*, steel spring fixed at *f*, its other end, *f'*, being connected with the lever *hh'* by a stiff wire. *s*, writing point of lever *hh'*. *na*, position that *hh'* would assume on excitation of the muscle.—After Fick.

the first part of the effort will be much

larger than in either of the two other cases; but during the succeeding part nothing further will be accomplished. There would, however, be no such fruitless period if the load were diminished throughout at the same rate as the length of the muscle; for in that case the muscle would at every moment have as much work as it could manage.

Acting on this principle, Fick has contrived an instrument (Fig. 190) which may be called a *cosine lever*. When this is interposed between the muscle and the weight it has to lift, the former is enabled to work under conditions which approximate to those required.

It consists of two bars which can be screwed together at any angle. They rotate on the axle *C*. From the left upper arm a weight can be hung at any distance from *C*. On the right upper arm at *M*, the muscle acts. The rotation of the lever is checked at *A* and *A'*. The cross must be so arranged that, during the period of shortening of the muscle, the rotatory moment of the weight shall diminish from a maximum—that of the initial tension—to zero; and *CM* must be of such length that the muscle in contracting with a minimal load shall rotate the bar *M* 60°, in which case the distance through which *M* descends must be equal to *CM*. For this purpose, it is convenient that the levers should be set at an angle of 60° to each other.

The mode of experimenting is as follows:—After being tetanised, the muscle is allowed to shorten, and in so doing to act on the shorter end of the lever *HH'*, the long arm being attached by a long cord to the cosine lever at *M*. In an experiment, of which the data are given by Fick, a weight of 200 grms., *L*, was attached to the lever at 90 mm. distance from *C*, while the muscle, which had been previously found to shorten from 50 to 24 mm., acted on the other lever at 52 mm. distance from the same axis. Obviously, the rotatory moment of *L* on the axis *C* is proportional to the cosine of the angle of inclination of the bar *LC*. The completely tetanised muscle had been found to exercise at *d* an initial traction of 800 grms., consequently at *M* of 400 grms., for *AH'* is twice as long as *A d*. Its rotatory moment was therefore $52 \times 400 \times \cos 30^\circ = 20,800 \cos 30^\circ$. As the rotation of *C* produced by the contraction of the muscle amounted to 60°, *M* was pulled down 52 mm., and *L* raised 45 mm., so that the amount of work done was 9000 grm. mm.¹

The amount of work which, according to calculation, would have been required to stretch the same excited muscle from its natural or equilibrium length in tetanus, to its equilibrium length when at rest, was 9200 grm. mm., an amount which so nearly corresponds with that of the external work it was found to be able to do, as to afford no sufficient reason for doubting that, under the conditions in question, the whole of the available mechanical energy of the muscle was brought into play. By a slight increase of the distance *LC*, the correspondence might have been made closer.

Other experiments show that it is not possible to make a muscle do the amount of external work which corresponds to the negative work done on it in extending it from its excited to its unexcited length, except under such conditions as have been stated, and that the more nearly these are approached the larger is the proportion of work actually done to what theoretically might be done. The muscle acts advantageously, because, during the whole period of its action, the work it is called upon to do is always as much as it can master, and diminishes as it becomes less fit for it; or, to use the language in which

¹ From 30° to 0° the cosines decrease nearly at the same rate as the angles. Between 60° and 30° they obviously decrease more slowly. This, however, does not appear to interfere with the result. It is possible to give a simpler form to the cosine lever. I prefer, however, not to modify Fick's figure.

the principle is formulated by Fick, "If a muscle is completely tetanised, and thereby overcomes an external force which at each moment nearly balances its tension, the mechanical effect, *i.e.* the negative work overcome, is exactly equal to the positive work as calculated from the extension curve."¹

The utmost amount of external work which can theoretically be done by a tetanised muscle during the period of effort is, in accordance with the principle which has just been enunciated, obtained by multiplying the load lifted by half the lift. It may be represented by a triangular area (Fig. 191), hereafter to be referred to as the work-diagram. If ac be the equilibrium-length of the muscle when tetanised, ab its equilibrium-length when relaxed, and bg represent the amount of the load required to stretch the excited muscle from the length ac to the length ab , it is obvious that the triangle cbg represents the product in question, *i.e.*, on the one hand the smallest amount of negative work required to extend the tetanised muscle to its unexcited length, and, on the other, the maximum amount of positive external work which it is capable of accomplishing under the most favourable circumstances.

The normal length of a muscle in the body, when said to be at rest, is not that of equilibrium, but of extension, *i.e.*, its length at the moment of beginning any effort exceeds that which it would possess if it were perfectly free to assume its natural form. This fact is advantageous to the organism in a way that the diagram helps to explain. In constructing it, it was assumed that, in order to extend the excited muscle to the length ab , a weight of 700 grms. was required. If, *before excitation*, an extending force of say 250 grms. had been applied to it, so that it would have assumed the length ad , it would require, as the diagram shows, in

order to stretch it to the same length *in the excited state*, the weight of 1200 grms. It would then be able, under perfectly favourable conditions, to do, when released from extension, an amount of work represented by the much larger area cdf . As the diagram also shows, by far the greater part of this work would be accomplished by the proper energy of the muscle at the expense of material contained in itself. But the remainder, indicated by the vertically shaded area bde , would be assignable to the negative work which must have been done on the muscle before excitation, in order to bring it to the length ad . The curved line be is, according to Fick, the "extension curve" of unexcited muscle, a curve of which the ordinates represent the successive lengths of such a muscle when extended by a load increasing

FIG. 191.—Work-diagram. ab , length of unexcited muscle; and be , its extension curve. ac , length of muscle when excited; and cf , its extension curve. cdf , the whole work capable of being done by an excited muscle in shortening from a length ad , to its proper length ac . The vertically shaded area represents the work done on the muscle in bringing it to the length ad before excitation; the horizontally shaded area the "useful effect."—After Fick.

¹ Fick, *op. cit.*, S. 61.

by equal increments from 0 to 250 grms. The concavity of this curve is always upwards; had it been rectilinear, the area would have been larger, but still inconsiderable as compared with the whole area *cdf*, so that we arrive at this conclusion, namely, that the stretching of a muscle *before* it is excited increases its efficiency in a degree out of all proportion to the amount of extrinsic work required for the purpose, the reason being that the amount of positive work done depends not on the very inconsiderable force actually used to extend the muscle, but on the negative work which would have been done had it been necessary to extend the *excited* muscle to the same length.

Response to a single instantaneous stimulus.—The twitch.—The mechanical change which takes place in a muscle in response to an instantaneous stimulation, is in all respects more complicated than that which is determined by continuous excitation, for whereas in studying the latter we have to compare a more or less persistent *state* which lasts as long as its cause, with the still more permanent condition of the muscle when inactive, we have in the former a *process* consisting of a succession of states, to the whole of which the instantaneous exciting cause is antecedent, and of which the duration and time-relations are entirely dependent on the physiological endowments of the muscle.

The knowledge which we possess of this process is gained by observing it and recording its effects under the two conditions already referred to—that in which the muscle is allowed to shorten without hindrance (*isotonic contraction*), and that in which no diminution of its length is allowed to take place. In the latter (*isometric contraction*) the force with which it strives to shorten may be recorded with the aid of suitable methods.

The graphic record of the response to a single excitation under isotonic conditions.—For recording the diminution of length which a

FIG. 192.—Isotonic curve drawn by a double semi-membranosus preparation attached to a lever similar to *HH* of Fig. 190. The dotted line shows the curve described when the lever is made as light as possible.—Fick.

muscle undergoes when instantaneously excited, Fick employed the lever of the form shown in Fig. 190, *HH'*. The weight to be lifted hangs by its cord from the side of the axial pulley, the radius of which is 4 mm. The muscle acts on the lever at a distance of 80 mm., so that if the weight is 200 grms. the tension of the muscle when at rest is only 10 grms. If the rate of horizontal movement of the recording surface is about 10 in. per second, the curve at ordinary temperatures has the form shown in Fig. 192. Even when the lightest possible writing lever is used, its movement is somewhat affected by its inertia; so that the real form of the curve is approximately that represented by the dotted line.

It is a familiar fact, that when, in a succession of experiments on the same muscle, the strength of the instantaneous stimulus, which at the beginning is very inconsiderable, is increased step by step, there is at first no response, that the muscle then shortens scarcely perceptibly, but that, when this point has been gained, a very slight further increase of the strength of the stimulus evokes a complete or, as it is technically called, a *maximal* contraction. This term is used to signify

that no further augmentation of effect can be gained by the same method.

The height to which the free end of the muscle is raised when contracting under isotonic conditions (which may be conveniently designated the lift), obviously depends on the load. If, as before, we measure the *load* in grammes and the *lift* in mm., and multiply the one by the other, we have the work done during the shortening of the muscle.

To investigate the relation of load to lift, we cause the muscle to inscribe a succession of curves, the load being increased by an equal amount after each inscription, in such a way that the corresponding points in all the curves are in the same vertical line, as shown in Fig. 193. As the attached (upper) end of the

FIG. 193.

FIG. 193.—Series of isotonic curves with increasing load. The number to each curve indicates the weight on the muscle in grammes. The broken line represents the first part of an inertia curve, taken with the same muscle with a load of 10 grms. See p. 360.—After Fick.

FIG. 193A.—Work-diagram (to be read from right to left) for the same muscle as it would be if the tension were a fraction of the length of the muscle at any particular moment after the beginning of the contraction. Diminution of length is expressed by the distance from *b*, in the base line *b a*, to the foot of the vertical line, of which the height expresses the corresponding tension. Both figures have been reduced in the same proportion. In the original, 1 grm. of tension was represented by 0.5 mm.—After Fick. See Note 1.

muscle is in the same position throughout, the writing lever attached to the free end takes a lower position in the successive curves, the difference between the base lines of the curves expressing the increase of length which the additional load has produced. In the series of isotonic contractions of which the curves are given in the figure, the loads and lifts were respectively as follows: ²—

Loads (in grms.)	5	10	20	30	40	50	60	70
Lifts (in mm.)	23.5	23.5	22.0	20.5	19.0	18.5	17.5	16.5
Products (grm.-mm.)	117.5	235	440	615	760	925	1050	1155

¹ The reader will understand this diagram (Fig. 193A) more easily if he imagines it placed on Fig. 193 with the base line vertical, and *b* on the beginning of the broken line.

² Fick, *op. cit.*, S. 112.

In attempting to form a conception of the change which a muscle undergoes in response to a single excitation, in its transition from the unexcited to the contracted state, we derive assistance from the provisional hypothesis, that it is capable of assuming two forms—a longer and a shorter—and that in each of them it is in *elastic equilibrium*. By this expression is meant that the internal elastic forces which are in operation in the structure of the organ are in each position so balanced, that if the organ is put out of shape by an external force, its equilibrium length is restored from the moment that this force ceases to act. In the case of a muscle arranged to contract under isotonic conditions in response to an instantaneous stimulus, we determine approximately the first of these positions, (*a*) when, without exciting the muscle, we employ an extremely light load; and the second (*b*) when, under similar mechanical conditions, we stimulate maximally; the excitatory change of form is a transition from *a* to *b*. The change, as it is observed by the graphic method, is found to occupy some time (in the muscles of the frog at ordinary temperatures about $\frac{8}{1000}$ of a second), but what is recorded is the result of an infinite number of constituent changes, which do not occur simultaneously in all parts. The transition from the unexcited to the excited state must be supposed to last in each part for a less time than the whole period of shortening of the muscle; so that, between its accomplishment and the attainment by the muscle of the new form, we may think of it as striving towards a new state of elastic equilibrium.¹

If we could consider the state of elastic equilibrium of a momentarily excited muscle, designated *b*, to be *constant under the same physiological conditions*, it would follow that the tension of a muscle at any moment during its period of shortening would always depend on its relative length, provided that the time lapsed since excitation remained the same, *i.e.*, that if in a muscle actually contracting in response to an instantaneous stimulus, the tension were measured at a given moment (say 4, 5, 6 or 7-hundredths of a second after excitation), it would always be the same in a muscle of the same length, by whatever means it had been brought to this length. Unless it can be shown that this is so, the provisional assumption set forth above must be accepted, with the reservation, not that a muscle in contracting is actuated by other than elastic forces, but that these forces or some of them are not constant.

The question whether or not a muscle of a certain length, at a certain temperature and at a certain time after excitation, will always, so long as it is in a normal condition, have the same tension, presents itself in relation to the following experiment: ²—

A series of isotonic curves having been drawn under the conditions described in the preceding paragraph, an additional curve is drawn with a load of 10 grms., with this difference, that to the light lever *HH'* (Fig. 190), previously used, a heavy equilibrated oscillating bar is attached, so that the one cannot move without the other. For this purpose a wooden bar is used, which rotates in the same vertical plane as *HH'*. It carries at either end a sliding weight of lead. The two weights, which are equal, can be so adjusted that the centre of gravity of lever and weight is in the axis. The writing point follows the course indicated by the broken line in Fig. 193, showing that the

¹ Weber, Wagner's "Handwörterbuch," Bd. iii. Abth. 2, S. 110.

² Fick, *op. cit.*, S. 120.

free end of the muscle, instead of at once ascending rapidly, as in the curve previously drawn with the light lever from the same starting point, rises very slowly at first, afterwards, *i.e.* at a period of about $\frac{4}{100}$ of a second later, as rapidly as when unhampered by having to set in motion an inert equilibrated mass. It will be noticed that this curve, which may be called an "inertia curve," crosses each of the previous ones twice. Each point of intersection indicates that the muscle has on two occasions been of the same length, at the same time after excitation. On each of the first occasions the tension of the muscle is known, for each occurred in the course of an isotonic curve of known tension. If the hypothesis above stated is correct, the tension on the two occasions must in each case have been the same. Consequently if, on the base line *ab* (Fig. 193A), we set off the lifts, *i.e.* the heights of the free end of the muscle corresponding to the intersections, and draw from the points thus marked ordinates, each representing the tension as indicated by the isotonic curve at the points of intersection, then a line joining the free ends of these ordinates (broken line in the figure) exhibits the relation of tension to length during the period that the lever was acted on by the contracting muscle. The space included between the broken line and the base line expresses, in gramme-millimetres, the work which would be done on the lever and oscillating bar during the same period, if the tension were a function of the length. The bar is made to do external work (in lifting a weight) which can be measured.¹ The amount of this work, *i.e.* of the actual work done by the muscle when acting on the lever, can therefore be compared with the amount estimated from the diagram. In numerous experiments, made by Professor Fick, it was found that the actual work done exceeds—in some instances considerably—the amount estimated. It therefore appears that a muscle when resisted in the way above described, acquires a tension during its period of effort, which is greater than it possesses under what seem to be precisely the same physiological conditions, and is extended to the same length by a weight which it is lifting without any further resistance. In other words, the effort made by a muscle at any given moment after an instantaneous excitation, does not depend exclusively on its length, but is also affected by the mechanical conditions under which it shortens. The question whether this "reaction" of a muscle to resistance is physiological or physical will be considered later.

Considering that a muscle in the discharge of its normal function is always resisted, it is of more immediate importance to inquire how it deals with resistance, than to investigate, as we have done in the preceding pages, its behaviour when allowed to contract so as to lift a weight attached to its free end. At a very early period in the progress of experimental physiology, Schwann, one of the founders of the science, enunciated the fundamental principle that, on the whole, under the same physiological conditions, the tension of a contracting muscle varies with its length. For this purpose he used a very simple method, now called the method of "after-loading." He attached the upwardly directed tendon of the gastrocnemius of the frog to one end of a balance, of which the other end supported a weight. The beam at the muscle end was prevented from rising by a stop, so that the muscle, so long as it was relaxed, was not stretched by the weight. The experiment consisted in exciting the muscle, and observing what weight was just *insufficient* to hold the beam against the stop—in other words, what

¹ This is effected by hanging the weight on a pulley on the axis of the equilibrated bar, in such a way that the weight begins to be lifted at the moment that the shortening of the muscle is completed. The height to which the weight is carried is recorded graphically. From the record, the work done on the equilibrated bar can be estimated.

weight the muscle could just lift under the mechanical conditions present. This having been ascertained, the stop was lowered so that the weight began to act a little later. The weight, which was now in excess, having been adjusted as before, the stop was then again lowered and the observation was repeated with a similar result, and so on. It was thus found that the longer after excitation the muscle encountered the resistance of the weight (or, in other words, the more it had already contracted), the less able was it to overcome that resistance.¹

The aim of Schwann's experiment was limited to the investigation of the relation between the length to which an excited muscle is extended, and the force which, when so extended, it is able to exert in contraction. Helmholtz² subsequently applied the method of after-loading in an investigation which differed from that of Schwann in this respect, that instead of determining the tensions ("forces") corresponding to a series of lengths, he made the *length constant*, and observed the

FIG. 194.—Isotonic (continuous line) and isometric (dotted line) curve of the same muscle, represented as springing from the same base line. The two ascending lines designate the fourth and eighth-hundredth of a second after excitation. On one of them the tension in grammes for the isometric curve are indicated. The isotonic curve is drawn with the muscle loaded with 30 grms.—After Fick (modified from Fig. 28, *loc. cit.*, p. 132).

relation between the tensions and the *times after excitation* at which they occurred. By setting off the times on a base line, and drawing ordinates which represented the tensions as measured by the after-loading method, he obtained a curve which he called the "energy curve," the essential characters of

which are identical with those of the *isometric muscle curve* (see Fig. 194) as now obtained by a single observation. The most important outcome of the facts which have so far presented themselves, in relation to the isometric curve, is that which was shadowed forth in the preceding paragraph, namely, that the tension of a resisted muscle, especially during the first part of its period of effort, is much greater in proportion to its length than that of the same muscle when it attains the same length in the course of an isotonic contraction; and consequently that, although in muscle, whether in the relaxed or contracted state, we have sufficient evidence that the relation between tension and length is that which characterises elastic bodies, it cannot be asserted, even with the proviso that the comparison is made at the same stage in the excitatory process, that, the length being known, the tension can be estimated from it. As Professor Fick expresses it, a muscle is always

¹ Schwann's experiment was first described in Müller's "Physiologie," 1837, Bd. ii. S. 59-61.

² *Arch. f. Anat., Physiol. u. wissenschaft. Med.*, Leipzig, 1850, S. 303.

an elastic structure, but not always the same elastic structure, even when observed under the same physiological conditions.¹

Influence of mechanical conditions on the course of the excitatory process.—In the preceding paragraph it has been shown that resistance exercises a very material influence on the character of the mechanical response to instantaneous stimulation. Although the question how this influence is exercised has during the last ten years engaged the attention of some of the most skilful experimenters, it has not yet been completely elucidated. What strikes us as remarkable is that the order of the phenomena which characterise the excitatory process in muscle, so long as the muscle contracts freely, gives place to a new order when the muscle is prevented from shortening. Can we so define the fundamental change which is undergone in a muscle when it is excited, as to be able to deduce therefrom an explanation sufficient to account, on physical principles, for both orders; or must we have recourse to the hypothesis of a secondary excitatory action of a physiological nature, caused by resistance, in which the primary change evoked by the stimulus excites in its turn secondary changes, which add their influence to the change which evoked them? Each of these views has at the present time strenuous supporters. I propose in the following pages to give an account of the experimental data which appear to be of most value as a basis for the discussion of this question.

Instead of using the term "resistance," it is convenient to refer to the condition which is produced by resistance to contraction, of an extended elastic body. This condition is commonly designated "tension." We shall afterwards find it convenient to designate as *contractile stress* that particular form of tension which expresses the effort made by a muscle in response to excitation, to overcome a resistance—whether that of a load which it is able to lift, or of a spring which it is able to bend or stretch. Whether we use the isotonic or the isometric method, we measure contractile stress in grammes.

Although it has been long recognised that the character of the mechanical response to an instantaneous stimulation depends not only on the strength of the stimulus, but also on the resistance to be overcome, it was not until seventeen years ago that J. v. Kries (now Professor at Freiburg), when working in Ludwig's laboratory, showed experimentally² that mechanical conditions affecting the process at any stage in its progress, may alter its character. Referring to this action in a more recent paper,³ he appears to admit the possibility of its being due to a kind of secondary stimulation—the muscle being re-excited by the very effort which it makes in contracting or striving to contract. A similar view has been advanced by other writers in connection with a doctrine which has since become the subject of much controversy—the doctrine that the excitatory process is made up of two antagonistic component processes, one of which is associated with shortening, the other with relaxation, and that, inasmuch as the contractile component manifestly prevails at the beginning, that of relaxation towards the end, we may associate the two periods of a contraction with these two processes respectively. As it

¹ Fick, *op. cit.*, S. 138.

² *Arch. f. Physiol.*, Leipzig, 1880, S. 370.

³ *Ibid.*; 1892, S. 3.

appeared to Professor Fick necessary that the whole subject of the mechanical conditions which affect muscular activity, especially with reference to their influence on the terminal stage, should be worked out, his pupil and assistant, Dr. Schenck,¹ has with infinite perseverance subjected these conditions to experimental investigation. Regarding resistance to shortening as the most important of them, he aims at showing how the tension so produced acts directly on the two processes which he supposes to be concerned in the twitch—"the one which causes shortening, and the one which effectuates relaxation"²—the most characteristic effect of tension being, according to him, that it hastens the supervention of the "second process." Schenck regards the two processes as complementary to each other, and consequently holds that any alteration of the intensity or time-relations of either constituent process must affect the character of the whole. Whilst this view was being set forth at Würzburg, under Fick's immediate influence, Professor Gad of Berlin, and his pupil Kohnstamm, had been led by Fick's previous suggestions to speculate in a very similar direction. There are, according to them,³ two processes by which energy is transformed in the muscular response to stimulation. Both are heat-producing, but the first, which is associated with contraction, more so than the second, which is associated with relaxation. Both are favoured more or less by increase of temperature, as well as by increased intensity of stimulus, but the first only is favoured by increase of tension. The difference between the two theories lies in the fact that Gad does not recognise what appears to be Schenck's fundamental notion, namely, that whenever a muscular contraction is resisted, the action of the primary instantaneous stimulus is supplemented or reinforced by a second stimulation, having its source in the tension which the resistance produces. Both authors show that the course (order of phenomena) of the excitatory process can be modified during its progress by external conditions, and think that these modifications can be best understood by supposing that the process itself is dual, *i.e.* that it is made up of two constituent processes, more or less antagonistic to each other, and that the effect of resistance in modifying the course of the excitatory process depends on its influence on the two constituent processes.

The sketch I have given of these speculations, although scanty, may serve the purpose of facilitating the understanding of the very remarkable influence of tension on the excitatory process, of which the experiments made during the last half-dozen years by v. Kries, Schenck, Gad, Kaiser, and others, give evidence. The examination of these observations will afford us the opportunity for such theoretical comments as may appear necessary.

Methods and instruments.—In Helmholtz's original myographic method, the changes recorded were partly of length, partly of tension. Marey was the first to show that, if it is desired to register changes of length correctly, very light writing-levers must be used, so as to avoid the errors arising from inertia; and it was he who taught us how to obtain myograms, the forms of which approach that of the true isotonic curve. Then, twenty years ago, Fick, by discovering and showing how to apply the isometric method, opened a new line of inquiry. His first tension-writer (represented in Fig. 190, p. 355) was

¹ *Arch. f. d. ges. Physiol.*, Bonn, 1891, Bd. 1. S. 166; 1892, Bd. lii. S. 117.

² Schenck, *ibid.*, Bd. lv. S. 626.

³ Gad, *Arch. f. Physiol.*, Leipzig, 1893, S. 170.

the parent of many other contrivances for the same purpose. It consists of a light lever hh' , round the axis of which, a , runs a pliable but inextensible thread with a hook at its free end, c , which is attached to the lever HH' previously described, at the same point d at which the muscle is attached; connected with the lever hh' by a stiff wire is a rigid bar, ff' , fixed at f .

FIG. 195.—Blix's apparatus for recording isometric and isotonic curves synchronically. p , the support; tt' , isometric lever; l , isotonic lever; x and y , wires from the secondary coil of an inductorium. The muscle occupies the position indicated by the broken line. For taking an isometric curve, the lever l and the attachment of the muscle to it, are made immovable by means of the clamp, Cl . When the clamp is open, l records an isotonic curve. Its movement is resisted by a weight, the thread supporting which is wound round the axle. A screw serves to adjust the isometric lever in the way shown in Fig. 195A.

When the muscle is excited it strives to rotate the axis a , but is opposed in this effort by the steel spring ff' . The tension it acquires is recorded graphically by a writer s . If during the existence of this tension the hook c is unhitched from its pin d , the excited muscle at once shortens to the length which it possesses when left to itself. This shortening can also be recorded by a writer s' , on the lever HH' .

Fick's first purpose was to register the changes of tension in a muscle striving to contract, but entirely prevented from doing so. Subsequently, the method was extended to the case in which a muscle contracts against resistance, and instruments were contrived by which tension and shortening could be recorded simultaneously. Although Fick's original myotonograph gave curves which exhibit to a considerable extent the deformation which arises from friction and inertia, the records obtained by the more perfect tension-writer of his pupils Schönlein and Schenck are not open to this objection.¹

FIG. 195A.—Enlarged view of the same apparatus, to show the torsion rod from above.

¹ Schenck, *Arch. f. d. ges. Physiol.*, Bonn, 1892, Bd. lii. S. 108.

A tension-writer which has the further advantage of greater simplicity is that of Professor Blix¹ (see Fig. 195 and 195A). The muscle acts by torsion on a cylindrical rod of steel *c*, 5 mm. long, and nearly 1 mm. thick. This is fixed horizontally at one end; the other is free, but is supported at *s*. From a point near the free end a metal bar *t'* springs, of which the tension-recording arm *t* is a continuation. At known distances the bar is perforated for the reception of a steel hook, to which the muscle is attached, the usual distance being 3 mm. from the axis. The resistance which the steel rod offers to torsion is such that a weight of 10 to 20 grms. depresses the writing end only 1 mm. The arm is 9.6 cms. long, and together with the steel rod weighs only 0.05 gm. The figure shows the way in which the tension-writer is combined with the shortening-writer, so as to register the isometric and isotonic curves synchronically, *i.e.* the curves occupying corresponding positions on the recording surface of the cylinder. The shortening-writer *l* is a strip of bamboo, of which the free end is 18 cms. from its axis. It is perforated transversely by a needle about 8 cms. from the axis; to this needle the lower end of the muscle is attached. This instrument is not only very free from the errors due to inertia and friction, but has the advantage that in employing it for drawing an isometric curve alone, the length of the muscle diminishes extremely little as the tension increases. A tension of 100 grms. can be attained with a diminution of length of no more than 0.06 mm.

It is desirable for all myographic purposes that the rate of rotation of the recording cylinder should be constant and equable, that the position of the lever at the moment of excitation should be invariable, and that the vibrator which marks the time should start simultaneously with the record. In the instrument designed by Blix all these ends are secured. The rotation of the cylinder is urged by a spring, but is restrained by a detent, on the withdrawal of which the cylinder flies round. In doing so, it liberates a reed which writes its vibrations on the blackened surface, and at a later moment opens the primary circuit of the induction coil. The heavy cylinder, which before this happens has ceased to be acted on by the spring, continues its rotation at a nearly uniform rate, until, after the curves have been drawn, it is arrested by a mechanism which need not be here described. Before the next observation, it must of course be brought back to its original position and adjustment. Although the apparatus above described may admit of further improvement, it answers for the present the requirements of the investigator. It enables him to obtain a true graphic representation of each of the mechanical changes which a muscle undergoes in consequence of excitation by an instantaneous stimulus; and, by registering tension and length synchronically, to determine both their quantitative relation to each other at any moment, and the relation existing at any moment between their rates of change.

Experiments in which the mechanical conditions are varied during the response.—In v. Kries' first series of experiments relating to this subject, the conditions were such that, although when in the unexcited state the muscle is of its natural length and has no tension, it cannot contract without encountering resistance, which, however, it overcomes as soon as it has gathered sufficient strength. The moment at which this happens is the longer delayed the heavier the weight. In this case the excitatory process begins isometrically and proceeds isotonicly. The figure (Fig. 196) shows what happens.

Curve 1 in both series is drawn by the unloaded muscle, Curves 2, 3, 4, and 5 by the same muscle, when loaded successively with increasing weights. All

¹ *Skandin. Arch. f. Physiol.*, Leipzig, 1892, Bd. iii. S. 295.

the curves culminate about the same time, but the inclination of the rise, *i.e.* the rate of shortening, diminishes as the load increases. The changes of tension are shown in the curves of the upper series. In each case the horizontal part of the tracing indicates that, during the time to which it corresponds, the muscle is working isotonically. Curve 5 of this series is identical with Helmholtz's "energy curve" (see p. 362). In this case it is evident that, as the load increases the rate of increase of length lessens, while the tension remains the same.

FIG. 196.—Series of "after-loading" curves, with increasing load.—After v. Kries.

Fig. 197 shows the simple mechanism with the aid of which these curves are recorded. Before the muscle begins to shorten, the descent of the load is arrested by the stop *So*, the height of which is so adjusted that until the moment of excitation there shall be no tension. The stop *Su* in this case is not used. When the muscle relaxes, and the prolongation of the lever again strikes *So*, the curve again becomes isometric.

In another series of experiments the same contrivance was employed to produce sudden increase of tension at a later period during the response, the stop *Su* being now brought into play, the stop *So* not being used. The contractions recorded are of the kind called by v. Kries, *Anschlagszuckungen* (arrested contractions). The load is increased as before, after each observation, and consequently each successive curve begins at a lower level. In order that the length of the muscle may be the same at the moment of arrest in each case, the stop *Su* must remain throughout at the same height. It is therefore encountered by the prolongation of the shortening lever later each time, and

FIG. 197.—v. Kries' apparatus for taking "after-loading" curves and "arrested-contraction" curves. *j*, isometric lever with its axis at *k*; *gg*, isotonic lever with its axis at *a*, 30 mm. to the right of *g*; *So* and *Su*, screws held by two horizontal arms of a support, *Q*² and *Q*¹; *m*, muscle (Fick's double adductor preparation, with the two groups of muscles used abreast).

the interval of time between the moment of encounter and that of culmination diminishes. In this case each response begins isotonically, and proceeds isometrically, as seen in Fig. 198.¹ When the lever, on the relaxation of the muscle, leaves the stop, the curve again follows an isotonic course.

To make clear the bearing of these empirical data, some further explanation is necessary. The reader must first understand that the purpose of both the methods above described is to investigate at any moment in the response, the two functional activities (*Leistungsfähigkeiten*) of a muscle—the *Fähigkeit Verkürzung zu leisten*, and the *Fähigkeit Spannung zu erzeugen*. These are represented by the slant of the isometric and isotonic curves respectively, at the moment that the lever parts from *So* or encounters *Su*. To indicate these times the vertical broken lines have been added to von Kries' figure. The important point in the curve of after-loading is that whereas the isotonic curve rises with an initial inclination which diminishes as the load increases, the isometric has nearly the same initial inclination throughout. This means that "the ability of the muscle to generate tension" is unchanged, while its "ability to produce shortening" diminishes. The relation between these he calls "the apparent extensibility" of the muscle. In the experiment given in Fig. 198, the load which is at first minimal is increased after each observation ;

FIG. 198.—Series of "arrested contraction" curves, with increasing load, the length of the muscle being the same at the moment of arrest in each case.—After v. Kries.

but as it is not supported, the lift begins at a lower and lower level. At the moment of arrest, which of course occurs later and later, the length of the muscle is always the same. Its rate of shortening diminishes as in the previous case, but its rate of increase of tension is not constant as before, but diminishes with the rate of shortening ; so

that the "apparent extensibility" remains nearly the same. The explanation given by v. Kries is as follows:—In a muscle, notwithstanding that length and tension remain the same, the relation between the two functional capacities differs according to the "way in which the portion of the response which precedes the transition" has occurred (see p. 369). He supposes that what happens at the beginning of the contraction influences the subsequent state of the muscle by its influence in determining the number of fibres which participate in the process, and surmises that the effect of initial tension (*starke Spannung im Moment der Reizung*) is to augment the number of acting fibres, and thereby to bring about a condition in which the rate of change of tension corresponds to that of change of form. The data seem to me to admit of a simpler explanation. The contractile stress of the muscular fibres at the moment of transition is in each case truly indicated by the rate of augmentation of tension—that is, by the initial inclination of the isometric curve, and is accordingly greater in the first series than at the corresponding period in the second. But the reason why this is so, is that the measurements relating to the first series are made at an

¹ v. Kries, *Arch. f. Physiol.*, Leipzig, 1892, S. 10.

earlier stage in the response than those relating to the second; and, consequently, that the diminution of the rate of augmentation of tension in that series means nothing more than that the contractile stress of the muscle has already passed its maximum.

v. Kries also made experiments in which the load (and therefore the initial length of the muscle) was constant, but in which its length at the time the stop was applied, varied. A method founded on the same principle was adopted by Schenck in investigating the influence of tension on the time-relations of the excitatory process. His experiment is as follows:—A muscle is made to contract isotonically with a small load. It draws the curve indicated by the dotted line in the figure (Figs. 199 and 200). Immediately

Fig. 199.—Isotonic curve (dotted line) and arrest curve (continuous line) of the same muscle as in Fig. 200, cooled to 6° C.

Fig. 200.—Isotonic curve (dotted line) and arrest curve (continuous line) of a muscle warmed to 31°·5 C. (double adductor preparation, the two groups of muscles arranged as shown in Fig. 189), the arrest taking place when the point of the writing-lever was at z.—After Schenck.

afterwards a second curve is drawn, with the stop so placed as to arrest the shortening of the muscle half-way. He found that if the observation is made at a low temperature, *e.g.* 6° C. (Fig. 199), the period of contraction is prolonged; if at a high temperature, *e.g.* 31°·5 C. (Fig. 200), it is abbreviated, as compared with an unarrested isotonic contraction at the same temperature. At an intermediate temperature the fall of the arrested curve coincides with that of the isotonic curve.¹

Schenck explains these apparently inconsistent results by assuming that tension has a twofold action—that it “strengthens and protracts the process of contraction,” and that at the same time it “hastens relaxation.” “In the warm muscle, the second of these actions predominates; in the cold, the first.”² He also found that the first effect is the more pronounced the less the muscle is loaded, and connects this with the fact, to be referred to in a later section, that the result of increasing the load in isotonic contractions is to increase the production of heat. It is to be noted that Schenck applies the arrest when the muscle is half-way between its natural unexcited length and that

¹ Schenck, *Arch. f. d. ges. Physiol.*, Bonn, 1894, Bd. lv. S. 629.

² Schenck, *ibid.*, 1894, Bd. lvii. S. 606.

which it eventually attains, and that this position is different in relation to the former in a cooled muscle from what it is in one that has been warmed. It will be seen later, that in this observation he is comparing very different stages in the progress of a muscle from the unexcited to the excited condition.

Similar considerations led Schenck to investigate the effect of different kinds of augmentation of tension, having regard especially to its amount,

FIG. 201.—*m*, Normal isometric curve; *t*, normal isotonic curve of the same muscle; *a a'*, inertia curves of tension and shortening respectively, the heavy lever described on p. 360 being used but not weighted; *b b'*, similar curves with the lever weighted on either side of the axis with 500 grms.—After Schenck.

muscle is delayed by the inertia of the bar before the commencement of shortening, or later, so long as the increase of tension ceases during the first

half of the period of contraction, as happens when the bar is unloaded, the fall of the curve of shortening *a*, is either in front of, or almost coincides with, that of the isotonic curve *t*. If, however, the moment of inertia of the bar is augmented by weighting its ends, so that the augmentation of tension lasts much longer (curve *b*), the maximum of contraction is reached later, and the fall of the curve is beyond what it would have been in the absence of the bar.

FIG. 202.—Schenck's apparatus for taking "jerk curves." *L*, isotonic lever; *HH'*, light wooden lever, working on the axle *A*, with one arm attached to lower end of muscle and isotonic lever by the thread *nk*; *F*, spring fixed at *B*, which can be held down by the electro-magnet *E*, and which, when let go, strikes *H'*.—After Schenck.

with the isotonic curve. The later the jerk took place, the sooner the relaxation of the muscle occurred (Fig. 203, B). The contrast between the

He subsequently experimented with more sudden and transient augmentations of tension by jerking the writing-lever downwards during an isotonic contraction.¹ By an ingenious contrivance, shown in Fig. 202, this could be done at any desired period, and it was found that if done at the very beginning of an isotonic contraction, the jerk scarcely affected the time of relaxation (Fig. 203, A); for the jerk curve (as I propose to call curves produced in this way) coincided in its decline

¹ Schenck, *Arch. f. d. ges. Physiol.*, Bonn, 1895, Bd. lxi. S. 77.

last set of experiments and the preceding inertia experiment needs scarcely to be indicated. When the jerk method was used, the rise of tension was abrupt and forcible. In the contractions with the equilibrated bar, it rose and subsided gradually.

Schenck also made experiments with arrested contractions, for the purpose of comparing the effects of the arrest on loaded and unloaded muscles,¹ and found that similar differences present themselves. If the contraction of a lightly loaded muscle is arrested when already half accomplished, it gives way so promptly that the writer at once leaves the stop in the same way as in Fig. 200. The more the load is increased, the less the relaxation is hastened, until eventually the writer is held against the stop during the whole period of isotonic shortening, or even longer. In one case the tension is augmented at the moment of arrest, from a very small amount to one which is fifty or a hundred times as great; in the other, from an amount already large to another a little larger.² As has already been stated, cold has a similar effect to load, so that the same muscle which at 20° C. promptly relaxes during the period of arrest, holds the writer against the stop during the whole

FIG. 203.—Isotonic (dotted line) and jerk curves (continuous line); z, position of point of writing-lever when jerk took place.—After Schenck.

period of isometric contraction, when the temperature approaches 0° C. (Fig. 199).

Schenck sums up his conclusions as to the influence of augmentation of tension on the isotonic contraction of a lightly loaded muscle as follows:³—Sudden and extensive alterations of tension hasten relaxation; changes of longer duration, which develop slowly and are of small amount, tend to increase contraction and to defer relaxation. Of the two effects, the former follows the change of tension immediately, the other often not until a little later.

It can scarcely be questioned that this statement is in accordance with the experimental data which have been given; but when we pass from the observed facts to their explanation, we find ourselves in considerable perplexity. Schenck finds the link which connects the hastening of relaxation (*verfrühte Erschlaffung*), with the conditions which produce it, in the paradox of inhibitory excitation. He imagines

¹ Schenck, *Arch. f. d. ges. Physiol.*, 1894, Bd. lvii. S. 608.

² It is here again to be noted that the length of the muscle at the time that the arrest was applied in these experiments was not the same.

³ Schenck, *Arch. f. d. ges. Physiol.*, Bonn, Bd. lxi. S. 85, 103.

it possible for a muscular fibre to be stimulated into relaxation—wakened into sleep. After again stating that the more abrupt and transitory the change of tension, the more marked is its relaxing action, he continues (p. 104): “A contracted muscle is, according to Pflüger’s theory, a labile group of atoms.” These he supposes to form a chain, of which the “loosely joined links” are more easily sundered by a “short forcible jerk than by slow persistent tension”; the latter, on the other hand, is more effectual in evoking contraction, for the very reason that it is itself of relatively slow development.

The case which seems chiefly to require such a theory is that of the jerk relaxation. Schenck himself tells us that in this experiment the muscle receives an *Erschütterung*—a shatter—a process by which we know experimentally that heat is liberated. It is difficult to accept a doctrine which identifies this with inhibition, and much more easy to suppose that the influence of jerk or shatter is simply to put a stop to the whole process, by changing the mode in which energy is liberated, substituting the production of heat for that of work, and to regard both the changes which follow excitation—relaxation no less than contraction—as parts of the same process. We may then inquire whether or not it is necessary to call in the aid of an auxiliary theory of secondary excitation.¹

The “simple experiment” which led Schenck to the discovery of the remarkable fact, that a muscle which is arrested in the course of an isotonic contraction, if lightly loaded, promptly relaxes, rather suggests questions than answers them. It has been subjected to criticism by other experimenters, particularly by Kaiser,² who has shown that both at high and low temperatures, the question whether the muscle relaxes or not immediately after the arrest, depends on the height of the stop, *i.e.* on the length of the muscle at the time the stop is applied as compared with its natural length when unloaded and unexcited. On this observation he has founded what may be called a new method of observing the phenomena of isotonic contraction and relaxation, which promises to be very fruitful. Starting from Weber’s conception of the process, according to which the excited contractile molecular structure, at the moment of excitation, takes the place of the unexcited, and is replaced by it at the end of the period of excitation (see p. 360), he begins by seeking for a criterion by which the state of excitation may be characterised in a muscle which is allowed to change its form in response to an instantaneous stimulus without mechanical interference. The character by which an excited muscle can be most easily distinguished from an unexcited one is its length as recorded in the isotonic curve. He therefore takes as the object of observation, a muscle (*gastrocnemius*) arranged for writing its curve isotonically with the lightest possible load.

The upper end of the muscle is fixed during the whole course of each series of observations; consequently the horizontal line which corresponds to the natural length (Fig. 205, *l*) of the muscle when unexcited and unloaded is also constant. When in the progress of the observation the muscle is loaded,

¹ The paper on this subject already referred to (*Arch. f. d. ges. Physiol.*, Bonn, Bd. iv. S. 629) is entitled “Ein einfacher Versuch zur Demonstration des Einflusses der Spannung, u. s. w.”

² “Zur Analyse der Zuckungcurve des quergestreiften Muskels,” *Ztschr. f. Biol.*, München, 1896, Bd. xxii. S. 157–178; “Untersuch. ueber die Natur der bei der Contraction des quergestreiften Muskels wirksame Kräfte,” S. 361.

care is taken to avoid the slightest change of position of the fixed end, so that the graphic record of each length, due to extension by the load, may be absolutely reliable.

The first step is to determine and record graphically in the unweighted muscle its "natural" length when excited by a maximal stimulus. If we call this length λ we may designate the horizontal line corresponding to it by the same letter. The position of that line is determined as follows:—An ordinary isotonic curve having been drawn with an "unloaded" muscle, a series of arrest curves are taken from the same starting-point, as shown in the figure (Fig. 204), the stop being slightly raised after each excitation. At first the lever hesitates at the stop for several hundredths of a second; but, as the succeeding curves show, the period of hesitation gets less and less, until finally the lever falls immediately. The same thing happens, whatever the temperature of the muscle; and if the experiment is repeated with the same unweighted muscle, at temperatures, say, of 0°, 14°, and 30° C., it is found that

Fig. 204.—Curves of isotonic and arrested contractions of an unloaded muscle, with maximal stimulation at ordinary temperature. x' , x'' , x''' , and λ , points at which the lever was arrested in successive curves.—After Kaiser.

Fig. 205.

- (1) Isotonic curve of unloaded muscle at temperature 14° C. ; (2) the same, at 25° C. ; (3) at 0° C. ; (4) at 14° C., with load on muscle. ab indicates level of fixed end of muscle. l indicates level of free end of muscle in its first equilibrium position (*i.e.* when unloaded and at rest); λ denotes the length of muscle in its second equilibrium position (*i.e.* that which it tends to assume when unloaded, in response to a single maximal stimulation); g , line representing length of muscle when so loaded that the summit of the curve is at λ ; x , x' , point at which the lever falls at once on arrest, in curves drawn with muscle at 14° and 25° C. respectively; x'' and x''' , summit of curves drawn with muscle at 0° C. and when loaded respectively. The marks on the λ line indicate hundredths of a second.—After Kaiser.

the height at which there is no hesitation of the lever is the same for each, however much the height of the summit of the curve, and its duration may vary. A horizontal line at this height is therefore the one required. It is represented in the diagram (Fig. 205), in which its relation to the summit of

the curve, under varying physical conditions, is shown. As regards temperature, this relation may be stated generally thus:—At 0° C. the summit of the curve does not rise above λ , and only rises to this level slowly, whereas above 0° C. the height of the summit increases with the temperature, as does also the rapidity with which it attains this height. Kaiser therefore concludes that there is a certain limit in the response of a muscle to a single instantaneous excitation, at which the contractile stress which causes shortening ceases to act; and he believes that any further diminution of length is due to the velocity imparted to the process of shortening by this stress, and varies accordingly.

FIG. 206.—Isotonic curves of muscle so loaded that its summit is in the second equilibrium position, in the one case (continuous line) unloaded on the summit. z , line indicating equilibrium length of muscle at rest when unloaded; g , the length when loaded.—After Kaiser.

FIG. 207.—Isotonic curve with the same muscle more heavily loaded to begin with, and unloaded on the summit. g' , line indicating length of muscle when loaded.—After Kaiser.

To complete the evidence that this limit is that of the excitatory equilibrium position of the muscle (*i.e.* that it is λ), Kaiser seeks to demonstrate that it is constant under other varying physical conditions besides temperature. He has given satisfactory proof that this is so in the case of load, which, after temperature, is the physical condition of most importance in determining the "form" of an isotonic contraction. His method consisted in unloading differently weighted muscles at different points on their course, whereby he found that it is only when the muscle is unloaded at the moment that it is at the length λ , as ascertained from the isotonic curve of an unweighted

FIG. 208.—Series of release curves following arrest, with muscle cooled to 0° C.

muscle, that the free end of the muscle returns at once to its original unexcited level, z . Two of Kaiser's curves showing this are given in Figs. 206 and 207. In the first experiment (Fig. 206) the muscle was so loaded that the summit of the curve was at the level of λ ; it was relieved of its load at the moment of culmination of the curve, and it is seen that it relaxes at once to its natural length, z —apparently indicating that there was no more available contractile stress at the moment when unloading took place. In the experiment to which Fig. 207 refers, the weight on the muscle was heavier, so that the summit of the curve was below the level of λ . It was again relieved of its load at the moment of the culmination of the curve, and the occurrence of

a second twitch indicated that contractile stress was then still present. The series of twelve curves, reproduced in Fig. 208, were obtained by a similar method, with the exception that before each release of the lever it was arrested at a level about halfway between l and λ , and that the muscle had been cooled to a temperature of 0° C.

These curves show that, although in each muscular element the transition from the unexcited to the excited state may be instantaneous, a certain time is required in order that the contractile stress of the whole may attain its maximum. This time Kaiser refers to as that of the *Entwicklung der Verkürzungskraft*. Thus, although a low temperature does not affect the position of λ , and accordingly does not increase the contractile stress, it may yet enable the muscle to raise a weight to a greater height by postponing the moment at which the contractile stress ceases to act.

FIG. 209.—Isotonic and arrest curves of an unloaded muscle, with maximal stimulation and with summation of stimuli. Arrest at λ in both cases; λ^2 indicates the point which represents the probable second equilibrium length of the muscle, as excited by the two stimuli.—Modified from Kaiser.

It having been found that the second equilibrium length of the muscle is independent of the physical conditions under which it may be placed, the next step is to demonstrate its relation to the physiological conditions. Now, the means by which *function* is evoked in a muscle is excitation. We may regard a muscle when “maximally” stimulated (and not fatigued) as in a definite physiological condition. The condition is altered when a supramaximal response is evoked, as may be done by applying two instantaneous stimuli, both of which are maximal, within a period of one- or two-hundredths of a second, or a submaximal one, by applying a stimulus weaker than that required to produce a maximal contraction. Comparing the curves so obtained with a normal maximal curve of the same muscle, Kaiser found that in the case of supramaximal stimulation (Fig. 209), although the summit of the curve is not much higher, there is a hesitation of the writing-lever when it is arrested at a height which corresponded to λ in a maximal contraction, indicating that the second equilibrium position of a muscle excited by a summation of stimuli, is at a higher level, say at λ^2 . Conversely, when the lever is arrested at different points in the course of a submaximal response (Fig. 210), its sudden fall occurs when it is at a considerably lower level than that of λ in the curve of maximal stimulation, indicating that the second equilibrium position of a muscle, submaximally stimulated, is at a lower level, say at λ° . It thus appears that the equilibrium length of an excited muscle varies with the degree of action of the exciting cause,

FIG. 210.—Two isotonic curves of an unloaded muscle, the one with maximal and the other with submaximal stimulation. λ and λ° the positions representing the second equilibrium length in the two cases.—Two figures combined, after Kaiser.

so that λ is the expression of the capacity of the muscle to respond to a maximal instantaneous stimulation, and we are justified in designating the contractile stress which determines the change from the first to the second equilibrium position as "physiological," although it acts as if it were "elastic." Kaiser gives the name of *Verkürzungskraft* to this contractile stress.

The preceding summary will be sufficient to give the reader an idea of the scope of Kaiser's research, a main purpose of which was to elucidate the relation between the length of a muscle, when allowed to shorten freely in response to a single maximal stimulation, and the isotonic curve of such a contraction. The experimental data obtained, lead him to reject the theory that the single contraction is a *dual* process. Following out Weber's original idea, he thinks of the "forces" operative in the process as elastic, and accounts for all that happens by supposing that shortening expresses transition from the "natural" unexcited condition to the "natural" excited condition; and that lengthening is a process which is simply the reverse of the other. The first is the direct response to excitation, the second a necessary consequence of the first. The proof that the stage of relaxation is a mere

FIG. 211.—Isotonic curve and release curve, after arrest, of an unloaded muscle.
—After Kaiser.

consequence of that of contraction, he finds in the fact that temperature, which has so marked an influence on the first part—that in which the muscle is actively contracting—has no effect on the second, for the curve drawn by the same muscle in relaxing is always precisely the same, provided that it is unloaded and that the muscle at the starting-point of relaxation is of its natural length when excited, *i.e.*, that its unattached end has to accomplish,

in transition from the excited to the unexcited state, the distance above designated as $l-\lambda$.¹

Before concluding the consideration of the equilibrium length of excited muscle, it may be well once more to refer to the difference between the maximum degree of contraction which is evoked by a single instantaneous stimulation, and that more intense state of excitation which exists in tetanus.

When a lightly loaded muscle is excited by maximal instantaneous excitations which succeed one another with sufficient frequency (100 per second), the contraction being recorded isotonically, the lever rapidly

¹ To the reader who consults Kaiser's papers it may be of use to note that he employs the terms *erster* and *zweiter Fusspunkt* to designate the position of the unattached end of the unextended muscle in the unexcited and excited states respectively. I have in the text made no reference to Kaiser's theoretical explanation of the isotonic curve. He attributes the descent of the lever at the moment indicated by λ in Fig. 204, not to the rebound of the lever against the stop, but to a downwards impulse of the muscle, and connects this with the theory that so much of the ascent of the lever as is above λ is due, not to the action of the lever, but to the action on it of the muscle, which, after attaining its equilibrium length λ , shortens, by virtue of its previous motion, to a length less than its equilibrium length. Actual experiment does not favour this conclusion, for Schenck has shown that if the lever is supported at the height of λ , before the muscle is excited, it remains motionless (*Arch. f. d. ges. Physiol.*, Bonn, Bd. lxx. S. 325). This being the case, it is clear that, so far as concerns the part of the isotonic curve which is above λ , the lever is not actuated by the muscle.

rises to its maximal height, after which it remains for a time at the same level—indicating that the muscle is fully tetanised. In this state it is free from stress of any kind, so that its actual length and equilibrium length, which may be designated Λ , are the same. Although we have no experimental data which enable us to state what the relation of λ to Λ is, there is reason to believe that the former length exceeds the latter by about three-quarters. In a muscle excited in the manner above described, the tetanic state is produced not so much by the superposition of effects (as in Helmholtz's well-known experiments), as by the summation of stimuli; for each excitation occurs before the contraction evoked by its predecessor has begun. Consequently, in the transition of a muscle from the imperfect state of excitation to which λ relates, to that of complete tetanus, there may be any number of stages of contraction, each characterised by an equilibrium length intermediate between λ and Λ . In this connection it will be remembered that in the response to two maximal stimuli, following each other at a very short interval, the equilibrium length λ^2 takes a higher position in the curve than in that which follows a single excitation of the same strength (Fig. 209).

Muscular tonus.—Throughout the preceding discussions relating to the mechanical properties of muscle, it has been found convenient to regard the length of an unexcited muscle as constant, and to designate it by the letter l . There are, however, many instances which show that a muscle may, although at rest and under conditions which cannot be regarded as abnormal, be of a different length at different times. States of relaxation, in which muscles are longer than they are ordinarily, are not recognised; so that we need not consider them. It is only necessary to designate those conditions in which the fibres are permanently short. All such states come under the term *Tonus*.

The lengthening which the muscles of the higher animals undergo, in consequence of destruction of the motor centres by which they are innervated, may be taken as evidence that in the natural state their fibres are not perfectly at rest. This state, to which the term "skeletal tone"¹ is applied, is essentially one of continuous indirect excitation; for it manifestly depends on the influence of the nervous system. There are, however, conditions of tone in the production and maintenance of which the central nervous system appears to take no part. Of these the most instructive examples are (1) the tone of the claw muscles of the crayfish; and (2) that of the heart of *Helix*.

The first of these has been most recently investigated by Piotrowsky, who has shown that lengthening of the abductor muscle can be produced as easily by direct as by indirect stimulation, provided that the muscle when stimulated is in a tonic state. The phenomenon can, however, be only observed in winter, and then only when the temperature is about 8° C. or lower. At higher temperatures the muscle contracts normally when stimulated, so that, according to the degree of tonus present, you may have contraction, relaxation, or a mixed result.

The heart of the snail affords quite as striking an example of the same relation between excitatory relaxation and tonus. The mode of observing it is as follows:—A narrow glass tube is drawn out at one end, and shaped into a cannula, to which the ventricle is tied. The

¹ Foster's "Physiology," 7th edition, part 3, p. 996.

cavity of the ventricle and the tube are filled with salt solution, which, when the tube is fixed in an upright position, stands in it at the height of a few centimetres. The heart thereupon begins to beat, but eventually stops in systole. By a suitable arrangement, a voltaic current is led through the ventricle from base to apex, or the reverse. On closing the current the ventricle relaxes at the anode, and the wave of relaxation is propagated towards the cathode. If the closure is of short duration, the ventricle returns, when the current is opened, to its previous state of tonus, and the observation may be repeated. Here again it is seen that the effect of the current is to annul an existing state of excitation, rather than to bring into existence a new state.

The fact that, in these instances, the elements of muscular structure lengthen when subjected to mechanical or electrical disturbance, is difficult to understand, chiefly because it appears to be against the purpose to which those elements are adapted in the organism, *i.e.*, against their function. If, therefore, stimulation is the equivalent of *Auslösung*—the discharge of function—we cannot designate as stimulation an action by which activity is quelled. A living organism cannot be waked into inactivity.

Yet the fact remains that the agents which we are in the habit of regarding as stimuli may, by their direct action, quell function. Since Pflüger discovered that by the voltaic current we can at will modify the vital condition of a motor nerve in either of the two possible directions,—augmentation and diminution,—we have recognised in nerve and in other excitable structures, an up and a down state. The essence of what we know about these states is, first, that the down state is a concomitant of activity, the up state is similarly associated with rest; and, secondly, that the latter is the antecedent condition of restitution or repair, the former of capacity for function (*Functionsfähigkeit*). Hence the two states constitute one cyclical process, in which each state is alike the consequence and cause of the other. But no sooner have we expressed this intimate relation, than again the essential difference between the two presents itself—the contrast between functional activity and repose. The contrast consists mainly in this, that while in the former the thermogenetic and electrical changes are sudden, easily recognised, and are so conspicuous that they constitute the most characteristic phenomena of animal life, those of assimilation or restitution are so little obvious that their existence is rather a matter of inference than of observation.

Summation of a series of mechanical responses—Genesis of tetanus.—Tetanus has already been defined as the response to a succession of instantaneous stimuli. The typical form of this response (complete tetanus) is obtained when the frequency of the excitations is such that the intervals between them are each equal to the time required for the muscle, excited by a single instantaneous stimulus under isometric conditions, to attain its greatest tension. A muscle, so tetanised, has an equilibrium length Δ , which, as we have already seen, is considerably less than λ , the length which it strives to attain (and may overshoot) in response to a single instantaneous excitation; in other words, the distance $l - \Delta$ is considerably greater than $l - \lambda$. When an "unloaded" muscle, *i.e.* one with a load say of 0.5 grm., is tetanised, its actual length and its equilibrium length (Δ) are identical. The same unloaded muscle shortens nearly to the same extent when excited by an instantaneous

stimulus, but, as we have seen, the summit of the isotonic curve does not usually correspond to the equilibrium length λ . The question why a muscle shortens to a less equilibrium length when it is tetanised, than when it is maximally excited by a single stimulus, will be better understood when we have had under consideration the order of the changes which occur in response to a single stimulation. It will be seen that the first of these changes is oxidation, of which the excitatory electrical change is the sign and probably indicates the duration, and that as soon as it has attained its full development it is at once converted into mechanical tension (contractile stress). We shall also see that, although the link which connects the chemical change with the mechanical change is an unknown one, there is good reason for believing that in whatever way mechanical potential energy may arise out of chemical energy, no measurable time is lost in the conversion. Its visible effect, on the other hand, *i.e.* the change of form, is a process which requires time, and consequently overlasts its efficient cause. At the moment that the change of form is beginning, the electro-chemical change has already culminated. The mechanical effect subsides the moment it has reached the degree called maximal, its efficient cause being no longer operative. If, however, the excitation is repeated before this subsidence begins, the effect of the second excitation is added to that of the first, so that the curve may, as Helmholtz's well-known experiment shows, attain nearly double the height of the single isotonic curve. If a series of such excitations follow one another at equal time-intervals, their effects are so summed that the muscle shortens to a definite length, the difference between which and λ depends on the load. So that, when maximal excitations are used, it is the summation of the effects of successive excitatory changes, which causes the muscle to shorten to an equilibrium length less than that attained by it in response to a single such excitation. With reference to this summation, Fick's measurements (to be referred to later), determining that in such a succession of excitations the chemical changes as judged by their thermal effects are more intense in the first than in the subsequent responses, must be borne in mind in connection with the fact that, in the summation of effects, the increments due to the second and immediately following excitations are also much larger than those due to succeeding ones.

That the rise of the tetanus curve is due to something more than summation of stimuli, *i.e.* in large measure to the summation of effects, seems to be indicated by the fact that the electrical change, by which the chemical one can best be made apparent, shows no sign of summation. The moment a muscle is tetanised, the so-called "action current" has its full strength. Certain observations made by v. Frey,¹ relating to "supported" muscles, may have a similar bearing. He alleges that if the load is so supported that the muscle does not begin to lift it in response to a single excitation, until the muscle has attained a length but little in excess of its length when tetanised, it raises the load to the same height as that to which it would be raised in tetanus; the reason being that the amount of shortening to be accomplished being less, the limited time during which the muscular effort is at or near its maximum, has become

¹ v. Frey, "Versuche zur Auflösung der tetanischen Muskelcurve," *Beitr. z. Physiol. Carl Ludwig*, z. s. 70 *Geburtst.*, Leipzig, 1886.

sufficient for the completion of the contraction.¹ The question, however, whether, in the rise of tetanus, we can distinguish between the summation of excitations and the summation of their effects, requires further experimental investigation.

Summation of inadequate stimuli.—It was long ago observed by Helmholtz that when an instantaneous stimulus, which in itself is incapable of evoking a maximal response, is followed during the period of latency by a second of the same strength, a maximal response may be obtained. If the time-interval between the two stimuli is sufficiently short (less than $\frac{1}{500}$ second), there may, as we have already seen, be an increase of effect, even when the stimuli are maximal (see Fig. 209). Again, a succession of stimuli of sufficient frequency may be effectual, although each stimulus when alone is so weak as to produce no response. An instance of this is given in Fig. 212, which

FIG. 212.—Muscle curve, showing the effect of a succession of stimuli, each one of which alone was inadequate to produce contraction.—Richeť.

represents a tracing made by Richeť² with the claw-muscle of the cray-fish. Seven stimuli, each inadequate in itself to produce an effect, were sent through the muscle in succession. The first three gave rise to no response, the fourth to a very slight one, while the fifth, sixth, and seventh evoked contractions each stronger than that of its predecessor.

Such summation of submaximal stimuli can be much more easily observed in slowly contracting skeletal muscles, such as the claw-muscle of cray-fish, than in quickly contracting ones. The cardiac muscle of the frog, when stimulated by induction currents which singly are of insufficient strength to produce an effect, responds when these are repeated with sufficient frequency, the response being slower in occurring the less the frequency. Thus Engelmann found that in the bulb of the aorta³ a frequency of fifty inadequate stimulations per second produced a response after a delay of one second, a frequency of

four per second after two and a half seconds. In smooth muscle even strong single induction shocks are often inadequate to produce a response, at the same time that tetanisation with comparatively weak stimuli may be effectual.⁴

We must distinguish between instances such as those above referred to,

¹ From Kaiser's observations, we have learned that at the moment of culmination of the electro-chemical response to a maximal instantaneous stimulus (Case 1), a muscle, even when after-loaded, tends to assume the length λ , whereas, under the conditions of v. Frey's experiment (Case 2), it shortens to its eventual length in tetanus Λ . There is in reality no contradiction. In Case 2 the contraction culminates immediately after it begins, *i.e.* at a time when, as Bernstein has lately shown, the process by which chemical energy is transformed into muscular force is at its maximum. In Case 1 that process is already declining at the moment that its mechanical effect is at maximum. This may be expressed by saying that it is for want of time that the mechanical effect of a single stimulus falls short of that of repeated excitation. See Kaiser's criticism of v. Frey's interpretation of his observation, *loc. cit.*, p. 367.

² "Physiol. des muscles et des nerfs," Paris, 1882.

³ *Arch. f. d. ges. Physiol.*, Bonn, 1882, Bd. xxix. S. 453.

⁴ Engelmann, *ibid.*, 1870, Bd. iii. S. 280.

in which two submaximal stimuli acting practically simultaneously, produce the effect of a single maximal one, from those in which the first of two excitations following one another with an interval between them prepares for its successor, as in the so-called "staircase" phenomenon, first described by Bowditch in the heart.¹ When, after having cut off the apex of the ventricle of the frog's heart, single induction currents are led through it at intervals of from five to ten seconds, by electrodes at a very short distance from one another applied to its surface, the heights of the curves show that the second beat is stronger than the first, the third than the second, and so on, the increments diminishing progressively until the heights of the curves become uniform. In 1875 it was observed by Tiegel² that a similar augmentation takes place in skeletal muscles. It is best seen when a curarised gastrocnemius, in which the circulation is carefully maintained, is excited for a long time at regular intervals, in the same way as in Kronecker's experiments on exhaustion. In this case the augmentation of effect when the stimulation is maximal, may go on for some three hundred excitations, after which the heights of the successive curves begin to diminish. When stimuli which are not quite maximal are used, the increase is maintained longer, and was observed by Tiegel to be accompanied by a remarkable degree of vascular congestion in the muscle.

Period of latency of the mechanical response.—About half a century ago Helmholtz discovered that a considerable interval of time intervenes between the excitation of a muscle by an instantaneous stimulus, and the beginning of the response. He designated this interval the *period of latent stimulation*, and from his measurements of its duration—employing methods which have served all subsequent observers as models—concluded that it was about one-hundredth of a second. Although Helmholtz clearly indicated that the delay was influenced by the strength of the stimulus and by the excitability of the muscle, his estimate was regarded for many years in physiology as if it had the authority of a physical law, which could be applied without reserve, not only to the whole organ, but to each of its constituent structural elements. It was not until 1879 that Gad³ showed that about half of this delay was due to mechanical conditions which had been previously overlooked; for even when the load was very inconsiderable, he found that there was loss of time from inertia, which could be much diminished by interposing an elastic band between the weight and the lever. He further observed that when a parallel-fibred muscle is excited by an induction current led through its lower half, the contraction is not only delayed, but may even be preceded by a slight elongation. This he rightly attributed to the extension of the unexcited part, which takes place at the moment the excited part begins to shorten; and he pointed out that the yielding either of muscular parts not excited or of non-muscular parts is a second cause of delay.

A few years later similar conclusions were arrived at by Tigerstedt,⁴ both as regards the true duration of the delay, and the reason why, when observed in the ordinary way, it appears to be so long. His method of measurement consisted in recording the time after excitation at which a very delicately adjusted contact is broken by the contraction. He found that the gastrocnemius, when excited directly by an ascending over-maximal break induction

¹ *Arch. a. d. physiol. Anst. zu Leipzig*, Bd. i. S. 156.

⁴ *Arch. f. Physiol.*, Leipzig, 1895, S. 111.

current, and loaded with 4 grms., shortens sufficiently to break the contact 4·3 thousandths of a second after excitation. Under other conditions the delay was somewhat greater. Ten years later the present writer was able to show,

FIG. 213.—The induction current flows through the muscle *m*, from *a'* to *a*, the cathode being at *a*. The square rod is of vulcanite, the wires are of steel.

by the photographic method,¹ that the period is shorter by nearly another thousandth of a second. The expansion in thickness of the muscular fibres of the sartorius was registered photographically with the aid of the apparatus for photographic measurements, to be

described further on in its application to the capillary electrometer (p. 418). The spring indicator shown in Fig. 213 was applied to the muscle, the movement photographed being that of its point *x*. In the photograph (Fig. 214) the converging lines are one five-hundredth of a second apart, the distance between them corresponding to the vibration period of a fork of 500 double vibrations per second. The opening of the key by which the primary circuit of the inductorium is broken, is at the same time photographed on the plate, so that no doubt can exist, either as to the time after which the induction current must have reached the muscle, or as to the time before which the change of form must have begun. The photograph therefore affords incontrovertible evidence that a muscular fibre begins to contract under ordinary conditions not later than 0·0035 sec. after excitation.

FIG. 214.—Facsimile of the photographic record of the beginning of the contraction of the sartorius. The white space is limited by two polar ordinates, which converge to a centre half a metre distant. In the toothed line each tooth corresponds to $\frac{1}{1000}$ sec. Above it, the signal line indicates the instant of break of the primary circuit of the induction coil (first of the three vertical lines). It is seen that the time which intervenes between the break excitation and the response is about one and a half times the duration of a tooth, *i.e.* $\frac{1}{1000}$ sec.

shortest he was able to observe. He, however, gives no reason for declining to accept the shorter estimate.

The writer of this article has shown that, as measured photographically,

¹ Burdon Sanderson, *Journ. Physiol.*, Cambridge and London, vol. xviii. p. 146.

² *Arch. f. d. ges. Physiol.*, Bonn, 1897, Bd. lxxvii. S. 207.

the minimum delay which intervenes between instantaneous excitation of the nerve and the first observable change of form is about 7-thousandths of a second, and that in direct excitation this is diminished to about $3\frac{1}{2}$ -thousandths. The well-known observations of Bernstein¹ on the period of latency, which were published in 1882, and made by the ordinary myographic method, gave of course a much longer delay in both cases; but the difference in this respect between direct and indirect stimulation was as nearly as possible the same, namely, 0.0032 sec. The inference drawn from the observation of this difference was that in indirect stimulation about $\frac{1}{300}$ sec. is lost in transmission through the end-organs of the nerve. Doubt was thrown on the significance of Bernstein's experimental data by Hoisholt² in 1885, who concluded that inasmuch as when an induction current is led through a muscle the muscle fibres are excited partly by its direct action on them, partly by its action on intramuscular nerves, the greater promptitude of the response might be attributed to the summation of the two actions. The question has lately been reinvestigated by Boruttau,³ who has shown that, provided that strong ("over-maximal") currents are used, the abbreviation of the delay in direct stimulation is always in accordance with Bernstein's statement; he found, however, that when the current strength is slightly diminished, the period of latency acquires the duration which it possesses when the muscle is stimulated through its nerve.

Rate of propagation of the mechanical response.—When a curarised parallel-fibred muscle is subjected to the direct action of an instantaneous stimulus at any spot in its length, in such a way that all the fibres are affected by it, a thickening occurs at the excited spot; this at once divides into two parts, which separate from one another, and are propagated in opposite directions. Each of these advancing thickenings is called a *contraction wave*. In ordinary skeletal muscle of the frog, it travels, provided that the preparation is fresh and vigorous, at a rate which approaches 3 metres per second, and persists at each point in its course for about $\frac{1}{10}$ of a second, so that if the muscle were sufficiently long, it would be observed that at the moment the thickening ceases at one point it begins about 30 cms. further on in its course. In other words, the contraction wave has a length of about $\frac{3}{10}$ of a metre.

The contraction wave is a phenomenon intimately connected with two others; with the excitation wave on the one hand, and with the duration of the twitch, or response to instantaneous stimulation, on the other. By the term *excitation wave* is meant the initial change in the excitable mechanism contained in every contractile element which, in its progress, precedes the change of form, and is the harbinger of its advance. We shall learn subsequently how it can be observed and its rate of propagation determined. The *duration of the twitch* is the time which intervenes between the moment at which any particular part of a fibre or bundle of fibres departs from, and that at which it returns to, its normal form. It can therefore be better determined by measuring the change in thickness than the change in length of the muscle.

The first measurements of the rate of progress of the contraction

¹ "Die Erregungszeit der Nervenendorgane in den Muskeln," *Arch. f. Physiol.*, Leipzig, 1882, S. 329.

² *Journ. Physiol.*, Cambridge and London, vol. vi. p. 1.

³ "Zur Frage der spec. Erregungszeit der motor. Nervenendigungen," *Arch. f. Physiol.*, Leipzig, 1892, S. 454.

wave itself led to erroneous results. Bezold¹ (1861) measured the time-interval between the excitation and the beginning of response, when the muscle, clamped in the middle in such a way as to prevent the change of form, but not the excitation, from passing, was excited at one end and observed at the other. Aeby² (1860) caused a muscle excited at one end, to record simultaneously, on the same rapidly moving surface, its thickening at two points as far removed from one another as possible; two curves being thus obtained, of which the one drawn by the lever furthest removed from the exciting electrodes was a certain distance behind the other in time. Both of these modes of determining the rate of propagation gave results which fell short of the truth. Ten years later, Bernstein³ applied the more correct method of comparing the moments at which successive waves, travelling in the same direction from different points, reached a particular spot at a known distance from each of them. Bernstein used muscles of which the fibres are interrupted by tendinous insertions. Hermann,⁴ criticising this, made similar experiments with the sartorius, using for measurement Pouillet's instead of the graphic method, and obtained a mean result of 2·7 metres per second as the rate of propagation therein. Notwithstanding the disadvantages just referred to, Bernstein's estimate, although it closely approximated to that of Hermann, was a little higher, so that we may accept the statement usually made, that the rate in frog muscles is about 3 metres per second, as correct. In mammalian muscle the rate is, as a rule, much greater than this; the elaborate investigations of Rollett⁵ show that, although it is not more than 3·4 metres in the red muscles of the rabbit, the rate of propagation may be as much as 11 metres per second in the white. The duration of the twitch is correspondingly longer in the red muscle than in the pale, the observations of Kronecker and Stirling⁶ having shown that it is three times as long in the one as in the other. Cash⁷ has demonstrated that similar, though less considerable, differences in duration present themselves in the different muscles of the frog, a single twitch of the gastrocnemius, *e.g.*, lasting 0·12 sec., while that of the hyoglossus may last as long as 0·3 sec.

Conduction of slow waves in transversely striated muscle.—On this subject very little is definitely known, for the existence of slow waves has only been established as regards muscles which are under abnormal conditions. They are most readily observed in insect muscles. Rollett⁸ has shown that in the living larva of *Corethra* they occur side by side with the quick contractions or twitches, and may alternate with them or be interrupted by them. They are therefore independent phenomena; and whereas the twitch seems to be dependent on influences emanating from the nervous system, predominating when the animal is most vigorous, the slow contractions seem to be idiomuscular, *i.e.*, to emanate from the muscle itself; for they only begin to appear as the animal loses its vivacity and as the control exercised by the nervous system is withdrawn. They persist even when death

⁸ *Loc. cit.*

is approaching, and after the quick contractions have already ceased. Rollett also observed them in strips of excised beetle muscle, and estimated the rate of propagation of the wave to be about 0.116 mm. per second. He found it impossible to measure the rate of propagation of the twitch in insects, on account of its extreme quickness, which must considerably exceed that of the quickest muscles of vertebrates. The length of the slow wave he found to be very inconsiderable, being only about 0.097 mm. *i.e.*, involving from twelve to twenty-nine transverse striations of the fibre.

In those vertebrates in which they have been observed,¹ slowly progressing waves are only called into existence by mechanical stimuli applied directly to the muscle when it is in some peculiar, but as yet undefined, condition, which is not that of diminished excitability. The local muscular swellings first described by Schiff,² which may be produced in much the same way, also under abnormal but equally indefinable conditions, may represent arrested slow waves which are prevented by loss of excitability and conductivity of the muscle from being propagated. They will be again referred to in the next section.

EXHAUSTION AND DEATH OF MUSCLE.

Exhaustion (fatigue).—By the word exhaustion, as applied to muscle, is meant a state consequent on previous exertion, in which the maximal effect of stimulation, whether instantaneous or tetanic, as measured either by increase of tension or diminution of length, is less than normal. The notion suggested by the word, namely, that the chemical material which is the source of mechanical energy set free in contraction has been during the antecedent period of exertion used up more rapidly than it has been replaced, is substantially true. Exhaustion may also be defined as a condition in which the normal relation of tension to length is altered. An excited muscle requires, when exhausted, a less weight to extend it to any given length than it did before; the quotient $\frac{\text{tension}}{\text{length}}$ is therefore diminished at the same time that the value of Δ —*i.e.* the equilibrium length of the muscle in the excited state—is increased. This may be also expressed by saying that the extensibility of excited muscle is increased by exhaustion. As is implied by the lengthening of Δ , the same stimulus which before was adequate to raise a weight to a certain height becomes inadequate in muscular exhaustion. To obtain the same result as before—that is, to shorten Δ to its original length, and to restore the relation of tension to length to its previous value—the strength of the stimulus must be increased.

In the muscles of the frog two changes relating to its power of contracting, present themselves for examination, namely—(1) The gradual lengthening of a tetanised muscle, which immediately follows the attainment of its maximum degree of shortening; and (2) the much slower diminution of the height to which a weight is lifted, when a muscle is successively excited at time-intervals of such length that the effect of each excitation passes off before that of the succeeding one begins. The first of these effects was described by Ed. Weber fifty years ago, and was afterwards recorded graphically by Wundt, who found that the descending limb of the curve of a prolonged tetanus is concave upwards, indicating that the muscle lengthens quickly at first, less and less so afterwards. The first investigation of the fatigue produced by subjecting a loaded

¹ See Biedermann, "Elektrophysiologie," S. 129 ff.

² "Lehrbuch d. Physiologie," S. 26.

muscle to a succession of instantaneous stimuli of unvarying strength and frequency, was made by Volkmann,¹ but it was not until ten years later that the elaborate research of Kronecker in Ludwig's laboratory afforded the basis for the more exact knowledge of the subject which we now possess.²

The muscle used was the triceps femoris of the frog. It remained *in situ*, so that the circulation could be maintained, and worked under isotonic conditions, either loaded or after-loaded. The load varied in different series of experiments, but never exceeded 50 grms. The nerve was excited by opening induction currents, of which the direction was reversed between each excitation and the succeeding one, regularity being insured by the employment of automatic arrangements throughout. When the method of after-loading was used, it was established that, under the conditions above described (equal stimuli of equal frequency), the successive diminutions of the excitatory shortening of the muscle were exactly equal; so that, when the contractions were recorded on a slowly moving surface, the tops of the vertical marks which represented the successive twitches were in a straight line (p. 204). The inclination or slope of this line depends on the frequency of the excitations, so that if at any time during the decline an interval of longer duration occurs, the difference in height between the record of the preceding and of the succeeding twitch is correspondingly diminished. The graphic record therefore shows that in after-loaded muscles the decline is equable throughout, the height to which the weight is raised being diminished by equal amounts, until the muscle no longer shortens to a length less than its equilibrium length l ; for although it continues to contract after this point has been reached, the weight is not lifted, and consequently the contractions are not recorded. In the graphic records of loaded muscle with the weight unsupported, the contractions are recorded until they cease. In this case it is observed that towards the close of the observation the curve of decline becomes more and more concave upwards, approaching the base line (the line which corresponds to the length of the muscle when unexcited, but extended by the weight) asymptotically. It is further found that the load may be varied in different experiments, up to a certain limit, without changing the rate of fatigue, *i.e.*, that the height to which at any moment during the decline the muscle can lift a given load, depends not on the weight which it has up to that moment lifted, and consequently not on the work it has done, but exclusively on the number of times that it has been maximally excited. This result was subsequently confirmed by Kronecker and Gotch³ as regards exhaustion by tetanus.

Kronecker found that the triceps would go on contracting more than two thousand times when excited every two minutes. When he diminished the interval to a quarter of a minute, the height of the contractions declined more rapidly. This appeared to be also the case when, with a frequency of six per second, the contractions became eventually blended; whence it appears that there is no essential difference between the exhaustion produced by tetanus (as seen in the decline of the tetanus curve) and that which results from less frequently repeated stimulations.

¹ *Arch. f. Anat., Physiol. u. wissenschaft. Med.*, Leipzig, 1860.

² "Ueber die Ermüdung und Erholung der quergestreiften Muskeln," *Arch. a. d. physiol. Anst. zu Leipzig*, 1871, S. 177.

³ *Arch. f. Physiol.*, Leipzig, 1880, S. 438.

If exhaustion is regarded as meaning diminution of the height to which a muscle is able to lift a given weight, it is evident that the assumption frequently made cannot be accepted, namely, that so long as the time occupied in doing the work remains the same, exhaustion increases with the sum of the work which has produced it; in other words, that it may be expressed as the product obtained by multiplying the number of efforts by the work done in each. If we represent the successive lifts in Kronecker's series by the vertical lines enclosed in the triangular space ABC (Fig. 215), it is obvious that the sum of the work done at the moment that any contraction (*e.g.* at D) takes place is represented by the area $ABDE$, and that this area increases very rapidly during the first part of the period represented by the base of the triangle, very slowly towards the end. A muscle, for example, which contracts and lifts a weight a hundred times at equal intervals, is only half exhausted when it has made fifty efforts, though it has done three-quarters of the work.

Further evidence that the rate of exhaustion does not depend on the amount of work previously done, may be obtained by comparing the graphic records of two similar muscles after-loaded with different weights. In these the lines of decline begin at a level which is the higher the less the weight. They are both straight lines, and their inclination is the same,

so that if they were written one above the other on the same recording surface, they would be parallel. As however the difference between the heights to which a weight is

FIG. 215.

raised in two successive contractions in each series is always the same so long as the interval is unchanged and the excitation is maximal, it follows that when a muscle is heavily after-loaded, the contractions disappear from the record earlier than when the after-load is less. The earlier disappearance does not mean that the muscle is sooner exhausted, but only that its actual length when excited and extended by the weight, becomes greater than l a longer time before it is exhausted; for, as has been already seen, when the after-loading method is used, no contraction, in which the muscle fails to shorten to this length, is recorded.

The application of these results to the study of muscular exhaustion in man is attended with considerable difficulty. Professor Mosso has lately invented an instrument (*ergograph*) by which graphic records of fatigue, resembling those of Kronecker, may be obtained in human muscle. The muscle of which the contractions are recorded is the flexor of the fingers, the nerve is the median, the movement of a weight lifted by the middle finger being inscribed on a suitable recording surface. The weight is hung upon the finger, and supported during the intervals between successive excitations, so that the muscle is "after-loaded." In general the line of decline is nearly straight, but, as might be expected, it is more variable than in Kronecker's experiments. Although it is difficult to say whether the numerous observations made by this method have materially contributed to the understanding of the nature of exhaustion, they have proved to be of great value as a means of determining the influence of psychical, pharmacological, and other conditions on the process. Another

instrument for investigating muscular fatigue in man has been employed by Dr. Waller; the essential difference between the two methods being, that in the one the muscle contracts isotonically, in the other isometrically.

The exhausting effect of continuous voluntary contraction was investigated by Donders, in man, with special reference to the case in which a weight is sustained by the hand with the forearm supine and horizontal. The method is analogous to that previously described. A cord is attached to the weight, by the severing of which the forearm is liberated. Instantly the hand rises, hastening to assume a position which corresponds to the equilibrium length of the acting muscle, the biceps. This length can be calculated with approximate accuracy from the angular measurement of the movement executed by the forearm in assuming its new position. The experiment affords direct proof that the effect of muscular fatigue is, as has been already explained, to increase the equilibrium length of the excited muscle; whence it follows that the longer the effort lasts and the oftener it is repeated, the stronger is the influence which must be exercised on the muscle by the central nervous system. The *sensation* of fatigue which by a conscious effort we strive to overcome, in keeping up the weight as long as possible, is probably a fairly true index of the gradual intensification of the excitatory process in the motor cell and motor nerve.

Effect of exhaustion on the duration of the response to single excitations.

—The observation was originally made by Helmholtz, that when a muscle

FIG. 216.—Muscle curves showing the effect of fatigue.—After Waller.

is excited repeatedly by an instantaneous stimulus, the time occupied by the response increases at the same time that the height of the curve diminishes. This was subsequently shown in a striking way by Wundt, who so arranged a muscle that each time it relaxed after excitation, it re-established an exciting contact which, in contracting, it immediately broke. The diminishing frequency of the contractions thus automatically produced, showed that each lasts a little longer than its predecessor. The character of the change of form of the isotonic curve which is thus produced, is well seen in Fig. 216, which represents a succession of such curves with their starting-points coincident. Their heights at first increase, then diminish as the spans of the curves become greater. It has been stated that the increase of duration is due to failure in the process of relaxation, but of this such curves can afford no evidence. All that they show is that the state of excitation and the contractile stress by which it expresses itself, both increase and diminish more slowly.

To understand the prolongation of the mechanical response in a tired muscle, we have only to consider that the response itself is a "wave of contraction" which is normally propagated at a certain rate; and if we assume that the wave length remains the same, and that the propagation rate is diminished, the duration of the effect at any point over which the wave passes must increase proportionally to that diminution.

It must, however, be remembered that the diminution of the rate of propagation in fatigue has not been proved experimentally.

Efficient causes of exhaustion.—It was shown long ago by Ranke¹ that the definition of exhaustion which we have characterised as in the main correct—that which regards it as a state in which restitution lags behind waste—is not wholly adequate. Without denying that mere disturbance of balance of nutrition in the muscle substance may produce the effects of fatigue, he showed that in the frog these may be got rid of by the circulation through the muscle of normal salt solution, *i.e.* of a liquid which has no nutritive properties; and that a state which cannot be distinguished from fatigue can be produced in fresh muscles, by the injection of aqueous extract of the fatigued muscles of another animal.

Mosso² has shown much more recently, that even the introduction of the blood of a fatigued animal (*e.g.* a dog) into the circulation of a normal one will give rise in the latter to all the symptoms of fatigue (respiratory, cardiac, etc.). It would appear, therefore, that some toxic substance is produced in the muscles by tetanising them. Ranke at first inferred from what was known at the time as to the production of lactic acid in protracted muscular exertion, that the acid was the true cause of exhaustion; and he was thus led to make the well-known experiments by which it was proved that the introduction into the circulation of normal physiological salt solution, containing a very small percentage of this acid, produces exhaustion, and that the muscles regain their natural vigour when the lactic acid is withdrawn, and the circulating fluid rendered alkaline by a trace of sodium carbonate. He soon, however, began to surmise that the fatiguing action belonged to lactic in common with other acid bodies, and this led to the discovery that, even when no free acid was present, a reaction due to the monophosphates of the alkali metals was sufficient to produce the result. It was subsequently found that the presence of lactates had no effect in a neutral solution, so that exhaustion can only be attributed to lactic acid, in so far as the production of this body is the immediate cause of the acid reaction of fatigued muscle. The facts just stated prove no more than that acid reaction is *one* of the conditions of exhaustion. It is not probable that it is its only cause; for it has been shown by Abelous as well as by Mosso, that the alkaline serum of a fatigued animal also produces fatigue. It cannot, therefore, be doubted that among the products of muscular activity there exists a substance endowed with the property of rendering muscle less competent, although we have as yet no sufficient knowledge either of the nature or the mode of action of this substance.

The remarkable fact insisted on by Waller,³ that in the ordinary process of exhaustion of muscle, the indirect excitability disappears while the direct excitability persists, has been also shown to obtain by Abelous⁴ with fresh muscle (frog) when supplied with blood derived from fatigued muscle. His method consisted in severing one sciatic, and then throwing the whole muscular system with the exception

¹ "Grundzüge der Physiologie," S. 632.

² *Trans. Internat. Med. Cong.*, Berlin, 1890.

³ "Physiology," 2nd edition, p. 380.

⁴ Abelous and Langlois, *Arch. de physiol. norm. et path.*, Paris, 1893, tome v. pp. 437-448; and 1894, tome vi. p. 432.

of the paralysed limb, into tetanus by faradising the spinal cord, the circulation remaining intact. In this way the paralysed muscles, although inactive, become fatigued. The process of fatigue is tested at regular intervals by direct and indirect stimulation, and it is found that the indirect excitability disappears first. Abelous therefore concludes that, as nerve is inexhaustible, the end-organs are more directly affected by the "fatigue substance" than the muscular fibres themselves.

Death of muscle.—When muscle is immersed in boiling water it at once shortens and thickens, losing its elasticity and becoming opaque. In muscle so treated the proteids coagulate, and all functional chemical changes are brought suddenly to an end. This method is therefore frequently used for the purpose of ascertaining the chemical condition of a muscle at any desired moment, so far as relates to those constituents which are known not to be affected by boiling temperature. If the temperature of a muscle is raised gradually, the change of form occurs in stages. According to the recent observations of Brodie, a first shortening occurs at 32° C., ceasing at about 40° C.; a second begins at 46° C. and ceases at 50° C.; a third at 56° C., ending at 60° C.; and at 63° C. there is a final shrinking which ceases at 75° C. As these temperatures closely correspond with the temperatures of coagulation of the several proteid bodies contained in muscle,¹ the observations afford better evidence than had before been given of the connection of coagulation with the changes produced in a muscle by warming it. But although coagulation may serve to account both for the loss of elasticity and the opacity produced by heat, it does not sufficiently explain its shortening; nor does there seem to be any reason why, even when the process is very gradual, the successive diminutions of length should not be in part attributed to contractility. The shortening may be a response to the stimulating action of the temperature, and the opacity may be due to coagulation.

The production of heat rigor is a more simple process than the similar change which occurs spontaneously at a certain time after death—true rigor mortis, or, as it is called by German writers, *Zeitstarre*. The same question, however, presents itself as regards the immediate cause in the two cases, for in rigor mortis we have, on the one hand, shortening which may be compared to the effect of excitation; on the other, opacity and loss of elasticity, which may be attributed to solidification of previously fluid constituents of the muscular substance. We will first inquire what grounds there are for supposing that muscle in the process of dying, passes into a state analogous to that produced by excitation.

The notion that it does so is an old one. Nysten (1811) compared rigor with vital contraction, and spoke of it as the last effort of dying muscle. This vitalistic idea, after holding its ground for more than a generation, was displaced by the theory usually attributed to Brücke, that the process is solely one of coagulation. It may be questioned whether Brücke took so exclusive a view as these words imply; but, in any case, the physiologists of thirty years ago were justified by experimental results, in regarding the solidification of myosin as the most important consequence of the cessation of vital activity. Kühne had shown² that a muscle can be kept in a living state, *i.e.* prevented

¹ See Halliburton's article in vol. i. of the present book, and Vernon's paper in the *Journal of Physiology*, 1899.

² "Lehrbuch der physiologischen Chemie," 1866, S. 274, 285.

from going into rigor, by subjecting it immediately after removal to a temperature approaching 0° C., and that a liquid squeezed out of it by pressure when in this state, remains fluid so long as this temperature is maintained, but that myosin separates from it as soon as the temperature rises; and, further, that although a certain quantity of liquid can be squeezed out of muscle which not having been kept cold had become rigid, this is incapable of spontaneous coagulation, inasmuch as it contains no myosin. It thus appeared as if the characteristic proteid of muscle were affected by low temperature in the same way as the muscular tissue itself, and this seemed to afford a cogent proof that in the properties of myosin the explanation of rigor was to be found. There were, however, always those who held to the old view of Nysten, that in muscle the process of death is continuous with that of life. Brown-Séquard indicated as the result of numerous observations, partly clinical, partly experimental, that rigor occurs under conditions which can have nothing to do with coagulation, that it occurs in muscles which are still "living," that it associates itself with excitatory states, and that it can be warded off by passive movement, recurring when this is discontinued. Schiff¹ also found it to be closely related to certain forms of contraction, particularly that localised form to which he applied the term "idiomuscular."

The true relation of the spasmodic to the other phenomena of rigor was not ascertained with accuracy until in 1881 the inquiry was taken up by Hermann and worked out by his pupils. By them it was shown, both in the frog and in mammals, that rigor was retarded in the muscles of a limb by severing its nerves, or by hemisection of the spinal cord, the operation being in either case performed immediately after death, so as to avoid the possibility of interference with the previous state of the circulation or nutrition of the muscles. It thus appeared that the nervous system continues to exercise a certain influence on the muscles after death, and that interference with the innervation of a muscle is unfavourable to the development of rigor. The following experiment of Nagel² makes it probable that this statement may be extended to the peripheral parts of motor nerves:—

A frog, in which one hind-limb has been protected by ligature, is curarised; the spinal cord is destroyed, and both sciatics are immediately divided. It is then found that rigor is retarded on the curarised side as compared with the other side, a result which shows that, even when separated from the central nervous system, the peripheral parts of the motor nerves exercise an influence in initiating the post-mortem contraction of the muscles to which they are distributed.

From the observations of Bierfreund,³ it appears that muscles which contract differently also behave differently with regard to rigor. Thus, in the red muscles of the rabbit the post-mortem contraction is so much retarded as compared with that of the pale muscles, that the contraction of the latter may have ceased at the time that that of the other is only half over (Fig. 217).

Other differences in the behaviour of muscles in rigor, depending upon individual peculiarities of the muscles themselves, have been observed by Langendorff and Gerlach.⁴ When the hind-limbs of a frog are freely suspended in normal salt solution, the attitudes which they assume indicate that the flexors pass into rigor before the extensors. Nagel has confirmed this observation as regards toads and certain specimens of *R. temporaria* which had been kept through the winter. In other frogs he found that both sets of muscles went into rigor simultaneously.

As regards the cessation of rigor, Bierfreund showed that it was neither due, as Brücke supposed, to the development of acid reaction, nor, as other observers have thought, to the commencement of putrefactive change, but that the time of its occurrence is rather dependent on individual peculiarities of the muscle used. That it is not due to sepsis, is proved by the fact that it occurs in muscles perfectly sterilised by the injection of salt solution containing car-

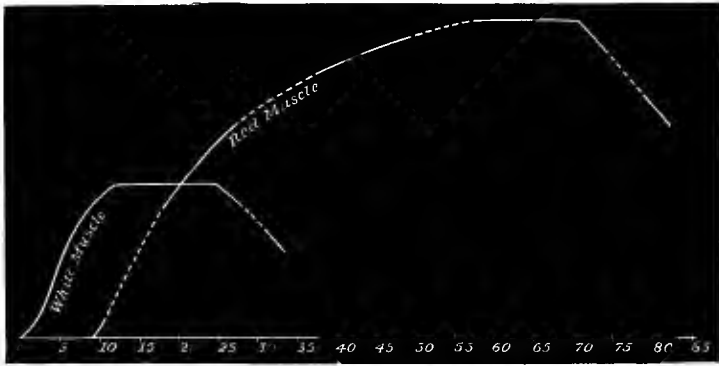

FIG. 217.—Showing curves of rigor mortis of white (*gastrocnemius*) and red (*soleus*) muscles of rabbit. Rigor occurs eight hours after death in the former, fifteen hours in the latter. The red muscle also shortens more than the pale. On comparing these curves with the ordinary isotonic curves of the same muscles, their heights are found to be in similar proportion to each other.—After Bierfreund.

bolic acid. This, however, does not exclude the possibility that a putrefactive change, if present, might arrest rigor; and Nagel¹ has mentioned instances in which the early occurrence of putrefaction was associated with the absence of rigor. Nagel, however, agrees with Bierfreund in not regarding putrefaction as the ordinary cause of cessation of rigor, for he has also found many cases of rigor persisting in muscles which have undergone a good deal of putre-

fective change, and some in which it has appeared, although no putrefactive change could be perceived.

The well-known fact that a muscle exhausted by previous tetanisation, or by the spasms of strychnine, passes more quickly into rigor than a normal muscle, is well illustrated by an experiment of Nagel, of which Fig. 218 gives the result. The shortening of a *gastrocnemius*, which had been repeatedly tetanised, was compared with the unfatigued

FIG. 218.—Curves of rigor mortis in fresh and exhausted muscle.—After Nagel.

gastrocnemius in another frog. Rigor supervened sixteen hours later in the one than in the other.

It has already been mentioned that Schiff, at an early period, connected the incipient stage of rigor with localised or "idiomuscular" contractions. He imagined that it might be initiated by the direct action on the still excitable muscular substance, of some product coming into existence either after death or when death was approaching. The

¹ *Loc. cit.*, 1894, Bd. lv. S. 481.

following phenomena, many of which have been indicated by Schiff or his pupils, tend to support this view:¹—(1) Whenever rigor comes on very gradually, the muscles continue for some time to respond to appropriate stimuli (interruption of a battery current led through the muscle, or tapping of the surface). If the stimulated parts are afterwards compared with other parts, they are found to be rigid and unexcitable. This can be observed both in the frog and in mammals. (2) If a muscle in the transition state above referred to, is observed with the aid of the electrometer, the meniscus is seen to oscillate in such a way as to indicate the existence of irregular action currents. In some muscles, when going into rigor, irregular contractions are observable. This is chiefly seen in mammalian muscles (Brown-Séguard), although it is also noticeable in some amphibians, *e.g.* in toads and, to a less extent, in *Rana temporaria*. In *R. esculenta* the passing into rigor is almost always a continuous process. (3) Schiff finds it impossible to determine when the initial shortening of muscles deprived of their supply of arterial blood by ligature, as in Stenson's experiment, ceases to be contraction and becomes rigor. The distinction between them is so gradual, that the muscles can at first be brought back to their normal state by restoring the circulation; later, this becomes more and more difficult. (4) In a frog poisoned by strychnine after one sciatic nerve has been divided, the spasm of strychnine in the poisoned limb passes so immediately into that of rigor, that it is difficult to distinguish them. Here Schiff attributes the initial contraction to the chemical stimulus (lactic acid?) brought into existence by the previous spasm. For, according to his pupil, C. Schipiloff, the first effect of the circulation of salt solution containing 0.1 per cent. of sarcolactic acid, is to produce spasm. The muscles, however, retain their translucency, and can be brought back to the normal by substituting alkaline for acid salt solution. If this is not done, the spasm passes into rigor.

The general result of the preceding considerations relating to the nature of rigor mortis is—(1) That rigor is a mixed process, of which the first stage is spasmodic, the second coagulatory; (2) that although the spasmodic phenomena for the most part precede the coagulatory, the two may present themselves simultaneously; (3) that although there is no sufficient evidence that the presence of free lactic acid is the cause of the dying contraction of muscle, acid reaction is its earliest concomitant; (4) that post-mortem spasm is of similar nature to those continuous contractions which, although they occur during life, are characterised by (*a*) extreme slowness or even absence of propagation, (*b*) slowness of development, and (*c*) by the fact that they are relatively more readily evoked by stimuli of a certain duration than by instantaneous stimuli.

NATURE OF THE PROCESS BY WHICH CHEMICAL ENERGY IS TRANSFORMED INTO MECHANICAL ENERGY IN MUSCULAR CONTRACTION.

The mechanical potential energy which suddenly comes into existence when a muscle is excited, whether this is allowed to manifest itself in lifting a weight, or is compelled to appear exclusively as tension, has its ultimate source in the chemical potential energy of certain constituents

¹ "Beitr. z. Physiol.," 1894, S. 97-124.

of muscular structure. The mechanical effects, although the consequence rather than the concomitant of the chemical change, follow it instantaneously and invariably. What further happens depends upon mechanical conditions, in relation to which three cases may be distinguished. If (Case 1) the muscle is prevented from shortening, heat is produced in quantity equal to the heat value of the material disintegrated. If (Case 2) the muscle is allowed to do external work, *e.g.* in lifting a weight, the energy so used is transferred to the weight, and lost; but if (Case 3) the weight after being lifted is allowed to fall, that energy is returned to the muscle at the moment of its relaxation, and manifests itself by producing in it an amount of heat which is the equivalent of the potential energy immediately before transferred to the weight. Consequently, the *eventual* result in Cases 1 and 3 is of the same kind. In both, the first mechanical result is the appearance of tension; in Case 1, potential mechanical energy is transformed directly into heat; in Case 3, it is not transformed until a certain proportion of it has undergone translation and retranslation.

The chemical change which, as has been stated above, precedes all others in the response of a muscle to stimulation, is an oxidation. This does not necessarily mean that the chemical energy which is concerned in the combination of oxygen atoms with those of carbon and hydrogen, is directly transformed into the mechanical energy which manifests itself in muscular effort. It is *prima facie* quite as reasonable to suppose that muscle in doing work may act after the manner of a thermodynamic machine, such as a steam-engine; *i.e.*, that it may first produce heat by oxidation, and then use that heat in the doing of work. If this is so, we have to suppose that between the initial stage of chemical change and the manifestation of potential mechanical energy in the form of tension, there is an intermediate stage or phase in which the whole of the energy concerned in the process becomes kinetic, as heat; in other words, that between chemical attraction and mechanical tension, there is a thermogenetic link in the chain of events, so that the immediate agent in the production of the mechanical response is heat, not chemical attraction.

The doctrine set forth above was first enunciated in 1845 by J. R. Mayer,¹ in the treatise which was the foundation of all that we know as to the relation of heat and work in the living organism. It was not until 1882 that the objections to it were clearly stated by Fick² in the book already so often referred to, and, more at length, in his "Medical Physics." These are as follows: In every thermodynamic machine, *i.e.* in every machine in which work is produced as in the steam-engine at the expense of heat, the process by which this is effected consists in the translation of heat from a body of higher temperature *A*, to a body of lower temperature *B*, under such conditions that a certain part of the heat so translated is converted into work. The utmost quantity of work so producible can be determined with absolute certainty, provided that the quantity of heat transmitted, the temperature of *A* and *B*, and that of the medium of transmission, are known, and that the process is a "cyclical" one, *i.e.*, that the final state of the medium of transmission is

¹ "Die organische Bewegung in ihrem Zusammenhang mit dem Stoffwechsel," Heilbronn, 1845.

² "Mechanische Arbeit, u.s.w.," S. 154, 158; "Medizinische Physik," 1885, Aufl. 3, S. 206.

the same as the initial. The nature of this relation is set forth in the second law of thermodynamics. It is such that, unless a very high estimate be taken of the difference of temperature which in muscular contraction can exist between *A* and *B*, *i.e.* between the source of heat and its environment, the quantity of work resulting from the heat transmitted would be a small fraction only of the quantity actually produced by the combustion of an amount of material of corresponding heat value. Thus, if muscle could be made the medium of a thermodynamic process, *i.e.*, could be made to do work at the expense of heat transmitted through it from outside, the quantity of heat *transformed* into work would bear so small a proportion to the quantity *transmitted*, that no comparison could be made between the hypothetical experiment and what actually happens in contracting muscle.

Such a hypothetical process as is described in the following lines, is suggested by Fick :—

A muscle is extended by a weight, at a temperature of 20° C., and then warmed to 30° C. It shortens as soon as it is allowed to do so, and lifts the weight. It is then made to do further work, by gradually unloading it at this temperature until the extending weight = 0. The muscle is next cooled to 20° C., so that it reassumes its unextended length at that temperature. Work is then done upon it by extending it gradually, until the extending weight is of the original amount.

The muscle is again warmed to 30°, and so the cycle recommences. There is therefore in each repetition of the process a gain of external mechanical work, the amount of which is in accordance with the second thermodynamic law.

This law may be expressed as follows:—In every thermodynamic cyclical process, the heat value of the work Q , which can be produced by the translation of a given quantity of heat Q_1 , from a warmer to a colder body, depends (1) on the *absolute* temperature of the medium T , *i.e.*, the temperature at which the process takes place, and (2) on the difference of temperature between *A* and *B* ($T_1 - T_2$).¹ Consequently, unless it is possible to suppose the existence of very large differences of temperature in the environment of the acting parts of muscular substance, the doing of work in muscular contraction cannot be regarded as a thermodynamic process.

The reader will find in Engelmann's Croonian Lecture,² his solution of this problem. He contends that a rise of temperature of the whole substance of the contracting muscle, amounting to $\frac{1}{10000}$ ° C., would involve a very high temperature of the chemically active particles, the number of which he estimates to be exceedingly small. The objection that the high temperature required is incompatible with life, he meets on the same ground, namely, the extremely small proportion to the whole of the part in which this high temperature exists. In the same lecture, experiments were adduced which seemed to give support to a thermodynamic theory of muscular contraction. Of these the most important related to the work which can be got out of either soaked fiddlestrings or caoutchouc, by warming these substances. The method is as follows :—

¹ The formula by which this is expressed is—

$$\frac{Q}{Q_1} = T \left(\frac{T_1 - T_2}{T_2 T_1} \right)$$

If the difference between the value of T and that of T_1 or T_2 is relatively small, the right side of the equation approximates to $\frac{T_1 - T_2}{T}$, so that the value $\frac{Q}{Q_1}$ comes to depend on the difference of temperature between *A* and *B*. In the case now in question, Q must always be extremely small as compared with Q_1 .

² *Proc. Roy. Soc. London*, vol. lvii. pp. 411-433.

A bit of E string 2 in. long is so arranged that its shortening may be recorded myographically (Fig. 219). It is extended by a load of 50 grms. and surrounded by a coil of thin platinum wire in connection with the two poles of a fairly strong battery, so that it can be promptly heated or brought back again to the temperature of the water in which it is immersed, by closing or opening the current which flows through the wire. Before making the experiment, the water is warmed gradually to a temperature above that at which the experiment is to be made, namely, to about 50° C., in consequence of which the string is permanently shortened to a certain length. Under these conditions momentary closure of the current is followed by a rapid rise of the writing-lever, which describes a curve resembling a myogram.

FIG. 219.—Engelmann's apparatus for recording contractions of a violin string on heating. *ba*, support, to the one end of which (*a*) the previously swollen violin string is attached. *H*, writing-lever, supported at *c*, to which the other end of the string is attached. *d* and *d'*, weights for altering tension. + and -, the two ends of the platinum wire coiled round the string leading to the two poles of a battery. *th*, thermometer with its bulb in the same bath in which the string is immersed.

By soaking and heating the cord before the experiment, it has been made to assume a constant condition, *i.e.*, one in which the observation can be repeated any number of times. We have therefore before us a process in which work, comparable to that of muscular contraction, is done by a "cyclical" process at the expense of heat; a tension of 300 grms. being, for example, developed in a string 30 mm. long and only 1 square mm. in transverse section, by raising the temperature 75° C.¹ If the same experiment be made with stretched indiarubber instead of violin string, the effect is even greater; if heated by only about 20° C. it shortens in the direction in which it has been extended, and can be made thereby to do an amount of work "sixty times as great as the maximum afforded by

human muscles of the same transverse sections."²

The three substances—catgut, stretched caoutchouc, and muscle—all resemble one another in being doubly refractive or containing doubly refractive elements. The property of contracting *when heated* is one which, according to Engelmann, is met with in doubly refractive bodies, and varies with the degree in which they are so.³ It is for this reason that stretched indiarubber, which is made up entirely of doubly refractive substance, can do more work than either a muscle or catgut string when similarly heated. A further resemblance that he finds between muscle and other such substances is, that within

¹ Engelmann, "Sur l'origine de la force musculaire," *Arch. néerl. d. sc. exactes*, vol. xxvii. p. 24. See also Engelmann, "Ueber einige gegen meine Ansicht vom Ursprung der Muskelkraft erhobene Bedenken," *Arch. f. d. ges. Physiol.*, Bonn, Bd. liv. S. 637.

² Croonian Lecture, p. 426.

³ *Ibid.*, p. 419.

certain limits the shortening power increases with the load to be lifted.¹ This he attributes also to the fact that extension in all these substances increases the property of double refraction. He concludes, therefore, that the cause of the development of contractile stress in living muscle is to be sought for in the warming of its doubly refractive particles. Heat sufficient for this purpose he thinks can be produced by the transformation of the chemical potential energy of the constituents of muscle, which follows excitation. Having regard to the "infinitesimally small number of particles concerned in a contraction," he can see no reason why the difference of temperature between the heat-producing and the work-producing particles should not be sufficient to account for the existence of such a relation between the amounts of work heat and of translated heat as would be required by the second thermodynamic law. He does not maintain that his catgut and indiarubber models represent all that happens in living muscle, but points out that they present phenomena which are among the most important of those of muscular contraction.

From the preceding considerations it will be seen that, in regarding the origin of muscular force as a thermodynamic process, Engelmann recognises that the development of high temperature at the foci of origin of mechanical energy in muscle is a necessary link in the process. Before we accept Fick's conclusion that no such link is wanted, let us remember that the view usually entertained by physiologists, that at the moment of excitation the attraction of carbon and oxygen atoms is directly converted into axial tension, involves difficulties of which the character can be best judged by reading the pages in which Fick himself sets forth what he regards as the simplest molecular mechanism by which the transformation of chemical into mechanical energy can be effected.² The question how the former is converted into the latter is rather physical than physiological. The physiological chemist may proceed with his inquiries as to the sources of chemical energy, and the experimental physiologist pursue the lines of investigation which will be sketched in the next section, without waiting for the decision of the question whether muscular contraction is or is not a thermodynamic process. It may be surmised that, whenever that question is answered, it will be by following the indications given by Engelmann in his Croonian Lecture, namely, by the investigation of an analogous process in a non-living structure.

THE PRODUCTION OF HEAT IN MUSCULAR CONTRACTION.

The reasons which compel the physiologist, in studying the mechanical phenomena of muscular contraction, to have recourse, in the first instance, to the muscles of the frog, have even greater force when his purpose is to investigate the changes of temperature which are associated with these phenomena. For here the quantities to be measured are very small, and the experiments require an even greater degree of precision than those which relate to the mechanical effects of stimulation. This can only be secured by repeating the observations a sufficient number of times under constant conditions. In the muscles of a homœothermic animal, such constancy is scarcely attainable; for the necessity of maintaining the circulation introduces sources of error which it is hard to guard against.

¹ Croonian Lecture, p. 422.

² Fick, *Arch. f. d. ges. Physiol.*, Bonn, 1893, Bd. liii. S. 611.

It was one of the great discoveries of Helmholtz, that when a muscle is tetanised its temperature increases. The method of measuring this increase, and of determining its relation to the other phenomena of the excitatory state, was subsequently elaborated by Heidenhain.¹

Methods.—It need scarcely be mentioned here that both of these great observers used the thermo-electric method. Heidenhain employed a small thermopile specially made for the purpose, of fifteen bismuth and antimony couples, of which one set of junctions was covered by the muscle to be investigated (the gastrocnemius of the frog), while a dead muscle was similarly applied to the junctions on the opposite side of the thermopile; and this, when the method is carried out in accordance with his directions, is found to be abundantly sensitive for its purpose. But this very sensitiveness brings the observer face to face with great technical difficulties; for it is found that even if two inactive muscles are compared with each other by applying them severally to the opposite sides of the thermopile, it is extremely difficult, even when the instrument is kept in a "moist chamber" and protected from changes of temperature in the environment, to bring the needle to a fixed position. As no observations can be made until the accidental disturbances which prevent this have been got rid of, much time is unavoidably lost. Nor is this the only practical objection to the method, for it has further to be borne in mind in dealing with the result, that what is measured is not the temperature of the muscle itself, but that of the junctions, because, from the form of the thermopile, these cannot be brought into such proximity to the muscle that the two temperatures can be considered the same. These considerations induced Fick,² more than twenty years ago, to give to the thermopile such a form that, although the instrument is rendered less sensitive, it affords more reliable indications of the changes which occur in the muscle. Fick's thermopile consists of very slender strips of iron and German silver. The end of each strip is filed away on one side, and is soldered to its fellow in such a way that the surface of junction of the two ends does not extend more than half a millimetre. As their united ends are as thin as paper, their mass is so inconsiderable that they assume the temperature of the muscular substance by which they are surrounded, without altering it. The end of this thermopile resembles a comb of six teeth, each of which is a junction; its form renders it possible to introduce it between the fibres of a muscle with very little injury; it is, however, more advantageous to avoid all risk of this kind by introducing it between the two adductor groups of muscles (Fig. 189) placed abreast of each other. These, when properly arranged and excited simultaneously, apply themselves by their opposed internal surfaces to the junctions as perfectly as if its knife-like edge were plunged into the muscular substance. Whatever form of thermopile is used, it must be graduated. The data for graduation are—(1) The deflection obtained with a larger element of the same material as that used in making the thermopile, with a known resistance in circuit and a known (considerable) difference of temperature between the junctions; and (2) the resistance of the thermopile circuit, as actually used for measurement.

Relation between thermogenetic and inogenetic processes.—Before proceeding to the discussion of the influence of physiological and other conditions on the production of heat in a contracting muscle, it will be useful to set forth the general results of experiments as to the

¹ "Mechanische Leistung, Wärmeerzeugung u. Stoffumsatz bei der Muskelthätigkeit," Leipzig, 1864, S. 63.

² "Ueber die Wärmeerzeugung bei der Muskelzuckung," *Arch. f. d. ges. Physiol.*, Bonn, 1877, Bd. xiv, S. 31.

relation between the thermogenetic and inogenetic processes. In all experiments in which it is desired to obtain quantitative results, the muscle to be investigated is regarded as if it were a calorimeter. Having placed it under such conditions as to prevent the transference of heat to or from the surrounding media during the period of observation, the amount of heat produced during any thermogenetic process is estimated by multiplying the increase of temperature by the weight of the muscle, and the product by the specific heat of muscular substance. Measurements of this kind are regarded as reliable, because it is found that when the experiment is so made that the whole of the heat which disappears in doing work can be measured, its relation to the quantity of work done is in accordance with the first thermodynamic law.

To prove this conformity, the amount of work done is measured in a series of instantaneous excitations, following one another with such frequency as *just* to allow the muscle to relax between each contraction and its successor. This is done by a contrivance called a "work-collector," consisting of a wheel around the horizontal axle of which a cord supporting a weight is wound. Each time the muscle contracts, it works on the periphery of the wheel so as to rotate it and thereby lift the weight. As the wheel is prevented from moving back by a catch, the weight is raised a little by each contraction, but never descends. The total lifting work done in the series can thus be measured. The heat produced during the series is measured at the same time. If H denotes the heat value of the material oxidised, and Wh the heat equivalent of the work done, $H - Wh$ denotes the result of this measurement. To ascertain the value of H the collector is dispensed with, and a second experiment is made, in which the heat produced in the muscle is measured in an exactly similar series of excitations, with the weight hung on to the muscle itself. In this case the weight falls between each contraction and its successor, so that the heat lost during contraction in doing external work is *returned* to the muscle during relaxation. Consequently the amount of heat produced during this series exceeds that measured in the first experiment by Wh , *i.e.*, the equivalent of the work done. If it were possible to make this experiment with perfect exactitude, this difference, measured in microcalories, would be to the work done, measured in gramme-millimetres, as 1 to 425.

From experiments of this kind we learn what was the relation between the quantity of material oxidised and the work done in any particular case investigated. But no general inference can be drawn from it as to the normal relation of material expended to work produced in muscle, unless it is known that the conditions under which the muscle worked were favourable, *i.e.*, that they were such that the amount of material used yielded the largest attainable result in work. What these conditions are will be shown in the following paragraphs. For the present purpose it is sufficient to say that for every muscle there is a certain amount of load which cannot be either increased or diminished without disadvantage, as regards the relation between the work done and the material expended. If we seek to increase the work done by increasing the load, we soon find that the effect of doing so is more than made up for by the diminution of the lift, and similarly we cannot increase the lift without finding the effect more than counterbalanced by the diminution of the load.

For the gastrocnemius of the frog such a load is about 200 grms. When this is employed, the relation obtained between the heat-value of the work done and that of the material used is about 1 to 4. In man

it is estimated from recent experimental data, that the heat produced during a period of active muscular exertion in the whole body is about five times as great as the heat-equivalent of the external work done; so that the work-heat is to the heat-equivalent of the total chemical oxidation of the body as 1 to 6. Assuming this estimate to be correct, about three-fifths of the total heat set free in the body during exercise, must be produced in the muscles (*i.e.* the quotient $\frac{H - Wh}{Wh}$ is, in muscle 3, in the whole body 5), provided always that the proportion above given, 1 to 4, holds for mammalian muscle.¹

Recurring to the first and third of the three cases referred to at the beginning of the last section, p. 394, we find that whether, as in Case 1, the muscle is prevented from shortening when stimulated, or, as in Case 3, is allowed to lift a weight which falls when the effort ceases, the whole of the chemical work done is represented by its equivalent in heat, and indicated by the rise of temperature consequent on the excitation. When a muscle is subjected to instantaneous stimulation, of which the intensity exceeds the maximum, no corresponding increase of the response is observed, and hence it might be inferred that the effect of such a stimulation is to "explode" the whole of the oxidisable material which the muscle at the time has at its disposal. The most important result of Heidenhain's researches was the proof which they afforded that this is not the case,² and that, although we are quite right in regarding the muscular response as a process of discharge, the amount of chemical potential energy liberated by excitation varies, even when the strength of the stimulus remains the same, according to the circumstances under which the discharge takes place. Of these circumstances resistance is the most influential. This is plainly shown when the thermal responses, in a series of excitations in which the muscle is allowed to lift and let fall different weights—say, 30, 60, and 90 grms.—are compared with each other. It is found that the quantity of heat produced is not the same in the three experiments, as we should expect it to be if it were dependent on the amount of available energy in store, but increases with the quantity of work done in each lift of the weight. It does not, however, increase in the same proportion with the work done, for Heidenhain found in all his experiments³ that in maximal stimulation the ratio of heat produced to work done diminishes as the quantity of work done increases. In other words, the muscle works more economically when moderately loaded than when lifting a very small weight.

It was further found that when a muscle is called upon to make repeated efforts in lifting and letting fall the same weight, the exhaustion thereby produced tells much more rapidly on thermogenesis than on working power. The exhausted muscle does less work, but does it more economically. In like manner it appeared that when a muscle is "after-loaded,"⁴ so that, contracting at first without obstacle it encounters the resistance subsequently, the effect of a given load on heat production is not so great as it would be if the muscle were loaded in the ordinary way. From these data Heidenhain concluded, that in

¹ See Gad and Heyman's "Lehrbuch," S. 504.

² Heidenhain, *loc. cit.*, S. 85.

³ Heidenhain, *loc. cit.*, S. 88.

⁴ Heidenhain, *loc. cit.*, S. 103.

general the chemical work done by a muscle, as indicated by the heat produced in contracting in response to an instantaneous stimulus, is determined by the resistance offered, up to a certain limit. If this limit is exceeded, the thermal effect cannot be increased, and may even be diminished by increasing the load.

Relation of thermogenetic effect to strength of stimulus.—The question whether and to what extent the chemical, *i.e.* the thermal, response is dependent on the strength of the stimulus, was investigated many years ago in Heidenhain's laboratory.¹ For this purpose the increase of temperature produced in lifting and letting fall a weight, was measured in a series of excitations with "inadequate" stimuli of graduated strengths. The difficulty of making such measurement is considerable, for the strength of a maximal excitation differs so little from that of an excitation which is just sufficient to evoke a measurable response, that the range of excitation values which can be compared experimentally is very limited. On the whole, it was found that in isotonic contractions the thermal effect varies with the stimulus, in the same way that the work varies; but that, *if the load remains the same*, the increase of heat production which results from increasing the stimulus is more than proportional to the greater lift. The meaning of this fact will be considered later.

The experimental results which have been already referred to might all be understood as consistent with the notion that the one condition which is influential in determining the amount of the thermal response to a single maximal stimulation, is tension or strain. It was, however, recognised by Fick many years ago that the evidence in favour of so simple a relation between tension and thermogenesis was insufficient. It was therefore necessary to devise an experimental method by which the question could be elucidated. If the thermal response depended solely on tension, it was obvious that its amount must be greater under isometric conditions than under any other. This could be tested by comparing two cases,² in one of which (*a*) the muscle was under isometric conditions during the whole of the mechanical response, while in the other (*b*) it was released at the moment of maximum tension and allowed to lift a weight of 20 grms. The result showed that, notwithstanding that in *b* the tension was at once reduced at the moment of release, the thermogenesis was greater than in *a*. The numbers, each of which represents a deflection of the galvanometer, were as follows:—

(<i>a</i>) No work done	25	22	22	22	22	22	22	22	22	etc.
(<i>b</i>) Weight lifted and let fall	29	28	28	29	29	28	28	28	28	etc.

The numbers relate to successive excitations.

By this experiment it was shown for the first time that in muscular action the sum of the thermogenetic values of tension and work is greater than the maximum thermogenetic value of tension by itself. In our study of continuous contraction we shall see to what important results this leads.

Production of heat in tetanus.—It does not necessarily follow from the facts which have been stated, that persistent contraction,

¹ J. Nawalichin, "Myothermische Untersuchungen," *Arch. f. d. ges. Physiol.*, Bonn, Bd. xiv. S. 293.

² Fick, "Myothermische Fragen, u.s.w.," *Verhandl. d. phys.-med. Gesellsch. zu Würzburg*, 1884, N. F., Bd. xviii. S. 12, Sep. Abd.

whether evoked by repeated or continuous excitation, should be a heat producing process. If a muscle to which a weight is attached contracts persistently, it does no external work, whatever the load may be. And if we are to regard the state of contraction as nothing more than one in which the natural length of each fibre (*i.e.* the length it possesses when unexcited) is diminished, there is no more reason why we should expect that in the state of extension the excited muscle should produce heat, than that an elastic band, or an unexcited muscle, under the same conditions, should do so. We know that it actually does produce heat when contracted, although no external work is done, and therefore conclude that the difference between the excited and unexcited muscle does not consist exclusively in the difference of the relation of length to tension. To explain the active thermogenesis of a muscle which holds up a load persistently at the same height, it must possess some property which does not belong to a stretched elastic cord.

This consideration reminds us of the suggestion that every muscular contraction consists essentially of two processes, of which the second is mechanically a reversal of the first; and that when a muscle is subjected to frequently repeated excitation (tetanus), so as to alternate between states of increasing and diminishing tension, these are accompanied, or rather ushered in, by corresponding chemical actions. In the first stage it has been suggested that, as the immediate result of stimulation, some body (*e.g.* lactic acid) comes into existence¹ and occasions an increase of tension, which in the second is annulled by the oxidation of its efficient cause. Both processes are in the chemical sense disintegrative, *i.e.*, consist in the transformation of bodies of greater heat-value into others of less; in other words, both are thermogenetic.

Even as regards tetanus produced by repeated stimulations, it is difficult to see how this explanation facilitates the understanding of the result; for if we suppose the frequency of the excitations to be no more than 100 per second, it is difficult to imagine that the muscular element can pass through the two stages of the chemical process above referred to, in the interval between two successive excitations. The difficulty is still greater in applying this explanation to prolonged contraction of central origin, in respect of which we have no evidence that the excitation by which it is evoked is discontinuous. It therefore seems that we must seek for some other solution of the fact that all continuous muscular effort, whether effectual or not, is accompanied by the production of heat, in quantity which in the main depends on the intensity of the effort. Just as, in comparing the thermal effect of single excitations which are not adequate to produce a maximal contraction, it was found that this effect depends on the efficacy of the excitation as indicated by the lift, so in tetanus, as long as the frequency of the excitations is insufficient to evoke a maximal tetanic contraction, the heat produced by a tetanus of given duration increases with the height to which the load is lifted. Thus the thermogenetic effect, no less than the mechanical effect, depends on the frequency of the excitations. But from the moment that the contraction becomes maximal, frequency ceases to have any influence; so that, in a series of similar experiments, in each of which a muscle is completely tetanised but with stimuli of different frequency, the quantity of heat produced in the same time is always the same. It is also found, by comparing equal periods of a tetanus brought about by a series of maximal stimuli of constant frequency, that more than twice as much heat is produced in the first period, *i.e.*, that in which the muscle shortens, than in any succeeding period. Provided that

¹ Gad, "Zur Theorie der Erregungsvorgänge im Muskel," *Arch. f. Physiol.*, Leipzig, 1893, S. 166.

the excitations are strong enough and frequent enough to produce a full thermal effect, they may be altered in both these respects without interfering with the result. When the frequency of the stimuli is not only insufficient to produce a maximal tetanus, but fails to evoke a continuous contraction at all, as is the case in a series of maximal excitations, following one another at intervals of such length as to allow the muscle time to relax between each contraction and its successor, more heat is produced than in a tetanus, whether complete or incomplete, of the same duration.

It may be noted that Fick¹ summarises these results by the statements— (1) That in tetanus the quantity of heat which is assignable to each excitation varies inversely with the frequency, and (2) that in a series of responses to instantaneous excitations, the thermogenetic effect of each excitation far exceeds that which is attributable to each member of a series of stimulations of such frequency as to evoke complete tetanus.²

For the reasons stated on p. 394, oxidation must be considered as the first in order of time of the processes which constitute the response of a muscle to excitation. In the excitation of a muscular element, the direct action of the stimulus is to induce in it chemical changes, whereby either heat is produced or work is done. But we have seen that not only the proportion between the inogenetic and thermogenetic changes varies according to the mechanical conditions, but that the total amount of chemical work done is also dependent on them. We are thus led, with Fick, to adopt the general principle that the "chemical process is in part determined by the external conditions under which the muscle is placed when it is excited." How far this influence extends is one of the most important problems in muscle physiology; for in all discussions of the relation between the useful result obtained, and the quantity of material expended in its production, it is this problem that we have to encounter.

In voluntary movement we may well suppose that when the central nervous system sends its mandate to a muscular element to contract, it does so without definite information (if I may so express myself) as to the amount of material which it will be necessary to use or waste in fulfilling that mandate, and that if the demand first made is found to be inadequate, as, *e.g.*, in consequence of unanticipated resistance, the supply will be proportionately increased. There is, in short, no difficulty in supposing that during the performance of a voluntary act, expenditure is continuously adapted to requirement. In skilled movements, such as those of drawing, writing, or playing on an instrument, it is difficult to see how such adaptation could be dispensed with. We might without difficulty found upon this consideration the hypothesis that in general the adaptation of supply to demand is a function of the nervous system. Inasmuch, however, as in muscles rendered nerveless by curare, this adaptation is as remarkable (see p. 361), though not so perfect, as in muscles working under the guidance of nerve cells, no such general statement can be made.

We have already seen (p. 357) that if a muscle sustaining a weight which it is just able to lift, is tetanised for a limited period, during which its load is gradually diminished in such a way that throughout the period of excitation the lifting power of the muscle is only just in excess of the resistance it has to overcome, it will do more work than under any ordinary conditions, for throughout its effort it is doing its utmost. It eventually attains its maximum degree of shortening, at

¹ "Mech. Arbeit," S. 216.

² *Loc. cit.*, S. 213.

which moment it no longer has any load to lift. If the same muscle is tetanised for the same period, sustaining a weight which, at first approximately 0, is gradually increased to the amount of the initial weight in the previous case, it will then (after first promptly shortening in response to the excitation) be stretched to the length which it had before, when charged as it is now with a load it was only just able to lift.

In the two cases the excitation is the same; the contrast between them consists in the mechanical conditions under which the muscle responds. In the first case it does its utmost amount of work; in the second case it not only does no work, but is *worked upon* by the descending weight which stretches it. In both, the temperature of the muscle is raised, but in the former this represents only a part of the chemical change (oxidation) which takes place; the remainder becomes external in work. In the latter the warming of the muscular substance represents more than the heat production due to oxidation, for a considerable part of it is due to the action of an external cause, the extension of the muscle by the weight.

FIG. 220.—Blix's apparatus for taking the extension curves of muscle with the load either increasing or decreasing.—After Fick.

The results of the experimental comparison of the two cases have been given by Fick in one of his recent researches.¹ The method will be readily understood with the aid of the diagram (Fig. 220), which represents Blix's ingenious contrivance for obtaining the extension curve of a muscle. The slider *SS* can be freely moved backwards and forwards on the rails *RR'*, *KK'*, between which it works. At one end of it there is a support *A*, from which the muscle is suspended. The other end of the muscle is attached to the myographic lever at *b*. The axle *a* on which this lever rotates is carried by the slider. The load is sustained by a vertical rod *f*, which rests on the lever at *r*, and moves freely up and down between the pins *tt* and *tt'*; consequently the distance between the point at which the load is sustained by the lever, and the axle *a* varies according to the position of *SS*. The plate on which the lever writes is fixed. The curved lines inscribed on it are such as would be drawn by an up-and-down movement of *p*, if the index of the slider were brought in succession to the points 1, 2, 3, etc., on the scale and back again. It will be seen at once that if the muscle is unexcited, *p* will describe its extension curve on the plate, whenever the slider is moved along its whole course in either direction. If the load is 1000 grms., and the maximum distance between *r* and *a* one-half of this distance) will correspond to 50 grms. of tension. If during the time (say 2 seconds) that the slider accomplishes its backward and forward journeys, the muscle is tetanised, it draws in like manner the *extension curve of tetanised muscle*. If contracted muscular fibre were to behave in

¹ Fick, "Neue Beiträge zur Kenntniss von der Wärmeentwicklung im Muskel," *Arch. f. d. ges. Physiol.*, Bonn, 1892, Bd. li. S. 541.

exactly the same way as an elastic cord, the curve drawn when the slider was moving from 0 to 10 would be identical with that drawn during the return movement from 10 to 0. The curves (Fig. 221) show that it is not so. With diminishing load the writer follows the line ab ; with increasing load, the line $b'a'$, or rather $b'a'$; nor does it make any difference (with the exception indicated in the description of the figure) which of the two curves is drawn first. Now, as was explained in p. 357, every extension curve serves as a "work diagram." The area included between the line ba , the vertical line be , and the horizontal line ea , represents the amount of positive work done by the muscle in contracting when carrying a diminishing load. Similarly, the area limited by the lines $b'a'$, $b'e$, $e'a'$, expresses on the same scale the negative work done by the weight on the muscle in the act of extension. As indicated by the figure, this area is always larger than the other, exceeding it by the area enclosed between aa' and the two curves drawn by the muscle in extension and in shortening respectively. Consequently, in order to get at the true amount of heat attributable to the chemical change which has taken place in the muscle during the period of observation, the amount of heat corresponding to the excess of the negative over the positive area must be deducted from the total quantity indicated by the increase of temperature.

As has been already stated, it makes no difference as regards the amount of work done, whether the load first increases then diminishes, or first diminishes then increases; but, as regards the total production of heat, the experiments yielded a very remarkable though not unexpected result, for it was found that the heat-effect is nearly twice as great when the muscle is allowed to do external work during the first half of the period of excitation, than in the contrary case. The meaning of this fact will be better understood if we first refer to the results of preliminary experiments, in which the heat production was measured of a muscle tetanised for equal times, e.g., 1.9 seconds, in one case (*A*) with diminishing, in another (*B*) with increasing, load. In *A* the total amount of heat produced, as indicated by the rise of temperature, was 123.4 microcalories, and the heat equivalent of the positive work done during the period of shortening was 18.3 microcalories. Hence the total heat product of the oxidation which took place during the same period, was 131.7 ($=h + wh$). In *B* the total thermogenesis was 118.5 microcalories, and the heat equivalent of the negative work done 32.3. The heat value of the material oxidised was therefore 86.2 ($h - wh$). The chemical process was thus more active when the work done was positive than when it was negative, in the proportion of $\frac{1.53}{1}$. In the form of experiment (*C*) in which the thermogenetic effects of two excitations of equal duration are compared, in one of which (a after b , i.e. ba) a diminishing load is preceded, in the other (b after a , i.e. ab) is followed, by an increasing one, there was a very considerable difference between ba and ab . The measurements in microcalories were when b followed a , 137, when b preceded a , 92. As in each case the amount of heat produced by stretching, namely 19 micro-

FIG. 221. — Two extension curves of the same excited muscle taken continuously with decreasing (ab) and increasing ($b'a'$) loads. The figure is modified from the original (Fick, *loc. cit.*, Fig. 6, p. 550), by the addition of the dotted line which indicates the course the writer must have actually followed in the case described. When the order of the experiment is reversed, so that the increase of load precedes the decrease, the tracing follows the continuous line $e'b'a'a'b$. The part of the tracing above b is no doubt chiefly due to the inertia of the lever.

calories, *i.e.*, the amount of heat corresponding to the excess of the negative over the positive work, must be deducted, we have, as the actual amount of heat produced by oxidation during the period in question—for *a b*, 118 microcalories; for *b a*, 63 microcalories.

The question on which these experimental results throw light, is that of the *conditions which determine the expenditure of oxidisable material in a muscle when in the excited state*. With reference to this question, they may be set forth as follows:—

From the data of experiments *A* and *B*, it is seen that during a brief period of excitation (two seconds) the expenditure of the excited muscle is greatest when the resistance opposed to its shortening is such as it can overcome, so as to do its utmost amount of external work; and that it is least when the resistance is considerably greater than it can overcome, *i.e.*, when the opposing force of the load is sufficient to lengthen it to its utmost. Between these two contrasting conditions comes that in which the muscle neither prevails nor yields—that in which it is excited isometrically. Here the heat produced must be *less* than in contraction against resistance, *greater* than when the effort to contract is overpowered by an antagonistic force—or, putting it otherwise, to hold on against an opposing force involves expenditure, of which the amount is proportional to the effort made; but, provided that the effort remains the same, to hold on against an unyielding resistance is *less* expensive than to overcome an opposing force, *more* expensive than to be overcome by it.

From experiment *C* it appears that if an excited muscle is allowed to shorten, and thereby to do work under the conditions which we know to be most favourable, *i.e.*, in lifting a diminishing load, the expenditure of material which accompanies this effort is affected in a remarkable way by *antecedent* mechanical conditions; if (case *a b*) it is excited when it is at its natural length, and at the same moment its shortening is opposed by a decreasing load, of which the initial amount is the greatest that it can lift, it expends much more material than if (case *b a*), before beginning its effort, it is stretched from its natural length when excited (λ) to its natural length when relaxed (l). The contrast between the two cases can only be explained by supposing that the negative work, which in case *b a* has been done on the muscle towards the end of the previous period of extension, leaves behind it mechanical potential energy which, in the succeeding act of shortening, takes the place of part of the mechanical energy which in case *a b* was derived from the transformation of chemical energy. The theory of this transformation can of course not be given, so long as the problem of the origin of muscular force remains unsolved.

The practical importance of both results lies in their bearing on the conditions of exhaustion—meaning thereby that kind of exhaustion which depends on the using up of oxidisable material. Experience teaches that different kinds of muscular effort differ from each other in a remarkable way in their relative aptness to induce fatigue, and that this does not depend on the muscular tension with which the effort is accompanied. Going up hill is exhausting because external work is done against resistance. Descending is not exhausting, although the muscles are as frequently in action, and as tense when in action as in ascending. The reason why there is so little fatigue is that each muscular effort is overcome by a superior opposing force—the weight of

the body. The muscles work with relatively little expenditure of thermogenetic material, because, for the most part, each effort is preceded and prepared for by previous extension.

Looking at this subject in a more general way, and seeing that even curarised muscles have a certain power of regulating their own expenditure in accordance with the work they are required to do, the experimental data which we have had before us indicate that this regulation is such as must unquestionably tend to the advantage of the organism.

THE ELECTRICAL PROPERTIES OF MUSCLE.

In all excitable organs differences of potential present themselves between different parts of the surface, which cannot be attributed to accidental or external, physical or chemical conditions. These have a definite relation to the structure of the organ, to its general state of functional activity, and to the relative state of functional activity of its parts; so that when the whole organ or any part of it passes from the state of rest (relative inactivity) to that of activity, or the reverse, this change is indicated by a corresponding change in the distribution of electrical tension (*i.e.* of differences of potential) at its surface. These changes of tension can be investigated with the aid of suitable instruments. They derive their importance from their correlation with the physiological changes which they accompany. This correlation can be determined by the comparison of concomitant variations of different orders, *i.e.*, of variations of functional activity on the one hand, with variations of distribution of electrical tension on the other. If the parts of the surface of an organ between which differences of potential exist, are so connected with a galvanoscope that they are included in its circuit, they are of course indicated in the instrument as currents. As some form of galvanoscope is generally used as the means of investigation, the variations or states so observed are ordinarily spoken of as "currents." Those currents which indicate the normal distribution of tension on the surface of muscle are called currents of rest, or "muscle currents." Those which appear as concomitants of transition from relative rest to functional activity, are called "action currents." With reference to all of them, it has to be remembered that what is observed and measured is not what occurs in the organ under investigation, but in the galvanoscope. For although currents actually exist in the organ itself, we learn nothing by our observation, either as to their direction or relative strength. All that is revealed to us, when we compare the two parts of the surface by applying to them the terminals of our galvanoscopic circuit, is the measurable difference of potential between the two parts.

Electromotive phenomena of muscle in the unexcited state.—Inasmuch as the electrical changes which accompany increase, diminution, or cessation of functional activity, can only be spoken of in their relation to the normal state from which the structure has departed, and to which it tends to return, it is obviously desirable that the study of that state—the state of relative rest—should precede that of activity or disturbance.

It is important in the employment of muscles for the investigation of electromotive phenomena, to distinguish between those which are

parallel-fibred and others. In some parallel-fibred muscles the fibres are as long as the whole muscle. Each fibre is provided with one or (in the frog) more nerve-endings, and these are disposed either near the middle, or on either side of it; none occur at the ends. Consequently, when the muscle is excited through the nerve, the excitatory influence reaches the middle of the muscle first. The tendons extend so short a distance into the muscle, that muscular fibres underlie the surface everywhere. Of such a muscle the *sartorius* is a type. If this muscle is prepared with due care, its surface is found to be nearly *equipotential*, i.e., no appreciable current is indicated by a galvanometer of which the terminal electrodes are applied to its surface, whatever the situation of the contacts. In some parallel-fibred muscles, as in the *adductor internus* or *gracilis* and the *semi-membranosus*, the fibres are interrupted by tendinous "inscriptions" (see Fig. 189), the presence of which, as will be seen subsequently, modifies the electromotive properties of the organ.

FIG. 222.—Diagram showing the arrangement of the fibres in the gastrocnemius muscle. The letter *f* is on the dorsal surface, close to the edge of the tendinous expansion; *s*, on the ventral surface, marks the edge of the dorso-ventral tendinous plate. In the third figure this plate is seen in section.

Of muscles in which the fibres are not parallel, the *gastrocnemius* is the most important example. In this muscle more than half the surface is tendinous, and the fibres spring from an incomplete median dorso-ventral tendinous plate, of which the border is seen on the ventral surface of the muscle, dividing that surface into an outer and an inner half. From this plate as origin, the fibres sweep round, to be inserted dorsally in the deep surface of a tendinous expansion of the *tendo Achillis* (Fig. 222). Each fibre in this case receives a single nerve-ending. In the *gastrocnemius* and other muscles of similar structure, considerable differences of potential present themselves, especially between the muscular and tendinous parts of the surface. Before considering these, it will be advantageous to describe the general method of examining a muscle galvanometrically.

Method of observation.—In English laboratories a "Thomson" galvanometer of high resistance (8000 to 20,000 ohms) is used. The galvanometer is provided with a shunt, by means of which $\frac{1}{10}$, $\frac{1}{100}$, or $\frac{1}{1000}$ respectively, of any current may be led through the coils. The circuit may be arranged according to some such plan as is shown in Fig. 223. From the principal terminals of the shunt, *n* and *s*, the wires lead to the north and south terminals of the galvanometer. When the plug between *n* and *s* is withdrawn, the galvanometer is in the circuit, but with a plug in the position marked $\frac{1}{10}$ in the figure, only one-tenth of the current in the circuit flows through the galvanometer. When the keys *K*, *K*¹, and *K*² are plugged, the circuit is completed through the plugs. When the plug of *K* is withdrawn, it is completed through the preparation *pr d*, the wire from *d* leading to the north terminal of the galvanometer, the wire from *pr* to the south terminal. When the key *K*¹ is unplugged, so much of the wire *BC* as intervenes between *C* and the sliding contact is included in the circuit. The wire stretched between the two blocks *C* and *B* is a rheochord through which, when the key *K*² is plugged, the current of a battery flows. *BC* is a metre long, and is

provided with a millimetre scale, by means of which the distance of the sliding contact from the block *C* can be measured. Between the block *B* and a block *A* is a resistance coil. The resistance of the wire *BC* having been determined, that of the coil must be so adjusted that the former is to the latter as 1 to 13·56, for a reason which will appear immediately.

The wire which connects the battery with *C* passes through a rheostat. The terminals of a Latimer Clark's standard battery can be connected with *C* and *A*, by closing a key. Between the key and *A* is a galvanoscope *g*, by which it can be observed whether any current is flowing between *A* and *C* or not. The branch of the Daniell battery which flows through *g* is opposed to the current of the standard cell. Before making the experiment, it is reduced with the aid of the rheostat, until *g* indicates no current. When this is the case, the difference of potential between *C* and *A* is 1·456 volt, *i.e.*, the electromotive force of the standard cell. Consequently, as the resistance of *CB* is to that of the coil as 1 to 13·56; the difference of potential between *C* and *B* is to that between *B* and *A* as 1 to 13·56; and hence to that between

FIG. 223.

C and *A* as 1 to 14·56, or 0·1 to 1·456. That between *C* and *A* being 1·456 volt, the difference between the two ends of the metre wire will be 0·1 volt, and each centimetre of it will correspond to a difference of $\frac{1}{1000}$ volt.¹

The arrangement just described (the rheochord in connection with the "balanced" cell) is called a "Compensator." The use of an instrument of this kind, for measuring physiological differences of potential, dates from 1861, when du Bois-Reymond described the two forms of compensator which are used in Germany, the "long" and the "round." Of these, and the method of using them, a description will be found in Hermann's "Muskel-physik." The arrangement described above has the advantage, as compared with these, that so long as the standard cell for which the scale is graduated is used, no calculation is required.

The ends of the wires at *pr* and *d* are connected with the surface of the muscle by non-polarisable electrodes. Of such *electrodes* a suitable form

¹ The form of instrument mentioned above was described by the writer in 1873, in the "Practical Exercises" for the Laboratory of University College, London.

is represented in Fig. 224. A glass U-tube *u*, containing saturated solution of zinc sulphate, is supported by a brass block *b* and holder which slides on a horizontal vulcanite rod *r*. The block also supports an L-shaped zinc wire *L*, of which the arm dips into the solution in the U-tube. It is also provided with a terminal, for attaching the wire by which the electrode is connected with the circuit. The arm of each zinc rod is flattened by hammering, at the end which dips into the zinc solution, so as to take the form of the blade of an oar, and its surface is carefully smoothed, and then amalgamated. The straight tube *T* (too narrow in the figure) is of such width that it fits loosely into the other end of the U-tube; it is prevented from slipping in by the flange *f*. It is charged with paste, made by kneading kaolin with the zinc solution. To prepare the electrodes for use, a lump of kaolin paste *k*, made with 0.6 per cent. solution of sodium chloride, is stuck on the summit of the straight tube, a groove being made across the top of this lump with an ivory knife, in which the end of a "cable" of cotton wick thoroughly soaked in physiological salt solution is placed. By this means the clay is brought into connection with the surface of the muscle to be examined.

Before establishing this connection, it is necessary to test the electrodes by making contact between the two lumps. If the galvanometer is sufficiently sensitive, some current will generally be indicated, the electromotive force

FIG. 224.—Non-polarisable electrode.

and direction of which can be readily ascertained with the aid of the compensator. If it is considerable (electromotive force exceeding 100000 volt), the electrodes must be remade. To avoid mistakes of direction, it is desirable to label the electrodes *N* and *S* respectively—it being understood that the wire of the *N* electrode runs to the north terminal of the galvanometer, and accordingly that a current flowing therefrom is indicated by a movement of the spot of light southwards.

In exploring a muscle in the resting state galvanometrically, the differences of potential between different parts of its surface are measured in hundredths of the divided metre of the compensator, *i.e.* in millivolts. In such observations the "muscle current" is balanced by a current of opposite direction from the compensator, by working the slider until the galvanometer is at zero.

When the capillary electrometer is substituted for the galvanometer, the arrangement of the circuit is the same. But, with the aid of a scale by which the excursion of the mercurial meniscus from its normal or zero position is measured, the observer is enabled to determine approximately the difference of potential between the two contacts, provided that the value of the graduation in decimals of a volt is known.

In the gastrocnemius, as has been indicated above, however carefully it is prepared, a considerable difference of potential usually presents itself between the tendon end and the most positive part (Fig. 224, *f*) of the natural surface, notwithstanding that Hermann found that under conditions which absolutely exclude sources of injury this difference is inappreciable. The difference, when present, diminishes as the electrode on the tendon is brought step by step nearer to the other. In uninjured parallel-fibred muscles, on the other hand, the differences

of potential between different parts are, as has been said, scarcely measurable, for which reason these are best adapted for the study of the natural electromotive phenomena of muscle, and their modifications.

"Current" of injury.—When the tendinous expansion of the tendo Achillis is injured by heat or otherwise, a very much larger difference of potential comes into existence between it and the proximal contact at *f*. Heat injury may be effected either by dipping the end of the muscle into salt solution at any temperature above 55° C., or by applying a camel-hair pencil, which has been dipped in hot salt solution, to the surface of the muscle at the tendon end. Whichever plan is used, the ends of the fibres are made to shorten and swell. In the gastrocnemius the difference may amount to more than $\frac{4}{100}$ of a volt. When the sartorius is similarly treated, the difference seldom exceeds $\frac{2}{100}$. A muscle injured at one end in the way above described is referred to by physiological writers as having a "thermal section." As this expression is founded on du Bois-Reymond's "doctrine of the muscle cylinder," it will now be convenient to discuss this subject.

It may be assumed that the essential physiological properties of a muscle are possessed by each of its constituent fibres. If it were possible to divide a muscle fibre into parts by cross-sections without injuring it, each part might be expected to exhibit the endowments of the whole muscle. Proceeding from this consideration, the theory in question further supposes that each such cylindrical part of a fibre is built up of structural elements which have the same properties; these in their turn consist of electromotive molecules, to the endowments of which those of the whole organ are attributable. It is obvious that cylinders cut from single fibres could not be subjected to direct investigation. The experimental basis for the theory of electromotive molecules had therefore to be sought for in the data to be obtained by the examination of a truncated, cylindrical, and parallel-fibred muscle. A cylinder so prepared possesses a natural and two cut surfaces. These are called by du Bois-Reymond respectively "longitudinal" and "transverse," designations which are open to the objection that they conceal the all-important fact that each transverse sectional surface is that of a wound. At the centres of the opposite cut surfaces there are found to be spots which are mutually equipotential, but relatively negative to all other parts; and on the natural surface there is an equatorial zone which divides the cylinder into two, and is positive to all other parts. If the other parts of the surface are explored galvanometrically, by placing one electrode on the equator, the other first on the centre of an end surface, and then successively on spots nearer and nearer to the equator, it is found that the difference of potential in each successive observation is less than in the preceding one. The exact relation between these differences has been minutely investigated both theoretically and empirically by du Bois-Reymond, but has little physiological interest. The essential point is that the distribution of tension on either side of the equator is symmetrical. If the cylinder is cut from a muscle of irregular construction like the gastrocnemius, no such symmetry is observed; for the central spot of the cut surface which faces the tendon is negative to the corresponding spot in the surface which looks in the opposite direction. The reason of this must now be considered.

The muscle rhombus.—Long ago, du Bois-Reymond discovered that

if, in preparing the muscle cylinder from a parallel-fibred muscle, the fibres are cut obliquely, so that a section parallel to the long axes of the elliptical cut surfaces is rhombic, the sharp and blunt edges of such a rhombus are not equipotential, but the sharp edge is relatively negative to the other, for a reason which the diagram (Fig. 225) will help to explain. In an obliquely cut sectional surface, the fibres are imbricated. In each fibre, a is negative to a' , b to b' , and so on; for, as we have already seen, a more injured part is negative to a less injured. The difference of potential (Δ) between them is the same in all. b is also negative to a' , and c to b' , and so on; but this difference is smaller than Δ by a certain amount (δ), which is consequently the difference of potential between a and b , b and c , and so on. And if the cut surface is of the width of a hundred fibres, there will be a difference of potential of a hundred times the amount δ between the two borders. In other words, the ends of the fibres in an obliquely cut surface act like voltaic elements in series; whereas in a transverse surface they act as if in multiple arc. These considerations help us to understand the fact that the tendon end of the intact gastrocnemius is ordinarily strongly negative to the middle. If the tendinous expansion were not there, the relation of the exposed ends of the fibres would be precisely that which has just been described in an obliquely cut surface. Any part further from f would be negative to any nearer spot.

FIG. 225.

Before proceeding to the study of the excitatory response, it will be convenient to inquire, in a preliminary way, whether the facts we have had before us relating to the electromotive properties of unexcited muscles—particularly those relating to the equipotentiality of certain muscles when sufficiently carefully prepared, and to the readiness with which the slightest damage renders any part of the surface, more especially in the neighbourhood of the tendon, negative to the rest—can be comprehended under any general statement.

prepared, and to the readiness with which the slightest damage renders any part of the surface, more especially in the neighbourhood of the tendon, negative to the rest—can be comprehended under any general statement.

In any excitable organ two kinds of functional difference may exist between parts. They may either have *permanently* differing functional endowments, *e.g.* nerved and nerveless parts of the same muscles, or they may be at the moment of observation in different states of fitness for the discharge of function, this being due to the circumstance that they are in different stages of actual discharge of function or of exhaustion therefrom; or dependent upon injury, difference of temperature, or other external conditions which affect function. It may be generally stated as regards excitable organs, such as muscle and nerve, that in comparing parts which are similarly endowed, those which are functionally in a more capable state are *positive* to those which are functionally less capable. No such "law" applies to organs which do not possess the property of responding to stimulation. It appears to me impossible to suppose that this fundamental difference between the one group of organs and the other—those organs, namely, in which functional activity has no concomitant electrical phenomena, and those, on the other hand, in which this occurs without fail—should manifest itself independently of the existence in the one set of organs of a special mechanism which in the other set is absent. Nor can it be doubted

that this mechanism is molecular, *i.e.*, that the electromotive function of muscular substance or of nerve substance is dependent on their respective molecular structures. Although, therefore, du Bois-Reymond's molecular theory, in the form given to it by its author, does not appear to aid in the understanding of the relation between the mechanical, chemical, and electrical processes which are concerned in the response of a muscular element to stimulation, the recent development by Bernstein of the chemical aspect of the theory appears to be of greater value.

Du Bois-Reymond's "molecules" were electromotive only. They were of prismatic form, and were supposed to be arranged in series end to end, their ends or poles being negative to their equators. Bernstein's molecules are also prisms arranged in the same way, but their fundamental attribute is chemical, that is, their poles are able to attach to themselves electro-negative groups of atoms (oxidisable material), while their sides attach oxygen. This change, which may be designated polarisation, is the first effect of excitation. It is the immediate antecedent of the explosive oxidation of which the transformation of chemical into mechanical energy is the consequence. Any molecule which is the seat of this change is able to communicate a similar state to the molecules on either side, of which the poles face its poles; and so we have the propagation in two directions of the "excitatory wave."

The chemical processes above described necessarily involve mechanical and thermal consequences. At the moment of explosive oxidation, mechanical stress takes the place of the chemical tension which is thereby relieved. This mechanical stress is itself transformed into heat and external work, in proportions which are dependent on the conditions set forth in the preceding section. As regards the order in which these changes occur, Bernstein's scheme is in accordance with views which have been already stated. Chemical explosion comes first with its concomitant electrical manifestations, then follow the thermal and mechanical phenomena of muscular contraction.

Such is Bernstein's theory. It explains nothing, but it is of use as enabling us to think of excitation, propagation, oxidation, electrical change, mechanical stress, change of form, production of heat, as all parts or manifestations of one and the same process.

The simple statement already made, that in muscle and nerve, relative capability of function (*i.e.* fitness for its performance) is indicated by relative electrical positivity (that is to say, that of two parts of identical function, in structural continuity with each other, the one which is at the time most capable of performing that function is positive to the other), springs out of experimental results independently of any theory. In accordance with this statement, it will be shown in the next paragraph that action is always attended by disappearance or diminution of the capability of acting; a part, in becoming active, becomes at the same time relatively negative to other parts.

Electromotive phenomena of muscle when excited.—The two kinds of mechanical change which were studied in the first chapter—the single response which follows an instantaneous stimulation and the persistent one which is evoked by continuous stimulation—have their counterparts in the electrical phenomena which we have now to examine. The *continuous* electrical change which corresponds to tetanus has been long known. It was recognised by Matteucci, and investigated by du Bois-Reymond, who bestowed on it the designation *Negative Variation*,

in which the word "negative" is used in its algebraic, not in its electrical sense. The *transitory* change which corresponds to the single contraction is of very short duration, and is propagated in such a way that by the time it reaches the end of a muscle furthest from the seat of excitation, it may have already ceased in the neighbourhood of the excited part. This being so, it is not difficult to understand that the response to instantaneous stimulation remained unrecognised for many years after the electromotive properties of muscle in the resting state and the "negative variation" (in the original sense of du Bois-Reymond) were well known.

Whereas the "negative variation" is persistent and not propagated, the response to instantaneous stimulation is transitory and spreads at a rate of many feet per second. In both cases the change manifests itself by relative electrical negativity of the affected part of the surface. In discussing these changes, it is necessary to bear in mind the caution already given, that the phenomena observed are those of the instruments we employ rather than those of the organs we explore. If we talk of

"action currents," we refer to currents as they really exist in the galvanometric circuit; if we say that a certain spot is "negative," we mean that there is a difference of potential between the surface of contact to which we refer, and another contact surface to which the other electrode is applied—which difference we measure either by the compensator or the electrometer.

FIG. 226.—Bernstein's differential rheotome.

(a) The electrical response to an instantaneous

stimulus—Its time-relations.—It was known from an experiment made by Helmholtz, which will be referred to further on (p. 421), that the electrical response to an instantaneous excitation is of very short duration, and that it precedes the change of form. But it was not until twenty years later that Bernstein devised a method for investigating its time-relations, and particularly its rate of propagation, and was further enabled to distinguish the differences between the phenomena of the electrical response, as they present themselves in injured and in uninjured muscles respectively. The description of the instrument, which he called a *Differential Rheotome*, is now to be found in most textbooks. It will be sufficient, therefore, to refer to the original diagram, which is reproduced in Fig. 226.¹

¹ From Bernstein's "Lehrbuch der Physiologie," S. 354.

A bar of non-conducting material revolves on a vertical axis a , 5 to 10 times per second; p^1 and p^2 are isolated metal points which dip into the mercury pools, $Q Q$; when both of them touch the mercury, the galvanometer circuit is closed; this happens every time the bar revolves. The opposite end of the bar carries a pin p which touches the wire d and so closes the primary circuit just before p^1 and p^2 dip into the mercury. The time-interval between the two contacts—at d and Q —can be determined by reference to the scale, which is divided into hundredths of a revolution. At the same moment that p touches d , the muscle is excited at r . As long as the interval between the two contacts remains the same, each repetition of the stimulus as the bar goes on revolving, produces the same electrical effect. Consequently the similar effects rapidly following one another may be taken as one, which has been so magnified by repetition as to be measurable.

To make an observation, the instrument is brought into circuit by closing the key, K^4 (Fig. 226), the binding screws of which are connected with Q and Q . The contacts of p^1 and p^2 with $Q Q$ may be so adjusted, that, supposing the rate of revolution of the bar to be 10 per second, the duration of closure of the galvanometer circuit shall be $\frac{2}{1000}$ of the period of revolution, *i.e.* 0.002 second. The rheotome is set in motion, and the key in the circuit of the secondary coil, S , opened. If any deflection is observable, it is compensated, and the key again closed. The contact $p d$ is then so adjusted that d is struck by p , say 0.01 second before the galvanometer circuit is closed at $Q Q$; then, the rheotome being still in motion, the same key is opened, for as short time as is necessary to obtain a full effect, and the deflection noted. The time-interval between the contacts is then reduced from 0.01 second to, say, 0.008 second, and the observation repeated, and so on with further reduction of the time-interval by the same amount each time until there is no longer any deflection, a result which will be obtained when the interval has been reduced to 0.002. This having been accomplished, the first observation (time-interval 0.01 second) is repeated, and a second series made in which the time-interval is lengthened between each two observations, in the same way as that in which it was before shortened. In this way a series of numbers, each representing a galvanometric deflection, is obtained. The corresponding time-intervals between excitation and closure of the galvanometric circuit vary from 0.002 second to 0.020 second. If the circuit is arranged as in Fig. 223, the first set of deflections will probably be southwards, the second set northwards. It is important to note that between each observation and its successor, the muscle current (pre-existing difference of potential) must be carefully compensated, for a muscle cannot be subjected to repeated excitations without its electrical condition being altered.

The result of such a series of observations is stated by Bernstein as follows:—When a muscle is excited at r at a given moment, by an induction shock, a certain time elapses before the excitatory variation begins at l (*i.e.* at the proximal leading-off electrode). Here the effect culminates very rapidly, and disappears so promptly, that it has already ceased by the time that the “wave of contraction” has reached the same point. The shading represents the “part of the fibre,” the elements of which participate in the process of negative change at the moment that l is reached. This process lasts in each “element,” according to Bernstein’s observations, about $\frac{1}{2500}$ to $\frac{1}{3000}$ second. It advances along the muscular fibre at a rate of 3 or 4 cms. in $\frac{1}{1000}$ second. He therefore designated it the *Reizwelle* or Excitation-wave. What he supposes actually to happen in an uninjured muscle is illustrated by the diagram (Fig. 227). Each excitation wave that starts from $r r$ reaches first l^1 then l^2 . When it is at l^1 a current exists in the direction of the arrow \rightarrow , when it is at l^2 there is a current in the opposite direction. In such a muscle

the variation, *i.e.* the galvanometric effect, as observed with the aid of the rheotome, is diphasic. During the exceedingly short period that the wave is under the electrode l^1 , a current from l^2 to l^1 passes through the galvanometer. During the similar period that it is under the electrode l^2 , a current flows in the opposite direction. If we accept Bernstein's estimate of the rate of propagation and of the duration of the wave, and assume the electrodes to be over 2 cms. apart, there will be an interval of time between the two periods during which there will be no current either way. It will be seen further on that the excitatory change lasts longer than Bernstein supposed.

In a muscle truncated at one end, with the electrode l^2 on the injured part, the case is different. The variation has one phase only. The wave, as in the other case, makes its way along the fibres, but on its arrival at the injured part *it is suppressed*, so that its presence there is without galvanometric effect. Consequently, in the injured muscle, from the moment that the excitatory change has ceased at the electrode l^1 the variation is at an end. Hence the whole monophasic variation of the injured muscle represents the first phase of the diphasic of the uninjured.

FIG. 227.—Progress of the wave of excitation, according to Bernstein.

From Bernstein's description of the single excitatory variation, founded on his observations with the rheotome, we may pass to Hermann's more recent (1893) account of the same phenomenon, based on a different method of using the same instrument. This method is of such importance that it must be shortly described.

From the description of the rheotome given above, it will be seen that during each observation of the series, *i.e.* during each period of excitation of the muscle, the time-interval between excitation and the beginning of the "closing time" remains unaltered. For the better understanding of Hermann's method, let it be supposed that the excitation is continued for a period of two seconds, that this period is divided into ten equal parts, and that at the end of each part the interval between excitation and closure of the galvanometer circuit is increased by $\frac{1}{1000}$ second. It is obvious that during each successive part or period of $\frac{1}{5}$ second, the difference of potential between the leading-off electrodes represents that which actually exists during the corresponding period of $\frac{1}{500}$ second, and that if the ten measurements were arranged on an abscissal axis, the ordinates representing relative negativity of the proximal electrode being directed upwards, those representing relative positivity of the same electrode downwards, and the ends of the ordinates joined, we should have a graphic representation of the

variation. The observations extending over a period of two seconds, divided into ten parts, would represent an actual period of $\frac{2}{100}$ second, made up of successive periods of $\frac{2}{1000}$ second. It is this method that Hermann has followed, with the important modification that instead of increasing the time-interval periodically, he increases it continuously and equally during the whole period. His period of excitation is also relatively longer, each hundredth of a second in the actual variation being represented by 3.47 second.¹ The process thus prolonged can be followed by a galvanometer with a light aperiodic magnet, so as to give a true graphic record of the variations.

Observations were made both with uninjured muscles, and with muscles of which the surface of contact at the tendon end had been injured by lunar caustic. By bringing together the two curves *a* and *b* resulting from these observations, so that they lie with corresponding points over one another on the same axis, and drawing a third curve *c*, any ordinate of which when summed algebraically with the corresponding ordinate of *a* would give the corresponding ordinate of *b*, the combination reproduced in Fig. 228 was obtained, in which *a* represents the curve of variation at the proximal electrode (the curve of injury), *b* the diphasic curve of the uninjured muscle, and *c* the (deduced) curve of variation at the distal electrode. The figure shows that the relative duration of the instrumental effect of the first phase of the diphasic variation is considerably less than that of the monophasic variation. This, of course, does not imply that the actual process which takes place at the proximal electrode in the muscle itself is different in the two cases.

In Fig. 229 I have endeavoured to show the time-relations of the same two processes according to Bernstein's estimate of the duration of each, represented on the same scale as Hermann's curves, with the contacts at the same distance from one another. The reader will see at once that the difference between them consists in this, that the duration of each phase is according to Bernstein much shorter, and that, although the maxima of the phases are about equal distance from one another in the two cases, there is, according to Bernstein's conception, an interval between them during which the two contacts are equipotential, so that the curve is as it would appear if the galvanometer were acted upon by the summits of the waves only.

We may now pass to the further knowledge which we are able to obtain by means of the capillary electrometer. But in order to make the experimental data on which that knowledge is founded intelligible, it will be necessary to state shortly the principles by which observers

must be guided in interpreting them. The data in question are, as most readers now know, curves obtained by projecting the image of the mercury column of an electrometer (Fig. 230) on to a photographic plate, which moves at an equable rate behind a slit. The instrument takes the place of the galvanometer and shunt, in the circuit represented in Fig. 223,¹ the electrode on the injured end of the muscle, marked *d* in that figure, being supposed in the following paragraphs to be connected

FIG. 230.—Burch's projecting electrometer. The shorter limb of the wide tube contains a piece of thick walled tube *c*, which is ground in like a stopper. The front of this tube is ground away so that its bore is laid open from end to end, forming a trough wide enough to contain the capillary. A thin cover glass closes the trough in front, which is kept full of liquid by the surface tension of the acid. For further description see "The Capillary Electrometer," London, 1896.

with the capillary, and that on the muscular surface, marked *pr*, with the sulphuric acid; the current of a muscle injured at one end and placed as shown in the figure, would therefore be indicated by a movement of the meniscus from the point of the capillary. The shadow of a vibrating prong of a tuning-fork falls on the same plate at the same time, so that the time-relations of the movements of the meniscus of the mercurial column can be measured; and, by an automatic arrangement, the moment at which the circuit of the primary coil of the inductorium which serves to excite the muscle preparation, is opened, is also shadowed on the plate. The discovery which furnished the key to the interpretation of the curves so obtained, as indicating the nature and time-relations of the almost instantaneous electromotive changes we have now under consideration, was made by Mr. G. Burch, in the course of experiments carried out in the Oxford Physiological Laboratory, the results of which were communicated to the Royal Society in 1892.² He showed that the difference of potential at the moment corresponding to any point in such a curve of electrical variation, can be readily estimated from quantities which may be determined by the examination of the curve itself at that point. These are—(1) *The distance through which the meniscus has moved from its zero position,* and (2) *the inclination of the curve representing the velocity of the mercury,*

at the particular moment. Each of these quantities has its value in positive or negative difference of potential. To estimate their values, another curve must be obtained by photographing the excursion when a known difference of potential (say of 0.01 volt), derived from the compensator, is allowed to act on the electrometer, so as to determine a movement of the mercury towards the point of the

¹ If it is desired to use the galvanometer at the same time, the electrometer may be connected with K^4 .

² Burch, *Phil. Trans.*, London, vol. clxxxiii. p. 81.

capillary tube. This photograph of what may be called a "normal" or "comparison curve" having been taken, the reverser of the compensator is turned over, and a second photograph of the same kind is obtained with the same electromotive force acting in the opposite direction. The first of these curves is reproduced in Fig. 231. Its character is such that, at the moment corresponding to any point whatever in its course, the difference of potential acting on the electrometer is to the total such difference (in this case 0.01 volt) as the distance from that point to the asymptote α is to the distance of this line from the starting point of the curve. From the latter distance, the true value

in volts of the distance (1) referred to above, can be readily calculated. If, for example, the difference in question be 10 mm., and the corresponding difference of potential 0.01 volt, the value of each millimetre is then known to be one millivolt. To find (2), *i.e.* the value of the angle of inclination at any point in the variation curve, the point in the comparison curve at which the inclination is identical must be sought. The distance in mm. of this point in the comparison curve from the asymptote then gives the corresponding difference of potential in millivolts. For reasons which need not be here entered upon, the comparison curves must be taken under the same conditions as the variation curve to be referred to them, and the points compared in the two curves must be at the same distance from the centre of rotation of the disc.

The photographic record of a diphasic response is shown in Fig. 232; the time of excitation, *i.e.* the moment at which the primary circuit is broken, being indicated by the radial line. The ascending part of the curve corresponds in the main to the first phase—the descending to the second.¹ The essential points to be determined by the investigation of

FIG. 231.—Comparison curve. It is of such a character that any two ordinates at an angular distance of one degree from each other are, as measured from the asymptote α , in the proportion of 1 : 1.3. The straight line touching the curve is drawn as nearly as possible parallel to the steepest part of the ascent of the diphasic curve, and is, where it touches the comparison curve, 23 mm. from the asymptote. If it be assumed that 0.01 volt corresponds to 10 mm., the greatest acting difference of potential during the first phase is 23 millivolts. Adding to this estimate the difference due to the previous rise of the mercury up to the point of contact, we have 25 millivolts, the height above the base line being about 2 mm. The fact that the curve is inscribed as if on the surface of a disc, must be noted. To obtain strictly correct results, the corresponding points in the two curves should be at the same distance from the centre of the disc on which they are inscribed. If they are not so, a correction is necessary. Thus, in the case figured, the inclination of the experimental curve must be increased about 1 per cent.

The photographic record of a diphasic response is shown in Fig. 232; the time of excitation, *i.e.* the moment at which the primary circuit is broken, being indicated by the radial line. The ascending part of the curve corresponds in the main to the first phase—the descending to the second.¹ The essential points to be determined by the investigation of

¹ Elaborate analyses of several curves kindly made for me by Mr. Burch by his method, have been published elsewhere (see *Journ. Physiol.*, Cambridge and London, 1895, vol. xviii. p. 130).

such curves of an uninjured parallel-fibred muscle are—(1) The rate of propagation of the excitatory wave; (2) the time after excitation at which the two contacts become equipotential; and (3) the moments at which the first and second phases respectively attain their maxima, and the differences of potential which exist at these moments. The propagation-rate is determined by the comparison of the curves of two observations in which the distance between the seat of excitation and the contact nearest to it is different (the distance between the leading-off electrodes remaining the same). The time-interval between the moment of excitation and the moment corresponding to the summit

FIG. 232.—Copies of the diphasic (black) and monophasic (grey) curves of the sarorius, as they are seen when the two photographic records are placed one over the other, so that the beginnings coincide. Up to the beginning of the second phase the curves are identical. Rate of movement of the plate as in Fig. 231.

of the curve in each case can thus be estimated and compared. The moment of equipotentiality is that at which the positive difference of potential, indicated by the downward inclination of the curve, becomes equal to the negative, corresponding to the upward displacement of the meniscus. This event is indicated in the diagram, Fig. 233, by the vertical line, and coincides with the arrival of the excitatory wave at the midpoint between the contacts. The rate of propagation and the moment of equipotentiality having thus been determined, the times of culmination of each of the two phases of the excitatory wave can be readily deduced from them. Thus, if the propagation-rate be 2000 mm. per second, and the distance between the electrodes 20 mm., it is obvious that the excitatory change must arrive at the proximal electrode 0.005 seconds *before* the moment of equipotentiality, at the distal electrode 0.005 second *after* that event. It

FIG. 233.

may be seen from the photographic curve reproduced in Fig. 232 that the culmination of the first phase coincides with the middle of the ascending limb of the curve, that of the second phase with the beginning of the descending limb. The photographic record of a monophasic response, as obtained from the same sarorius muscle when one end has been devitalised by immersion in normal salt solution at the temperature of over 60° C., is shown in Fig. 232, by the shaded area. It will be observed that it differs from that yielded by the uninjured muscle chiefly by the absence of the second phase. In both cases the arrangement of the leading-off contacts was the same, the proximal contact being near the

middle of the muscle, the distal near its tibial end, which in the one case was devitalised, but not in the other. It is seen that the ascending limb is identical in the two curves, but that, from the point at which the diphasic curve approaches its culmination, the "injury curve" diverges from it, continuing to ascend. The inclination, however, rapidly diminishes until, from $\frac{3}{1000}$ to $\frac{5}{1000}$ of a second after excitation, the line becomes first horizontal and then begins slowly to decline. Shortly after the beginning of the decline, the two leading-off contacts become equipotential. The meniscus, however, does not reach its zero position until later. During the period which corresponds to the second phase in the uninjured muscle, the difference of potential in the injured muscle, which at the moment corresponding to the divergence of the two curves is still strongly negative, diminishes at first rapidly, then very gradually, until it finally disappears.

The estimate usually given of the duration of the monophasic variation is mainly founded on a beautiful experiment of Helmholtz's, in which he measured the latency-period in the same muscle when excited under different conditions. In one case the nerve was excited directly by an induction shock, and the muscle through it; in the other, the nerve of the same muscle was excited by the monophasic variation of another muscle, of which the nerve was excited directly. In the first case the period of latency was shorter than in the other by about $\frac{1}{2000}$ second. He therefore concluded that the rheoscopic limb receives the excitation to which it responds, $\frac{5}{10000}$ of a second later than it would have received it had its nerve been directly excited—or, as he then supposed, at the middle of the period of latent stimulation of the exciting muscle. Our photographic records tell us that at that moment the column of the electrometer is shot up by the sudden rise of tension at the proximal electrode; and it can scarcely be doubted that it is by this change that, in Helmholtz's experiment, the nerve of the recording muscle is excited.

At the moments of culmination of the diphasic and monophasic variations respectively, the difference of potential is expressed in much larger proportion by the inclination of the curve at the point corresponding to that moment, than by the distance of that point from the zero line. Thus, in the examples published in 1895,¹ the maximum "negativity" was found to be from $\frac{6}{1000}$ to $\frac{8}{1000}$ of a volt, of which amount only $\frac{3}{10000}$ or $\frac{4}{10000}$ were due to the height of the meniscus above its zero position. Fig. 234, which must be understood to be nothing more than a diagram, serves to illustrate this. The black area is that of the diphasic variation, the black and shaded together make up that of the monophasic. The line *oabd* is that of the "tension curve" of the diphasic, the line *oacd* that of the monophasic. The difference of potential between the contacts at the moment of culmination of the first phase is two or three times as great as that of the "negative variation," as estimated by du Bois-Reymond. This important fact was proved some years ago by a method of investigation employed by myself in association

FIG. 234.

¹ Burdon Sanderson, "The Electrical Response to Stimulation of Muscle," *Journ. Physiol.*, Cambridge and London, 1895, vol. xviii. p. 117.

with Professor Gotch.¹ The sartorius muscle is connected with the galvanometer circuit, which is arranged as in Fig. 223. The nerve is excited by a rheotome, the galvanometer wires of which go to κ^4 . This also closes the galvanometer circuit automatically at any desired time after excitation. The "closing time" of the rheotome is very short—usually $\frac{1}{500}$ second, it having been found that the greatest (negative) deflection is obtained when the closure begins about 0.006 second after excitation. The slider of the compensator is so adjusted that the derived current is in the opposite direction, and of just sufficient strength to annul the deflection when the excitation is repeated. In the gastrocnemius the mean difference of potential in five series of observations was found to be 0.084 volt.

(b) The electrical response to a series of stimulations.—The nature of the change which accompanies *tetanus*, when observed in an injured muscle, with leading-off contacts on the natural and cross sections respectively, was investigated by du Bois-Reymond some fifty years ago.² He interpreted the imperfect data which the methods then available afforded, with wonderful sagacity—drawing therefrom inferences which were surprisingly near the truth. It was more than twenty years later³ that, with the aid of the much better instruments which his own ingenuity and the progress of science had placed in his hands,

FIG. 235.—After du Bois-Reymond.

he published an account of the phenomena to which he applied the term "negative variation." His general view of what happens in tetanus can be best understood by referring to the curves by which he represents it, as reproduced in Fig. 235. The broken line is the curve of what he calls the *Gesamtschwankung*, the integral curve of the "variation." The successive effects of which it is supposed to be made up are represented by the teeth of the "ctenoid curve," the relation of which to the integral curve is such that, if as many equidistant ordinates were drawn to the latter as there are teeth, the space enclosed between the horizontal line *ab*, the curve, and any two neighbouring ordinates, would represent the integral of the differences of potential existing between the contacts during the corresponding period. Each tooth, therefore, represents the response to a single instantaneous excitation. The figure further denotes that tetanisation is followed by an "after-effect"—a slight diminution of the previous difference of potential.

The "negative variation" of uninjured muscle was also investigated by du Bois-Reymond in the same exhaustive way, particularly that of the gastrocnemius, and he represented his conception of it graphically. He found that, even when there was previously no difference of potential between the contacts, the proximal contact became negative during

¹ See "Proc. Physiol. Soc.," *Journ. Physiol.*, Cambridge and London, 1891, vol. xii. p. 43.

² du Bois-Reymond, "Untersuch. ueber thierische Electricität," 1894, Bd. ii. S. 91, Fig. 89.

³ du Bois-Reymond, "Gesammelte Abhandlungen," Bd. ii. S. 559.

tetanic excitation. The change, however, was less in amount than in injured muscle, and irregular in development, and moreover lasted longer after the excitation ceased than when the distal electrode was on an injured surface. As has already been pointed out, du Bois-Reymond regarded the "negative variation" as a diminutional effect, using the word negative in its algebraic sense. In order to explain its presence when there was no muscle current, he had recourse to the auxiliary theory, that the "natural cross-section," *i.e.* the end surface of every muscle, presents peculiarities of molecular structure, which he designated by the term "parelectronomy." He was thus able to account in the most ingenious way for the irregularities he observed, as resulting from the interference of parelectronomic effects having their seat in the ends of the fibres, with the normal ones.

As has been already stated, the molecular theory of du Bois-Reymond is not now accepted by physiologists. The other theory, however, with which it is associated, namely, that which attributes the negative variation, no less of injured than of uninjured muscle, to the summation of individual electrical responses evoked by instantaneous stimuli, has not as yet, so far as I know, been questioned.

In the case of injured muscles with the leading-off contacts, as in Fig. 236, A, the monophasic character of the single response appears to be adequate to explain the course of the tetanic variation; but as regards uninjured muscles it is at first sight difficult to see why the summed effect of a series of diphasic variations should take the direction of the first phase, as was found to be the case in the gastrocnemius by du Bois-Reymond. Many years ago (1868), Hermann suggested that when it occurs, it is due to the fact that every excitatory wave becomes weaker as it progresses. Soon afterwards, Bernstein, as the result of his rheotome experiments, was led to believe this surmise to be correct, and Hermann, later, in repeating an old experiment, showed that in a sartorius with the electrodes arranged as in Fig. 236, B, there is usually a "decremental" tetanic effect—the proximal contact becoming negative to the distal.¹ The total difference of potential in the tetanic response of an uninjured muscle was explained by him, on the supposition that each excitatory wave becomes weaker as it progresses, the second phase of each diphasic effect being weaker than the first. The complete absence of negative variation in tetanus of the human forearm indicates that in perfectly normal muscles there is, as Hermann says, *no decrement*.²

The tetanic variation, or, as Hermann calls it, the "tetanic action-current," can be observed in different ways. When a galvanometer of high resistance is used, the needle being so damped as to be nearly aperiodic, only $\frac{1}{100}$ part of the current passing through the hobbins, the spot assumes a position which corresponds to the integral difference of potential, the value of which can be easily determined from the deflection with the aid of a compensator. As the time required for the

FIG. 236.—X denotes the seat of excitation; the upright lines show the positions of the leading-off contacts.

needle to come to rest depends on instrumental, not on physiological, conditions, it has no special interest.

When the capillary electrometer is used, a toothed curve is obtained (uninjured sartorius), which brings to mind the ideal representation of the "negative variation" in tetanus given by du Bois-Reymond. In the photographic curve shown in Fig. 237, obtained from the *injured* sartorius, it is easy to distinguish the general or integral form on which the humps are inscribed, each corresponding to the description given of a single monophasic variation (Fig. 232). If the frequency of excitation be about 30 per second, the starting-point of each individual curve of the series will coincide with the very beginning of the decline of the

FIG. 237.—Tetanus curve of injured sartorius.

preceding one. The form of the integral curve is such as to show that the electrical change which takes place at the beginning of a tetanus is a sudden one. This is proved by the following experiment:—

The apparatus is so arranged that immediately the advancing edge of the plate passes behind the slit, the tetanising induction currents begin to act. The excursion in the electrometer is photographed, and a comparison curve is then made in the way already described, by introducing at a given moment a known difference of potential with the same muscle in circuit. The general form of this comparison curve is the same as that produced by excitation, with the exception that the comparison curve has of course no inequalities. What we learn from this correspondence is that in each case the difference of potential attains its eventual amount at once.

If an uninjured muscle, with the contacts arranged in a similar way, is observed, it may happen that the meniscus remains nearly at the

FIG. 238.—Responses to ten excitations of an uninjured gastrocnemius. Frequency about 40 per second.

same height throughout the period of tetanic excitation. In this case the integral curve is nearly parallel to the zero line. The spikes which represent the successive excitations project upwards from the curve, each having the form of a normal

diphasic response to a single instantaneous stimulation (Fig. 238).

The writer¹ has shown that other forms of continuous contraction, evoked either by a single instantaneous stimulation, or otherwise, are accompanied by electrical changes which, while they resemble in general

¹ *Loc. cit.*, p. 142.

that of tetanus produced by repeated stimulation, differ from this in certain important particulars. Among these forms of continuous contraction are—(1) That which is evoked when a muscle is excited by the passage of a constant current through its nerve; (2) that caused by a single instantaneous stimulation when a muscle has been poisoned by an extremely small dose of veratrine; and (3) the reflex spasm of strychnine.

To observe Case 1, it is best to use the muscle of a frog which has been kept at a temperature approaching 0° C. In such a preparation¹ it is easy to

FIG. 239.—Response to indirect excitation of a cooled muscle, injured at the tendon end by plunging into hot salt solution, on closure of a constant current (gastrocnemius).

bring about a sufficiently persistent contraction, even with currents of moderate strength. The form of the curve is seen in Fig. 239. It gives the same evidence as before, that the muscle passes promptly into the excited state. The curve exhibits undulations which occur with surprising regularity, the significance of which cannot as yet be stated. A muscle which has been

FIG. 240.—Response to direct excitation of a veratrinised sartorius devitalised at the tibial end.

thoroughly veratrinised (Case 2), furnishes similar curves in response either to direct or indirect stimulation, which, however, do not exhibit any undulations (Fig. 240). For the observation of the strychnine spasm (Case 3), a frog must be used which has received by injection into the lymph sac, an extremely small dose of the drug. After exposing the muscle to be observed, the leading-off electrodes are applied with as little interference with

¹ Hering, "Biological Memoirs," Oxford, vol. i. p. 136.

the circulation as possible. An observation may be made when a condition has been reached in which an induction current led through the skin of the flank evokes a prolonged contraction instead of an instantaneous twitch. Here, again, the integral curve obtained resembles the tetanic curve of injury; the proximal electrode becomes, on the whole, negative to the distal. This general movement of the meniscus is interrupted by alternating upward and downward movements (Fig. 241). The ascents are produced by spasms, each of

FIG. 241.—Response to a reflex excitation—of an uninjured gastrocnemius—(strychnine).

which lasts $\frac{4}{100}$ or $\frac{5}{100}$ of a second. The descents correspond to the intervals between these spasms, and continue longer, the two together having a duration of from $\frac{8}{100}$ to $\frac{12}{100}$ of a second. It is noticeable that undulations are observed in each ascent, similar to those shown in Fig. 239. The larger oscillations of the meniscus were long ago described by Lovén, who regarded each as a response to a single instantaneous stimulus emanating from the spinal cord.¹

PHENOMENA WHICH ARE PRODUCED BY THE DIRECT ACTION OF VOLTAIC CURRENTS ON MUSCLES.

Polarisation of muscle.—*Experimental data.*—In 1883 it was shown by du Bois-Reymond that, when a battery current is led for a very short period from end to end through a living muscle by means of terminal electrodes, the muscle being so connected by the same electrodes with a galvanometer that its circuit can be closed through the muscle immediately after the opening of the battery circuit, currents present themselves of which the direction varies according to the conditions of the experiment. These were called by du Bois-Reymond “secondary.” They are also termed “polarisation” currents, and the current which produces them is termed the “polarising” current. If this current is of sufficient duration, the direction of the secondary current is opposed to that of the polarising current. If it is strong and of short duration, its direction is the same as that of the polarising current. Both of these phenomena were described by du Bois-Reymond, under the term *secondary electromotive phenomena*.

The simplest way of demonstrating the two phenomena is indicated in the diagram (Fig. 242), which shows an ordinary Pohl’s reverser made of hard paraffin without cross-wires, so arranged as to enable the observer to direct the current of the battery (B) by the hand through the muscle. When the bridge is turned over, the muscle is in the circuit of the galvanometer. For investigating the phenomena, however, an automatic key or rheotome² must be

¹ Lovén, *Centralbl. f. d. med. Wissensch.*, Berlin, 1881, No. 7. On the subject of the preceding section further details will be found in two papers published by the writer since this article was in type. See *Journ. Physiol.*, Cambridge and London, November 1898, and *Proc. Roy. Soc. London*, 1899 (Croonian Lecture).

² Such an instrument is described in the *Phil. Trans.*, London, 1888, p. 421.

used. This consists of a revolving bar, which carries platinum contacts so arranged that the battery circuit is closed at each revolution, and immediately afterwards the galvanometer circuit is closed. The duration of the closure can be varied at will.

The *opposed* secondary current resembles so closely the so-called negative polarisation current of electrolytes, investigated many years ago by Peltier, that there need be no hesitation in regarding it as a physical phenomenon, and applying to it the term polarisation, in the sense in which it is used by physicists. The effect in question shows itself immediately after the polarising circuit is opened, and is very transitory. The most important facts relating to it are—(1) That it is not confined to the anode or cathode, but can be shown to exist throughout the region through which the polarising current has flowed; (2) that it subsides very rapidly; and (3) that its amount is in obvious relation to the strength and duration of the polarising current. In all these respects the results obtained in experiments on muscle (*e.g.* on the sartorius) correspond with those observed when a conductor of similar form, consisting of porous material soaked with liquid containing electrolytes, is investigated in a similar way (Peltier's polarisation). Another point of importance, as showing that it is dependent on the structural and chemical properties of muscle, not on its functional activity, is that although absent in muscles of which the structure has been altered by subjecting them to high temperature, or otherwise, the *negative* after-effects can be nearly as well observed in an exhausted muscle which fails to respond to stimulation, as in a fresh muscle.

FIG. 242.—*p* is a paraffin block with mercury pools at *qqqq*; *t* is also a paraffin block, and tilts on its bearings at *aa*. When *rr* on the battery side dip into *gg*, the muscle is in circuit with the battery. In the diagram it is represented in circuit with the galvanometer.

The secondary current, of which the direction is the same as that of the polarising current, is of a different nature. Its characteristics are—(1) That it chiefly manifests itself in the neighbourhood of the anode, *i.e.*, that the effect is best observed when the galvanometer contacts are placed, one at the anode, the other at a short distance from it; (2) that in this case the effect is increased by shortening the duration and increasing the intensity of the polarising current¹; (3) that it fails to appear unless the muscle experimented on is fresh and vigorous. The phenomenon appears to be dependent on the functional disturbance which the muscular structure undergoes in consequence of the passage of the current. By du Bois-Reymond it was called *polarisa-*

¹ Four to six Daniells, for from a half to a quarter of a second, may be used for the sartorius.

tion, because it associates itself so closely with ordinary polarisation, that it is often difficult to distinguish the one effect from the other; *positive*, because it is in the same direction as the led-through current. The significance of these characteristics becomes at once plain from the moment that it is understood that this phenomenon is of the nature of excitation.

After the opening of a current flowing through a muscle, the presence of the effect just described indicates that the region of the anode, that is, the seat of disturbance, is itself relatively negative. If the experimental current is strong, this effect is so immediate and powerful that the polarisation effect proper is overpowered by it. If it is weaker, a diphasic movement of the needle is observed, in which the transitory true polarisation effect is followed by the other. If in a succession of experiments the strength of the "polarising" or external current is gradually increased, the brief duration remaining the same, the effects which are at first opposed in direction to the external current become diphasic (the movement due to polarisation being followed by that due to the anodic disturbance), and eventually have only the direction of the external current; and this gradual change is best seen when one galvanometer contact is at the anode. Perhaps the best proof of the excitatory nature of the phenomenon is obtained when, the muscle having been injured by heat so as to produce a "thermal section" at its tibial end, one electrode is placed on the injured part, the other on the natural surface at the pelvic end. In this case, if the anode of the polarising current is on the injured surface, the effect is scarcely perceptible, whereas with the polarising current reversed (anode on the uninjured pelvic end) a descending after-current is observed.

These experiments justify the application to the phenomena in question, in preference to du Bois-Reymond's original designation (positive polarisation), of the term "anodic after-effect" used by other writers, as denoting the localisation of the effect at the anode and the time of its occurrence, without suggesting any theory of its nature. Considering that relative negativity of a part is a sign of the excitatory state, and that in nerve the anode is the seat of the excitatory effects which take place at the opening of a current led along it, it is not unreasonable to regard the effect as excitatory. The reader will find that some difference of statement exists between leading physiologists as to the degree in which the anodic after-effect is limited to the anode. According to some observers, the whole of the anelectrotonic region becomes relatively negative.

The phenomena which have just been described are those which are best known. The admission, however, that the anodic after-effect is the result of a polar change, dependent on the cessation of the inflow of the current, carries with it the suggestion that the cessation of the outflow at the cathode may have a corresponding after-effect, that is, one in which the cathodic region becomes relatively positive. Phenomena which are in accordance with this surmise have been observed by Biedermann in the sartorius; but in order to make them appreciable, one end of the muscle must be steeped in salt solution containing veratrine. The part thus treated can be thrown by a single instantaneous excitation into a state of continuous spasm of sufficient duration to make it possible to examine its properties experimentally.

If a voltaic current is led through such a muscle, with the cathode on the *excited and veratrinised* end, no effect is produced so long as the current is closed, but on opening it the anelectrotonic state manifests itself by relative positivity of the anodic part.

In the adductor muscle of Anodonta, which is normally in a state of tonus, Biedermann has shown that the cathodic relaxation which follows the opening of a polarising current is accompanied by a corresponding electrical state (relative positivity), but this observation does not bear on the question whether or not, in the absence of tonus (produced either naturally, by veratrine, or by other chemical agencies), an inhibitory after-effect, marked by relative positivity and muscular relaxation, can be observed at the cathode in normal skeletal muscle.¹ On this point the only information we possess is derived from certain observations of Hering to which reference is made by Biedermann.

In all experiments on polarisation care must be taken to select muscles which are free from tendinous inscriptions, for, as Hering conclusively showed, these exhibit the physiological properties of cathodes and anodes. At each inscription the current leaves the muscular substance to enter tendon, and again leaves tendon to enter muscle. An after-effect in the same direction may consequently manifest itself even when both galvanometer electrodes are at a distance from the cathode and anode, provided that an inscription occurs in the region from which the effect is led off.

In nerve the phenomena of polarisation can be studied more advantageously than in muscle, and are of greater physiological importance. The reader will therefore find it useful to refer to the Article on Nerve, in connection with the preceding paragraph.

Polar effects on excitability during and after the passage of a voltaic current.—If a curarised sartorius be so arranged that during the flow of a battery current from end to end, an induction current is led through the same electrodes in the same direction, it is observed that the response to the induction current is much augmented. Thus an induction current of which the strength is such as to produce a minimal contraction when the voltaic current is open, at once evokes a maximal response if this current has previously been closed,—a fact which led v. Bezold, who first observed it, to the erroneous supposition that a general increase of excitability of the muscle is produced by the flow of a voltaic current through it.²

The arrangement of this old experiment will be best understood from the description of the diagram (Fig. 243), with the addition that the metallic electrodes originally used should be replaced by non-polarisable ones. It affords evidence that during the passage of a current, excitability is augmented at the anode, diminished at the cathode, but gives no indication of the state of the region between the poles.

As in the case of nerve, so also in that of muscle, the observation of inter-polar excitability by means of electrical excitation is attended with great difficulty, consequent on the interference of the testing current with the

¹ With reference to the apparently similar case, in which a polarising current is led through a sartorius with a devitalised tibial end, see Locke's paper, *Arch. f. d. ges. Physiol.*, Bonn, Bd. liv. S. 520.

² "Biological Memoirs," Oxford, 1887, "On the Phenomena of Inhibition, etc., and on Positive Cathodic Polarisation," p. 331. See also "Elektrophysiologie," S. 386; Translation, vol. i. p. 454.

polarising one. For, in the experiment just referred to, the current of each circuit must, if both are closed at the same time, flow into the other, in proportion dependent on its resistance. The same thing would happen if the testing electrodes were separated from the others, to whatever part of the muscle they were applied. Consequently, the existence of these derivation currents would modify the excitability of the parts explored, and thus vitiate the results of the comparisons. Biedermann¹ seeks to avoid this difficulty by introducing into the exciting circuit a resistance so great, that the derivation currents in question are too inconsiderable to have any effect. By this method he has arrived at the conclusion, that in the curarised sartorius, so long as the testing electrodes are applied outside of the polar regions, no alteration of excitability can be detected during the flow of the polarising current.

FIG. 243.—*I* and *II* the primary and secondary coils of the Inductorium. *R*, rheochord through which the current of *B* flows in the direction of the arrow. A current derived therefrom flows from *a* to *b* through the muscle *M* and the secondary coil. The current through the primary coil can be closed by the key *k*'. At the moment that this takes place a closing induction shock flows through the circuit *a M b* in the same direction as the battery current.

In experiments of this kind, the current should be so weak that its closure scarcely evokes an excitation. So long as this is the case, the effect continues without alteration. By increasing its intensity the effect is at first increased, but beyond a certain degree of intensity, which is soon reached, it begins to diminish.² The effect is strongest during the fifteen or twenty seconds immediately following closure, and disappears if the circuit remains closed. A few seconds later the response to the induction shock may be so weakened as to suggest that the increased excitability which at first presents itself has produced a sort of fatigue. The previous state of increased response, Biedermann speaks of as a "latent state of excitation."³ The changes of excitability at the anode during the passage of a voltaic current have also been investigated by him, and have yielded results which appear to be in harmony with those above stated.

We have seen that in curarised muscles the cathodic increase of excitability which shows itself immediately after the closure of a voltaic current, diminishes in a few seconds, and is eventually replaced by an opposite state. If a current of sufficient strength to evoke a strong response at closure is broken, and after a very short interval of time again closed, the second closure is often without effect. But on closing the current in the opposite direction the response is as strong as before. This phenomenon is analogous to that which in nerve has been long known as that of "voltaic alternatives." The failure of the second closure is evidently another manifestation of the state resembling fatigue already referred to. It can, however, be shown that a muscle of which the excitability has been diminished by real

¹ "Elektrophysiologie," 1895, S. 238; Translation, vol. i. p. 281.
² *Loc. cit.*, S. 242; Translation, vol. i. pp. 284-286.
³ *Loc. cit.*, S. 244.

fatigue, regains it at the cathode the moment a voltaic current is led through it; whence it is evident that the cathodic after-effect cannot be of the nature of exhaustion. Another reason for this conclusion is that the decrease of the excitability at the cathode after opening, has its counterpart in increase at the anode. The preceding facts are comprised in the general statement that, during closure of the voltaic current, each of the polar states first brought into existence (the cathodic augmentation and the anodic diminution) gives way to the contrary state, and the relation between these two effects can be best understood by saying that the normal state of muscle is intermediate between two opposite states, which contrast with each other both as regards the ability of the tissue to contract and the readiness with which it responds to stimulation. This being so, we may expect that the loss of the second of these qualities at a pole of the voltaic current would also be attended with loss of conductivity. That this is so can be easily shown experimentally, for if a curarised sartorius is so arranged that a current is led to the middle of the muscle from its pelvic end, and if on its cessation the tibial end is excited by an induction current, *no response takes place at the pelvic end*, the wave of contraction being stopped half-way by the cathode of the voltaic current. If the current is strong enough, the block persists for some time after opening, but after the passage of the same current in the reverse direction the *status quo* is restored. What the cathode has done the anode has annulled, so that the wave of contraction passes freely once more from end to end.¹

Polar excitation of muscle by the voltaic current.—Localisation of the excitatory effects at the poles.—When a voltaic current is led for a short time through a curarised muscle in the direction of the fibres, it contracts when the current is closed. This closing contraction starts at the cathode.

The first experimental indication that the closing excitation is localised at the cathode, was given by Schiff about half a century ago.² He found that in a muscle in which the mechanical response to electrical stimulation is no longer propagated, in consequence of poisons or cessation of circulation, a very slight "idiomuscular hump" is formed at the cathode when a battery current is closed through it, which does not spread. Not many years later, v. Bezold³ showed that the localisation thus indicated had no necessary connection with the absence of propagation, or the peculiar conditions of Schiff's experiment, but could be demonstrated on fresh curarised muscle. His method was founded on the consideration that, inasmuch as the period of latency in curarised muscle increases with the distance from the seat of excitation of the part where the change of form is being observed, this distance can be computed from the loss of time. A sartorius was laid in a shallow groove cut in a cork plate, and kept in its place by two wires which crossed it at a distance of half a centimetre from each other. These served as electrodes for the battery current. The tendon end of the muscle was attached to a writing lever, and the muscle so arranged that the latent period could be measured graphically. This was found to be longer at closure when the current was directed from the tendon, than when it was in the opposite direction. This difference in the period of latency in the two cases evidently indicated that the starting-point of the excitation wave must in either case have been the cathode.

¹ Biedermann, *loc. cit.*, S. 252; Translation, vol. i. p. 296.

² Schiff, see "Beitr. z. Physiol.," Bd. ii. S. 13, 14.

³ "Untersuch. ueber die electriche Erregung der Nerven und Muskeln," Leipzig, 1861, S. 239-244.

The prolonged contraction.—The important distinction between the persistent contraction which is scarcely, if at all, propagated, and the twitch or wave of contraction, was further illustrated by Engelmann,¹ by a method of preparing the sartorius which has since proved to be of great value in experimental work. The middle of the muscle is grasped by a holder tight enough to prevent it from slipping when the tibial end is made to lift a very light writing lever attached to the tendon, but not tight enough to interfere with the propagation of excitation. The battery electrodes are placed on opposite sides of the holder, and the current is closed first from, then towards the tendon. In the former case the curve has the character of the single twitch, in the latter there is in addition a prolonged contraction.

The specific character of the prolonged contraction, *i.e.* its claim to be regarded as a phenomenon by itself, and not merely as an after-effect or sequel to the primary response or twitch, is indicated, not only by its persistence and the fact that its tendency to spread is inappreciable, but also by the analogy of the conditions under which it manifests itself with those which favour the production of Schiff's "idiomuscular contraction." The resemblance is sufficient to justify the surmise that they are closely related phenomena.

Some of the experimental facts by which earlier observers proved the localisation of the make-excitations can be very satisfactorily demonstrated

FIG. 244.—Hering's double myograph. The sartorius muscle is held in the middle between two pads of oil-clay (underneath *q*), so that each half can be extended horizontally independently of the other. Non-polarisable electrodes *ee* are applied to the bony attachments of the muscle. These are supported on the vulcanite rod *g* in such a way that they follow the movements of the ends of the muscle, so that when it is excited through them it can contract freely. Each end is attached to a weight by a thread which passes over the pulleys *R, r*. *RR* are provided with pointers *zz*, which record their movements.—After Hering.

with the aid of Hering's double myograph, the construction of which will be readily understood from the figure (Fig. 244). If it is desired to confirm *v. Bezold's* experiment, the use of this instrument is combined with a method of measuring the period of latency, in which the same act that closes the current sets a tuning fork in vibration.

In Fig. 245, it is seen that these vibrations are inscribed on a rapidly moving recording surface between the two myographs, the upper of which is that of the tibial half, the lower of the pelvic half of

the sartorius. In the instance given, the current was descending, *i.e.* directed towards the tibial tendon; the contraction of the tibial (cathodic) half began 0.034 second after excitation, that of the pelvic (anodic) half 0.045 second.

¹ Engelmann, "Beitr. z. allg. Muskel- und Nerven-physiologie," *Arch. f. d. ges. Physiol.*, Bonn, Bd. iii. S. 316-318.

Comparing these time-intervals with the corresponding distances of the cathodes, we have a rate of propagation of from 1 to 2 metres per second. The double myograph can also be used for comparing the character of the two contractions, both myograms being recorded for this purpose on a slowly moving surface. They show (Fig. 246) that the closure of a descending current evokes in both halves of the muscle, but in the tibial (cathodic) half, the contraction is prolonged until the current is broken, the reason being that, whereas the twitch is rapidly propagated from the tibial to the pelvic end as a wave of contraction, a prolonged contraction occurs in the tibial half which shows but slight, if any, tendency to spread. For the same reason, when the direction of the current is reversed, both halves twitch, but the pelvic end, which before relaxed instantly to its natural length, is now cathodic and behaves accordingly.

FIG. 245.—After Biedermann.

If the muscle is injured at one end (by dipping it into hot salt solution), these phenomena are considerably modified. If the cathode is placed on the devitalised part, there is scarcely any response on closing;¹ both halves twitch slightly. If the injured end is anodic, the responses on closure are the same as they would have been had there been no injury.

FIG. 246.—Contractions of the two ends of the sartorius, as recorded by the double myograph. *v* is the record of the tibial half, *o* of the pelvic half of the muscle. Note that the descending arrows indicate an ascending current. The numbers indicate that the strength of the current was the same throughout.—After Biedermann.

One of the facts stated above as to the polar effects of the voltaic current may be confirmed by direct inspection with the aid of a lens of

the surface through which the current enters or escapes. It can thus be seen that if a current is led from end to end of a muscle, the cathodic end swells during its passage. Other details may be made out by a method devised by Biedermann—that of streaking the surface with a paste of sepia, rubbed up with 0.6 per cent. salt solution. If the streaks cross the fibres and are equidistant, it is easy to see that at the cathode the streaks are drawn together from each side, and that this effect is a

¹ This fact was discovered at the same time (1880) by Engelmann and Biedermann. See Engelmann, *Arch. f. d. ges. Physiol.*, Bonn, Bd. xxvi. S. 97; and Biedermann, *Sitzungsb. d. k. Akad. d. Wissensch.*, Wien, Bd. lxxx. Abth. 3, S. 367.

protracted one which does not spread. A change of an opposite nature has been described at the anode; a slight depression presents itself at the surface of contact, on either side of which the streaks sweep in curves.

The conditions under which the cathodic persistent contraction presents itself have not as yet been sufficiently studied. The utmost that can be said on the subject is, that the appearance of this phenomenon is favoured by any cause which tends to diminish the promptitude with which the muscular elements directly excited respond to the stimulus, as well as the readiness with which the excitatory state is taken up from them by neighbouring elements. The best known of the conditions in question is that of cold. In the sartorius of a frog which has been kept at a temperature a little above that of freezing, as Hermann has shown, the cathodic continuous contraction is very readily produced.

The anodic closing contraction.—It occasionally happens, when a current of considerable strength is led through the sartorius from the tibial to the pelvic end, that a contraction appears at the anode simultaneously with that at the cathode. When the pelvic end is injured, so as to annul the cathodic effect, this contraction is more obvious, and has been recorded graphically by Biedermann. By careful observation with the lens, Biedermann has satisfied himself that the seat of contraction is a part of the muscle between the anode and the middle, and that in fact the fibres at the anode itself are relaxed. A similar appearance presents itself when the current is led in by the anode only, the cathode being at a distance. Biedermann no doubt rightly attributes this phenomenon to the passing of threads of current from one muscular fibre to another. It derives special interest from its connection with a much more striking effect of very strong currents on the sartorius—the *galvanic wave*. By this is meant that when a very strong current is led through the sartorius, visible waves of contraction follow each other in the direction of the current with a peculiar surging motion. This only happens when the muscle is in a good state and its fibres are relaxed so as to be more or less wavy. Professor Hermann, who has studied the phenomenon minutely, has no doubt that this, like the anodic closing contraction just referred to, is due to want of conformity between the threads of current and the muscular fibres, and that although each wave starts from near the anode, its origin at any point in a muscular fibre is in reality cathodic, for it is determined by the passing out of the fibre of a thread of current.

Influence of currents led through muscular fibres transversely.—If, as appears from the facts we have had before us, the actions of the two poles are antagonistic to each other, so that the exciting effect of the cathode is “inhibited” by the quelling effect of the anode, we should expect to find that neither of these effects could be produced on any muscular element, unless the direction of the current either coincided with that of the axis of the element or crossed it obliquely. For, if it crossed it transversely, the action of the two poles would neutralise one another. In other words, we should expect that if the current threads were parallel to each other, and the fibres of the muscle were also parallel, a current led across a muscle would have no effect whatever. The difficulty of testing this anticipation by experiment is so great, that there has been considerable difference of statement with reference to it.

The method by which the question has now been settled is as follows:¹—

An oblong trough is divided by upright partitions of plaster of Paris into three chambers, of which the middle one is square, the two end ones being narrow but of the same length as one side of the square. The middle chamber contains physiological salt solution, each of the end ones saturated solution of zinc sulphate. Into these last are plunged amalgamated zinc plates, in which the battery circuit ends. The current flows in nearly parallel threads through the salt solution from one porous partition to the other. The muscle is prepared with its bony attachments intact, and supported independently of the trough, and is so held that it is immersed in the salt solution with its fibres horizontal. As the trough can be freely rotated, without moving the muscle, the threads of current may be made to cross the fibres at any desired angle.

It can thus be proved that the excitatory response to closure of the current is strongest when the direction of the fibres is the same as that of the current; that it is much weaker when there is a difference between them of 45°, and is annulled when they cross at right angles. In muscles with injured ends no effect is produced unless the strength of the current is excessive; whence it may be inferred that the ends of muscular fibres are much more susceptible to this kind of stimulation than the other parts. This fact is analogous to that referred to above—the refusal of an injured muscle to respond to cathodic excitation, when the cathode is on the injured part.

From the preceding facts we have learned that the exciting effects of the current on curarised muscle are chiefly of two kinds, those which are evoked by its sudden closure, and those which are dependent on its continuance.

The first are of the nature of the excitatory responses which (p. 414) have been attributed to instantaneous stimulation. These are (1) the excitation wave with its concomitant electrical change, and (2) the wave of contraction. The intimate relation between these is shown by the fact that each is propagated in the direction of the fibres at the same velocity, and that both affect each muscular element for a strictly limited period of exceedingly brief duration. The dependence of rapidly propagated effects (*Reizwellen* and *Contractionswellen*) on the suddenness with which the change which produces them is accomplished, has been studied with great exactness in nerve. With reference to it, du Bois-Reymond enunciated many years ago his well-known "Law of Excitation,"² according to which the excitatory efficiency at any moment of a current led along a nerve depends on "the rate of change of the current density" (*i.e.*, of the relation between current strength and sectional area). There are no experimental data which would justify the extension of du Bois-Reymond's law to the case of curarised muscle. It is, however, so evident that in muscle as in nerve, rapidly propagated excitatory effects are exclusively produced by sudden changes of current strength, that we may fairly assume the relation in muscle between rate of change and these characteristic effects, to be analogous to that which is expressed as regards nerve in du Bois-Reymond's law. This being admitted, there is little difficulty in understanding why excitatory effects of the kind in

¹ Leicher, "Ueber den Einfluss des Durchströmungswinkels, etc.," *Untersuch. a. d. physiol. Inst. d. Univ. Halle*, 1888, S. 1.

² "Untersuchungen," 1848, Bd. i. S. 258.

question are chiefly polar; for it is at the anode and cathode that the changes of current density are most abrupt. This consideration, however, affords us no explanation of the other fact of which we have such convincing proofs, namely, that in muscle as in nerve, excitation waves start from the cathode at the moment of closure, from the anode at the moment of opening of the current. As regards nerve, the fact just stated has been expressed by Pflüger in the form of a law as well known as that of du Bois-Reymond, according to which it is an essential condition of the efficiency of a polar change, not only that it should be abrupt, but that it should be *towards* cathelectrotonus or *from* anelectrotonus—meaning by these terms the condition or state which exists at the cathode or anode respectively—in other words, from the normal to the cathodic state, or from the anodic to the normal. It is obvious that the changes in the opposite direction, namely, from normal to anodic at the anode on closure, and from cathodic to normal on opening, although they are no less abrupt, have no exciting effect—a fact which will be more advantageously dealt with in connection with the discussion of the corresponding phenomena in nerve.

As regards the excitatory effects of the second kind, those which are dependent on the duration of the current, nothing further need be added. Attention has, however, not been drawn to the remarkable difference which presents itself in this respect between nerve and muscle. Physiologists are so little inclined to admit that a nerve is continuously excited by the flow along it of a current, that the doctrine of du Bois-Reymond, that so long as a current is of constant strength it has no exciting effect, has the authority of a “law”; whereas in muscle the contrary has been familiar to us ever since “Wundt’s curves” have been copied into every text-book. At first sight the contrast appears very striking. More careful consideration leads us, however, to surmise that the difference may be more phenomenal than essential. In muscle, contraction is the sign of the cathodic state; in nerve, increased excitability. In the former it is transitory, soon giving way to “exhaustion.” In nerve, which is incapable of fatigue, it is persistent. These differences seem, however, to afford no ground for doubting that the underlying process is the same in the two cases.

Secondary muscular and neuro-muscular electrical excitation.—More than half a century ago, du Bois-Reymond¹ proved by experiments, in which conductors of different kinds were interposed between the exciting muscle and the excited nerve of the physiological rheoscope, that the change in the former which evokes the response of the latter, is electrical. In the ordinary form of the experiment it is accordingly found that the secondary neuro-muscular response is best observed when the parts bridged over by the nerve are, either in the unexcited or in the excited state, at considerably different potentials. Experience, however, shows that if both preparations are in good condition, the rheoscopic limb reacts even when the position of the nerve is apparently very unfavourable—as, *e.g.*, when it is applied to the sartorius in such a way as to cross the fibres transversely.² The best results are, as might be expected, obtained when winter frogs are used, which have been kept at a temperature approaching that of freezing. In this case, if the primary muscle is rhythmically excited

¹ *Loc. cit.*, Bd. ii. S. 87.

² Biedermann, “*Elektrophysiologie*,” S. 355.

through its nerve at intervals, say of $\frac{1}{2}$ second, the secondary twitches are exact counterparts of the primary; and if the frequency is sufficiently increased, tetanic contractions are obtained which cannot be distinguished from primary ones. When the same experiment is made after the primary muscle has become exhausted, it often happens that the secondary muscle responds to tetanus of the primary by a single initial twitch, in which case the normal result may be expected to reappear if the muscle is allowed to rest.

It is not by any means essential that the primary excitation should be indirect. A curarised sartorius, whether excited by a single induction current, or tetanised in the same way, evokes corresponding neuro-muscular responses; but this effect, namely, the secondary twitch in response to direct excitation of the primary muscle, is best obtained when a battery current is led for a few millimetres along the fibres of the uninjured muscle to a terminal cathode.¹

The secondary neuro-muscular response has long been recognised as a means of distinguishing different kinds of continuous contraction. Its value for this purpose can be best judged of by referring to the instances in which it fails:—

1. No continuous contraction of central origin, whether cerebral or spinal, has as yet been observed to evoke a secondary neuro-muscular response of the same character as the primary, with the striking exception that the reflex muscular contractions of frogs poisoned by strychnine induce in the physiological rheoscope neuro-muscular contractions which have a strong superficial resemblance to tetanus. When they are recorded graphically, they are seen to consist of a series of twitches, following each other with a frequency of about eight or ten per second, each of which corresponds to the beginning of one of the series of spasms which constitute the primary response.²

2. Secondary neuro-muscular spasm is, as a rule, not produced by any of the prolonged contractions which are evoked by continuous stimulation, whether direct or indirect. As examples may be mentioned the closing continuous contraction by indirect excitation (Ritter's tetanus);³ the spasm consequent on partial drying of a nerve; or that produced by the action of common salt thereon.⁴ There is, however, an exception to this general statement of such importance that it must be specially considered.

Some years ago, the fact that a muscle can be excited directly by its own current, or by that of a beating heart of the tortoise, suggested to Kühne the inquiry whether an excited muscle could be made to communicate its state of excitation directly to another muscle at rest, if the two were brought into relation with each other in a suitable manner. The result of this investigation was the discovery that, although the mere contact of an excited muscle with an unexcited produces no effect whatever in the latter, it is different if contact is accompanied by pressure, and particularly that if the ends of two sartorius muscles are squeezed together in such a degree as not seriously to injure the compressed parts, the two muscles so "welded" together respond to the excitation of either as if they were structurally united.

¹ Biedermann, *loc. cit.*

² Kühne, *Untersuch. a. d. physiol. Inst. d. Univ. Heidelberg*, 1880, Bd. iii. S. 59.

³ Friedrich, *Sitzungsber. d. k. Akad. d. Wissensch.*, Wien, 1875, Bd. lxxii. Abth. 3, S. 413.

⁴ Kühne, S. 61.

But this union is not the only, or even the most important way in which the physiological action of compression manifests itself. A muscle of which one end is squeezed, passes in consequence into such a state of abnormal excitability, that a stimulus which would ordinarily evoke a single twitch is followed by a persistent tetanus-like spasm. So long as this spasm lasts, the muscle acts on the physiological rheoscope with the greatest energy, producing secondary contractions which, when they are recorded graphically, seem to consist of an arrhythmical series of unequal twitches. Kühne explains this effect as produced by a kind of electrical storm in the compressed muscle, and attributes to the intensity of the electromotive changes of which it is the seat so long as the spasm lasts, the extraordinary energy with which it acts on the rheoscopic limb.¹

A state of altered excitability similar to that which is produced by compression, manifests itself in muscles which have been subjected to partial dessication, *e.g.* in the limbs of frogs, which, after having been stripped, are left exposed. In limbs so prepared, slight mechanical irritation produces spasm which spreads not only to the whole of the muscle irritated, but to its neighbours. Biedermann has also found that if two muscles, of which the surfaces have been allowed to dry, are applied without pressure to each other, the spasm of the muscle primarily excited is faithfully imitated by the other; and, further, that muscles so acted on have the same power of exciting secondary neuromuscular spasm in the rheoscopic limb as compressed muscles. The analogy thus indicated between the two effects has led both Biedermann and Kühne to believe that the abnormal excitability is attributable in the two cases to the same cause—privation of water. In the one case water is squeezed out of the compressed part, which thereby becomes in the excited muscle a focus from which irregular waves of excitation emanate; in the other, the surface fibres which have lost water by evaporation play the same part.

Voltaic currents of brief duration — Induction currents. — When a current is closed for a very small fraction of a second, *e.g.* $\frac{1}{100}$, through a curarised muscle, those characters of the response which are dependent on its duration disappear. The effect produced is that of a single instantaneous excitation, the seat of which is at the cathode. An excitation wave, with its accompanying contraction wave, starts from the cathode in either direction. If the current is of sufficient strength, a closure of 0.005 seconds evokes a maximal response. If the closure is shortened, the height of the resulting twitch diminishes with the duration. This can be best shown by a method devised by Fick many years ago. The instrument² used for the purpose is such that a brass tongue, springing from a revolving horizontal bar, rubs against an insulated triangular brass plate in its revolution, the brass plate and the tongue being in circuit. The time of contact can be varied (1) by varying the rate of rotation, and (2) by adjusting the plate so that the tongue rubs over a greater or less extent of its surface. Experiments made on Fick's plan show that even when the closure is so short that the anodic excitation is indistinguishable, the excitatory process may yet be of a measurable duration.

¹ *Loc. cit.*, Bd. xxvi. S. 222.

² A full description of the instrument will be found in Fick's, "Medizinische Physik," 1866, S. 425.

All that has been said on the mode of action of battery currents of short closure applies to induction currents. The induction current which is produced in the secondary circuit of a du Bois-Reymond's inductorium at closure of the primary circuit, evokes an excitation which has its origin exclusively at the cathode. It has been long known that nerveless muscles react relatively more readily to closure of the voltaic current than to the induction current. This is in accordance with the observation, that in muscles of which the motor nerves have been severed for a sufficient time to produce complete degeneration, even strong induction shocks evoke no contraction, notwithstanding that they respond readily to battery currents of moderate strength.

In connection with these facts, it may be noted that in unstriped muscles a relation presents itself between duration of closure and response, similar to that in Fick's experiment. The two cases are, however, scarcely comparable. In striped muscle we are concerned with thousandths of a second, in smooth muscle with durations of several seconds; and that the difference is not one of degree only, but of kind, is probable, for, as we have already seen, there is in striped muscle a second kind of effect introduced when currents of long duration are used. In Engelmann's observations on the ureter of the rabbit, it was found that even with very strong currents a closure of a quarter of a second was required to evoke a response; and that, if the strength of the current was diminished, it was necessary to close it for a still longer time. Similarly, Biedermann could not obtain a full contraction of the adductor of *Anodonta* with a shorter closure than one of four seconds. Shorter closures evoked responses, but of much smaller amount.

CARDIAC MUSCLE.

In the preceding account of the physiological properties of striped muscular fibre, only occasional reference has been made to that form of it which exists in the heart.

The physiological properties of cardiac muscular tissue may be discussed in the same way as those of skeletal muscle. It responds similarly to an instantaneous stimulus, and can be excited to contraction either directly or indirectly. Further, the response (of the ventricle) to indirect stimulation (*i.e.* of the auricle) cannot be distinguished from the beat evoked by the natural stimulus, arising at and propagated from the venous orifices. The phenomena of the beat may therefore be studied in the same order as those of a single muscular contraction. As, however, we possess but little information as to the chemical and thermal changes which in the heart are associated with activity, the present subject need only be discussed here under the following headings:—

1. The mechanical phenomena of the response;
2. The electrical phenomena of the response; and
3. The physiological differences between cardiac excitability and that of ordinary muscle.

THE MECHANICAL RESPONSE.

For reasons similar to those previously given in relation to skeletal muscle, the systole of the ventricle of the frog's heart may be taken to represent the normal action of cardiac muscle. The most striking

phenomenon of the systole of this organ is the apparent diminution of its volume. As in the case of skeletal muscle, this diminution is only apparent. Each of the individual muscular fibres of which the organ is made up, occupies approximately the same space in systole as it did in diastole; it is its shape that has altered. All the fibres have widened and shortened, and, in consequence, the blood which previously occupied the central cavity and the innumerable channels which, in the frog's ventricle, extend therefrom almost to the surface, has been squeezed out. If the expulsion of the blood takes place freely, each fibre assumes its new form with very inconsiderable production of tension. If it is so resisted that no blood can escape, a state of effort comes into existence, in which each fibre sooner or later participates. During the very brief period occupied by the spread of the contraction in the cardiac tissue (about $\frac{1}{20}$ second), there may be a change of form due to the action of the

FIG. 247.—Diagram of Frank's apparatus for recording isometric curve of frog's ventricle with different initial impletions. Tap I. is closed and the heart allowed to empty itself. Then Tap II. is closed and tracings are taken with Manometer II. with no impletion, and then with gradually increasing impletion—a known quantity of circulating fluid being let in from the graduated tube on the right between each two successive observations.—Frank.

excited fibres on those which are as yet relaxed, but it may be considered certain that all eventually occupy the same space as they did in diastole. In the case just described the effort is isometric. It corresponds to the isometric response of skeletal muscle. If the resistance is due to a constant lateral pressure exercised by the blood against the wall of the ventricle, which the ventricle is able to overcome, the organ contracts under isotonic conditions.

The isotonic contraction of the ventricle is best observed by a plethysmograph,¹ the changes of volume being measured by a piston-recorder, or by Marey's tambour,² or they may be recorded photographically. The curve so obtained corresponds, as has been shown by Otto Frank³ in a series of important

researches, to the ordinary isotonic myogram, and is modified by mechanical conditions, in ways already studied in relation to skeletal muscle.

The form of the isometric curve of the ventricle is shown in Fig. 248, *a*. It is obtained by arranging the heart as shown in the diagram (Fig. 247). As in ordinary muscle, the height of the curve, *i.e.* the maximum pressure attained during the response, varies with the length of the muscular fibres when relaxed, *i.e.* with the previous fulness of the ventricle. In a good-sized ventricle, if the initial content is very small, this maximum is correspondingly inconsiderable, but when the initial capacity is increased, say to a third of a cubic centimetre, the maximum may attain to over 60 mm. Beyond some such point as this, Frank

¹ Schäfer, *Journ. Physiol.*, Cambridge and London, vol. v. p. 130. ² *Ibid.* p. 127.

³ Frank, "Zur Dynamik des Herzmuskels," *Ztschr. f. Biol.*, 1895, Bd. xxxii. S. 370, and "Die Wirkung von Digitalis auf das Herz," *Sitzungsber. d. Gesellsch. f. Morphol. u. Physiol. in München*, Heft 2, S. 30.

found that no further increase of intraventricular pressure could be obtained, so that there appeared to be a certain initial impletion which was most advantageous, and which could neither be exceeded nor reduced without loss of effect. In skeletal muscle we measure the "absolute force" by estimating the relation between the sectional area of the contracting fibres and the weight which the muscle can just lift. The same mode of estimation cannot be applied to the heart, because the area of the cardiac fibres concerned in systole cannot be measured.

It is probable that the product of the number and the mean sectional areas of the fibres in the ventricle may be considered as proportional to its size, so that we may express the absolute force of the ventricle correctly by the *maximum pressure* which it is able to produce when contracting against resistance. This can be easily got at by recording the isometric curve in the way above indicated, in a series of experiments in which the initial impletion of the ventricle is increased after each observation, until the point is reached at which the maximum pressure in question is attained. The observations can be made so quickly that the results can be verified by repetition, without risk of exhausting the organ (*l.c.* p. 386).

The effect of after-loading.—It is not within the scope of this article to deal with the mechanical relations of the circulation. It must suffice to indicate the application of elementary principles derived from the investigation of ordinary striped muscle, to the ventricle doing its normal work. As we have already seen, the action of the ventricle when contracting automatically does not differ in any respect from its response to stimulation of the auricle by an induction shock. Both are comparable to the response of a muscle when made to contract under corresponding mechanical conditions. In the method of after-loading a skeletal muscle, which is illustrated in Fig. 198, p. 368, we have seen that the mechanical response to a single induction shock is divisible into three periods, during the first and third of which the muscle is under isometric conditions, while during the intervening period it does its work isotonicallly. The normal action of the ventricle is, as Frank shows, in a similar manner divisible into three stages—those of distension, expulsion, and relaxation, the first being separated from the second by the opening of the aortic valve, the second from the third by its closure. During the first period, contractile stress rapidly increases; during the third, it more gradually diminishes. During the intervening stage, that of expulsion, the relation between change of tension and change of volume differs according to the lateral pressure, this being determined by the resistance in front and the initial change. The effect of increasing the resistance in front, in the case of the ventricle, corresponds to that of increasing the load in the case of muscle. Empirical evidence of this correspondence was obtained by Frank by comparing the curves of intraventricular pressure in a series of experiments, in which the resistance in front was successively increased by equal increments. In skeletal muscle the effects of increasing the after-load are to defer the beginning of the isotonic period, to shorten its duration, to diminish the velocity of the upward movement of the free end of the muscle, and consequently to diminish the lift. In the ventricle, the corresponding results of increasing the resistance in front are to defer the beginning of the period of expulsion, *i.e.* the opening of the aortic valve, to shorten the period between opening and closure of the valve, and to diminish the rate of flow through the aortic

orifice, and consequently to diminish the systolic discharge. Stated numerically, the result of such experiments on the frog's ventricle is that when the resistance increases from a pressure of, in round numbers, 10 mm. to 40 mm. of mercury, the flow decreases from 0.6 c.c. per second to 0.2 c.c. per second, and the period of expulsion diminishes from 0.56 second to 0.51 second, the systolic discharge consequently diminishing from 0.33 c.c. to 0.08 c.c. As throughout the series of experiments on which this statement is founded the initial impletion of the ventricle was the same, it is obvious that the quantity of fluid which remains when the valve closes, *i.e.* when the flow through the aortic orifice ceases, increases with the diminution of the systolic discharge.

In the experiments just referred to, the element of elasticity is, for the sake of simplicity, excluded. It is easy to modify the apparatus used so as to include it. The effect of doing this is, that the attainment of the maximum of intraventricular pressure is postponed, and that, in connection therewith, the notch produced by the back-flow from the aorta at the moment that the valve closes is accentuated.

The preceding considerations may be summarised as follows:—(1) The isometric curve of muscle is represented by the pressure curve of the systole

FIG. 248.—Isometric and isotonic curves of the ventricle of the heart of the frog (given to the writer by Dr. O. Frank). The rate of movement of the recording surface is indicated by the horizontal line. *a*, The isometric curve is the record of a membrane manometer (Frank's) in connection with the cavity of the ventricle, of which the impletion was constant. *b*, The isotonic curve is the record of a Marey's capsule in connection with a plethysmographic chamber containing the heart. In the cavity of the ventricle the lateral pressure was constant, and amounted to 10 cm. of water.

of the charged ventricle with arrested discharge. (2) The isotonic curve of muscle is represented by the volume curve of the ventricle; the load, by the resistance in front as measured by the aortic pressure. (3) As in muscle the isometric curve culminates before the isotonic, so in the ventricle the isometric pressure curve culminates sooner than the isotonic volume curve (Fig. 248). The pressure curves and volume curves recorded in a ventricle working under conditions which exist in the circulation, resemble in general the after-loading curves of muscle. If the arterial pressure during the discharge is constant, the resemblance is complete. The want of this constancy in the circulation is dependent on conditions which lie outside our present inquiry.

Certain points in respect of which cardiac and skeletal muscle seem to differ, will be referred to in the concluding paragraph of this section. In the meantime we are justified by the analogies indicated above relating to the mechanical phenomena of the response, in stating that, for their elucidation, cardiac muscle is quite as available as skeletal. There are, indeed, several reasons why the former can be referred to with greater advantage; the long duration of the ventricular systole, and the facility with which the organ can be preserved in a normal state after removal from the animal, being conditions extremely favourable to exact observation. If, for example, the theory that is now entertained by many physiologists, that the character of the second part of a muscular contraction is affected by the stimulating influence of resistance or other conditions present during the first part, we should expect to be able to observe this more readily in the deliberate systole of the heart than in the almost instantaneous twitch of a muscle. So far as I am aware, no suggestion of the kind has been offered.

RATE OF PROPAGATION.

It was discovered by Engelmann in 1875,¹ that the change by which each muscular element of the ventricle passes from the unexcited state into that of excitation is propagated from element to element with equal facility in every direction. This he showed to be the case by the following experiment:—The ventricle of a freshly-killed frog is separated into a number of small pieces, united to one another by bridges of muscular substance not more than a millimetre wide, and is left for half an hour or so in a moist chamber, in order that the living tissue may recover from the immediate effects of the injury. It is then found that a contraction wave proceeds with equal facility in any direction, from any portion which has been stimulated. In a ventricle so injured, the rate of conduction was not more than 20 mm. per second; but Engelmann recognised that in uninjured tissue the rate must be much greater. By recently published experiments, he has now shown that, when the circulation is going on under normal conditions, it may be more than 150 mm. per second in the auricle, and rather less than this in the ventricle.²

In other experiments with the “suspended” heart, in which the organ was removed from the body, the rate was much less. By removing it, however, Engelmann was able to show that cardiac muscle deprived of its power of *visibly* contracting by immersing it in 0.2 per cent. NaCl, still retained its power of propagating the excitatory state.

THE ELECTRICAL PHENOMENA OF THE RESPONSE.

Historical.—In 1856, Kölliker and H. Müller³ made the discovery that the “negative variation” can be observed in the beating heart. They applied the nerve of a rheoscopic limb to the pulsating ventricle, and found that whether the nerve was laid across the ventricle, or in the direction of its length, the muscle of the preparation contracted a “scarcely perceptible time before the systole.” In certain cases a second feebler twitch was observed in the beginning of the diastole. This they considered to be dependent on a “positive variation” of the

¹ Engelmann, *Arch. f. d. ges. Physiol.*, Bonn, Bd. xi. S. 465.

² *Ibid.*, 1894, Bd. lvi. S. 149.

³ *Verhandl. d. phys.-med. Gesellsch. in Würzburg*, Bd. vi. S. 528.

muscle current of the ventricle, coincident with relaxation. Subsequently (1872), Donders¹ confirmed these observations, and, by skilful application of the graphic method, determined the time relations of the phenomena. The subject was next taken up by Engelmann² in 1873, who then established that, when at rest, "the surface of the uninjured heart exhibits no difference of electric tension" (*i.e.* is equipotential), and by means of the galvanometer and rheotome, investigated the duration and time-relations of the excitatory change. He found that, in general, when the ventricle was excited at a point near to one of the leading-off electrodes and remote from the other, "the nearer of the two became on excitation first negative, then positive to the more remote." As the result was the same whether the contacts were at base and apex, or on opposite sides of the ventricle, it was concluded that every excited part becomes momentarily "*negativelectromotorisch wirksam*," and that this negativity "is propagated from the seat of excitation in all directions"³ (*loc. cit.*, p. 73). Such a diphasic effect was termed by Engelmann a *Doppelschwankung*. When the negativity of the nearer contact culminated at 0.16 second after excitation, it was succeeded 0.14 second later by relative positivity (*positive Schwankung*), *i.e.* negativity of the further contact, and had completely subsided half a second after excitation. Considering that each phase was of very short duration, and that the wave of excitation may reach the second electrode before it has culminated at the first, he concluded that the whole period occupied by the electrical disturbance is not more than $\frac{1}{10}$ of a second.

In 1879 I made, in conjunction with Mr. Page,⁴ an extensive series of experiments, in which the electromotive phenomena of the response were investigated with the galvanometer and rheotome, and also with the electrometer, the photographic method being used for recording (see p. 418). For both series of observations the preparation chiefly used was the "Stannius heart," *i.e.* one brought into a state of atonic quiescence by a ligature applied between the sinus and the auricle.

The rheotome observations showed that in such a heart, at 15° C., the variation evoked by excitation of the auricle consists of two phases, separated from one another by a period during which the surface of the ventricle is equipotential. The first lasts about 0.05 second, the equipotential period 1.3 second. The duration of the second phase exceeds that of the first, but its difference of potential is relatively very inconsiderable. The duration of the ventricular systole was recorded graphically at the same time, and found to be about 1.1 second, so that it did not last quite as long as the interval between the two phases. There was no difficulty in explaining the first phase of the variation in accordance with the principles already laid down by Engelmann; but the existence of a second phase, separated from the other by a long period of equipotentiality, was a new fact which neither he nor anyone else excepting Kölliker and Müller had observed, for Engelmann applied the term *Doppelschwankung* exclusively to the initial period of about a third of a second, during which (in the normal beat) the base becomes first negative, then positive, to the apex. It seemed probable from the

¹ Donders, *Onderszoek. ged. in h. physiol. Lab. d. Utrecht. Hoogesch.*, 1872, Bd. i. S. 256.

² Engelmann, *ibid.*, Bd. iii. S. 806.

³ *Arch. f. d. ges. Physiol.*, Bonn, 1874, Bd. xvii. S. 68.

⁴ *Journ. Physiol.*, Cambridge and London, vol. ii. p. 384.

incidence of the terminal phase almost immediately *after* the end of the systole, that it marked the duration of the electrical change which is a concomitant of functional activity. To ascertain whether this relation was a constant one, a comparison was made of the relative durations of the systole and of the interval in question at different temperatures, an arrangement being adopted by which the rheotome observations could be repeated at temperatures varying from 12° to 20° C. It was found, as was anticipated, that the duration of the interval of equipotentiality always a little exceeded that of the systole.

The interpretation applied to these observations eighteen years ago has proved to be correct. As was then indicated, the fact of the existence of a relatively long period of equipotentiality (over 2 seconds in a cooled heart) does not necessarily imply that both contacts are in a state of electrical inactivity, but may mean that the electromotive forces at work at the one electrode happen to balance precisely those that are at work at the other.¹

Latent period.—For the purpose of determining the earliest moment at which an electrical change can be observed, experiments were made in which the exciting electrodes were placed one on either side of the proximal leading-off electrode. With this mode of stimulation, the first effect was not observed until more than 0.02 sec. after excitation. The period of closure was always 0.03 second. When it terminated 0.02 sec. after excitation, there was no effect, showing that up to that moment there was no response.

The injured ventricle.—Further proof of the long duration of the excitatory electrical change was obtained by a similar mode of observation, the only difference being that the surface under one of the leading-off electrodes was devitalised. It was already known that in the heart, as in other striped muscle, an injured surface is negative to a sound one, but it was by no means clearly understood that the relative negativity was due, not to any abnormal activity at the injured part, but to unbalanced activity of the living tissue at the opposite electrode. As had already been shown by Engelmann, the resting difference of potential in question (*i.e.* the relative positivity of the uninjured surface) immediately after the injury is very considerable, amounting to $\frac{2}{10}$ of a Daniell, or more; but it soon subsides. In a heart recently injured at the apex, during the whole period of the systole the sound surface at the base becomes relatively negative to the devitalised part at the apex; so that the previous difference suffers a diminution to about half its initial amount.

The meaning of the prolonged negativity of the uninjured surface during systole is not difficult to understand,—that surface, in common with all other uninjured parts of the excited ventricle, being in a state of functional activity, in which the injured part alone does not participate. Its duration, like that of the systole and of the equipotential period, varies with temperature. Inasmuch as the duration of this “negative variation” can be easily measured, it affords the readiest means of proving the important fact, that the excitatory electrical change lasts about the same time as the systole.

Effect of local application of heat on the variation.—Local inequalities of temperature may be produced in two ways, namely, either by placing the heart upon a support of which one part is warmer

¹ *Loc. cit.*, p. 398.

than the other, or by bringing near to the surface which it is desired to warm, a minute coil of platinum wire, heated to any required amount by leading a battery current through it. By the first method it may be shown that a very slight difference of temperature between the apex and base of the ventricle is sufficient to alter the character of the variation. If, with the proximal contact on the former and the distal on the latter, the temperature of the apex is slightly raised, the effect shows itself in the strengthening of the terminal phase, and shortening of the isoelectric interval. The second method has the advantage that it enables us to localise the action of warmth with more exactitude, and to prove that, whether the contacts are on the opposite sides of the ventricle, or at opposite ends, the electrical response of the unwarmed contact to stimulation is always greater than when both contacts are at the same temperature. It is further found that, in the absence of excitation, a warmed surface becomes slightly positive to an unwarmed, the amount of difference of potential, however, not exceeding $\frac{1}{1000}$ of a volt, and soon giving way to an effect in the opposite direction.

The excitatory variation as observed by the capillary electrometer.—Two years later, the rheotome results above described were verified and extended by this method, which was then new.¹ A large number of photographic records were taken, relating to the ventricle of the heart of the frog and of the tortoise, in which the time-relations of the excitatory variation were fully demonstrated. The character of the results can be best understood by the following series of tracings (Fig. 249), copied from photographs made in August 1882:—

FIG. 249.

No. 1 represents the normal variation of the ventricle of a Stannius preparation excited from the auricle, with the proximal leading-off electrode at the base, the distal on the apex. Period of latency, 0.45 sec.; interval between first and second phase, 1.4 sec.

No. 2. The same with the apex devitalised by heat.

No. 3. Uninjured ventricle, leading-off electrodes as before; excitation at the apex close to what was before the distal contact.

No. 4. The same; the now proximal contact warmed by a platinum coil placed at a distance of 3 mm. from the surface.

No. 5 shows the actual differences of potential during the two phases of the variation represented in No. 1, as deduced from more recent photographs obtained with a more sensitive instrument. The first phase corresponds,

both as regards differences of potential and time-relations, to Engelmann's curve, published in 1878,² representing the mean result of thirty-three observations of the variation in the

¹ Sanderson & Page, *Journ. Physiol.*, Cambridge and London, vol. iv. p. 327.

² Engelmann, *Arch. f. d. ges. Physiol.*, Bonn, Bd. xvii. S. 68.

uninjured ventricle, with the leading-off electrodes at a similar distance apart. According to Engelmann's curve (Fig. 1 in his paper), the relation between the differences observed and the time elapsed after excitation was as follows:—

Up to 6 hundredths of a second	.	.	No deflection.
At 7	"	"	Beginning of variation.
" 16	"	"	Negative maximum.
" 26	"	"	Equipotentiality.
" 30	"	"	Positive maximum.
" 56	"	"	End of variation.

No. 6 shows the appearance that such a curve would represent if reduced to the same scale as No. 5.

The rate of propagation of the electrical response, which is the sign of the excitatory state, admits of being determined by two methods. The first is founded on the comparison of two measurements, *i.e.*, of the time after excitation at which the first indication of electrical changes are appreciable at the proximal contact, and of the distance of that contact from the seat of excitation. This method was used by Engelmann, and led in his hands to the conclusion that the rate of propagation is less than 50 mm. per second. We were, however, able to show in 1882, that correct observations cannot be obtained by a single comparison of the distance between the seat of excitation and any point in its progress, with the time at which its arrival at that point is indicated, because neither the exact starting-point of the excitation wave, nor the moment at which it starts, can be determined with certainty. This being so, the only satisfactory way of measuring the rate of transmission by this method is to compare the results of two observations, in each of which the wave of excitation starts from the same point, but in the one, the proximal electrode rests on a spot nearer to the starting-point than in the other. The relation between the difference of time at which each of the two points is attained and their distance from each other, accurately represents the rate of propagation. An equally correct method on the same principle is to compare two observations in which, the position of the proximal electrode being unchanged, the exciting electrodes are at varying distances from it. It was thus determined that at 12° C. the rate of propagation might be as much as 125 mm. per second, but only so long as the ventricle was perfectly fresh (*cf.* p. 443).

The second method, which consists in measuring the time-interval between the beginning and culmination of the first phase, yields similar results, but it has not been much used. There is, however, no reason to doubt that it is equally reliable.

Electromotive phenomena of the mammalian heart.—In 1892, Bayliss and Starling¹ investigated the electrical phenomena of the normal beat in the mammalian heart with maintenance of circulation. Their experiments showed that in the ventricle of the dog, when the leading-off electrodes to the electrometer are applied to the base and apex respectively, the excursions of the mercurial column are such as to indicate that "the variation is always diphasic, . . . negativity of the base preceding that at the apex," whether the pericardium be opened or not. They found that difference of temperature and differences of physiological state between the two contacts produce modifications

¹ *Internat. Monatschr. f. Anat. u. Physiol.*, Leipzig, 1892, Bd. ix. Heft 7.

of the normal variation, which correspond with those described by myself and Mr. Page in the ventricle of the frog. There is, however, one important difference between their results and ours, namely, that in general they observed no interval between the diphasic variation which constitutes Engelmann's *Doppelschwankung*, and the later movement which marks the end of the contraction. The absence of this interval Bayliss and Starling attribute to the short duration of the beat. Here it must be mentioned that one of these observers (Bayliss, *loc. cit.*, p. 13) has made observations on the heart of the frog and the tortoise, the photographic records of which show that, in his preparations, Engelmann's second phase (see Fig. 249, 6) was apparently much stronger than in ours. This relatively unimportant discrepancy cannot be explained without further investigation.

The fact that the electromotive changes which accompany the

action of the heart can be observed in man was discovered by Waller some ten years ago. The effect observed varies according to the mode of leading off. This may consist either in placing one electrode on the chest at the seat of impulse, and the other on the right hand, or the one on the right hand and the other on the left. The former of these

FIG. 250.—Einthoven's Electrocardiogram of man.

methods has been employed by Bayliss and Starling, the latter by Einthoven. The form of the photographic record¹ indicates that the variation begins with a strongly marked change, in which the base becomes first negative then positive to the apex, followed by a more prolonged movement in the former direction. In Einthoven's experiments the contacts were on the right and left hands respectively. The character of the photographic record is shown in Fig. 250 (*ABCDX*). From it the curve (*OPQRSTX*) is deduced by a process of analysis, which is essentially the same as that of Burch, and leads to similar results. It may therefore be compared with curve 5 of Fig. 249. Einthoven declines to go further in the physiological interpretation of this curve, than to point out that *R*, which corresponds to the negative phase of Engelmann's *Doppelschwankung*, denotes the beginning of the ventricular systole, and that its end is indicated by *T* (or *D*).

PHYSIOLOGICAL PECULIARITIES OF CARDIAC MUSCLE AS
COMPARED WITH SKELETAL.

There are two respects in which the excitatory properties of cardiac muscle appear to differ from those of skeletal, namely—(1) The existence of periodic variations of excitability; (2) the characteristic relation of response to stimulus known as the “all or none” principle, according to which the vigour of the response evoked by a stimulus adequate to produce an effect, is independent of the strength of the stimulus.

1. **Periodic variations of excitability.**—There can be no doubt that any part of the heart tends to respond rhythmically to a stimulus which acts continuously. The continuous stimulus may be mechanical, *e.g.*, an increase of intracardiac pressure, or it may be electrical. A notable instance of the effect of the former may be seen in the snail's heart, which, when quite quiescent, can be made to beat rhythmically by distending it. The same thing happens in nearly as striking a way in a motionless apex preparation of the ventricle of the heart of the frog, when similarly treated. The rhythmical effect of a continuous electrical stimulus, such as that of a succession of alternating induction currents following one another with very great frequency, can be well seen in a strip of muscle cut from the border of the ventricle of the heart of the tortoise. It is, I think, usual to explain such instances of the apparent transformation of a constant excitatory action into a recurrent one, by saying that cardiac fibres can only respond rhythmically—that they are essentially incapable of tetanus, etc. According to a similar mode of explanation, this rhythmicality is attributed to the liability of the heart to be “refractory” for a certain period after each excitation. Neither of these modes of expression brings us, however, any nearer to an understanding of the phenomenon we have under consideration; they are merely different ways of stating it. There are so many non-physiological examples (such as, *e.g.*, the dropping of water from a narrow aperture under a constant pressure) of the conversion of a continuous action into a rhythmical one, that we need not be surprised at the same thing happening in muscular tissue. The difficulty lies rather in the fact that in skeletal muscle no such conversion appears to take place, than that it occurs in cardiac muscle. Before, however, we admit that it does not occur in the former, we must inquire what form it would assume in such muscle, if it could be observed. In so far as the response to a single stimulation is strictly limited in duration, varying with the muscle employed and with temperature, skeletal muscle has also its *period*. What the period is may be estimated either from the mechanical or from the electrical response to an instantaneous stimulation, but much more easily from the latter than from the former. The monophasic response lasts less than one-fiftieth of a second; so that a “refractory period,” if such there be, should, by analogy with the heart, have a similar duration. In the heart the corresponding monophasic variation, at a temperature of 12° C., lasts about two seconds, so that where cardiac muscle responds once a second, we should expect, under the same conditions, skeletal muscle to respond a hundred times a second. It has not yet been proved, experimentally, that a continuously excited muscle does thrill mechanically at any such rate, but there are indications, not yet investigated, of an electrical thrill of this order of frequency produced by continuous stimulation.

2. The "all or none" principle.—The second respect in which cardiac muscle differs physiologically from skeletal muscle, namely, its property of responding fully to any stimulus to which it responds at all, whatever the strength of the stimulus, is much easier to explain, inasmuch as it may be accounted for by the structural peculiarities of cardiac muscle. In curarised skeletal muscle there is no communication of the excitatory state from element to element. In the ventricle, such communication is essential to the production of a single contraction or beat. In order that it may happen, the excitatory change produced at the seat of excitation must have a certain intensity, for which a certain strength of stimulus is necessary.

The same "law" with regard to the propagation of the excitatory process prevails, for a similar reason, in the excitable tissues of plants as, *e.g.*, in the leaf of *Dionæa*, where also a stimulus, whether mechanical or electrical, is either fully adequate or else inadequate. If a stimulus applied to one lobe is adequate to evoke a response in the opposite lobe, the latter responds in the same way, whatever be the strength of the stimulus.

NERVE.

THE FUNDAMENTAL CHARACTERISTICS OF NERVE PHENOMENA.

General review of nerve functions.—The physiological phenomena exhibited by nerve may be considered under three different aspects, indicated by the terms "excitability," "conductivity," and the "state of excitation."

Excitability is pre-eminently the attribute of nervous tissue; hence the phenomena of nerve comprised under this expression represent more definitely than those of other excitable structures the conditions which determine its possession, and the circumstances which modify its manifestation. A tissue is said to be excitable if it responds by the development of specific changes to the local action of external change in its immediate environment. The altered condition thus produced is termed "the excitatory state," whilst the external agent which has evoked this is termed the "stimulus" or "exciting cause."

The excitatory state may be successively assumed by other portions of the excited tissue, and is thus propagated from the point of stimulation to more remote structures; the changes evoked in such structures are the objective sign of the possession by the stimulated nerve of the property of "conductivity."

The special structure of nerve fibres is the undoubted basis for the high development in these of this attribute of "conductivity," the natural and fundamental function of a living nerve, inasmuch as propagation is the purpose which the structure is especially framed to subserve.

It is evidently closely associated with that of excitability, but although the relationship is an intimate one, the experimental investigations of recent years seem to show that the two attributes, "conductivity" and "excitability," must be regarded as more or less distinct, since conditions may modify the manifestations of the one without affecting those of the other.

There is no doubt not only that an axis cylinder transmits in both directions the excitatory state evoked by the stimulus, but that it transmits this state along all its branches.

The isolation of the excitatory nerve change just referred to is an expression for the familiar fact that, when a particular group of nerve fibres is excited, the excitatory state thus evoked is propagated along the excited fibres and their branches, and along these only. The definite character of the experimental results observed in the excitation of efferent nerves, whether medullated or non-medullated, is due to this definite restriction of the path along which the propagation of the change occurs. This localisation, although so familiar as to be generally accepted without criticism, is by no means easily explained.

It has been suggested that the sheaths, and in particular the medullated sheath, may play an important part in securing adequate insulation, but although it is not improbable that some such rôle may be attributed to them, the fact of the insulation being present where such sheaths fail (in non-medullated nerves) forbids the assumption that their presence is essential for its attainment. It must be regarded as the property of the axis cylinder itself, and the sheaths, if they play any such part, can only afford additional security.

Although it appears that axis cylinder continuity is a sufficient guarantee that the change, which is successively assumed by its various portions, shall be localised in the nerve fibre in which it started, it is evident that where such continuity ceases the isolation of the propagation also comes to an end, and that conduction will now become diffuse. This is the case at the distal and central terminal branches. In the case of the distal terminations, if these are motor, the specific character of the ending, and its restriction to special muscle fibres, renders the subsequent events still precise in their locality; but, as regards the central terminations, spread must take place, and the subsequent propagation appears to be determined very largely by the extent of such spread and the proximity of other terminal branches. Thus the excitatory state must be assumed to leave its axis cylinder path where this ends, and, crossing an intermediate region, to enter another path, preferably that in more immediate contiguity. This passage from one

fibre to another is associated with very special characteristics, which will be referred to later in considering the excitatory changes present in nerve-endings. It is mentioned here, in order to guard against the inference that the functional isolation now under consideration is an absolute one; it is evident that it is only relative isolation; wherever the axis cylinder path exists, the propagation is restricted to it, when it ceases a passage can be forced through other routes.

Phenomena of the excitatory state.—The excitatory state evoked by a stimulus manifests itself in nerve fibre by electromotive changes, and, as far as our present knowledge goes, by these only. This state may spread to successive portions of the nerve beyond the region subjected to the action of the stimulus, the spread being accompanied by similar electromotive changes. All theories as to the nature of the hidden events which take place in the living tissue, and constitute this excitatory state, must embrace these demonstrable facts.

It is further demonstrable that any alteration in the nerve, evoked by the operation of an external agent, is succeeded on the removal of the producing cause by a reversed state. Just as, in a muscle, relaxation succeeds contraction, and the whole cycle constitutes the response, so, in a nerve, the excitatory state is in fact, as in conception, composed of changes in one direction, succeeded after a very brief interval by others of opposite character.

The conception of such an excitable living tissue as nerve, implies that of a molecular state which is in stable equilibrium; this equilibrium can be readily upset by an external agency, the stimulus, but the term "stable" expresses the fact that a change in any direction must be succeeded by one of opposite character, this being the return of the living structure to its previous state. Thus the electrical manifestation of the excitatory state is one whose duration depends upon the time during which the external agent is able to upset and retain in a new poise the living equilibrium, and if this is extremely brief, then the recoil of the tissue causes such manifestation to be itself of very short duration. Whether our conception of the actual physico-chemical conditions of this living equilibrium, whose disturbance is excitation, be mechanical (du Bois-Reymond, Pflüger), chemical (Hering, Biedermann), electrochemical (Bernstein, Hermann, Boruttau), the above statement is equally true. No departure from the normal in consequence of excitation takes place without being succeeded by the opposite condition. Throughout the whole of the phenomena of nerve this consideration must be always kept in view. Such well-known experimental investigations as those of the polar changes in excitability are framed for its direct demonstration, and there is little likelihood in these of its being forgotten, but in others, in which its determination is not the direct object of inquiry, it is apt to be passed over. It is for this reason that this fundamental conception is introduced at this early stage in the consideration of nerve phenomena.

Metabolism during nerve activity.—During the activity of a muscle, changes of four different kinds are revealed—mechanical, electrical, chemical, and thermal. In nerve the electrical changes are readily demonstrable, but the chemical ones, upon which these are presumably based, are extremely slight, whilst any thermal effects, in consequence of such chemical processes, have not hitherto been ascer-

tained. The negative character of the evidence of metabolism is an important circumstance in connection with the rationale of nerve phenomena, and such positive data as exist support the conclusion that nerve metabolism must be very small in amount.

Waller considers the close agreement between the effect upon the functional changes of external CO_2 , and of previous nerve activity, to be an indication that CO_2 is produced during the active state.¹ Funke found that nerve fibres had an acid reaction after prolonged activity, such as that caused by strychnia, although alkaline under normal conditions;² the statement has, however, been contradicted by other observers.³ It is agreed that destruction by heating to 50°C ., mechanical pressure, etc., causes the nerve to have this acid reaction. The electrical organ of fish is a nervous structure, being a nerve-ending of a most extensive kind. In the resting state it is faintly alkaline in the uninjured living fish, but after excision it has been observed to be neutral or faintly acid, and it becomes acid when heated to 50°C .⁴ By means of intravital injection of acid fuchsine, a dye which is blanched by the normal alkalinity of the tissues, it has been found that the two organs of a strychninised torpedo differ in appearance, if the nerves of one had been divided before the injection. The active-nerved organ was seen to be red, whilst the paralysed one was blanched.⁵ This method was found by Dreser to give marked results in muscle; it gave no definite result in nerve. It appears, therefore, that the evidence of acidity during nerve activity is scanty and uncertain. Finally, the blood supply of nerve is too limited to admit of any pronounced metabolism, and nerve fibres appear to be incapable of fatigue in consequence of their activity.

There is the same want of evidence of any thermal change during nerve activity. Such change was described by Schiff,⁶ but the most delicate methods had failed to reveal its development in the hands of other observers.⁷ A careful investigation by Rolleston, with the exceedingly sensitive method of Callander, confirmed the absence of any appreciable thermal effect.⁸ On the other hand, post mortem changes, such as are produced by chemical reagents or heat, always cause an appreciable development of heat. A development of heat during the activity of the cerebral hemispheres has been observed by Mosso,⁹ whose extensive investigations along this line have been taken as proving the localisation of such thermal changes in the central nerve substance. The validity of this conclusion has, however, been disputed; moreover, the results are opposed by the observation that the production of CO_2 during cerebral activity is very slightly, if at all, augmented.¹⁰ From these data it is evident that metabolism during activity is either

extremely small, or is such that any chemical dissociation is rapidly compensated for by subsequent association.

The conductivity of nerve—Rate of transmission.—The propagation of the excitatory state along the nerve fibre, from the seat of excitation, is probably the most fundamental fact in nerve physiology. The experimental basis of the fact is the series of observations made by Helmholtz; these showed that, when the sciatic nerve of the frog was excited at its central end, the period between such excitation and the response evoked in the attached muscle was perceptibly longer than in the case of excitation at the muscular end of the nerve. The period of delay was increased in the former case by '001 sec. when, with the nerve at 15° C., a distance of 27 mm. lay between the central and peripheral seats of excitation. In order to ascertain the interval of time between the excitation and the muscular response, Helmholtz employed the galvanometric method of Pouillet.¹ The movement of a suitable key caused an induced current to traverse and excite the nerve, whilst it closed, at the same instant, a galvanic current of known intensity through a circuit comprising a galvanometer. The contraction of the muscle evoked by the arrival of the excitatory state was utilised to break a contact in this galvanometer circuit, and thus the duration of the galvanic current comprised the period between the nerve excitation and the lift of the contact through the muscle response. As the extent of the deflection of the needle was, in the instrument used, proportional to the time of current flow, the difference between this time with a central and a peripheral stimulation could be readily ascertained.

Similar experiments were carried out by Helmholtz on man, the muscles in the ball of the thumb being used as the index, and the nerve excited at the root of the neck and bend of the elbow respectively.

The experiments have been repeated under many varying conditions, the movement of the muscular response being recorded by any one of the methods employed for the accurate determination of the period of delay in the response of muscle to indirect or direct excitation.

The transmission is undoubtedly due to each successive portion of the continuous nerve fibre being thrown into the state of excitation, in consequence of the production of this state in the neighbouring portion. This view is confirmed by the determination of the rate of propagation of the excitatory state itself, as evidenced by its accompanying electromotive changes. These are transmitted in the case of the sciatic nerve of the frog at a rate which is similar to that deduced from the time-relations of the muscle response.²

The propagation rate (27 metres per second) is slow compared with that of sound, light, etc., but is much faster than exists in the case of muscle. It differs in different classes of nerves, and may be altered by a large number of agencies, which will be considered in the succeeding sections.

The alteration is one not merely of the rate but also of the intensity of transmitted effect. Thus, on passing through a locally cooled region, the transmission is both delayed in time and diminished as to intensity; the resultant muscular response thus occurs later, and may be smaller than it otherwise would be.

¹ Helmholtz, *Arch. f. Anat., Physiol. u. wissenschaft. Med.*, 1850 and 1852.

² Bernstein, "Untersuch. u. d. Erregungsvorgang in Nerven u. Muskeln," 1891.

Transmission in both directions.—Another aspect of this fundamental fact of propagation is that known as transmission in both directions. If a nerve fibre is stimulated in the course of its continuity, the excitatory state is transmitted along both its peripheral and its central portions. The property possessed by the nerve is thus one of conductivity in both directions.

It is clear that it is not easy to secure proofs of such doubly directed propagation, since the index for either the efferent or the afferent nerve is afforded by the response of a structure (muscle or central nervous system) situated at one end only. In order to secure a double terminus, each capable of responding on the arrival of the excitatory state in precisely the same way, the division of efferent axis cylinders in the neighbourhood of their terminations has been taken advantage of. In the sartorius muscle of the frog

FIG. 251.—A, Sartorius split at iliac end; excitation at x_1 or x_2 evokes contraction of excited half only; excitation at x_3 or x_4 evokes contraction in both halves. B, Gracilis with peninsula of muscle cut, so that the continuity of its fibres is interrupted. Excitation of nerve in muscle peninsula (x_1) evokes contraction in all parts of the muscle. C, Three portions of *Malapterurus* electrical organ, connected by single nerve fibre. Excitation at either x_1 or x_2 evokes an electrical response in all three portions.

evokes a response on both sides. The gracilis muscle may be so cut that different regions shall have independent muscle fibres, but retain a nerve supply from the divisions of the same axis cylinders (Fig. 251). A similar double response of its separated regions is evoked when any one part with its contained nerve fibres is stimulated.¹ The electrical organ of *Malapterurus* is a notable instance of an enormous nerve supply attained by the divisions of a single axis cylinder. It can be detached from the fish, and the nerve with its single axis cylinder can be divided where it courses upon the inner surface of the organ, and excited at either its central or its peripheral end. Further, any single branch may be cut off from its peripheral connections, and similarly excited. The response of the electrical organ is a very distinct one, and is evoked in every part, whether a peripheral twig or the main

¹ Kühne, *Ztschr. f. Biol.*, Bd. xxii. S. 305.

termination may be found, since the axis cylinders divide into two main groups, each of which ascends some distance towards the upper iliac end between the parallel muscular fibres. It is possible to divide this end of the muscle into two halves for some little distance; the stimulation of either tip, where there are no nerves, evokes a response in that strip only, the excitation of the strip where the nerves are present

stem of the nerve fibre is excited.¹ The only possible interpretation of these phenomena is the transmission of the excitatory state up the efferent nerve fibre to the main stem, and along every one of its branches; if these lead to a terminal organ which responds to the arrival of the state, such response is evoked.

A question of some interest does not appear as yet to have been investigated. Is the rate of such propagation the same whether it is opposed to that of the normal functional activity, or is similarly directed to this? In other words, is there any evidence of irreciprocal conductivity? The writer has attempted to obtain information on this point by utilising the comparatively long single axis cylinder of the electrical nerve of *Malapterurus*. The difficulties are largely due to the slight differences in time measurement which are involved. As far as the series of experiments throws light upon the subject, it appears that the rate of transmission in the preparations used was not materially affected by the direction of such transmission; at any rate, it may be safely said that the average rate was the same, whether the propagation ascended or descended this efferent nerve (Fig. 251, C, excitation at x_1 and x_2 respectively).

A further proof of this conductivity in both directions is that afforded by the electrical changes accompanying the development of the excitatory state in the nerve. This, in the case of efferent nerves, is shown by the division of an anterior root of the sciatic plexus in an animal such as the cat, and the connection of the root with an appropriate galvanometer. Excitation of the trunk of the sciatic evokes both a response in the muscles of the limb and electrical changes in the anterior root, due to the propagation of the excitatory state upwards towards the central nervous system. A remarkable feature of this propagation up efferent nerves is its absolute extinction on its arrival at the central nervous system, there being no trace of any excitatory electrical change in the spinal cord.² Similar methods may be applied to afferent nerves; here it is sufficient to expose and excite a posterior root, and determine the existence of excitatory electrical changes in the central end of the cut sciatic. These are produced not only by the stimulation of the posterior root, but by excitation of the spinal cord after all the anterior roots have been cut, due to the circumstance that the posterior root fibres are directly prolonged by branches into the posterior columns of the cord.

Various expedients were formerly resorted to in order to demonstrate the possibility of reversed propagation along afferent nerves. Among these is that of dividing the hypoglossal and lingual nerves in the dog, and then suturing the peripheral portion of the former and the central portion of the latter. It was thought that the fact of the contraction of the tongue muscles, which could after some weeks be evoked by the excitation of the lingual, showed transmission along the afferent fibres of this nerve, which had become united to the efferent ones of the hypoglossal. Such experiments, and those of Paul Bert, which involved a transplantation of the tail of the rat, by grafting its cut tip in a fresh situation on the skin, are all futile, since they were carried out before the phenomena of nerve degeneration, and nerve regeneration had been adequately appreciated. There is no evidence of such direct union of nerve fibres as that demanded by these experiments, nor, if

¹ Babuchin, *Arch. f. Physiol.*, Leipzig, 1877, S. 66.

² Gotch and Horsley, *Phil. Trans.*, London, 1891, vol. clxxxii. B., p. 485.

this highly improbable premise were granted, would the deduction as to transmission in the lingual be sound, since this is known to possess efferent fibres derived from the chorda tympani. Langley¹ has recently recorded experiments on the rabbit, which seem to show that the central end of the cervical vagus can establish physiological connection with the cells of the superior ganglion of the cervical sympathetic, if the cut cephalic ends of these two nerves are brought into contiguity and left for from seventy-three to 123 days.

The conductivity of any nerve fibre is influenced by a large number of conditions; these are especially changes in its environment, and will be considered in connection with alterations in excitability due to the same causes. One influence only will be referred to now, namely, that due to the intensity of the excitatory state. It was observed by Helmholtz, in his experiments on the rate of propagation along the nerves of the arm in man, that the excitatory state evoked in nerve by an intense stimulus was propagated more rapidly than that caused by a weaker one. This result has been confirmed in the motor nerve of the frog by Vintschgau,² and in the non-medullated nerves of *Anodon* by A. Fick.³

It is, however, questionable whether this result is true for all forms of stimulation, mechanical as well as electrical; the employment of the latter as the means of starting the excitatory state is open to the criticism that, when intense, it is difficult to localise it. Since the precise localisation of the starting point is essential for experiments upon the rate of propagation, any uncertainty as to its being strictly limited must render the results dubious. The apparent decrease in the period between nerve excitation and muscle response, when the nerve is stimulated with stronger induced currents, may, in many cases, be due to the spread of such currents along the nerve, and the consequent stimulation of portions which lie between the electrodes and the responding muscles.

The essential facts of nerve transmission may be summed up as dependent upon the successive excitation of the various contiguous portions of the nerve fibre. Two conditions must be assumed to determine the realisation of this succession, the potency of the exciting cause, and the degree of susceptibility of the tissue which has to be aroused. Our present knowledge leads us to regard the exciting cause as an agent able to produce a particular molecular rearrangement in the nerve; this constitutes the state of excitation, and is accompanied by localised electrical changes as an ascertained physical concomitant. It has been suggested that these local electrical changes are themselves the agents concerned in the stimulation of the quiescent portions of nerve in immediate proximity, and that this process is carried on in succession down to the nerve-endings, where it forms the releasing agent for the muscular response.⁴ It is certain that electrolytic processes play a most important part in the whole process, and that the intensity of any one local excitatory effect determines, other things being equal, that of the effect aroused in the neighbouring portion. The view is supported by other considerations, which will be alluded to later.

Attention may now be drawn to the second condition for propagation, the susceptibility of the unexcited neighbouring portion. The possession of this susceptibility, when the stimulating agent is an external change, is the attribute of excitability; when the stimulating agent is the excitatory state itself in a neighbouring portion, it is expressed as conductivity. It is evident that the two are phases of one fundamental characteristic, but they are certainly more or less independent phases of this. The evidence for such separation will be furnished in detail in the sections dealing with the influence of various conditions upon excitability and conductivity.

THE EXCITATION OF NERVE.

Modes of stimulation.—The term “excitability” is conveniently limited to the possession by living nerve of a capability of responding by a definite change to the action of an *external* agent, and every external agency which is capable of evoking such a response is an efficient or adequate stimulus. Such “excitability” may be measured in terms of the intensity of the minimal efficient stimulus, if the exciting agent or stimulus is itself a measurable one. The direct index of a nerve response is the electrical change, which is the sole physical alteration at present ascertained in active nerve, but an indirect index is afforded by the propagation of the excitatory change from the seat of the local stimulus to such a peripheral organ as a muscle, a contraction of which is evoked on the arrival of the transmitted nerve effect. It is evident that this indirect index is complicated by being the response of another structure, and that all conclusions deduced from experimental investigations in which this method is used, can only be made after full allowance for this. In the great majority of the investigations upon nerve this muscular index has been employed, and the results are thus, for the most part, confined to motor nerves. The electrical response will be treated in the concluding chapters, so that in the present and immediately succeeding sections the subject matter will be largely limited to the evidence afforded by what may be termed the indirect index. In the case of afferent nerves, a similar indirect index is the reaction of the central nervous system as indicated either by reflex effects in peripheral organs, or by the development of those changes which are transmuted in the crucible of consciousness into sensation. A large variety of external agencies can act as local stimuli for nerve fibres; they may be grouped as electrical, mechanical, chemical, and thermal.

Of these the electrical stimulus is that principally employed on account of the ease with which it can be applied to a definite region of the nerve, the facilities its employment offers for graduating the intensity of the stimulus, and the comparatively small amount of injury which it causes in the tissue subjected to its action.

Electrical stimulation.—(1) *Make and break induced currents.*—The forms of electrical stimulus most frequently made use of are the induced currents occurring in the secondary coil on the commencement or the cessation of a current flow through the primary coil of an induction machine.

They are susceptible of very accurate graduation as to intensity by altering the distance between the secondary and primary coils, and, in

consequence of comparatively large electromotive force, brief duration, and rapidity of development, they form the most effective of all nerve stimuli.

Their employment necessitates the adoption of certain precautions due to their character and method of production. These currents are largely modified by the presence of the extra current in the primary coil, and therefore by the nature of this coil; if, as in most induction apparatus, this contains a core, then such modification is very pronounced. Under any circumstances the "make" induced effect is slower in its development and subsidence than the "break" (Fig. 252, *A*). This is due to the variation in the counteracting influence of the extra current,¹ which, on closing the primary circuit, is of some intensity, but on opening is comparatively feeble, since, in the latter case, the circuit being opened, it must traverse the gap as a spark. The time-relations of the break induced current are thus dependent upon the velocity with which the key in the primary circuit is opened. It will be seen that rapidity of development is an important factor in determining the stimulating intensity of a current; hence, in the case of the break induced current, its excitation value is dependent upon the rate at which the circuit of the primary coil is opened.

For many experiments it is necessary that the time-relations of each one of

FIG. 252.—*A*, Time relations of make (*m*) and break (*b*) induced currents (ordinates = current intensity). *B*, Time relations of induced currents obtained by Helmholtz side wire method. *C*, Time relations of magneto-induced currents obtained by rapid rotation machine.

a series of stimulating induced currents should be absolutely uniform; to insure this, a key must be used, such that the primary circuit shall be always opened at a constant velocity. If all other conditions are constant, then the more quickly the primary circuit is opened, the more rapid will be the development of the break induced current, and the more

powerful its stimulating effect. A large number of different forms of apparatus of varying degrees of efficiency have been employed to effect this end; a spring which on its release separates two surfaces, or a traveller driven by either a weight or some constant force, which opens at a uniform velocity an appropriate key.

It is less easy to secure a constant closure, hence the break is to be preferred to the make induced current.

A useful and sufficiently uniform stimulus is that produced by a closure of the primary circuit for a definite but very short period, such as can be effected by the striking of a steel needle as it passes over and lightly touches a stretched wire; this is made use of in many forms of rheotome, and, when produced by a rotator travelling at a constant and sufficiently rapid velocity, causes a series of uniform induced currents in the secondary circuit.

The production of such a rapid series of uniform induced currents is ordinarily effected by the use of the spring hammer of the inductorium, which causes make and break induced currents recurring at regular intervals. The objection that the fact of the break being different in time of development to the make effect, must, when both rapidly recur, cause an overpowering series of currents in one direction, is got rid of by the interposition of a side wire, which is so disposed that the interrupter opens and closes a short circuit of the primary coil. Under these circumstances the

¹ See Rosenthal, "Electricitätslehre f. prakt. Aerzte."

extra current is approximately the same, whether the current in the primary coil is augmented or decreased (Fig. 252, *B*); thus a series of induced currents, recurring at rapid intervals, can be produced, alternate in direction and of approximately equal intensity. Various devices have been employed in order to insure mechanical accuracy in the closing and opening of the contacts effected by the oscillations of the spring or fork; of these the most effectual is Kronecker's capillary contact, in which the spring causes a platinum wire to dip in and out of mercury, whilst a stream of water removes any electrolytic products formed at the point of contact. A rotator with two strikers and two batteries, coupled up by opposite poles, produces very good results, and obviates the necessity for the introduction of the side wire.

(2) *Undulatory induced currents*.—For precise stimulation with a rapid series of alternating currents, probably the most effectual method is the employment of a magneto-electric machine. A convenient form consists of two sets of small coils of wire, fixed in a frame a short distance above one another, so as to allow of the rapid passage of a magnet or series of magnets between them. One set of coils is connected with a battery, the other with the exciting circuit, or with the primary coil of an induction machine. The disc with the magnets is rotated by means of a motor at a rapid rate, and a series of precisely similar alternating currents are thus induced in the apparatus. If these are allowed to traverse the primary coil of an induction machine, this acts as a transformer, and a series of currents are produced in the secondary, the varying intensity of which would, if represented graphically, assume the form of a symmetrically undulating curve (Fig. 252, *C*), and may, by appropriate choice of coils, be made strictly sinusoidal in character.¹

The production of single or slowly recurring currents of similar physical character to those just described, can be obtained by allowing a magnet to fall with constant velocity through the centre of a coil.² The elaborate instrument used by Mareš for the purpose may be replaced by the following simple form.

A primary coil containing an internal core of the usual character is fixed upon a pendulum and is connected with a battery;³ a secondary coil is fixed immediately below the stationary position of the pendulum and its coil. Each swing of the pendulum produces an effect in the stationary secondary coil, which can be made of such character as to have a current intensity augmenting and diminishing in a perfectly regular way; the effect of several swings is thus to produce a series of alternating currents, each of which is precisely similar as regards its time-relations. By varying the shape of the magnetised core, the time of development may be altered and the variations made sinusoidal in character. The uniform character of the time-relations of these effects insures uniformity in the physical characters of the stimulus.

(3) *Condenser discharges*.—Theoretically, the condenser discharge is in almost all respects an ideal form of electrical stimulus.

Its practical employment necessitates several precautions: two condenser plates, on being connected with an electromotive source, are charged up to the PD of this source; on disconnecting, the charge remains; but on connecting, through a second circuit, including a nerve, the charge rapidly equalises itself, and a current thus flows through the nerve. The rate at which the equalisation occurs depends upon

¹ Burch, *Journ. Physiol.*, Cambridge and London, 1897, vol. xxi. p. 231.

² Mareš, *Proc. Internat. Cong.*, Liège, 1892; *Centralbl. f. Physiol.*, Leipzig u. Wien, 1892, Bd. vi. S. 408.

³ Gotch and Macdonald, *Journ. Physiol.*, Cambridge and London, 1896, vol. xx. p. 247.

the resistance of the circuit and the capacity of the plates, being slower as either of these increases. The character of the discharge is thus expressed by a fall from the full potential to nothing, which fall varies in the time necessary for its completion. As condenser plates are liable to allow leakage between the opening of the charging and the closure of the discharging circuit, a useful method is to place the condenser plates in direct connection, through the nerve, with the electromotive source, and use one circuit only; on short circuiting the electromotive source the discharge of the plates occurs through the nerve.

The elaborate investigations of d'Arsonval, Hoorweg, Cybulski, and Waller¹ show that in this method of nerve excitation, the physical constants of the stimulus are capable of being accurately determined, and thus the stimulus energy in any one instance can be expressed in terms strictly comparable with that in another.

(4) *The galvanic current.*—The peculiar features of the excitation of nerve by galvanic currents will be considered in detail later. As a mode of stimulation, its employment has the disadvantage that the duration of the current causes electro-chemical changes in the tissue of a more pronounced character than those produced by the former methods.

These changes may, however, be reduced to a small amount by employing currents of very short duration, such as are produced by a rapidly rotating striker which effects a closure by lightly striking a stretched wire; and if, by a further arrangement, a second similar closure is also effected, two short galvanic currents opposite in direction may be produced, thus reducing the possibility of prolonged electrolytic changes to a minimum. By means of a rheochord the intensity of the current, and thus the stimulus, may be graduated with great precision, and a mode of stimulation can be thus obtained which has several points in its favour. The duration and character of the currents used for stimulation are constant, and can be determined with great precision, whilst the electromotive force employed is also readily ascertained.

(5) *Other modes of electrical excitation.*—The passage of any electrical current of sufficient intensity may act as a stimulus to a medullated motor nerve, especially if the time of its development is sufficiently short; thus the discharge between the knobs of a frictional machine will excite the nerve of a frog's muscle nerve preparation, when this is placed in air in the neighbourhood of either pole.² An anomaly, however, appears to exist in the case of electrical oscillations of very great frequency, such as those to which attention was drawn by Hertz. The Hertz waves, even when adequate to cause an incandescent lamp to glow, will only stimulate an exposed nerve at the moment of their onset, whilst, during their continuance, they appear to cause a paralysis of conductivity.³

The currents produced by Bell's telephone have been made use of for stimulation; a striking instance is their employment by Hürthle, in order to record the time-relation of the sounds of the heart, the currents thus caused being adequate to excite an exposed nerve.⁴

Finally, the vital electromotive changes present during the functional activity of electrical organs, voluntary muscle, cardiac muscle, and even nerve itself, may under appropriate conditions be employed as nerve stimuli.¹

(6) *Unipolar excitation.*—The employment of electrical currents for stimulation is, unless special precautions are observed, liable to lead to erroneous conclusions, through difficulty in localising the seat of their application. This is especially the case when the electromotive source is one of high potential, and one fruitful source of error is the existence of what is termed unipolar excitation. This phenomenon is readily demonstrated when induction currents are employed. If the sciatic nerve of the frog is connected with one terminal only of the secondary coil, the opening or closing of the primary circuit may still evoke a muscular response. The most careful insulation of the preparation is ineffectual to eliminate the exciting effect, but it disappears if the terminal connected with the nerve is in addition adequately connected with the earth by means of water-pipes, or the like. If the intensity of current employed is just inadequate to evoke the response, it becomes adequate when either the unconnected terminal of the coil, or any part of the insulated preparation, is touched with the finger: it is even possible to cause an excitation by approaching the nerve with the moist finger.

The cause of the phenomenon is the unequal surface distribution of electrical potential through the whole conducting mass, including the preparation.² With high potential, such as that of the induced current, any alteration in surface distribution is necessarily accompanied by the passage of considerable currents during the period of alteration; the rapidity with which this takes place is very considerable, owing to the quick development of the electromotive force, and thus increases the exciting value. It is possible to obtain such variations in surface distribution by suspending an insulated nerve muscle preparation in air, in the neighbourhood of Leyden jars connected with the poles of a suitable frictional machine; every time the distribution is altered by a discharge between the poles, a response occurs, owing to a similar variation of distribution in the preparation, and such response is augmented if the preparation is touched by the finger.

The use of electromotive changes of high potential is thus always liable to produce unipolar effects; it is for this reason that in the case of induced currents, especially break induced currents, the presence of a closing and opening key directly interposed in the secondary exciting circuit is inadmissible, and a short circuiting key, with effective metal contacts, must be employed.

Unipolar effects are a fruitful source of error, as changes will be constantly produced by the existence of currents which, being inadequate to evoke muscular effects, are disregarded; in all investigations upon the electromotive phenomena of nerve, the possibility of their presence must be always considered, and as far as possible guarded against.³ The employment of unipolar excitation offers some special advantages, and in the hands of Charpentier and others has yielded results which are obtained with difficulty, if at all, by other modes of stimulation.⁴

Chemical modes of stimulation.—Many chemical substances when applied locally to nerve act as stimuli; the exciting effects are irregular in character, and appear to be due partly to the withdrawal of water from the nerve, and partly to the specific effect of the chemical substance upon the molecular state of the nerve.

Although the subject will be referred to again in the section which deals with the influence of chemical substances upon nerve excitability and conductivity, it is advisable at this stage to enumerate those forms which appear to be most effective, and the mode of their employment.

(1) *The withdrawal of water by drying.*—The effect of drying a motor nerve is to cause first increased susceptibility to excitation by other modes of stimulation, then an irregular excitation which shows itself in the attached muscles by flickering irregular muscular tetanus, and finally loss of both excitability and conductivity. The effect increases with the length of the nerve thus dried, and when the drying is very rapid the final stage is reached so quickly that no responses are obtained.¹ Different nerves and different portions of the same nerve vary considerably as regards their susceptibility to stimulation by this agency. Thus in the case of the sciatic nerve of the frog, the lower end is far more readily excited than the upper, probably owing to the larger amount of connective tissue surrounding the upper fibres, which protects the essential structure. A large number of chemical agents act by withdrawing water, glycerine and sodium chloride being familiar instances.

(2) *Neutral salts.*—Almost all the neutral salts cause nerve excitation, whether they are applied by allowing a nerve to lie for some minutes in a bath containing an appropriate solution of the salt, or whether the salt is applied locally to a portion of the nerve. The exciting value varies directly with the degree of concentration, until a limit is reached at which the nerve functions are suspended, if not destroyed, by the rapid action of the strong solution. The investigation has been largely carried out on motor nerves, particularly the sciatic nerve of the frog, the muscular response being taken as the index of effective excitation, which resembles in its general characters that produced by drying.

Sodium chloride is the form which has been most frequently employed, and the salt tetanus evoked by its application has been studied by Eckhard, Kölliker, and others. An extended inquiry into the exciting value of different salts has been made by Grützner.² In order to obtain solutions of different salts which should admit of accurate comparison, the solutions used were not of equal percentage, but equimolecular. Thus, in comparing NaF, NaCl, NaBr and NaI (the varying molecular weights of which are respectively 41·9, 58·3, 102·7, 149·4), equimolecular solutions are those containing corresponding proportions by weight of the salts, namely, 4·2 NaF, 5·8 NaCl, 10·2 NaBr, 14·9 NaI. The effectiveness of these solutions for stimulating the sciatic nerve of the frog was found to be in the following order: NaF, NaI, NaBr, NaCl. The action of NaF is very intense; if this is excepted, the remaining salts act more strongly the higher their molecular weight, and even with equal percentages the same relationship holds good. It therefore appears that the withdrawal of water is not

¹ Harless, *Ztschr. f. rat. Med.*, 1859, Bd. vii.

² Grützner, *Arch. f. d. ges. Physiol.*, Bonn, 1893, Bd. liii. S. 83.

the sole factor which determines the exciting value of the salt, but that this must be largely dependent upon the specific action of the chemical compound upon the nerve. This is confirmed by the results of such substances as KI, KBr, and KCl, which excite motor nerves hardly at all.

The exciting value of equimolecular solutions of various neutral salts, when applied to motor nerves, may be contrasted with one another as follows:—

The stimulation of afferent nerves by such salts presents some remarkable features. In the first place, such stimulation, as evidenced by reflex responses, has been found to be so capricious and uncertain as to lead many investigators to state that sensory nerves are more or less refractory to such excitation. Grützner ingeniously utilised the well-known smarting sensation which follows the application of saline solutions to cuts upon the fingers. The production of this sensation is undoubted evidence that the sensory nerves are stimulated; on comparing various salts in equimolecular solution, he obtained with sodium salts results of which the following is a typical example:—

With NaI (14·9 per cent.) the sensation was evoked in five seconds, with NaBr (10·2 per cent.) in ten seconds, with NaCl (5·8 per cent.) in fifty seconds. This order is the same as that above referred to as prevailing with motor nerves. But he found, further, that whereas potassium salts have little exciting value for motor nerves, they are extraordinarily effective for sensory nerves. Solutions of all the potassium salts produced the smarting sensation when tested by the skin-cut method, and this when in a state of concentration which, with equimolecular solutions of sodium salts, was far too weak to be effectual. Similar results are obtained by experiments on the conjunctiva, whilst, in the frog, salts of potassium evoke reflexes, when applied to the skin, much more readily than those of sodium. Moreover, the form of potassium salt which is most effective is the chloride, while the chloride of sodium is the least effective.

The following table shows the comparative exciting efficiency of various neutral salts when applied to afferent nerves:—

The extraordinary contrast between the marked exciting value of KCl when applied to afferent nerves, and its inadequacy as a stimulating agent to motor nerve, is shown further by the following experiment. The sciatic plexus of a narcotised frog is exposed and divided on both sides. On applying potassium chloride to the central end of one plexus and to the peripheral end of the other, reflex movements of the flanks, etc., are evoked through the former, but no movement of the lower limb is produced by the latter application. On the other hand, a similar experiment with sodium chloride causes movements of the muscles whose nerves are directly excited, followed after some little interval by reflex effects in the flanks and other muscles.

These differences in the apparent excitability of afferent and efferent nerves to chemical stimulation may be dependent upon the difference between the responding end-organ present in the two cases. On this hypothesis, even though all the nerve fibres are excited, the indication of such excitation in the case of a motor nerve, *i.e.* the resultant muscular response, is one which is readily evoked by the transmitted excitatory states produced by sodium salts, but not by those started by potassium salts; on the other hand, in the case of afferent nerves, the excitatory state aroused by the potassium salt is of a character to evoke central (reflex) activity, and this in a more marked degree than is the case with that due to sodium salts. Any explanation must include those phenomena of isolated nerve, in which an electrical response is the index of activity. These are referred to in the section dealing with the electromotive phenomena of nerve.

(3) *Stimulation by bases.*—Considerable discrepancy exists as to the stimulating effects upon motor nerves of such alkalis as NaHO, KHO, and ammonia. According to the majority of observers, the first two will excite a motor nerve, even when weak, *e.g.* 0.1 per cent.¹ (On the other hand, Grützner found that KHO rarely if ever excites the motor nerve.) As regards ammonia, the great majority of observers are agreed that it does not excite such nerves. In all cases, these alkalis, if at all concentrated, rapidly destroy all functional activity,—a circumstance which may account for the discrepancies in the observations.

As regards afferent nerves, Grützner found that all three alkalis excited when tested by the skin-cut method, and that their comparative exciting efficiency was as follows, Ammonia, KHO, NaHO, thus showing again the marked contrast between the central system response and that of the peripheral muscle to chemical excitation of the centripetal and centrifugal nerves respectively.

(4) *Stimulation by acids.*—Acids excite both motor and sensory nerves.¹ As regards inorganic acids, their comparative exciting value is in strict accordance with their chemical avidity. Thus HNO₃ and HCl excite in weaker solution than H₂SO₄, whilst H₃PO₄ excites very feebly.² The organic acids excite only when concentrated, and some of them, such as oxalic acid, impair vitality without excitation.

(5) *Stimulation by salts of the heavy metals.*—The majority of metallic salts destroy nerve vitality without excitation. Mercuric nitrate, zinc chloride, zinc sulphate, and chloride of iron are exceptions. These excite, when solutions are used of a concentration which causes a comparatively slow injury. The first is by far the most potent, and the others differ as regards exciting efficiency in the order above given.¹

(6) *Stimulation by organic substances.*—Glycerin, if concentrated, excites motor nerves, probably through the withdrawal of water; and, as in the case of drying, the lower end of the frog's sciatic is far more readily stimulated than the upper end. Urea and sugar, if sufficiently concentrated, excite in a similar way; the former is remarkable inasmuch as it does not produce the eventual loss of vitality which is the common result of the prolonged action of other exciting chemical sub-

¹ Eckhard, *Ztschr. f. rat. Med.*, 1851 (2), Bd. i.; Kühne, *Arch. f. Anat., Physiol. u. wissensch. Med.*, 1859.

² Grützner, *loc. cit.*

stances. Hence the permanent impairment of tissue vitality is not a necessary termination to prolonged chemical excitation.¹

Mechanical stimulation.—Various modes of mechanical excitation have been devised. The simplest is that of a rapid compression, such as is caused by dividing the nerve trunk. In order to secure the repetition of the stimulus, du Bois-Reymond² employed a small toothed wheel which compressed successive portions of the nerve, and thus always affected a new region. Heidenhain used a hammer, which struck the nerve where it lay upon a vulcanite block, whilst by means of a small cylinder a fresh portion was brought under the vulcanite anvil in the interval between the ascent and descent of the hammer.³ A similar "tetanomotor" was employed by Wundt; it was materially modified by Tigerstedt, the hammer being made very light, and the force of the blow rendered capable of adjustment by altering the position of a small load, placed between the fulcrum of the hammer and its head.⁴ With this apparatus carefully adjusted, it is possible to excite once every few seconds upon the same spot many times in succession. Langendorff employed an entirely different method; the cut end of the sciatic nerve of the frog was ligatured and attached to the free end of a tuning-fork, which was then adjusted so as to lightly pull the nerve. On setting the tuning-fork in vibration, the nerve was alternately stretched and relaxed with each vibration and thus stimulated.⁵ The conditions which determine effective mechanical stimulation have been investigated by Uexküll,⁶ who states that this is best achieved by an arrangement in which the hammer is rigid but the counter-resistance extremely yielding. This condition is fulfilled when the nerve is rapidly shaken against an elastic pad by a vibrating ivory bar. The apparatus devised by Uexküll, and termed by him the nerve shaker, consists of a thin ivory lever, moving on a central fulcrum, and held in position by an adjustable spring. By means of a rotating toothed wheel one end of this lever is lightly struck in rapid succession, and the whole thus set in vibration. The nerve either rests upon a yielding pad under the further end of the lever, or is twisted round the lever point. The vibration of the lever is communicated to the nerve, and the shatter thus produced excites it. Each shatter of the lever can be registered by means of a small contact, which opens and closes an electrical circuit. Uexküll found that, with this apparatus, the nerve could be excited many times at the same spot, and that thus the injurious effects caused by striking with the hammer could be eliminated. The shatter appears to excite the motor nerve in the same way as the induced current, at least in so far as the time relations of the resulting muscular contraction are concerned.

A distinct mode of stimulation is that caused by suddenly lifting a compressing weight; it appears doubtful whether this is in reality a form of mechanical excitation, since it is possible that the release of the compression may cause the nerve to regain its condition of moisture, which during the squeeze has undoubtedly been diminished; the demarcation nerve current due to the injury of the squeeze is thus suddenly

⁶ Uexküll, *Ztschr. f. Biol.*, 1895, Bd. xxxi. and xxxii.

increased in intensity as in Hering's experiment, and this may excite the nerve.

According to Uexküll, all modes of mechanical stimulation are effective only in proportion as they shatter the nerve, and there is good ground for the belief that the withdrawal of water caused by drying, and by many chemical stimuli, act in a similar manner.

The method of mechanical stimulation eliminates all error due to the spread of the exciting agency to other portions of tissue, such as occurs when electrical modes are employed. The methods of Uexküll, or modifications of these, are likely to be of great service in the future, as their employment is not accompanied by nerve injury.

The conditions which determine the efficiency of a stimulus.—The excitation of a nerve by an external stimulus is favoured by two entirely independent sets of conditions,—one of these, it need hardly be said, is physiological, and is expressed by the term maintenance of high excitability; the circumstances which play upon this physiological state will be detailed in a succeeding section. The other conditions are incident to the exciting cause, and involve the consideration of the special characters which the external change must possess in order to render it an effective stimulus.

1. The intensity of the physical change.—The most obvious of these characters is that of the force of the exciting agency, in other words, the intensity of the stimulus, although it is a familiar fact that there are minimal and maximal limits to its potency. Thus, an electrical current of definite character, if very weak, is inadequate; but when gradually increased in intensity, without any alteration in its time relations, it will, at some given point, become sufficiently potent to stimulate.

It is, however, by no means a simple matter to determine for any one agent the point when its intensity has sufficiently developed to arouse a response in a nerve. What is the indication that such a response has been aroused? In the case of a motor nerve, the contraction of the attached muscle shows that it has been aroused sufficiently to produce an excitatory change of such extent that, when transmitted through the nerve-endings, it evokes the muscle response. But it is certain that the nerve itself must be affected by external agents which are inadequate to cause an indirect muscular contraction. The only physical indication of the excitatory change is the electrical response of the nerve.

In ascertaining, therefore, the relation between the intensity and the exciting value of any stimulating agent, the electrical response is the most reliable index of effective excitation.

Such comparison has been made by Waller, who recorded the effect produced when the strength of the exciting agent was gradually increased.¹ The record consisted of a series of galvanometric excursions, photographed on a slowly moving surface, each being the instrumental summation of a number of electrical responses of a nerve, evoked by a definite number of electrical stimuli (induction currents). The stimulation was repeated at regular intervals of one minute, and was gradually increased in intensity. The electrical nerve changes were contrasted with the records of the muscle lift due to the nerve excitation by the

¹ *Brain*, London, 1895, vol. xviii. p. 209.

same series of stimuli. The character of the two sets of results is shown in the following table :—

Strength of Stimuli.	Extent of Photographed Galvanometric Variation.	Muscle Lift.
1·52 units	2·5	0
1·65 „	5	4
1·79 „	7·5	9
2·13 „	15	12·5
2·32 „	19	12·5

It will be noticed that the nerve change increases in proportion as the intensity of the stimulus is augmented, and that this increase still occurs when the muscular response, having reached its maximum limit, is unable to indicate the augmentation. The relationship of electrical response to nerve stimulus will be again referred to in the section dealing with the electromotive phenomena.

2. The time relations of the change (the law of excitation).—These have been especially studied in connection with electrical modes of stimulation, and their consideration may be appropriately prefaced by a statement of the results arrived at by du Bois-Reymond, the consideration of which caused him to formulate the two propositions which constitute his “law of excitation.”¹

(a) It is not the absolute intensity of a current at any given moment which constitutes its effectiveness for the excitation of a motor nerve, but the variation in such intensity from one moment to another.

(b) The excitation by current variation with any given quantity is the more pronounced the more rapidly such variation is effected, *i.e.*, the greater the amount of such variation in a unit of time. In other words, the potency of an electrical current for the excitation of an excitable tissue such as nerve, is not so much a function of I as of $\frac{dI}{dT}$ where I represents the intensity and T the time.

There are here two statements,—the first indicates that it is the increase or decrease, the onset or cessation, of the flow of a current, and not its maintenance, which determines its exciting efficiency; the second, that in proportion as the onset or cessation is more rapidly effected, the exciting efficiency is increased.

The foundation for the first statement is a series of well-known and uncontested facts; they may all be sufficiently illustrated by one example, that of the exciting value of a galvanic current, when this is led through the sciatic nerve of the frog. The muscle to which such nerve is attached, responds by a single twitch synchronous with the closure, and by a second twitch synchronous with the opening, but during the maintenance of the closure it remains quiescent.

Although this and other facts of a similar nature appear to prove the validity of the first part of du Bois-Reymond’s law, there are many considerations which forbid its acceptance as a general law of excitation.

As already indicated, the muscular response, when present, is an

¹ E. du Bois-Reymond, “Untersuchungen,” 1849, Bd. i.

undoubted index of nerve excitation, but its absence cannot be taken as convincing proof of the failure of such nerve excitation. It is conceivable that the nerve equilibrium, although upset more potently at the moment of onset and cessation, may be similarly disturbed during and after the flow of a current, and indeed we have experimental proofs (electrotonus) that such is the case.

This prolonged disturbance is not termed in ordinary physiological parlance an excitation simply because the attached muscle does not respond on its being propagated to the motorial nerve-endings. The electromotive changes, which are the index of the production of the true nervous disturbance, are however present, and the disturbance may under favourable conditions be so pronounced that a muscular response is evoked, thus definitely proving its existence. It is well known that in the case of cooled nerves, or those which have been treated by chemical reagents (NaCl, etc.), either the closing or opening muscular twitch may be succeeded by a prolonged tetanic contraction.

In the case of other nerves, such as those of the adductor and abductor muscles of the crayfish claw, prolonged excitatory effects, evoking relaxation or augmentation of the muscular tonic contraction, occur during and following the closure of the current, whilst voluntary muscle responds by a continuous contraction to the passage of a galvanic current through its substance. The sciatic nerve of the cooled frog may be persistently stimulated by the demarcation current caused by its section, the excitation evoking a continuous muscular contraction.¹ It has been shown that stimulation of the afferent fibres in the vagus nerve of the mammal is produced during the whole time of the passage of such a current, as evidenced by the respiratory movements.² The glandular response to excitation of the glosso-pharyngeal nerve is similarly evoked, not merely at the onset, but still more effectually during the flow of a galvanic current through this nerve.³ Finally, it was shown by König⁴ that the duration of a galvanic current was an important factor in determining its efficiency as a nerve stimulus; this is strikingly the case in involuntary muscle, but it is easily demonstrable in cooled nerve, that for any given intensity there is a minimal period of closure below which the stimulating effect is decreased. Since the rise of the current intensity is practically instantaneous, this fact can only be interpreted as meaning a less efficient excitation, in consequence of the shortness of the period of flow.

As regards nerve, therefore, the first statement in the law of excitation requires limitation. Nerve being of all structures that in which the properties of excitability are most pronounced, is differentiated, so that it is more susceptible to variations in current intensity than to the maintenance of such intensity; but the excitatory condition, though produced at the onset and the cessation of the current, can be also evoked, though in less degree, both during and after the current flow.

The second portion of du Bois-Reymond's statement is, as regards the motor nerves of the frog and the mammal, of far more general

¹ Hering, *Sitzungsb. d. k. Akad. d. Wissensch.*, Wien, 1882, Bd. lxxxv. Abth. 3, S. 237; also, "Biological Memoirs," Oxford, 1887, p. 136.

application. With any given intensity the stimulating effect of the onset or cessation of a galvanic current is largely determined by the time relations, *i.e.*, by the rapidity with which either of these is effected. This is readily demonstrated by a rheonome, an apparatus designed so as to constitute a varying rheochord.¹

Fleischl's rheonome consists of a narrow circular canal, filled with saturated solution of zinc sulphate; a battery is connected with two fixed points in this canal at opposite ends of one diameter, whilst two revolving contacts dipping into the canal are connected with the derived or exciting circuit, and thus with the nerve (Fig. 253). At each complete revolution the difference of potential in the derived circuit is augmented and decreased in alternate directions with a rapidity dependent upon the rate of revolution, and since the apparatus provides for equal revolutions in equal times the variation is linear. With a very slow rate of revolution the current increase and decrease can be effected without causing a nerve excitation which shall be adequate to evoke

FIG. 253.—I, Diagram of rheonome. Circular trough containing saturated solution of $ZnSO_4$, connected by zincs at ZZ' with battery circuit; the revolving arm (A) dips by its end contacts into the trough; when it reaches the position (A') the two points of contact in the trough are equipotential. II, Diagrammatic representation of the variation in current, through the wires attached to the ends of the revolving arm, when this is slowly rotated.

a muscular contraction; as the rate increases the stimulus becomes effectual, evoking minimal and subsequently maximal contractions when a certain rapidity of development has been attained. The conditions are such that the maximum of current intensity is the same at whatever rate the revolving contacts move, hence the rapidity of development ($\frac{dI}{dT}$) is the effectual factor in determining the exciting efficiency.

The difference between the make and the break induced currents is largely due to varying rapidity of development; the break induced current, reaching its maximum more rapidly than the make, is more effectual.

The muscular nerves of the frog and of most mammals are differentiated so as to be extraordinarily susceptible to rapid variations of current intensity; the excitation of such a nerve by the static spread from the neighbourhood of the poles of a frictional machine or by telephone currents are illustrations of such susceptibility.

But, in spite of this, du Bois-Reymond's statement cannot be accepted as a fundamental law of excitation for excitable tissues

¹ Fleischl, *Sitzungsb. d. k. Akad. d. Wissensch.*, Wien, 1877, Bd. lxxvi. Abth. 3, S. 3; v. Kries, *Arch. f. Physiol.*, Leipzig, 1884.

generally. In many such tissues, involuntary muscle for instance, there is a limit beyond which increased rapidity of current change ceases to augment its excitatory value, and there are instances of such results even in nerve. Thus the motor nerves of the toad are more effectually excited by the make than by the break induced current,¹ and even the motor nerve of the frog, when locally cooled, will respond to slowly developed better than to very rapidly developed variations in current intensity.² Finally, the increased effectiveness for cooled nerve of condenser discharges, when with constant electromotive force the condenser capacity is augmented, shows that the duration of such discharge is a potent factor.³

All that can be said is that, as a rule, effectiveness of stimulation in the case of electrical currents is increased in proportion as the rate of variation in current flow is accelerated.

3. The influence of the direction of current upon its exciting value.—The above considerations relate to the intensity and time relationship of a current, a third important factor is its direction. It will be seen in a subsequent section that, owing to a blend of excitability and conductivity changes, the muscular response is affected to a very considerable degree by such alterations in direction as are implied by the terms "ascending" and "descending." There is, however, one feature in regard to direction which must be referred to at this stage, since it brings forward an important point in reference to the electrical stimulation of nerves. This is the great decrease in exciting value, when the current flow is so directed as to be in a plane which cuts the nerve fibres at right angles to their length. The attainment of such direction is by no means easy; it can, however, be approximately achieved by stretching the immersed nerve in a bath of physiological saline, as in Bernstein's trough experiment with the sartorius muscle.⁴ The stretched nerve is arranged so as to be strictly parallel to the facing sides of the trough which form the contacts through which the current is led into the liquid. Under these conditions the nerve appears to be almost inexcitable. In this connection the electrical resistance of nerve must be taken into account; this resistance for any given bulk of the tissue is five times as great in the transverse as it is in the longitudinal direction; but the increased resistance, although large, is insufficient to account for the failure in exciting efficiency. The most plausible explanation of the failure is the close proximity of the changes caused at the poles, which in this case are on either side of each single nerve fibre.

It may be remarked, in conclusion, that although the various factors which determine the exciting value of an external agent have been ascertained in the case of electrical currents, in their fundamental aspects they are true of other stimuli. Thus, mechanical pressure is most effectual at the moment of onset; and the exciting value of such onset is increased in proportion as this is more rapidly effected. By an ingenious arrangement, it can be shown that mechanical press-

ure may be wholly inadequate to evoke an indirect muscular response when slowly applied to a motor nerve, whilst the same pressure, rapidly produced, is fully adequate. A good illustration of the increased exciting value of mechanical change when this is rapid is that afforded by the use of the nerve shaker; the nerve may be thus adequately stimulated by very small, but rapidly effected, changes.

In regard to chemical stimuli, such comparisons are hardly possible, but in so far as these act by the withdrawal of water (glycerin, NaCl, etc.), the rapidity of such withdrawal is obviously increased by the strength of the chemical substance used. Provided that the nerve is not injured by the agent, the exciting value of such substances as those mentioned is in proportion to their degree of concentration. Finally, in regard to thermal agencies, it is only sudden and extensive change which causes these to have any exciting value at all.

The effect of the repetition of the stimulus.—The indefatigability of nerve.—To what extent can a stimulus be repeated and still remain efficient? The investigation of this question opens up a strictly physiological line of inquiry; for the efficiency can only fail on repetition, in consequence of the inability of the living tissue to respond to the constantly recurring physical change.

The subject has been investigated in several ways, which may be broadly divided into two groups. In the first, the nerve is excited with an efficient stimulus recurring at comparatively long intervals, and of uniform character and intensity. In the second, the nerve is excited by a series of stimuli which recur at great rapidity. Does nerve show signs of fatigue when subjected to excitations of the first kind? Does it show inability to respond when subjected to those of the second?

In the case of a motor nerve, the index of excitation afforded by the indirectly evoked muscle response is itself susceptible of fatigue; the gradual failure in this contraction, when the nerve is excited by a series of stimuli recurring every few seconds, is thus no indication of a failure in the nerve. It is possible to avoid this source of error by eliminating the muscle. This can be done in the mammal by the use of curare. A sufficient dose is given to paralyse the motor nerve-endings, and artificial respiration is employed until, after some hours, the effects of the drug disappear, in consequence of its elimination.¹ The exposed nerve is stimulated at intervals during the whole period, and, as the curare paralysis wears off, it is seen by the muscular contractions which now appear, that although the nerve has been subjected to this prolonged excitation, it still responds to the action of the stimulus.

Bernstein prevented the muscular contraction in the frog by blocking the transmission from the seat of nerve excitation to the muscle, this being effected by leading a galvanic current through a portion of the nerve. The nerve was then excited for a prolonged period above the block; on opening the galvanic current, the muscular contraction showed that the nerve was still being adequately excited.²

This method has been improved by using synchronous short periods for closing both the excitation and the blocking currents; by alternate reversal of the latter, any injurious effect due to their prolonged closure is largely got rid of.³ It is found that after such excitation

¹ Bowditch, *Arch. f. Anat., Physiol. u. wissenschaft. Med.*, 1870.

² Bernstein, *Arch. f. d. ges. Physiol.*, Bonn, 1877, Bd. xv.

³ Wedenskii, *Centralbl. f. d. med. Wissenschaft.*, Berlin, 1884.

has continued for six hours, with the sciatic nerve of the frog the nerve still responds to the stimulation, for, on the removal of the block, the muscular contraction reappears in its initial intensity.

The propagation has been blocked by the local application of ether vapour to a portion of nerve intervening between the excited region and the muscle; on removing the ether, the excitation of the nerve still caused the muscle to respond after twelve hours.¹ The secretory nerve-endings of the chorda tympani can be paralysed by atropin, and the continuous excitation of these fibres is seen to become effective as the atropin wears off.²

The electrical changes in the nerve have been taken as an index by Waller. In this case the indication of each group of electrical responses was obtained by photographing the galvanometric variation. The nerve was submitted to a short series of rapid excitations of similar intensity which recurred at regular intervals of one minute, and the resulting effects showed no evidence of diminution through fatigue.³

Nerve fibres are thus remarkable in being so differentiated as to be unaffected by repeated activity, and they offer a striking contrast in this respect to other parts of the nervous system. Thus the nerve junctions in the central nervous system and the neuromuscular connections are readily fatigued, the latter more readily than muscle itself; so that if a muscle is indirectly excited, until it can no longer respond, it will be found that it is still capable of contracting to direct stimulation.

In these cases we may assume either that the terminal nerve fibres differ from the fibres of the main trunk, or that the fatigue is localised in the field of conjunction which lies on the further side of these terminal fibres, whether in muscle, gland, or central grey matter. In this connection the fatigability of the isolated electrical organ may be referred to, the activity of which is in all probability that of the terminal nerve fibres.⁴

The limits of efficient stimulation by rapidly repeated stimuli.—The second method of inquiry, although apparently of a different character, involves to some extent the same issues. Can a nerve be excited by a series of stimuli, when these recur at very rapid intervals, and if so, at what point is a limit reached for such excitation? The muscular response is in this case an adequate index of nerve excitation, and the simplest method of obtaining information is one in which two electrical excitations of the nerve occur in rapid succession. Under these circumstances, the two muscular responses must obviously be fused, and when the second excitation occurs, at a very brief interval after the first, this summated muscular effect may be so slight as to be with difficulty distinguished from that of the single twitch. Those cases in which such a difference can be detected furnish undoubted evidence that the nerve has been adequately excited by the two stimuli. Various methods have been employed for obtaining two excitatory states in rapid succession. The nerve may be simultaneously excited at two points, one near, the other remote from the muscle. In this case, with a distance of 15 mm. between the seats of excitation, the difference in the length of the nerve along which the

excitatory states are propagated to the muscle is such that at 15° C the one will reach the motorial nerve endings only $\cdot 0005$ sec. in advance of the other. The results are complicated by the conditions of the experiment, since the part of the nerve subjected to the electrical stimulation is changed as regards both conductivity and excitability, these changes being dependent upon the direction and the intensity of the exciting currents. In the most favourable conditions, it has been found that the effect of the two excitations is to evoke a contraction which is larger than that evoked by either excitation alone. This may mean that two excitatory states recurring at $\frac{1}{2000}$ sec. interval can be propagated along the nerve without blending; in other words, the upset of nerve equilibrium by the first stimulus does not interfere with the production of a fresh disturbance by a second one at this interval.¹

Another method is that of exciting the nerve at the same point by two successive electrical stimuli. The alterations as regards both conductivity and excitability are even more pronounced under these conditions, but in spite of these it has been found possible, by the use of minimal stimuli, to evoke, with two excitations $\frac{1}{1000}$ sec. apart, a response which is larger than that produced by either single excitation.² Recent experiments carried out under the direction of the present writer have, however, limited the extent of this capacity of the nerve to respond to a second stimulus.³ These show that a summated muscle contraction cannot be evoked by double excitation of a nerve at 3° C, unless the stimuli are $\frac{1}{200}$ sec. apart, whereas at 15° there is evidence of summation with stimuli at $\frac{1}{1000}$ sec. to $\frac{2}{1000}$ sec. apart.

A large number of rapidly recurring excitations of the same point of the nerve have also been used. The difficulty in this case is the uniform production of the rapid series of electrical currents. By the use of a small dynamo, it is possible to obtain a series of sinusoidal current variations, at a rate of 1800 to 2000 per second. With this rate the nerve at 15° C can be excited, and the muscular response is a prolonged tetanic contraction.⁴ It was observed by Bernstein that with a rapid series of make and break induction shocks, the resultant muscular response, when these recurred at 500 per second, was not a tetanic but a single initial contraction.⁵ It was therefore surmised that only the first excitatory state was adequately produced. The facts just mentioned are opposed to any generalisation from these experiments. The failure of the tetanic response undoubtedly implies that at the temperature employed a relatively smaller nerve disturbance is produced by the successive excitations, as compared with that evoked by the first of the series, but it does not mean that at intervals of $\frac{1}{500}$ sec. nerve excitation is impossible.⁶ This is shown by experiments in which telephone currents, augmented by an appropriate microphone, are used for purposes of excitation. With these, Roth found that it was possible to excite the nerve so as to obtain a tetanic muscular response, with excitations recurring at from $\frac{1}{1000}$ sec. to $\frac{1}{5000}$ sec. interval. He observed, however, that as the rate increased the intensity of the stimuli

had to be augmented, and that if such augmentation was not made, the muscular response was an initial twitch.¹ Kronecker used magneto-induced currents, produced by the vibration of a steel core, within the primary coil of a specially constructed induction apparatus. The production of a note indicating 20,000 vibrations per second was effectual for the excitation of the nerve, the muscular response being at first a tetanus, but on repetition it became an initial twitch, and subsequently failed.² In this connection attention may be drawn to the fact that the Hertz oscillations, which are of a different order, being far in excess of any of these rates, only excite when very intense, and then generally evoke initial twitch.³

It thus appears that the nerve at 12° C is capable of being excited by stimuli recurring at very rapid intervals, but that the susceptibility to excitation is greatest at the commencement of such stimulation, and diminishes with the repetition. In explanation of this, Bernstein and others have laid stress on the possibility of functional interference due to the overlapping of the successive nerve responses, which thus become fused; it is, however, probable that no such fusion occurs. The duration of the excitatory disturbance in nerve is suggested by that of the electrical nerve response. This has been variously estimated in frog's nerve as lasting from $\frac{1}{1500}$ sec. to $\frac{1}{100}$ sec., and undoubtedly the duration is greatly increased at low temperatures. An overlapping is thus possible, particularly at low temperature, but the real question is how far the response to a second stimulus is prohibited under these conditions, by the fact that the response to a previous stimulus is still in progress. In other words, is there an inexcitable or "refractory" period during activity? Wedenskii determined the electrical excitatory changes by connecting a telephone with four sciatic nerves, placed side by side, and exciting with rapid stimulation at two points. The telephone note caused by the excitatory changes was always the same pitch, whether the excitation was double or single,—the only perceptible difference being that in the former case the character and intensity of the note varied at rhythmical intervals, due to alterations in nerve excitability.⁴

The graphic records of the electrical responses, evoked in nerve by two successive stimuli, and obtained by the capillary electrometer method, appear to show that a second response cannot be evoked if the change evoked by its predecessor is still in progress. The exact interval necessary for the second stimulus to be effective thus obviously depends upon the duration of the first change, and this is largely determined by temperature.⁵

Finally, it must be borne in mind that the experiments just referred to deal almost exclusively with the medullated motor nerves of the frog and mammal. At present there is no reliable information as to the possession of the same attributes by the non-medullated nerves or the afferent medullated nerves, as the determination by means of either the muscular index or the electrical nerve response presents great technical difficulties. On general grounds, it may be assumed as

¹ Roth, *Arch. f. d. ges. Physiol.*, Bonn, 1888, Bd. xlii. S. 91.

probable that nerves differ as to the possession of relative indefatigability and susceptibility to stimulation by rapidly recurring excitations. The rapid failure of non-medullated nerves, when removed from their connections, appears to indicate that they do not possess such properties to the same extent as medullated motor nerves.

CIRCUMSTANCES AFFECTING NERVE EXCITABILITY AND CONDUCTIVITY.

Maintenance of the circulation.—It is common knowledge that the blood supply is essential for the maintenance in their normal condition of the living structures of higher animals, and that the failure of vital activity in consequence of its cessation is one which is more rapidly produced in warm- than in cold-blooded animals. Thus the blood can be replaced in the frog by water containing suitable proportions of NaCl, KCl, CaCO₃, etc., and the animal kept alive in an apparently normal state for many days. A similar variation, as regards dependence upon blood supply, is observed in the different structures of any one animal, and in the different parts of the nervous system. It is well known that the central portions of this system are the first to fail in consequence of the cessation of the circulation, and that the cerebral cortex is more rapidly impaired than the bulbo-spinal system, whilst excised nerve trunks retain their excitability for a very considerable time. Such retention implies the possession by the fibres of nerve trunks of properties which enable them to resist the gradual invasion of those changes that bring about their death. This resistance depends very largely upon the general condition of the animal previous to the time at which the nerve is excised. Thus frogs kept in captivity during the summer become anæmic, and their nerves more rapidly fail on exposure than those of winter frogs.

It is to be expected, in view of the facts as to indefatigability; etc., brought forward in the preceding chapter, that nerve fibres should offer a very considerable resistance to functional failure, in consequence of the arrest of the circulation, their metabolism being such as to require but little assistance from extraneous sources.

If injurious effects of other kinds, such as loss of water through drying, temperature changes, etc., are avoided, the medullated fibres of a nerve trunk maintain their excitability for many hours, and, in the case of the frog, for days after the circulation has ceased.

Ritter-Valli law.—In the medullated fibres of the frog's sciatic, the failure is one which is gradual in its development, and is more rapidly produced in the central than the distal portions of the nerve. This is enunciated in the Ritter-Valli law, which states that the susceptibility of the nervous system to excitation, as indicated by the muscle response, fails first in the central portions, then in the peripheral nerve trunks, and, last, in the terminal arborisations within the muscle.¹

The experimental proof of these statements is, as regards a nerve trunk, complicated by the alterations produced by nerve-section; this always produces a very considerable rise in excitability, due to the electromotive changes caused in the neighbourhood of the section. These changes are such that a persistent current (demarkation current) flows through the nerve fibres from the injured to the uninjured portions

¹ *Vide* Budge, "Lehrbuch. d. Physiologie," Leipzig, 1862, S. 665.

in the immediate neighbourhood; as this spreads along the fibres, in accordance with the known distribution of currents in moist conductors, the nerve in the vicinity of the section is most subjected, and the further portions less subjected to its influence. Wherever it leaves the fibres, these are placed into a cathodic state of heightened excitability. The method, therefore, of preparing a nerve with its attached muscle, freeing it from all other connections and placing it in a moist chamber, involves both the alterations due to arrest of the circulation and those due to the section of the nerve at its central end, together with other similar changes wherever a branch from the main trunk has been cut. In order to diminish the extent of these injury effects, the sciatic nerve of the chloralised frog has been used. The removal of the sensorium, the exposure of the heart, the bleeding of the animal, and the slight dissection for the adequate exposure of the sciatic nerve in a central and a peripheral region, are the only operative procedures employed. In such a preparation the changes in excitability are ascertained by determining the intensity of a single given localised stimulus, which is adequate to evoke a minimal muscular twitch, *i.e.* the minimal exciting value of a local stimulus. Some form of electrical stimulus has been generally used in order that the physical factors may remain unaltered, and the particular one chiefly employed has been the break induced current. The minimal exciting value of such a stimulus for the more central regions is at first attained with slightly lower intensity than for the peripheral; subsequently, the conditions are gradually altered, until finally the central end demands a more intense stimulus than the peripheral one. Two sets of factors may contribute to the production of this final condition. The excitability alone may change, or the conductivity, or both functions; the phenomena would be equally present, whether failure in conductivity or in excitability existed in different degrees throughout the nerve. The separation between the properties of conductivity and excitability clearly admits of these two possible interpretations of the experimental facts.

Indeed, it has been suggested that the initial apparent increase in excitability observed in the neighbourhood of a nerve section is not due merely to the circumstance that the excitatory state at this point is more easily produced, but also to the development of an avalanche effect, occurring during the propagation of the state along the nerve to the muscle, the excitatory state gathering volume as it progresses.¹ There is, however, little confirmatory evidence of such an increment. It is certainly not present with all stimuli, for on using chemical stimulation the peripheral part of the nerve appears to be more excitable than the central,² whilst the experiments of Tigerstedt with mechanical excitation show that in an uninjured nerve all parts are at first equally excitable.³ Even in the case of induced currents, experiments made under the direction of the writer by Dear show that, with nerves kept in appropriate saline solutions, the excitability after eight hours gradually fails in all parts of the nerve equally,—thus contradicting the Ritter-Valli law.

Maintenance of continuity with nerve cells.—Every nerve fibre, whether medullated or non-medullated, is the specialised process of

¹ Pflüger, "Untersuch. ueber Electrotonus," Berlin, 1859, S. 140.

² Grützner, *Arch. f. d. ges. Physiol.*, Bonn, 1893, Bd. liii. S. 83.

³ Tigerstedt, "Studien u. mechanisch. Nervenreizung," 1880.

some nerve cell. The severance of the fibre cuts off the distal portion from such cellular connection. If this is carried out in the mammal, with no appreciable disturbance of the circulation, and the animal kept alive, changes manifest themselves in the distal portion (Wallerian law of degeneration). The substance of the sheath in medullated nerve is altered, so that this, instead of being a continuous mantle, is changed to a series of discontinuous swollen masses; the axis cylinder is broken up, and the primitive sheath nuclei are multiplied. Finally, the whole is invaded by wandering cells, the fragments of axis cylinder and medullary sheath disappear, and the nerve fibre is replaced by a strand of connective tissue. All these changes are gradually developed, commencing within a few days of the section, and being completed after some weeks or months. The initial change may commence within forty-eight hours of the section in the mammal, and soon presents itself throughout the whole length of the distal portion of the fibre. The maintenance of the normal condition of a nerve fibre, both structurally and functionally, is thus dependent upon the preservation of functional continuity with the cell of which it is a process, and there is reason to believe that the nutritive influence exerted by the cell is associated more especially with its nucleus. A mammalian nerve with unimpaired circulation, if severed from its cell connection, soon loses its fundamental physiological properties. In the case of the sciatic of the rabbit, stimulation below the point of severance evokes little or no response in the muscles to which it is distributed. This functional failure may appear forty-eight hours after the division of the nerve; it pervades the whole distal portion, and is evidently associated with loss of conductivity dependent upon the breaches in axis cylinder continuity, produced by degenerative changes.

Galvanometric observations made by the writer appear to show that, after three or four days, the rabbit's sciatic still gives indications of a localised electrical response, although no transmitted one can be detected.

The time of onset of the failure of function in consequence of degeneration differs very greatly, not only in different mammals, but in different nerves of the same animal. Thus Arloing found that with corresponding motor nerves of the dog and monkey, the section in the former caused total loss of functional conductivity in four days, whereas in the latter this failure was not established until a longer period. The time of onset of the failure differs in the sciatic, median, facial, and vagus of the same monkey. The different nerve fibres of any one nerve trunk vary in this respect; the well-known experiment as to vaso-constrictor and vaso-dilator fibres in the sciatic of the frog is an illustration of this, the latter maintaining their excitability longer than the former. The different fibres of the divided vagus nerve of the monkey lose their excitability at different times, the cardio-inhibitory fibres in eight days, whilst the motor fibres for the larynx and oesophagus may be still excitable after thirteen days.¹

The regeneration of medullated nerve appears, from the work of Ramier, which has been recently confirmed by Ströebe,² to be largely due to the growth of new medullated fibres from the central ends of

¹ Arloing, *Arch. de physiol. norm. et path.*, Paris, 1896, p. 75; see also Langley and Anderson, *Journ. Physiol.*, Cambridge and London, 1896, vol. xix. p. 381.

² *Beitr. z. path. Anat. u. z. allg. Path.*, Jena, 1893, Bd. xiii. S. 160.

the normal nerves. These invade the degenerated tracts, which offer especially favourable media for their growth, and serve as guides to the appropriate terminal structures. The suture of a divided mammalian nerve, such as the sciatic of the rabbit, is followed by an outgrowth of afferent fibres, whose excitation is capable of evoking reflex effects in eight days; the establishment of motor connections of the efferent fibres with the muscles is slower, movement not being possible until about forty days. The actual time of recovery must differ both in different animals and nerves.

Erb¹ states that after local compression of the nerve, the restoration of movement through spinal cord activity takes place at a date when the nerve peripheral to the injury is still inexcitable. This result the writer has failed to confirm; if true, it is an instance of the recovery of nerve conductivity for specific impulses, when excitability to external stimulation is still unrestored, and furnishes another instance of the separation of these two aspects of nerve activity.

Excitability and conductivity in different nerves, and in different parts of the same nerve.—The comparative excitability of different nerves may be ascertained by allowing the same stimulating electrical current to traverse simultaneously different nerves; or the bundles of different nerve fibres, which are bound up by epineurium into one nerve trunk. A well-known observation is that first made by Ritter, and confirmed by Rollet,² as to the minimal intensity of nerve stimulus adequate to arouse responses in the groups of muscles supplied respectively by the peroneal and tibial branches of the sciatic nerve of the frog. If the whole trunk is excited, the first-named group of muscles contract with an intensity of electrical stimulus which is inadequate to evoke a response in the second group; hence the neuromuscular apparatus of the flexors and abductors is more excitable than that of the extensors and adductors, and on etherisation a stage may be reached when excitation of the sciatic causes contraction of flexors only. It does not necessarily follow from these and other analogous experiments, that the nerves of the flexors possess greater excitability, since the whole neuromuscular connection is involved in the production of the effect. Thus Albanese has shown that a similar result is obtained after simultaneous local impairment of function in the peripheral neuro-muscular mechanism of both flexors and extensors.³ The difference between flexor and extensor response obtains for the rabbit as for the frog and toad, and for mechanical and chemical as well as electrical stimuli.⁴ Differences have been also observed in the neuromuscular mechanism of the larynx, the adductors responding to a weaker stimulus of the laryngeal branch of the vagus than that necessary to evoke a response in the abductors; and as regards the normal response to central nervous discharge, the abductors fail first through the local action of ether, cold, etc.⁵

A striking example of the varying excitability of the different nerve-fibres composing a nerve is furnished by the remarkable response of the crayfish muscles. The excitation of the nerve, with stimulus of

minimal intensity, evokes a contraction of the muscle opening the claw; with stronger stimuli the normal tonicity of this is actually diminished, whilst the muscle closing the claw is thrown into action. The results appear to show that there are two sets of nerve fibres, augmentor and inhibitory, for each muscle; hence the degree of excitability of these four sets of neuromuscular mechanisms is different for each set.

It is well known that the vago-sympathetic of the frog contains two sets of nerve fibres, the excitation of which causes in the one case inhibition and diminution, in the other augmentation and acceleration of the cardiac contraction. The former are stimulated by electrical currents which are too weak to excite the latter; on the other hand, the inhibitory fibres lose their excitability more rapidly than the augmentor.¹

The difference in the excitability of different nerves of the same animal, of which the above are illustrations, might be exemplified by many other instances; probably no two nerves are equally excitable. It is not, therefore, surprising that great differences exist in the nerves of widely different animals. One of the most striking instances of this is furnished by the electrical nerves supplying the electrical organs of fishes (*Torpedo*, *Malapterurus*, *Gymnotus*, etc.). These all possess a comparatively low degree of excitability. E. du Bois-Reymond claims for the whole nervous system of these fish, a low excitability, which confers upon them relative immunity to excitation by their own electrical shocks. Although the existence of such lessened excitability is questioned by Schönlein,² there is, in the opinion of the writer, little doubt as to its existence in *Malapterurus*. In this fish the nerve can only be adequately excited by an intensity of current out of all proportion to that requisite for the excitation of the frog's sciatic, the ratio being at least 100 to 1; whilst in neither *Torpedo* nor *Malapterurus* is the nerve at all readily excited by chemical agencies.³

A strict comparison of the excitability of different nerves is undoubtedly more or less vitiated by inequalities in the electrical resistance, by variations in the position and character of the sheathing investments, and still more by the unknown extent of alterations produced by exposure and dissection. Hence variations in excitability exist even with different regions of any single nerve, such as the frog's sciatic. Any dissection must inflict local injuries, and thus cause local heightened excitability. For this reason the upper two-thirds of the frog's sciatic, for some little time after dissection, is more excitable to electrical stimulation than the lower third, since more branches must be divided in exposing the upper part.⁴ The character of the electrical stimulus appears also to be a factor which has to be taken into account. Thus Fleischl found the excitability different for ascending and descending exciting currents, the former evoking a muscle response more easily in the distal than in the central portions, the latter the reverse.⁵ It has been already mentioned, that the

sciatic nerve in the living animal, with the circulation and central connections undisturbed, is equally excitable throughout its whole length to mechanical stimuli.¹ On the other hand, chemical stimuli (glycerin, NaCl, etc.), are far more effective with the peripheral than with the central portions of such a nerve. The results thus appear to be conflicting as regards comparative excitability of different regions of the same nerve, but undoubtedly some portions are less tolerant of the injurious effects of exposure than others; it is not improbable that unequal changes of this kind are the chief factors in determining the different excitability of the various nerves already referred to.

The conductivity of different portions of any nerve does not vary in so striking a manner as the excitability. There are, however, very great differences in the rate of transmission of structurally different nerves. Thus in the non-medullated nerves of the involuntary muscles, the rate of transmission was estimated by Chauveau as at most 8 metres per second; nearly four times as slow as that of medullated nerves to voluntary muscles. In the non-medullated nerves of *Octopus* a rate of 4 metres per second, in those of the *Anodon* a far slower rate of 1 cm. per second was found; whilst in the nerves to the mantle of *Eledone*, Uexküll found a rate of only one-half to 1 mm. per second.² In the medullated fibres of the electrical nerve of *Torpedo*, the rate is from 8 to 20 metres per second,³ whilst in the single medullated nerve fibre of the electrical organ of the *Malapterurus*, it is as rapid as that of the frog's sciatic, 28 metres per second.⁴

Attempts have been made to estimate the rate in afferent nerves, by utilising the reflex movement as an index of the amount of the transmitted excitatory state at the central nervous system. The results are undoubtedly ambiguous, through the uncertainty in the time relations of the reflex response, and when, as in experiments on man, the response is a voluntary one, involving the "personal time" of the individual, they become still more dubious. The only reliable data are rheotomic observations of the electrical response, and the rate of transmission in the afferent nerves of the frog appears with these methods to resemble closely that in efferent nerves. An inquiry of very great interest is that of the alteration in rate which occurs in the fine terminal arborisations of the nerves. Whether central or peripheral, these endings are such that the excitatory state has finally to leave the continuous axis cylinder and pass into other excitable tissues. It is known that an appreciable delay occurs under these circumstances; the central delay for afferent endings in the spinal cord is at least .006 sec., and may be considerably more; the peripheral delay in the case of a voluntary muscle has been already alluded to in the section dealing with muscle, it amounts to from .003 sec. to .005 sec.⁵ The electrical organ of *Malapterurus* furnishes an admirable object for the further investigation for this delay, as in this organ the nerve fibres split up, making a rich network in each electrical plate. The response of the organ producing an electrical shock is one which is

readily evoked by excitation, either of the nerve trunk or of the whole organ and its contained nerves. But whereas the muscular response is retarded by $\cdot 003$ sec. to $\cdot 005$ sec., with indirect as compared with direct modes of stimulation, no such difference is found in the electrical organ of either *Malapterurus* or *Torpedo*, provided the nerve trunk is excited close to its point of entry into the organ. In both cases a minimal delay of $\cdot 003$ sec. to $\cdot 005$ sec. occurs.¹ It would appear, therefore, that the electrical response is not that of another organ apart from the nerves, but is the excitatory change in the nerve-endings. If this is so, then the delay of $\cdot 003$ sec. to $\cdot 005$ sec. must be regarded as due to retarded transmission in the nerve arborisations. It is not improbable that a portion of the so-called excitatory time ($\cdot 003$ sec. to $\cdot 005$ sec.) of the motorial nerve-endings of muscle is in reality the time consumed by the slower rate of transmission along these fine nerve twigs, which thus resemble the non-medullated nerves in their retarded rate of propagation.

As regards the central terminations, we have no means at present of ascertaining how the extra delay is to be apportioned between the fine nerve-endings, the unknown field of conjunction, and the branches of the efferent cell through which it is discharged into the issuing efferent fibres. It is, however, logical to assume that in each one of these three situations the difference of structure involves a corresponding difference in the rate of propagation, and that central delay is the sum of the retardation in all these situations.

The transmission time through the substance of a nerve cell is commonly assumed to differ from that along a nerve fibre; but evidence of such difference cannot be said to be at all conclusive. For its ascertainment the preparation must be one in which the cell is bipolar, with processes on both sides of considerable length. Exner estimated the rate of propagation of the electrical nerve response along the sciatic nerve of the frog, through the posterior root ganglion into the posterior root, and found that the interposition of the ganglion did not appreciably affect the time relations of such excitatory electrical changes.² In opposition to this result is that of Wundt,³ who found the reflex response to be delayed when the ganglion formed part of the conducting afferent tract. Excitation on the proximal and distal side of the ganglion stellatum in *Eledone moschatus* is associated with an alteration in the muscular responses.⁴ Finally, Gad showed that the interposition of the vagus ganglion caused a very considerable retardation of from $\cdot 03$ sec. to $\cdot 04$ sec. in the respiratory centre inhibition, which is produced by excitation of the vagus trunk.⁵ It is not impossible that the change of the excitatory state in its passage through the ganglion cell may be of a complex kind, and that it may be so altered in character as to be a weaker afferent stimulus on its arrival at the central endings. Such a supposition would of itself account for the extra delay in the central response to impulses which have traversed the ganglion, irrespective of any additional retardation; hence the

results, although of great importance as indicating specific change in consequence of the interposition of the ganglion, cannot be taken as clear evidence that this change is brought about by decreased rapidity of transmission through the nerve cell. The delay, which is so marked a feature in the central nervous system, is obviously one involving nerve-endings and interposed breaches of continuity as well as nerve cells.¹

Influence of temperature upon nerve excitability and conductivity.—It has long been known that within certain limits the temperature of a nerve may be altered without causing any permanent impairment of its functions. The lower limit does not appear to be reached, even by a fall to 0° C.; the higher limit differs slightly in different animals, but is reached in the case of the frog by a temperature of 40° C., and in most mammals by one of 50° C.

In a remarkable work published in 1824, W. F. Edwards² dealt with the influence of many physical agents upon life, and described a number of interesting experiments as to the effects upon frogs, fish, etc., of prolonged immersion in the Seine when at different temperatures. The results showed that the low temperature of winter was far more favourable to life than the higher temperature of summer. The differences between winter and summer frogs are not improbably associated with the effect of rise of temperature, which augments the general tissue metabolism. It is well known that the nerves of summer frogs are less tolerant of exposure, but in addition the nerve functional activity as a whole is lowered. Thus the rate of propagation in the freshly prepared sciatic nerves of *R. esculenta* may be only 1.5 metres per sec. in summer, at 15° C., *i.e.*, half the rate obtained in winter specimens.³ These differences are caused by temperature affecting the whole organism. As regards the direct action of changes of temperature upon nerve trunks, permanent impairment is obviously caused by temperature alterations which exceed certain limits (45° C.), and temporary diminution or even abolition of function is produced by smaller variations within the limits, 0° C. to 40° C. One function, that of conductivity, appears to be very generally lowered by fall and augmented by rise of temperature up to 35° C.

It is otherwise with the property of excitability. It was long held that this was similarly augmented by a rise of temperature; but in opposition to this view was the well-known fact that the nerves of cooled frogs were far more excitable than those of frogs kept at the normal temperature.

In order to ascertain changes of excitability, it is necessary to eliminate as far as possible changes in the conductivity which may otherwise lead to erroneous conclusions as to excitability; this can be approximately affected by localising the change of temperature to a small portion of the nerve, and ascertaining the extent to which the minimal exciting intensity is changed in this region only. A further fruitful source of error is present when electrical currents are used as the exciting stimulus; this is due to the very marked alteration in the electrical resistance of the moist conductor which is produced by a change of temperature. Warming a moist electrolyte diminishes, cooling increases the resistance. A simple proof of this is afforded by the following experiment. An exciting induced current is allowed to traverse in succession similar portions of nerve in each of two muscle-nerve preparations

¹ See on this subject Schäfer's article "Nerve Cell" in this volume, p. 592.

² "De l'influence des agents physiques sur la vie," Paris, 1824.

³ Popielski, *Centralbl. f. Physiol.*, Leipzig u. Wien, 1896, No. 9, Bd. x.

(*A* and *B*), placed in the same circuit. A small glass tube through which water at different temperatures can flow is placed under the traversed region of *A*, and the intensity of the current is adjusted so that with both *A* and *B* at the normal temperature of 15° C., it is just adequate to excite and evoke in *B* a minimal contraction. On now warming the nerve of *A* a few degrees the contraction of *B* becomes maximal, on cooling it the contraction fails. Since the nerve of *B* is unaltered during the experiment, the apparent physiological alteration in its excitability is in reality due to physical increase and decrease in the current intensity through the change in the electrical resistance of *A*.¹

The experiments of Hirschberg, Efron, Howells,² etc., were made by stimulating with induction currents without providing against sources of error; hence the conclusion arrived at by them and others that nerve excitability is augmented by rise of temperature up to 35° C. cannot be legitimately deduced from their observations. The introduction of a sufficiently large external resistance, as in Fig. 254, renders any change of resistance too small to cause any marked alteration in current intensity. By using these and other precautions, it has been ascertained that nerve excitability is raised by local cooling for the following forms of external stimulus: galvanic currents, exciting either at closure or at opening; condenser discharges of large capacity; sinusoidal magneto-induction currents; mechanical and chemical stimuli. On the other hand, the excitability is definitely lowered by local cooling from 35° C. to 2° C., for the break induced currents (see Fig. 255) or discharges from condensers of small capacity.³ Galvanic and sinusoidal currents of very short duration, .002 sec. or under, appear to excite

FIG. 254.—*T*=Temperature tube under nerve. *R*=large resistance placed in exciting circuit, the nerve contacts of which are at *a* and *c*. The stimulating current is descending, and thus its closure excites at *c*.

rather better when the tissue is locally warmed from 2° C. to 35° C., but this augmentation is not so marked as in the case of the break induced current. It thus appears that whilst change of temperature alters the susceptibility of the nerve to excitation, the character of the alteration is one which is not the same for all methods of excitation. The results are the same for the motor nerves of the frog, rabbit, and cat, and for the afferent nerves. In the case of mechanical stimulation the augmentation of the excitability through cold is in harmony with the observation of Steinach, that in cooled frogs a single mechanical excitation can evoke a prolonged electrical response in the nerve.⁴

These facts can only be interpreted as indicating what various observations suggest, that break induced currents excite by the production of changes which are not of the same kind as those caused by

⁴ Steinach, *Arch. f. d. ges. Physiol.*, Bonn, 1894, Bd. lviii. S. 490.

more prolonged galvanic currents; the warmed nerve being in a state of greater molecular mobility, is best excited by energy which is rapidly applied for the purpose.¹

They also demonstrate that there is a difference between the susceptibility to respond to the action of an external agent (excitability), and the susceptibility to respond to the internal agent, that is, the excitatory state in the neighbouring portion of the nerve; this latter is the basis of nerve transmission (conductivity).

The propagation of the excitatory state is altered, as already stated, by changes of temperature, as regards both its rate and the magnitude of the transmitted excitatory state.

The alteration was observed by Helmholtz, who found that, in the case of the motor medullated nerves of the frog, the rate of transmission was lessened by cold and increased by heat up to 25° C.² In every class of nerve, and indeed in every excitable tissue through which an excitatory state is propagated by its successive establishment in

FIG. 255.—I, Response of gastrocnemius muscle to nerve excitation every 2 seconds by a break induced current. Temperature of nerve at seat of excitation varied from 5° to 30°, as indicated by recording thermometer, the rise of the line corresponding to rise of temperature. The stimulus becomes inadequate when the temperature falls. II, Nerve excited every 5 seconds by closure of a descending galvanic current. The stimulus becomes inadequate as the temperature rises.

different portions, the same alteration in the transmission of the excitatory change is produced by variations of temperature. On cooling a portion of a nerve, not only is the rate lessened, but the excitatory state diminishes in amount as it traverses the cooled region, and on emerging from this it continues with the same diminished intensity, so that it

evokes a smaller muscular response than it would otherwise do.

The employment of a series of uniform electrical stimulations recurring at regular intervals, and of minimal or nearly minimal exciting intensity, demonstrates this with great clearness. On cooling to 5° C. the muscular response is diminished or fails, on warming to 35° the response increases and becomes maximal (Fig. 256, A, left portion of record).

A striking discrepancy is sometimes obtained by the use of special modes of stimulation. Thus, if a short galvanic current or a condenser discharge, arranged to ascend the nerve, is used for the excitation of a portion of the frog's sciatic remote from the muscle, and the peripheral portion of the nerve is cooled 30 mm. below the seat of excitation,

¹ See Waller, "On the Characteristic of Nerve," *Journ. Physiol.*, Cambridge and London, vol. xxiv., *loc. cit.*, and *Proc. Roy. Soc. London*, 1899.

² Helmholtz, *loc. cit.*

it often happens that the muscular response is increased in intensity when the propagation has traversed such a cooled region of the nerve, and yet the rate of propagation is retarded (Fig. 256, B).¹

The cause of this anomaly may possibly be found in the simultaneous propagation of the condition produced at the proximal electrode of the ascending exciting current, the condition known as anelectrotonus. This is far more rapidly propagated than the excitatory state, and it appears to be less readily produced in the cold than in the warm. As it is a state of the nerve opposed to the change which constitutes an excitation, any local circumstances which diminish its extent will *ceteris paribus* augment that of the excitatory state by removing its inhibitory influence. The marked difference between excitation by descending and ascending currents under these circumstances favours this explanation of the anomaly.

The result opens up a most suggestive line of thought, since it implies that propagation is not necessarily the simple transmission of an excitatory change, but that it may be a complex disturbance, one element of which is derived from a specific alteration produced at the pole of a stimulating current. The transmitted effect thus may bear a specific character, determined by the nature of the external stimulating agent which evoked it. We are thus confronted by the possibility that an excitatory state, constituting by its

FIG. 256.

transmission what is familiarly termed a nervous impulse, may be different in kind when it is evoked by a different form of stimulus. It is scarcely necessary to dwell upon the importance of such variability in the character of the transmitted nerve effect due to variations in the character of the exciting cause. If true, its application to the excitatory phenomena of the sense organs would modify the doctrine of Johannes Müller, which assumes the peripheral sense organ to have been elaborated so as to be able, in response to specific stimuli, to start excitatory states, which are then propagated along nerve fibres having distinct terminal connections. Instead of this, it would be possible on physiological grounds to assume that excitatory states, evoked by different specific stimuli of the sense organ, might be transmitted along the same nerve fibre, and yet be so different as to cause in each instance a specific central response.²

Influence of chemical substances on excitability and conductivity.—The use of chemical substances for excitation has already been alluded to, and the response evoked by such means has been described as a series of muscular twitches, passing into a flickering tetanus and culminating in a prolonged continuous contraction.

If the kaolin paste forming the point of contact of a non-polarisable electrode is the medium for the salt, and arrangements are made such

¹ Gotch, *Journ. Roy. Inst.*, London, 1892.

² See also Rollett, *Arch. f. d. ges. Physiol.*, Bonn, 1899, Bd. lxxiv. S. 463.

that this is the cathode of an exciting galvanic or induced current, then, in the case of strong NaCl, the gradual alteration in excitability which precedes the appearance of these twitches may be readily observed. It will be found that an intensity of current, just inadequate to excite immediately after the electrode is placed in position, is in a very few minutes adequate, and that the passage of either the galvanic current or the induced current now evokes a maximal contraction. With a little longer time for the operation of the salt, the closure of the galvanic current evokes a closing continuous muscular contraction. The increased excitability thus renders the closing cathodic excitation fully adequate. In a similar way, if the anodic electrode is the salt contact, the opening of a current is rendered effectual, and an opening continuous contraction is evoked in the muscle, with an intensity of current which was inadequate under normal conditions to excite the nerve sufficiently to evoke even a twitch. The salt, NaCl, has thus raised the local excitability. The continuous contraction is due to the salt throwing the nerve into a state of continuous feeble excitation, but at first it stimulates it so slightly that the resultant transmitted nerve effect is unable to evoke the muscular response. The cathodic closure or anodic opening, with its rise of excitability, is sufficient to render this "latent excitation" adequate.

The most plausible view of the mode in which the nerve excitability is augmented by the salt is the following. The molecular equilibrium of the nerve is upset by the salt in the same manner as it is by any stimulating agent. The disturbance, however, is not in the first instance of sufficient magnitude to constitute an evident excitation, but it gradually becomes more pronounced, and may finally attain the requisite magnitude. In the earlier stages the equilibrium of the molecular state being upset, and thus rendered less stable, the action of any additional external disturbing agent readily causes the necessary magnitude of disturbance which constitutes an excitation. We have here an illustration of a fundamental characteristic of nerve. All stimulating agents, when too weak to be able to evoke an adequate excitation, operate upon the nerve so as to disturb it in a direction which, if more intense, would constitute an excitation, and they thus render it easier for an external stimulus to evoke the true excitatory effect, that is to say, they increase local excitability.

In the case of NaCl it is most probable that the *modus operandi* largely consists in the withdrawal of water from the nerve fibre, and that glycerin acts in a similar way. The withdrawal of water which takes place in drying, produces the same rise of excitability, passing on into a continuous excitation. It is difficult to localise its operation with the precision which the use of NaCl permits, but the careful experiments of Harless, Grünhagen, and others show that a nerve is more excitable to such stimuli as galvanic currents, when it is gradually dried.¹ The demonstration of this is carried out by experiments similar in character to that described with NaCl, but the drying of the nerve is effected far more slowly than the salt effect, even when, with a dry surrounding of high temperature, evaporation is favoured. The results of both NaCl and drying are most clearly brought forward by Biedermann in his *Elektrophysiologie*.²

¹ Harless, *Ztschr. f. rat. Med.* (3), Bd. vii. ; Grünhagen, *ibid.*, Bd. xvi.

² Biedermann, " *Elektrophysiologie*," 1895, S. 582.

A further point in connection with both these agencies is significant. Having first increased excitability, and then actually excited, they generally end by permanently impairing functional activity. This final extinction occurs rather suddenly, the excitability being first gradually diminished, and then rapidly disappearing, whilst conductivity is not notably affected for some little time afterwards. We have here another link in the chain of evidence which supports the distinction between these two forms of nerve activity.

Although there is but little doubt as to the general nature of the *modus operandi* of NaCl in augmenting nerve excitability, it is possible that other neutral salts may affect nerve by causing more specific chemical change than an alteration in the water content of the tissue, since this view, first put forward by Eckhard in regard to nerve, and extended by Kunkel to the action of ¹ neutral salts on muscle, does not explain the peculiar effect of certain salts.

Thus, in the case of KNO₃, though the effect described by Ranke is an initial increase with subsequent impairment of excitability, the latter phase is really dependent upon the nature of the stimulus.² Biedermann found that if the sciatic nerve of the frog is treated with a 1 per cent. solution of this salt, its excitability is lowered for most stimulating agencies. The passage of induced currents, or the closure of a galvanic current, evokes a far less pronounced muscular response than that produced by the same intensity of stimulating current before the treatment. On the other hand, the opening of the current now causes an excitation producing an opening muscular twitch, with a current intensity which, in the normal condition of the nerve, was quite inadequate to evoke an opening response.³

By placing the nerve in physiological NaCl (0.6 per cent.) for a few minutes, the conditions are again changed, and the nerve excitability restored to its normal condition. This remarkable opening effect will be alluded to again in dealing with the phenomena of polar excitation. It is introduced here to show that chemical agencies which lower excitability for one form of stimulation may raise it for another.

The comparative effects of various chemical substances upon nerve excitability has formed the subject of prolonged investigations carried out by Grützner. It has been already pointed out in connection with nerve excitation that such comparison can only be made when equimolecular solutions of the various salts are employed. The results of most interest as regards motor nerves are those relating to the action of neutral salts—their acid moieties, and their basic moieties.

FIG. 257.

Influence of neutral salts.—The alterations in local excitability of motor nerves through the action of neutral sodium salts is best expressed by the diagram (Fig. 257), in which the abscissæ indicate the

³ Biedermann, "Elektrophysiologie," 1895, S. 593.

time after the application of the salt, the ordinates the minimal exciting intensity of an induced current applied to the upper end of the nerve.

It is seen that sodium fluoride, 2.1 per cent., produces a very rapid rise in excitability, which soon subsides; and that sodium bromide 5.14 per cent., and chloride 2.92 per cent., each causes a rise which subsides comparatively slowly, whilst sodium iodide, 7.14 per cent., causes a fall. The middle and lower ends of the nerve are not so rapidly affected, and the rise when produced lasts longer; moreover, in these situations, all four salts cause a rise. Unlike sodium salts, all potassium salts lower the excitability for such stimuli as induced currents—potassium iodide more than potassium bromide, and potassium chloride least. Injurious effects are produced by any salt of sufficient concentration. These may amount to irreparable loss of excitability, or to an abeyance of this, from which the nerve may be recovered by immersion in isotonic indifferent liquids, blood serum or physiological saline solution. This loss of excitability is produced by some salts more rapidly than by others, the effect, as far as the bases are concerned, being in the following order:—K, Rub, Coes, Ca, Sr, Ba, Na. As regards the acid moieties of the neutral salts, the injurious action of iodine is more rapid than that of chlorine. It thus appears that initial rise of excitability to stimulation by induced currents is caused by appropriate solutions of sodium salts, and initial fall by potassium salts. In the section dealing with chemical stimulation, remarkable facts were referred to which showed that sensory nerves are more readily excited by potassium than by sodium salts, and it appears that the same difference is true as regards excitability, though the evidence on this point is more ambiguous.

The effect of salts upon the propagation of the excitatory state has not been so thoroughly investigated, owing to technical difficulties; the points of chief interest are those which show that conductivity is not affected to the same degree as excitability. It does not appear that an excitatory state is ever augmented during its propagation through a portion treated with NaCl; on the other hand, a gradual diminution in the intensity of the transmitted effect is often observed, and after prolonged action of the chemical reagent all propagation may cease. The final injurious influences upon conductivity, due to different salts, appears to be produced in the same order as those previously referred to in connection with excitability; in motor nerves potassium salts are more powerful in effecting them than sodium salts, and iodides than chlorides. All these chemical agencies, whether neutral salts, acids, alkalis, or other compounds, which, by their continued action, lower and finally abolish nerve excitability, will, if their action is further prolonged, lower and abolish conductivity; but, in most instances, excitability begins to fail some time before conductivity is appreciably affected. Thus the susceptibility to internal stimulation, which lies at the basis of nerve propagation, remains practically unaffected when, by the constant operation of a chemical substance, the susceptibility to stimulation by an external agent has partially or even wholly disappeared. A remarkable exception is that in which the sciatic nerve is treated in the middle of its course by such an agent as NaI 6.1 per cent. It can retain its diminished excitability to the induced current at this point when excitation of the central portion is quite ineffectual to evoke the muscular response; here conductivity appears to have

failed completely, whilst excitability is still present, though diminished.¹

The influence of anæsthetics.—It is the peculiar property of this class of chemical substances (ether, chloroform, carbonic acid, etc.) that they can diminish the functional attributes of living nerve fibres without causing any permanent impairment, and can do this when reaching the tissues through the blood, by inhalation, etc. The degree to which they affect the two main attributes of nerve fibres, excitability and conductivity, has been comparatively recently investigated in isolated nerve, and the results obtained by different observers are in some instances conflicting. The method for determining their direct action upon motor nerves is that first employed by Grünhagen in determining the effects of CO₂ gas.² This consisted in enclosing the middle portion of the sciatic nerve of a muscle-nerve preparation of the frog in a small chamber through which the gas could be passed (Fig. 258). The nerve could be excited either in the chamber or on the central side, and it was found that the passage of CO₂ gas caused the excitation by the induced current at X₂ within the chamber to be ineffectual, whilst similar excitation of the central end at X₁ still evoked the muscular response. Similar experiments by Luchsinger,³ in which the vapours of ether, chloroform, alcohol, and ammonia, as well as CO₂, were employed, showed results which

varied with the duration of the action of the vapour or gas. In the early stages the nerve in the chamber could no longer be excited so as to evoke a muscle response by an intensity of stimulus

FIG. 258.

which aroused it before the passage of the vapour, whilst excitation on the central side was unaffected; a subsequent stage was reached, in which even the strongest excitation of the central portion failed to evoke the response, whilst such strong excitation of the nerve in the chamber was still effective. This stage could be reached by CO₂ after fifteen to twenty minutes. Hirschberg repeated these experiments with CO₂ gas, but did not obtain the failure to the strong central excitation.

It is evident that the experiment is one of considerable importance in determining the extent to which excitability and conductivity are independent. The whole subject has been investigated with great care by Piotrowski.⁴ His observations were made along the same lines as the preceding, but were extended to include the action of several different modes of excitation, whilst the alterations of the nerve functions through the anæsthetic were determined in a variety of ways, including the variation in the extent of the muscle response evoked by an unaltered intensity of nerve stimulus, the variation in the intensity of the minimal adequate nerve stimulus, and the alteration in the rate of propagation of the nerve excitatory state.

³ *Ibid.*, Bd. xxiv.

⁴ *Arch. f. Physiol.*, Leipzig, 1893, S. 205-290.

The results were the same, whether the nerve stimulus was the induced current, the galvanic current, the condenser discharge, or mechanical compression; in all cases CO_2 or CO caused a marked diminution of the nerve excitability in the chamber, but had no such obvious effect upon the conductivity of this portion of nerve; on the cessation of the gas the excitability was rapidly restored to its normal value. On the other hand, alcohol vapour caused an initial increase in the local excitability and to a less degree in conductivity; this soon changed, the conductivity becoming rapidly impaired before the local excitability diminished; on the cessation of the alcohol vapour the normal conductivity and excitability were reinstated, but the latter returned quickly, the former much more slowly. A stage in the alcohol treatment was always obtained in which the excitation of the central end of the nerve was quite ineffectual, whilst that of the altered nerve in the chamber was increased in effectiveness. This result cannot be due simply to the fact that propagation occurs along a considerable length of the affected nerve when the excitation is central, but along a much smaller length when this occurs in the gas chamber. It is not due to the spread of the vapour or gas beyond the chamber to the central end, since simultaneous observation of the electrical change at this end shows that the central stimulus is not influenced as to its exciting value by the play of the gas or vapour on the more peripheral portion of the nerve. It must therefore be concluded that CO_2 and CO are agents which influence local excitability more than conductivity, whilst alcohol influences conductivity more than local excitability. The distinction between the effects of CO_2 and alcohol as regards conductivity is further demonstrated by determining the rate of propagation from the central excitation to the motorial nerve-endings. CO_2 and CO have but little influence upon this, whereas alcohol vapour causes a retardation from 28 to 4 metres per second.

Ether and chloroform act by diminishing both local excitability and conductivity; the former, however, is diminished much earlier and in a more pronounced manner than the latter. Thus, in one of the writer's experiments, ether vapour for thirty seconds produced a fall of local excitability such that the stimulus (break induction current) became quite inadequate, whilst conductivity, as tested by a similar central stimulus, was unimpaired. When the vapour was allowed to act for two minutes, the excitability was very much diminished, but still longer exposure was necessary to produce impairment of conductivity. On the cessation of the ether, the central excitation became again adequate in two minutes, showing the return of conductivity, whilst the local excitability did not reappear until fifteen minutes had elapsed, and even then was not restored completely for another ten minutes. Chloroform is far more toxic than ether; it produces the same effects, but is apt to permanently injure the nerve.

To the above experiments with ether, obtained under the direction of the present writer, may be added some with CO_2 . These show that it is always possible to abolish conductivity by this gas, but that excitability is invariably affected first, and the subsequent impairment of conductivity occurs only when the action of CO_2 is prolonged. Just as with ether, recovery takes place rapidly as regards conductivity, and far more slowly as regards excitability. Similar experiments with nitrous oxide showed no anæsthesia as affecting either nerve function; the local excitability seemed to be always slightly augmented by the

action of the gas, possibly through drying. The results may be compared with those obtained by Waller in isolated nerve, in which the electrical response is taken as the index of nerve excitation; these are referred to in detail in the section dealing with the electromotive phenomena.

Influence of electrical currents upon nerve excitability and conductivity—Polarisation changes.—The passage of electrical currents through a nerve causes profound changes in both its excitability and its conductivity. Since the nerve is a moist conductor, such passage produces electrolytic changes, which are most pronounced at the poles, *i.e.* the point of entry (anode) and point of exit (cathode). They spread in diminishing amount from these situations along the nerve fibres. These polarisation changes are presumably based upon the formation of electrolytic products or ions; they manifest themselves during closure by the establishment of an increased electrical resistance and extrapolar currents, on opening by the establishment of counter electromotive changes or polarisation currents, which in the intrapolar region are of opposite sign to the original or polarising current. The formation of ions, and thus the polarisation, may be distinguished broadly according to its locality as external and internal. When a current is led through a nerve by means of metallic electrodes, an extensive electrolytic change occurs at the actual points of metallic contact. The changes may be so pronounced as to produce on the opening of the polarising current a counter polarisation current of sufficient intensity to excite the nerve. Hence, if by means of metallic electrodes a galvanic current is led through the sciatic nerve of the frog, then, on the battery being disconnected, the closure and opening of the connections attached to the electrodes is accompanied by an excitation indicated by a muscular response.

Such external polarisation must mask the effect of any similar change in the nerve fibres themselves, and must be eliminated or reduced to very small proportions in all experiments in which electrical currents are used for nerve stimulation. It is reduced by employing platinum electrodes and currents of very short duration, and by arranging that, when a rapid series of these are used, they shall be alternate in direction, and as far as possible of similar duration and intensity. The make and break induced currents obtained by Helmholtz's modification (the side wire of the induction coil), are employed in order to attain this end. It is still further reduced by employing non-polarisable electrodes.

The most common form of such electrodes is that in which the metallic wire terminates in a zinc rod dipping into saturated sulphate of zinc, and this is connected to the nerve by means of an intervening moist conductor of physiological salt solution. Kaolin forms a convenient non-polarisable medium for the retention of the liquids, as it can be made into a paste and moulded to any desired shape. The actual contacts may be such paste, fine brushes, threads, or filter paper, steeped with the salt solution, or plastered by paste similarly steeped. Silver wires coated with a fine layer of fused silver chloride, and then covered with filter paper steeped in physiological salt solution, have been employed by D'Arsonval for similar purposes. Although advantageous in many respects, these electrodes offer a very large resistance, and are difficult to make as free from polarisation as the other form.

When a current is led through a nerve by non-polarisable electrodes,

although the external polarisation is comparatively insignificant, there is every indication of the formation of electrolytic ions within the nerve; this must be termed internal polarisation. It is dependent upon the structural and physiological properties of living nerve, and is especially marked in the case of medullated nerve fibres. It can be produced in any structure consisting of a better conducting continuous core, and a worse conducting moist envelope, such as the model devised by Hermann, in which a platinum wire lies within a tube of sulphate of zinc or saline solution. On closing the current, the internal polarisation changes are most intense at the poles (anode and cathode), but spread into the adjoining intrapolar and extrapolar regions.

These polarisation products are themselves electromotive, so that the nerve is in a peculiar condition termed by its discoverer, du Bois-Reymond, *electrotonus*.¹ It would be unprofitable at this stage to enter in any detail into these electrical effects, the foregoing reference being intended merely to introduce the excitability changes which are produced at the same time as these alterations in electrical state, and which have been therefore termed the electrotonic alterations in excitability.

Polar changes in excitability.—Pflüger's² work on this subject culminated in a series of general conclusions, deduced from a study of nerve, so careful and exhaustive, that the results have stood the test of time as few other physiological data have done. Subsequent work has extended but not materially modified the original statements, which may be briefly summed up as follows:—

1. Under the influence of a constant current flowing through a nerve, there is an increase in the nerve excitability, at and near the negative pole (cathode), a decrease at and near the positive pole (anode).

2. On the cessation of the current these changes are reversed, the cathode being the seat of a fall, and the anode that of a rise in excitability.

3. The alterations in excitability are most intense at the poles, but spread, diminishing with the distance into the intrapolar and extrapolar regions.

4. At some point in the intrapolar region the boundary between the two polar extensions is reached; this point is therefore unaffected, and is termed the indifference point.

5. The excitability changes are true for all forms of stimulation, electrical, mechanical, or chemical, and for both efferent and afferent nerves.

The experimental proof of the first two propositions is readily effected in a muscle-nerve preparation, by arranging so that a uniform stimulus of minimal exciting intensity is applied to the nerve just beyond the pole of the polarising current which is nearest to the muscle. If this pole be made the anode, the stimulus becomes, during closure, ineffectual; if the cathode, it becomes of maximal exciting intensity, and the alteration persists during the whole time of the closure of the current. A similar method demonstrates the anodic rise and the cathodic fall of excitability immediately after closure. The pronounced character of the alterations at the poles themselves can be ascertained by using such an arrangement as that employed by Grünhagen, in which a uniform exciting stimulus, the break or the make induced

¹ E. du Bois-Reymond, "Untersuchungen," *loc. cit.*

² "Electrotonus," Berlin, 1859.

current, is allowed to traverse the nerve by the same electrodes as those employed for the galvanic current, and is so directed as always to excite at the pole nearest the muscle.

The changes in an afferent nerve are demonstrable by similar experiments on the brainless frog, the more central pole and its neighbourhood being the seat of the uniform exciting stimulus, and the reflex response the index of the extent of the excitation thus produced.

The investigation of the changes in the intrapolar region is more difficult, since the employment of electrical modes of stimulation is impracticable, owing to the formation, at the exciting contacts, of a subsidiary intrapolar anode and cathode. By the use of mechanical or chemical modes of excitation, the intrapolar anodic and cathodic changes can be ascertained, and the position of the indifferent point determined.¹

The degree of anelectrotonic fall and catelectrotonic rise of excitability during closure, together with the extent of the spread of the two states, varies with the intensity and duration of the polarising current, and with the length of the nerve traversed by the current (*i.e.* the distance between the poles).

The influence of varying current intensity is shown diagrammatically in the left-hand portion of Fig. 259; the curves below the base line indicate anodic

FIG. 259.

fall, those above cathodic rise, of excitability, with *I.* weak, and *II.* strong currents respectively. It will be observed that the anodic fall tends to increase more than the cathodic rise, so that the indifferent point gradually gets closer to the cathode.

The right-hand portion of the diagram (Fig. 259) shows the influence of varying duration; here again the anodic change tends to spread at the expense of the cathodic. With currents of considerable intensity and prolonged duration, as in *III.*, the cathodic change may be completely swamped by the spread of the anodic into both extrapolar regions.

The influence of increasing the length of traversed nerve is easily demonstrated by passing the current through a long length of nerve, AC (Fig. 260), and testing the extrapolar excitability by induced currents at X.

FIG. 260.—The closure of K_1 allows a descending current to traverse the length of nerve from A to C. By opening K_1 and closing K_2 the current traverses the two lengths of nerve ($A'B'$ and BC). The length $AC = A'B' + BC$.

¹ Tigerstedt, *Mitth. v. physiol. Lab. d. Carolin, med.-chir. Inst. in Stockholm*, 1882, Bd. i.

portions of nerve together, equal in length to AC. Of these portions, one (A'B) is an isolated portion to make up the necessary length, the other (BC) is half the original nerve. The total resistance being the same in both cases, the current intensity is unaltered, but the anodic fall and cathodic rise at and near C is found to be far less marked in the second case.

The time relations of the effects.—(a) *Polar.*—Grünhagen interposed an induction coil in the polarising circuit, and excited with the make induction current caused by closing the polarising circuit; the nerve was thus stimulated the moment that the current flow commenced. Such an experiment establishes the fact that both the cathodic rise and anodic fall commence at the poles with no appreciable delay on the closure of the current. The electromotive effects of the polarisation changes have also been detected in the immediate neighbourhood of the poles, at an interval of .001 sec. after the closure of a very brief intense current, and are therefore in all probability instantaneous.

It may be pointed out that the absence of any delay is in harmony with the instantaneous character of the nerve electrical response to an exciting current.¹

(b) *Extrapolar.*—In regard to the development of the excitability changes in the extrapolar regions, there is considerable difference of view. The electromotive effects (electrotonic currents) have been detected by Hermann, Boruttau, etc., in the extrapolar regions of models and of nerve, very soon after their production at the poles, and hence the rate of their propagation has been considered as extremely rapid, 500 metres per second. On the other hand, Bernstein's investigation with the differential rheotome showed comparatively slow propagation of these electrotonic changes, 6 to 13 metres per second; the probable reasons for this discrepancy will be given in connection with electrotonus.

The recent work of Asher appears to indicate that the anelectrotonic fall spreads at a rate closely identical with that of the so-called nerve impulse. Kühne had shown by ingenious experiments that the motorial nerve-endings could be placed in the state of anelectrotonic decreased excitability. Thus a curarised sartorius is most excitable at the point of entry of its nerve, but this portion loses its predominant excitability when a galvanic current is led through the nerve, so that the anode is near the muscular termination. Further, glycerin excites the sartorius only through its nerves; it fails to do so if the muscle, with its entering nerves, is the anode of a galvanic current. Starting with such possibility of throwing the motorial nerve-endings into the anelectrotonic state, Asher arranged that a polarising current should be passed through the nerve, so that the anode should lie a known distance from the nerve termination. The muscle was excited directly by an induced current, and the polarising current closed either at the same instant, or at a definite interval before the excitation. There was no diminution in the response, unless the polarising current was closed .0007 sec. before the excitation; and on measuring the distance from the anode to the muscle, a propagation rate for the anelectrotonic decrease was deduced which corresponded with that of the nerve excitatory state, 30 metres per 1 sec.² The experiment led to the further interesting discovery that if the muscular response had commenced, the establishment of anelectrotonus in the nerve-endings had no effect upon the contraction. But grave doubt

¹ Bernstein, "Untersuch. ü. Nerven- u. Muskelsysteme."

² Asher, *Ztschr. f. Biol.*, 1895, Bd. xxxii.

is thrown upon the accuracy of Asher's conclusions by recent work done in Hermann's laboratory.¹ (See also footnote.)

Although the *extrapolar* development of the excitability alteration and of the electrotonic effects may not at present be considered as contemporaneous, the time relations of the development of these two states at the actual *poles* are closely similar. This parallelism between the formation of the electrotonic currents and the production of the excitability changes suggests a very close connection between the two classes of effects. It is probable that the electrotonic effects are due to what may be termed two different reactions in the nerve fibre, one the formation of ions, an electrolytic process rendered possible by the physical conditions presented by the living nerve structure, the other the establishment of prolonged excitatory changes with their accompanying electromotive phenomena. The further consideration of this may with advantage be postponed to the section dealing with the electromotive phenomena of nerve, but it may be pointed out that this second reaction is to a great extent the electrical indication of the alteration in excitability, which forms the proper subject of this section. It is not, therefore, surprising to find that the time relations of the development, in close proximity to the poles of excitability and of electrotonic changes, are to a large extent identical.

The two changes, excitability and electrotonic, both commence at the moment of closure, and they are both developed in increasing amount during the first period of such closure. Investigation with the rheotome shows that the anodic fall of excitability, and the anelectrotonic change, gradually increase at the anode during the continued flow of the current, and then slightly decrease; on the other hand, the cathodic rise and catelectrotonic change are both developed quickly, the development culminates much sooner than that of the anodic states, and may subside whilst the latter is still going on, if the closure is sufficiently long.

It is for this reason among others that duration of closure, apart from the intensity of the current, has such an appreciable effect upon the production and spread of excitability changes; the longer the duration, the more will the anodic fall overpower the subsiding cathodic rise, the indifference point moving at first nearer the cathode, until finally the anodic state may spread into the cathodic *extrapolar* region. For similar reasons a very short closure produces a cathodic rise of excitability, which is more obvious than the anodic fall, and thus a series of alternating induced currents, recurring at rapid intervals, will excite sufficiently to evoke a flickering muscle response, when one induced current of similar intensity and character is inadequate.

The excitability changes on the cessation of the current flow are to be regarded as due to a rebound of the tissue equilibrium, when released

¹ Hermann and Weiss, *Arch. f. d. ges. Physiol.*, Bonn, 1898, Bd. lxx. S. 237-296. The writer of this article agrees with the position taken up by Hermann, namely, that both the excitability and the electrotonic modifications commence almost instantaneously in all parts of the *extrapolar* regions. The fact that such modifications develop the more slowly and less extensively in the *extrapolar* region, as the region investigated is removed from the pole, accounts for many of the contradictory results hitherto obtained. A certain degree of change must occur before evidence, whether of decreased excitability or electrotonic effect, can be obtained; this degree can be attained instantaneously at the pole, but it may not be detected in the *extrapolar* region, although a feeble modification may have begun instantaneously even in this part. Such would be pre-eminently the case with the anodic effects, which have been those chiefly investigated.

from the new poise caused by the current. The anodic rise and cathodic fall both commence at the poles, on the moment of cessation with no appreciable delay; they probably extend from their polar seats of origin into extrapolar regions, although this has not been satisfactorily proved. The anodic polar rise is the most obvious; this is probably due to the fact that such opening effects are more demonstrable after long closures, and with these the anodic condition is always accentuated. Hence, during such a closure, the anodic fall is one which has to a great extent swamped the cathodic rise in consequence of its greater development, so that, on opening, the resulting anodic "rebound" is very appreciable, and a rise of excitability ensues, which increases to a maximum and then declines.

On the other hand, the circumstances which favour the cathodic rebound are, *cæteris paribus*, those which favour the production of the preceding cathodic rise; since, however, this rapidly attains its maximum and then subsides even during closure, the physiological condition which constitutes the rebound may be said to have begun even before the cessation of the current flow; hence, when such cessation occurs, the rebound constituting a cathodic fall of excitability is not a prominent feature. It is, however, demonstrable with closures of short duration, particularly by the use of mechanical excitation in the neighbourhood of the poles; this method has been employed by Tigerstedt with great success in the determination of the four polar excitability changes.¹

The whole cycle of change due to the passage of a current may be summed up as follows:—

<i>Closure.</i>	<i>Cessation.</i>
Anodic fall of excitability (<i>i.e.</i> greater stability of molecular equilibrium), established instantaneously, increasing slowly to a maximum, and slowly declining.	Anodic rise of excitability (rebound to lessened stability), established instantaneously, increasing, and subsiding slowly. ²
Cathodic rise of excitability (<i>i.e.</i> less stable molecular equilibrium), established instantaneously, increasing rapidly to a maximum, and subsiding quickly.	Cathodic fall of excitability (rebound to greater stability), established instantaneously and subsiding rapidly.

It has been suggested that the causation of the changes on cessation is to be found in the reversed or polarisation current, which is present in the nerve, and which is unmasked when the polarising current ceases; this, if present, would turn the former anode into a cathode, and *vice versa*. The changes on cessation would thus be, both as to causation and character, simply those due to the closure of a reversed polarisation current, which is unmasked by the cessation of the polarising one. This simple explanation has been applied, as it was logically compelled to be, to the explanation of the opening excitation as well as the excitability changes.³ There are, however,

¹ Tigerstedt, *loc. cit.*

² From experiments on the excitability produced on the nerves of man, Waller has concluded that the anodic fall produced by a closure may last for '03 sec. after the current has been opened, *Arch. de physiol. norm. et path.*, Paris, 1882, p. 383.

³ Tigerstedt, *Mitth. v. physiol. Lab. d. Carolin. med.-chir. Inst. in Stockholm*, "Biological Memoirs," Oxford, 1887, vol. i. p. 49.

many considerations which render it impossible to regard this as the sole cause. In the first place, it has been already indicated that the excitability after effects on cessation do not correspond in their time relations with those during closure; the anodic after effect is prolonged, unlike the cathodic closing effect. Secondly, the opening anodic excitation may be produced by merely diminishing the intensity of the polarising current to such a point that the reduced value of this is still in excess of the polarisation current, so that the latter does not come into play. Thirdly, as will be seen in the section dealing with the electromotive effects produced by currents, the anodic electrical response may be so pronounced and prolonged, on the cessation of the current, as to overpower the actual polarisation after effect, through its being of opposite sign, in which case no such reversal of poles can occur. Finally, in non-medullated nerves, such as those of the crayfish, etc., the amount of polarisation is relatively small, but the excitability changes both on closure and opening are extremely pronounced. There can be no question that the electrolytic phenomena, in so far as these are displayed by polarisation, profoundly modify the nerve conditions, but several facts render it difficult to assume that the polar changes of excitability are entirely dependent upon their presence. In many instances the two effects appear to be concomitant tissue reactions, but even in these cases the excitability changes, although intimately associated with the formation of ions, are presumably based upon a more subtle chemical rearrangement. As regards the nature of such rearrangement, the utmost that can be said is, that it presents itself in two phases, one of augmented, the other of lessened molecular stability. If an agent, such as a current, enforces by its continued passage the predominance of either phase, its cessation is followed by a rebound towards that of the other.

The alterations of excitability, due to the passage of electrical currents, may be caused by muscle or nerve demarcation currents. The latter is developed in the neighbourhood of a cut section or injury, the tissue here becoming galvanometrically negative to its surroundings; a current thus flows along the nerve fibres from the cut section, it then leaves the fibres to return by the juices of the tissue to the seat of its causation. The neighbourhood of a cut section is thus thrown into the condition of catelectrotonic rise of excitability, and in this way the increased excitability due to injury is explained.

Conductivity changes.—Nerve conductivity is also altered by the passage of electrical currents; this shows itself as an alteration, both in the magnitude of the transmitted excitatory change, and in the rate of propagation. The simplest demonstration of the former is that afforded by the following experiment. If the central part of the frog's sciatic be excited by a stimulus of minimal intensity, the resulting muscular response fails or is much diminished when a galvanic current is closed in either direction through the peripheral portion of the nerve. A more or less effective block for transmitted excitatory states is thus shown to be produced on and during closure at the anode; *i.e.*, the nerve in this region is rendered less responsive to the internal stimulus which is the basis of the transmission. The effect lasts for a little time after the cessation of the current, especially if this has been moderately intense and of short duration, but this after block is now localised at the cathode.

The closing anodic and opening cathodic blocks are evidenced in a different form of experiment, namely, that which affords evidence for the well-known third stage of Pfüger's law of contraction. Here the passage of an ascending current of considerable intensity excites, on closure, at the upper or central pole (the cathode), the transmission from this has to traverse the lower pole, the anode, and the size of the transmitted effect may in consequence be so much reduced as to be inadequate to evoke a muscular response. In a similar way the feeble muscular response evoked on opening a strong descending current is due to the inability of the opening excitation which occurs at the upper anodic contact, to force the after block present at the cathode. Both experiments show that the interference with conductivity must be established at the instant of closure and opening respectively. The terms block and after-block thus imply a condition of the tissue at the anode on closure, at the cathode on opening, in which conductivity is impaired. The degree of impairment, *i.e.* the extent of the block, depends primarily upon the intensity of the polarising current causing the change, but it also depends upon the duration of the closure; for although the anodic blocking commences at the instant of closure, it resembles the anodic fall in excitability in being augmented during the continued flow of the current. Thus a current of very short duration does not impair anodic conductivity to the same extent as one of long duration, and it may often happen that the stimulation of that portion of a nerve, central to the polarising current, may be at first adequate to force the block and evoke the muscle response, but may cease to be adequate as the polarising current continues to flow, rendering the block far more complete. An experiment illustrating this is the following. A series of galvanic currents of sufficient but uniform intensity are closed at regular intervals in the ascending direction through the sciatic nerve of the frog. The duration of closure is gradually increased from a minimal time of about $\cdot 001$ sec. or less. As the duration of each current is increased, the muscular response, which at first is not present, commences and increases in magnitude; it then diminishes and can utterly fail; finally, it reappears again, and may reattain its initial maximal size.¹ The failure, termed by Fick, the gap, is obviously due to an effective block at the lower anodic pole, and the resultant interference with the propagation of the excitatory effect evoked on closure at the upper cathodic pole. This block is only rendered adequate when a certain duration of current flow has been reached; beyond this point the return of the contraction is due to the opening excitation at the anodic lower pole. Increased duration thus acts like increased intensity in augmenting the anodic block, and the variation of either of these factors when the other is kept uniform can produce similar results. Thus the passage of a series of very brief galvanic currents of constant duration, but variable intensity, causes the same series of phenomena; the muscular responses appear when a certain intensity is reached, increase in size, and then diminish until they fail, and finally they reappear again and attain a definite maximum. The same results can even be obtained by the use of ascending induced currents, and their employment furnishes another proof of the truth of the statement, that the anodic interference, although produced at the

¹ Fick, *Sitzungsb. d. k. Akad. d. Wissensch.*, Wien, 1862-63, Abth. 3, Bde. xlvi., xlvii., xlvi.

instant of closure, is increased with the duration of the current which causes it, for Tigerstedt found that the more prolonged make induced currents gave the results far more easily than the more rapidly developed currents caused by the complete break of the primary coil circuit.¹

The above are experimental demonstrations in motor nerve of the effect of the anodic block, or cathodic after-block, upon the intensity of the excitatory change which has to be propagated through the altered region.

These alterations in conductivity, like those in excitability, have been shown to be valid for excitatory states evoked by all varieties of local stimuli, electrical, mechanical, and chemical, as well as for those due to discharge from the central nervous system. They are present in afferent as well as efferent nerves, and can be demonstrated in these by using the reflex response as the index of the propagation.

A further question upon which there is at present but little information is, whether transmission through the cathodic region during closure, or through the anodic on opening, augments the propagated excitatory state. As a rule the blocking effects more than counterbalance any such augmentation.

In order to reduce these, the most effective method is that in which tripolar leads are used for the galvanic currents.

The arrangement allows of three poles, for instance, an anode *B*, with a cathode on each side, at *A* and *C*, as in Fig. 261. During closure the excitation of a break induced current at *X*, above the

FIG. 261.

centripolar cathode *A*, evokes a far more pronounced muscle response than can be obtained by the reversed arrangement, with the cathode at *B* and the anodes at *A* and *C*. In both cases the same length of nerve is subjected to current flow; hence it may be inferred that the excitatory change in the first tripolar arrangement gathers force during its transmission through the second cathodic region.² A similar but less marked augmentation has been observed by the present writer, when, with the cathode in the middle and two anodes, one on each side, the nerve is excited at *X* immediately after the galvanic current is opened. In both instances the closure must be of short duration, and the current intensity comparatively low.

In addition to these changes in the magnitude of the transmitted effect, the polar conditions undoubtedly affect the rate of propagation.

The simplest proof of such alteration in rate is furnished by the experiments of von Bezold, whose work forms a valuable extension of Pflüger's.³ The method was utilised by Rutherford,⁴ and has been employed by the present writer. In its simplest form it consists in the

repetition of the classical transmission experiment of Helmholtz, with the addition of a polarising current on the central side of both exciting contacts (Fig. 262).

FIG. 262.

During the passage at *A* of an ascending galvanic current (of at most 0.5 Daniell), the maximal muscular responses evoked by excitation, with adequate induced current at the proximal and distal points *B* and *C*, are separated by a much larger interval than is normally the case; if the current is descending, the interval is less than the normal. von Bezold found that both currents increased the difference, but Rutherford found that the descending current diminished it, and the

FIG. 263.

present writer can fully confirm this observation. The curves in Fig. 263 are instances of such cathodic acceleration and anodic retardation; *C* being cathodic, *A* anodic, and the uppermost curves normal.

It will be observed that by this method the exciting stimuli are applied to the extrapolar region. If the whole polar region is interposed between the exciting electrode and the muscle, the conditions are

far more complex. I have been unable to find evidence of any marked alteration in propagation rate, unless the polarising current is intense or of prolonged duration, in which case it is always retarded. The presence of two polar regions, a cathodic accelerating and an anodic retarding, causes the one change to counterbalance the other; when, however, the conditions are such that the anodic effect is intense and the cathodic diminished, then retardation is observed. von Bezold's experiments involved the use of currents of considerable intensity and duration, hence the retardation found by him in all cases.

Even the opening changes can be seen to influence the rate of propagation. I have found that the opening cathodic retards more than the opening anodic, provided that the current has been of small intensity, short duration, and that excitation by induced currents occurs within one second of the opening.

Another proof of such polar effect on the rate of propagation is furnished by the increased duration of the delay of the indirect muscular response to polar excitation of its nerve by the galvanic current.

It is evident that the only cases of marked increase in delay are those in which the cathodic closing and anodic opening excitation are situated, so that the intrapolar region lies between them and the muscle, and the galvanic current is of some intensity. It appears to the writer that the chief factor in the production of the more marked delay is the slower propagation which

occurs in a nerve, the total functional capacity of which has fallen through the experimental procedure; such a fall, particularly in the intrapolar region, is produced in consequence of the passage of currents of considerable intensity, and is manifested by delayed transmission lasting for some little time after the current has ceased. Localised changes of a less pronounced type, at the anode on closure and at the cathode on opening, undoubtedly cause slight retardation, and account for those cases where the extra delay is small.

POLAR EXCITATION OF NERVE BY ELECTRICAL CURRENTS.

Pflüger's law of contraction.—The passage of a galvanic current through a motor nerve of sufficient duration to allow the muscular response evoked at closure to be distinct from that at opening, causes effects which vary in accordance with the intensity and direction of the current; they may be tabulated as regards their production into stages as follows:—

Pflüger's Law of Contraction.

	CURRENT INTENSITY.	ASCENDING DIRECTION.		DESCENDING DIRECTION.	
		Closure.	Opening.	Closure.	Opening.
First Stage .	Weak.	Minimal twitch.	...	Minimal twitch.	...
Second Stage .	Moderate.	Maximal twitch.	Minimal twitch.	Maximal twitch.	Minimal twitch.
Third Stage .	{ Stronger.	Minimal twitch.	Maximal twitch.	Maximal twitch.	Minimal twitch.
	{ Very Strong.	...	Maximal twitch.	Maximal twitch.	...

The muscular effects produced in the first two stages are dependent upon the circumstance that, at closure, the nerve excitation takes place at the cathode, and is associated with the sudden development of the state of lessened molecular stability; at the moment of cessation it takes place at the anode, and is associated with the sudden rebound

¹ The delay in the response to nerve excitation by the closing or opening of the galvanic current is in each case compared with that present when the nerve is excited by an induced current.

from the state of increased stability. Of these the first is the most effectual; it is therefore produced by weaker currents than those necessary to evoke the opening effect (Pflüger).

The effects in the third stage are due to such excitation, modified by the polar interferences with conductivity described in the preceding chapter. The nerve is locally excited, both at the cathode on closure and at the anode on cessation, the stimulation being more intense than in the preceding stages; but in the case of a motor nerve the excitatory state started by the cathodic excitation of an ascending current has to traverse the anodic region, and is greatly diminished in the passage, so that it evokes either a minimal or no muscular response.

Similarly, the descending current excites at both poles, but that started at the anode on its cessation has to traverse a region in which catelectrotonus is disappearing, and its propagation is interfered with in the same way, but complete block is more difficult to attain.

In afferent nerves the reflex response is used as the index, but the same laws hold good, although modified in the third stage. Since the effective propagation is now towards the central nervous system, it follows that in the third stage it is the descending current which fails to evoke the closing, and the ascending one which fails to evoke the opening reflex effect.¹

That the excitation on closure does actually occur at the cathode, and that on opening at the anode, may be directly demonstrated in nerve by experiments of the following kind. If a portion of a motor nerve be locally raised in excitability by such an agent as fall of temperature, then the closure of a very weak galvanic current causes a local excitation adequate to evoke a maximal muscular effect, provided that the cathode coincides with the altered region; on the other hand, when the anode coincides with this region, then, with an intensity of current too weak to adequately excite at closure, an opening response may be obtained. By locally raising the temperature, and thus diminishing the susceptibility to stimulation, the reverse effects can be produced. Finally, by locally raising the temperature at one pole and lowering it at the other, the passage of a current of appropriate intensity in either direction will excite only at the pole which is situated upon the cooled region; if this is the cathode the excitation occurs on closure, if the anode it occurs on opening.²

Any agent which causes a local alteration in excitability may be utilised for demonstrating the polar site of the excitation; temperature is convenient as it produces no permanent effect, but the local application of NaCl may be used for increasing local excitability, and gives the same results; the closure being effective when the salt is on the cathodic region, the opening when on the anodic. Ammonia may be used for abolishing local excitability, and the failure of cathodic closing or anodic opening excitation is then observed when either of these poles corresponds with the impaired region. By similar experiments it can be shown that the intrapolar region is not the seat of this sudden stimulation on closure and opening; it is limited to the neighbourhood of the poles. As the nerve loses its excitability by any of the previously described agencies, arrest of circulation, etc., the exciting effects of the stronger currents alter from the third to the second and finally to the first of Pflüger's three stages.³

¹ Pflüger, *loc. cit.*

² Gotch and Macdonald, *Journ. Physiol.*, Cambridge and London, 1896, vol. xx. p. 257.

³ Rosenthal and v. Bezold, *Arch. f. Anat., Physiol. u. wissenschaft. Med.*, 1859.

Apart from such variations in the general excitability of the nerve, the effectiveness of these polar excitatory phenomena is dependent upon the intensity of the polar change itself. This is mainly determined by four factors: intensity of current, direction of current, length of nerve subjected to the influence of the current, duration of current.

These have all been briefly referred to in the section dealing with modes of excitation. It has been already stated that a current loses its exciting value if the direction of flow is across the nerve fibres; this is not due to the increased resistance, nor to the failure of polarisation, since polarisation, owing to the multiple anodes and cathodes (each nerve fibre traversed having its own set), is more prominent than when an equal length of nerve is subjected to a longitudinally directed current flow. It must therefore be due to the interference of the two nerve disturbances, the cathodic lessened stability and the anodic augmented stability of the nerve equilibrium so balancing each other on the current closure that excitation (*i.e.* sudden lessened stability) becomes impracticable.

The local separation of these two states is thus an important factor in determining efficient polar excitation. It is for this reason that a nerve is excited more effectually the greater the length which is subjected to the longitudinal flow. In order to ascertain the fact, it is essential to eliminate the effect of increased electrical resistance, and the consequent diminution in current intensity produced by the greater length of nerve through which the current is led. The elimination may be approximately effected by using a very large external resistance, in comparison with which the alteration in nerve resistance becomes a negligible quantity. In this way du Bois-Reymond showed that the extrapolar electromotive changes associated with electrotonus are augmented by increase in the length of nerve between the poles.¹

Marcuse placed the nerve in a trough of physiological NaCl solution, arranged so that a current could be led through it; alteration in the length of nerve dipping in the trough now makes no appreciable difference in resistance.² He found that the minimal exciting current was of less intensity in proportion as the length of nerve traversed was increased; beyond a certain limit, the favourable influence of polar separation became gradually diminished, and disappeared. The result was the same whether the direction of current flow was ascending or descending. The simple method described in connection with excitability (see Fig. 260) also affords a ready means of ascertaining the same fact. A more remarkable influence is that afforded by multipolar contacts, first suggested by Setschenow,³ and employed in a modified form by Danilewsky.⁴

The arrangement for such contacts consists in placing upon the nerve three electrodes (*A, B, C*), at equal distances as in Fig. 264; these are so connected with the electromotive source that the current flow has its point of exit at the middle electrode, and its points of entry at the peripheral ones; by reversing the current direction, the points of exit are peripheral and central to the point of entry. A special side attachment with another nerve permits of

the exclusion of the centripolar electrode (*A*), without interfering with the resistance or current intensity; in the figure the opening of K_1 and K_3 , and the closure of K_2 , must produce the familiar bipolar arrangement of contacts *B*, *C*.

FIG. 264.

Danilewsky found that all stages of Pflüger's law were demonstrable with the tripolar as with the ordinary bipolar arrangement, but, with the tripolar arrangement, excitation both at closure and at opening was effectually produced by an intensity of current which was inadequate with bipolar contacts. This difference was obtained whether the direction of the currents was through the myopolar and centripolar regions of nerve to the middle point, or the reverse. It thus appears that the doubling of the intrapolar region favours excitation by electrical currents, even when this doubling is one which involves the presence of two symmetrically altered regions meeting at a middle point.

Both the length of nerve submitted to the action of the current and the number of poles are thus clearly shown to be important factors in determining the efficiency of excitation by electrical currents. The importance of the duplication of poles is further demonstrated by experiments in which alternating induced currents are used for excitation of a motor nerve. With the tripolar arrangement a muscular response can be evoked with induced currents which are quite inadequate to cause the response with the ordinary bipolar contacts.

The effect of the duration of the current upon polar excitation has been incidentally mentioned several times. The rapid development of catelectrotonus, and the slower development of anelectrotonus, causes currents of moderate strength, but of short duration, to excite only on closure, *i.e.* at the cathode. This is the case with condenser discharges, break induced currents, and short galvanic currents. In the case of the latter, a limit can be reached even for this cathodic excitation of medullated nerves, the minimum exciting duration at 15° C. being .0015 sec.;¹ it appears to be longer in nerves cooled to 0° C., amounting then to .02 sec.,² and is also longer in nerves the excitability of which has been lowered by excision, etc.³ With non-medullated nerves (*Anodon*) the limit and consequent failure is reached with still longer duration.⁴

The experimental proof of the main fact, that induced currents, unless intense, excite at the cathode only, is readily effected by the use of local alterations of temperature in the manner previously indicated, for these currents excite better when the seat of excitation is

⁴ Biedermann, "Elektrophysiologie," 1895, S. 546.

locally warmed. It can be easily demonstrated that an excitation of minimal exciting intensity becomes more effectual when the cathode of the induced current is on the region whose excitability to the stimulating agent has been thus locally augmented, but remains unaltered when the anode is on this region.

It has, however, been already pointed out that it is possible to obtain evidence of anodic alterations in both excitability and conductivity with rapid induced currents of sufficient intensity, and by similar means it is possible to demonstrate the existence of opening anodic excitation. The experiments previously referred to, in which, through a series of *ascending* induced currents of gradually increasing intensity, a series of muscular responses are evoked, which attain a maximum, then fail, and finally reappear, afford an illustration of this. The responses occurring after the failure are characterised by two peculiarities: the earlier ones have a prolonged period of delay, the characteristic of those evoked by weak opening anodic excitation, and the later ones are often larger than those of a single twitch. This is most probably due to a summation of effect in the muscle through two effective nerve stimulations occurring in succession, on closure at cathode and on opening at anode. The anodic block is insufficient to resist the intense state transmitted from the cathode, whilst the response to the anodic opening excitation, since it occurs later, is sufficiently retarded to produce with the former a summated muscular effect. In similar experiments with *descending* currents of short duration, there is no such failure, but the muscular response with gradually increasing intensity becomes augmented. The absence of failure is in strict accordance with Pfüger's law of contraction, since in this case the cathodic seat of the closing excitation is nearest the muscle; the sudden development of the augmented response implies a summated effect, due to the propagation of two successive nerve impulses, the first evoked on closure at the cathode being followed on the cessation of the brief current by one evoked at the anode.¹

That both poles can be the seats of an effective nerve excitation by intense induced currents, is confirmed by experiments in which the anodic pole is placed on the nerve near the muscle, and the cathodic near the central end. If the cathode only were the exciting point, then the period of delay between excitation and muscular response must be longer when the current is ascending than when it is descending, since the cathodic seat of excitation is in the former case distal, in the latter proximal to the muscle. If, however, a double excitation can occur at both poles, there should be, with adequate current intensity, but little perceptible difference in the time relations dependent upon change of direction. The latter appears, according to Mareš, to be the case.²

Pfüger's law of contraction in its first and second stages, and to some extent in its third stage, thus holds good for currents of short duration, though the anodic results are only obtained with currents of very considerable intensity.

The causation of the closing and opening excitation.—As stated by Pfüger, the closing excitation is associated with the sudden establishment of catelectrotonus, the opening one with the sudden disappearance of anelectrotonus.

¹ Fick, *loc. cit.*

² *Sitzungsb. d. k. böhm. Gesellsch. d. Wissensch.*, Prag, 1891.

There is little doubt that this statement expresses the general conditions underlying polar excitation of medullated nerves; instances, however, occur, due to the interference of unsuspected currents in the nerve, which have led some writers to attempt to associate all excitation with catelectrotonus only.

Influence of the demarcation current.—The opening contraction is generally obtained only on the cessation of currents of some intensity; it can, however, be obtained by much weaker currents, under the following conditions¹:—

If the nerve is divided from the spinal cord, and the cathode placed near the cross section, the opening excitation is produced with very weak ascending currents. As these increase in intensity, it fails to reappear again with currents of moderate strength. The earlier opening excitation of the ascending current may be due to the unmasking of the descending demarcation current. There are, however, other currents which will reinforce this. The galvanic current is succeeded by polarisation after effects; these polarisation currents are such as to make the anode into a cathode; they are unmasked by the cessation of the current flow, and may be adequate to evoke an excitation, especially if they coincide in direction with the feeble demarcation current. The opening excitation, if caused in this way, is in reality based not

FIG. 265.— K_1 =key in derived circuit of rheochord (rh); K_2 =key in battery circuit of rheochord. The darker arrow indicates the nerve demarcation current, the thin arrow indicates the battery derivation.

upon the disappearance of anelectrotonus, but, like the closing one, on the production of catelectrotonus, through feeble polarisation currents in the opposite direction to the original current summing with that of the nerve demarcation change.

That the demarcation current when it exists in some intensity, as in freshly injured nerve, can profoundly modify the results which are expressed in Pflüger's law, is shown, further, by Hering's experiments.² In these a nerve was used with a fresh cut section, and it was observed that the minimal intensity of the battery current adequate for excitation varied with the position K_1 and K_2 of the key which effects the closure and opening (see Fig. 265). If this is in the electrode circuit of the rheochord, at K_1 , its closure makes a circuit not only for the derivation of the battery current, but in addition for that of any nerve current present. If it is at K_2 , in the battery circuit of the rheochord, it makes a circuit for the voltaic current only, whilst the nerve current is continually flowing through the derived part of the rheochord circuit. It thus depends upon the respective directions of the battery current and nerve current what the precise variation will be as regards closing and opening excitation.

If the rheochord derivation is about equal to the nerve current, and

¹ Grützner, *Arch. f. d. ges. Physiol.*, Bonn, Bd. xxvii. S. 1882.

² Hering, *Sitzungsber. d. k. Akad. d. Wissensch.*, Wien, 1882, Bd. lxxxv. Abth. 3, S. 237.

the battery circuit key, K_2 , is kept closed, then the closure of K_1 simply completes the circuit for two equal and opposite derivations, one from the rheochord, the other from the nerve; it has therefore no exciting effect either on closure or on opening. With the electrode key, K_1 , closed, and K_2 open, a circuit for the nerve derivation is completed; although the closure of K_2 may not evoke contraction, its opening evokes one. The closure under these conditions brings about, in reality, the sudden cessation of the nerve current through the oppositely directed battery current, and the opening causes the reinstatement of the nerve current in its full intensity *plus* polarisation currents.

With a descending current since this is in the same direction as the nerve current, both the closure and the opening of K_1 evoke effects far more readily than the closure of K_2 .

Influence of polarisation currents.—A second means for increasing the exciting efficiency of the opening of a current is closely related to the above. It is efficacious in any region of the nerve, and in uninjured nerves (*i.e.* connected with the spinal cord) as well as in those with a cross section. It is best illustrated by an experimental description. A nerve having been prepared, is excited by the closure of a current too weak to excite on its cessation; an intense current is now used, which excites both at closure and cessation; and it is then found that, following this, the former weak current now excites both at closure and at opening. The polarisation after-current is here increased in its intensity by summing with that caused by its predecessors; and on opening it is unmasked, and, being suddenly established, excites at the anode, which is now its cathode.

The above facts show that there are circumstances under which an apparent opening excitation is in reality the closure of an oppositely directed current; hence the excitation in these instances is, as in the closing one, based upon the sudden development of catelectrotonus, which, owing to the altered direction of the after effects, occurs at what was the anode of the polarising current.

This view is further supported by the fact that such opening excitations, with their resultant muscular contractions, have the same time relations as the closing ones, the period of delay being identical in the two cases; whilst Tigerstedt found that such opening excitation is favoured by all agents which increase the actual amount of the polarisation current, as estimated by appropriate galvanometric methods.¹

It thus appears that, since the sudden establishment of catelectrotonus produces a closing single excitation, the same sudden establishment of catelectrotonus through polarisation currents, etc., if it occurs on opening at the anode, must produce an opening excitation. There is, however, ample proof that this is not the only factor concerned in the opening excitation. The matter has been already partly referred to; further evidence will now be adduced to show that we are still bound to employ Pflüger's expression, and assume that the disappearance of the state of anelectrotonus determines an excitation as well as the appearance of that of catelectrotonus.

Excitation in consequence of the disappearance of anelectrotonus is to be regarded as a rebound of the tissue from a greater state of stability (inexcitability) towards one of molecular instability. Biedermann has brought forward demonstrative evidence that the excitation

¹ Tigerstedt, "Biological Memoirs," Oxford, 1887, vol. i. pp. 49-74.

thus produced may possess special characters of which the most prominent is that of its duration. The evidence is founded upon the phenomena known as Ritter's tetanus, in which excitation is prolonged both during closure and after opening, but the conditions which favour the closing do not necessarily favour the opening effects.

Opening and closing tetanus.—The passage of strong currents through a motor nerve may cause not merely the third stage of Pflüger's law, but a prolonged excitation indicated by a continuous contraction of the muscle. This starts in the case of the ascending current at the moment of cessation, the phenomenon being known as Ritter's opening tetanus. In the case of the descending current it may occur during closure as a closing tetanus. In both cases the term "continuous contraction" expresses the condition far more precisely than the term "tetanus," since there is no proof of repeated excitation.

The opening tetanus with ascending currents is due to a state of prolonged excitation at the anode. This is shown by the following facts. If the effect is present, the severance of the nerve in the intrapolar region above the anodic pole does not stop the continuous contraction. It ceases if the current is again closed through the intact nerve, so as to make the anode the seat not of opening but of closing changes. The effect, if present, is increased if a current is closed in the reverse direction, thus making what was formerly the anode into a cathode. A continuous opening contraction can be obtained after the prolonged action of weaker currents, especially if the direction has been reversed several times, and the circuit opened when the current is ascending. This opening contraction is undoubtedly associated with the production of extensive anelectrotonus, which, owing to its spread, takes some time to disappear, and prolonged excitatory electromotive changes are now found in the nerve in the region of the anode.

Both the closing and the opening prolonged effects can be obtained with comparatively weak currents, if the region of the exciting pole is the seat of a continuous excitation too weak to evoke a muscular response; such a state is produced either by local drying, or by the local application of concentrated NaCl solution. If the whole nerve is treated with NaCl, then, since it is throughout in this condition of slight inadequate excitation, the closure of a comparatively weak descending current, or the opening of such an ascending one, now evokes a prolonged contraction in the muscle.

In these instances, of which Fig. 266 is an example, the current effect acts by producing changes in excitability rather than true excitation phenomena; continuous excitation is produced by the chemical or mechanical stimuli; it is made effectual on closure at the cathode, and on opening at the anode.¹ In other words, a "latent" (*i.e.* inadequate) nerve excitation is rendered adequate by the increased excitability which accompanies the closure at the cathode and follows the opening at the anode. That this condition may produce the results was shown by Grünhagen.² A nerve is traversed near its central end by an inadequate series of rapidly recurring induced currents; the passage of a current may now cause either a closing or an opening tetanus resembling in its time relations and form that just described. There is thus no evidence, so far, of any prolonged excitation by the

¹ Engelmann, *Arch. f. d. ges. Physiol.*, Bonn, 1870, Bd. iii. S. 403.

² *Ibid.*, 1871, Bd. iv. S. 548.

galvanic current, but only of the familiar alterations in excitability; and as regards the closing tetanus, it appears that in the medullated nerve of the frog the phenomenon is generally of this nature.

It is otherwise with the facts to be now detailed as to the opening contraction, in which it will be noted that, although the alterations in excitability are in all cases present, the effects cannot be accounted for by "latent" excitation.

It was shown by Mommsen¹ that weak alcoholic solutions of NaCl (1 per cent.) slightly increase the excitability of motor nerves which have been immersed in it. If such a nerve is subjected, on removal from the solution, to stimulation by weak ascending galvanic currents at periodic intervals, it is found that the closure evokes a large single contraction, and that in a few minutes the opening of the current evokes not merely the single twitch, but following this a prolonged contraction.

That the nerve itself is not in this instance continuously stimulated by the solution, is shown by the fact that no spontaneous contraction is evoked by its action alone; the excitability increases to a certain point,

FIG. 266.

and then remains in this condition. There is little doubt that the part played by the current in causing this continuous opening contraction is not the mere production of a prolonged local rise of excitability, but a true prolonged opening excitation, which is effectual because of the greater general excitability of the nerve.

The muscular response to the opening excitation shows two peculiarities: it is delayed in its appearance so as to occur at a distinct interval after the opening twitch, and it is dependent as to size and form upon the duration of the current closure.

In the last respect it differs from the opening tetanus, which has been previously described as produced in a nerve which is continuously but inadequately excited by drying or by concentrated NaCl. In these cases, when the opening of a weak current evokes the continuous effect, it is impossible to separate its start from that of the opening twitch. In the nerve treated with the alcoholic solution, the prolonged opening effect is produced only on the cessation of moderately strong currents, and varies directly with the length of the previous closure.²

¹ *Virchow's Archiv*, Bd. lxxxiii. S. 261.

² Biedermann, "Elektrophysiologie," 1895, S. 587.

A necessary condition for its production is the increased excitability of the nerve. Other chemical agents may be employed for increasing nerve excitability. In cooled nerves it sometimes happens that the opening of an ascending current evokes the single twitch, followed by a prolonged contraction, having the same characters as that seen in the above case.

The opening of the current may thus produce two excitation phenomena,—one sudden and rapidly developed, indicated by the initial opening twitch; the other prolonged and more slowly developed, indicated by the continuous contraction. These cannot be identical as to their causation, since it is possible to place the nerve under conditions which favour the production of the one, although they disfavour that of the other. General increase in excitability, such as that produced by immersion in 1 per cent. NaCl (alcoholic solution), favours the production of both effects; but a general decrease in excitability can be caused by appropriate reagents, which will disfavour the second whilst favouring the first. The most striking of these reagents are 10 per cent. solution of NaCl and 1 per cent. solution of KNO_3 .¹ If the nerve is immersed in the latter solution, the following facts are observed. Immediately after its removal a single twitch is evoked in the muscle by the closure of an ascending current, and on opening an initial single twitch is evoked which may, under appropriate conditions, be succeeded by a prolonged muscular response. As the experiment is repeated, the closing excitation response becomes feebler, showing gradual decrease in excitability; the opening initial single twitch becomes larger, whilst the prolonged opening effect becomes small and finally disappears. By placing the nerve in physiological salt solution, all these phenomena are replaced by those obtained in a normal nerve; they may be again produced by fresh immersion in the KNO_3 solution.

Hence it appears that the two opening effects differ as regards the condition of nerve most suitable for their manifestation. The single excitation evoking the twitch is favoured by some conditions which cause general lowering of excitability; the prolonged response is favoured by general rise of excitability. The probable causation of the initial opening effect is the polarisation after effect, aided by the demarcation nerve current, if this is of sufficient intensity and appropriate direction; the causation of the second continuous response is a prolonged molecular change, coincident with the gradual disappearance of anelectrotonus, in other words, a rebound of the nerve equilibrium from an enforced state of greater stability into one of instability.

As already stated, the closing tetanus in the frog appears to be an effect in which a continuous "latent" excitation becomes adequate at the cathode, through the local rise in excitability during closure. There are, however, clear indications that in some nerves there are prolonged excitation phenomena, even at closure.

The most striking instances of such closing effects are furnished by the results of the elaborate experiments made by Biedermann upon the non-medullated nerves of the muscles which open and close the claw of the crayfish; these experiments also afford demonstrative evidence of the validity of the above conclusions as to the character of the opening excitation.²

¹ Biedermann, "Elektrophysiologie," 1895, S. 590-594.

² Biedermann, *Sitzungsber. d. k. Akad. d. Wissensch.*, Wien, 1888, Bd. xcvi. Abth. 3, S. 49.

Polar excitation of the nerves of the crayfish.—The response to the excitation of the nerves supplying the claw is remarkable, inasmuch as a weak adequate stimulus, such as the faradic current, evokes augmentation of the tonic contraction of the abductor or opening muscle, at the same time that it causes relaxation of that of the adductor or closing muscle; on the other hand, a more intense stimulus of a similar kind causes an augmentation in the adductor contraction, accompanied by the relaxation of the abductor.

To account for this, we must assume the existence of four sets of nerves differing in the degree of their excitability, and in their susceptibility to respond to different external stimuli; the four sets comprise an augmentor and inhibitory set for each muscle.

The polar excitation of such a nerve trunk by galvanic currents is thus extraordinarily complicated, since to the inhibitory influences of the poles themselves must be added those produced by the polar excitation of the inhibitory nerves.

The simplest experiments are those made upon a preparation in which one muscle is dissected free of its insertion, and employed when it has lost its tonicity. In such a preparation all the three stages of Pflüger's law can be demonstrated, but there is this difference between

FIG. 267.

the results and those observed in the nerve-muscle preparation of the frog, the muscular contractions evoked at opening and closing are in all cases prolonged.¹ If, on the other hand, the muscle retains its tonicity, then the passage of a current in either direction evokes more complex effects. In the case of the adductor muscle (Fig. 267) the results are as follows:—

When the nerve is excited by weak currents, three changes are seen—*a*, an initial contraction on closure (*m* in Fig. 267), or an augmentation of tonicity, due to the excitation of the augmentor fibres; *b*, a persistent relaxation succeeding *a*, slowly subsiding during the closure, due to the inhibition of the effect; *c*, the return of the muscle to its normal state of tonicity on opening the current.

With more intense currents these effects are profoundly altered (see Fig. 267, right-hand figure). (*a*) The initial augmentation is fused with a persistent one, due to a prolonged excitation of the augmentor overpowering that of the inhibitory fibres; (*b*) this may be succeeded during closure by relaxation, and this again by contraction, so that a conflict between the response due to persistent excitation of augmentor and inhibitory nerve fibres occurs, in this conflict the augmentor effect has the advantage; (*c*) on opening, there is a relaxation of the muscle

¹ Biedermann, "Elektrophysiologie," 1895, S. 602-604.

due to a weak opening excitation of the inhibitory fibres, as in 1, *b*.

The results show that, as far as the closing excitation is concerned, this is of a twofold character, one set of nerve fibres being excited strongly on the instant of closure, whilst the other set is excited by the persistence of such closure, and that by altering the intensity of the current either set may be excited during the whole time that the circuit is closed.

Experiments with the abductor muscle prepared in a similar way give, as might be anticipated, different results; if the muscle still possesses tonicity, then the following facts are observed when the nerve is excited by weak and strong currents respectively (Fig. 268):—

Weak currents (abductor muscle).—Closure—(a) An initial relaxation due to excitation of the inhibitory fibres; (*b*) a prolonged persistent augmentation of tonicity (*i.e.* contraction) succeeding (*a*), lasting during closure, and due to the excitation of the augmentor fibres. *Opening—(c)* The return of the muscle to its normal state, this being fused with a more prolonged relaxation, which slowly passes away,

FIG. 268.

due to the weaker opening excitation of the inhibitory fibres, evoking a repetition of (*a*).

With stronger currents (Fig. 268, right-hand figure) the effects are changed—(*a*) The initial relaxation on closure becomes fused with a more prolonged effect of the same kind; (*b*) a conflict occurs during closure between the prolonged relaxation now evoked and a succeeding augmentation, due to simultaneous prolonged excitation of both sets of fibres, in which conflict the relaxation has the advantage for some time, but is finally overpowered; (*c*) on *opening*, an initial relaxation occurs succeeded by a prolonged augmentation, due to the overpowering effect of excitation of the augmentor fibres.

These results show that both at closure and at opening a twofold excitation occurs, those at the opening of a strong current being similar in character to such closure effects as are evoked by a weak one.

The interpretation here given rests on the supposition that the effects are all due to the excitation of augmentor and inhibitory nerve fibres supplying each muscle. It might, however, be urged that the second prolonged effect is in each case an actual polar inhibition; thus the closure effects in the abductor muscle might be excitation of the inhibitory set of fibres at the cathode, succeeded by overpowering inhibition of such excitation at the other pole, anode. This would

obviously cause an initial relaxation, succeeded by a return to tonicity, *i.e.* an augmentation. A further experiment makes it clear that such bipolar interference effects are not the causative factors. The abductor muscle free from tonus cannot relax in response to the excitation of its inhibitory nerve fibres, and any subsequent tonicity cannot therefore be due to anodic interference with such cathodic excitation of inhibitory fibres. Such a muscle shows no alteration at the instant the current is made, but the tonicity still develops during the closure. It must therefore be due to prolonged excitation of the augmentor nerves, the muscular effect of which is retarded in its onset. This retardation is undoubtedly due to the impairment of conductivity, since it becomes more pronounced as the stimulating current is increased in intensity.

The nerves to the muscles of the crayfish claw, owing to their different degrees of excitability, and to the distinctive characters of the muscular response evoked by their excitation, thus furnish an admirable object for demonstrating the possibility of polar excitation being a prolonged state.

The results do much to confirm the truth of Biedermann's views as to the twofold character of polar excitation in the medullated nerves of voluntary muscle.¹ These are pre-eminently susceptible under normal circumstances to the onset or cessation of current flow, but they can be so altered as to respond, in addition, to the prolonged polar change following current flow. The nerves of some other structures respond normally to both the initial and the prolonged changes. E. du Bois-Reymond's law of excitation, which places rapidity of variation in current intensity as the effective determinant of exciting efficiency, applies only to the production of the initial excitations, and is not therefore of general application. The efferent nerve appears to be differentiated, so that its susceptibility to the form of stimulus shall be related to the activity of the peripheral responding mechanism; if a continuous response is that most appropriate for the discharge of its functions, the nerve is susceptible to the continuous form of excitation.

It is in consequence of such varying susceptibility that certain nerves are incapable of electrical stimulation by currents of short duration, unless these are rapidly repeated. Thus the vasomotor nerves, whose stimulation in the cervical sympathetic causes constriction of the vessels in the rabbit's ear, are not easily excited by a single induced current, though readily excited by a series of such currents; the secretory nerves, such as the glosso-pharyngeal, the excitation of which causes secretory and corresponding electromotive changes in the frog's tongue, are readily stimulated by the closure and opening of galvanic currents of some duration, but are only slightly excited, if at all, by induced currents.²

Polar excitation in man.—The polar excitation of a nerve is complicated when this is surrounded by a mass of conducting tissue. In all the experiments previously referred to, care is taken to insure that the nerve between and on each side of the poles is free; but when, as in the excitation of nerves in man, one electrode is applied to the skin over the course of a nerve, it is clear that, though this may represent truly

¹ Biedermann, "Elektrophysiologie," 1895, S. 596, 597.

² Biedermann, *Arch. f. d. ges. Physiol.*, Bonn, 1893, Bd. liv. S. 241.

either an anode or a cathode, the polar region thus constituted is surrounded on all sides by what may be termed a peripolar region of opposite sign. The conditions are such that in the polar region of the actual electrode the current density will be most marked, whilst in the peripolar region it will be far less. With gradually increasing intensities of current, the muscular response to stimulation over the entry of the nerve must vary in consequence of these conditions. This is shown by the results given in the following table:¹—

Current Intensity.	Character of Surface Pole.	Condition of Circuit.	Effect observed.	Explanation of Result.
Weak	Cathode.	Closure.	Minimal response.	Polar cathodic excitation.
"	Anode.	"	Nil.	...
"	Cathode.	Opening.	Nil.	...
"	Anode.	"	Nil.	...
Moderate	Cathode.	Closure.	Maximal response.	Polar cathodic excitation.
"	Anode.	"	Minimal response.	Peripolar cathodic excitation.
"	Cathode.	Opening.	Nil.	...
"	Anode.	"	Minimal response.	Polar anodic excitation.
Strong	Cathode.	Closure.	Prolonged response.	Polar cathodic excitation.
"	Anode.	"	Maximal response.	Peripolar cathodic excitation.
"	Cathode.	Opening.	Minimal response.	Peripolar anodic excitation.
"	Anode.	"	Maximal response.	Polar anodic excitation.

A portion of the peripolar region is obviously on the myopolar side of the polar, and thus may cause conductivity changes when the current is sufficiently intense.

This and the great difference between the denser polar and diffuse peripolar regions readily explains the occurrence of the responses, which are therefore really in accordance with Pflüger's law as determined in isolated nerve. Two interesting features come into special prominence by the use of this method upon man. First, the prolonged response on the closure of strong currents with cathode upon surface; secondly, the marked increase in the period of delay in the muscular response to the opening polar anodic excitation. This was found by Waller to amount to 0.03 sec. It appears that the delay is associated with impairment in conductivity from which the nerve does not recover until 0.03 sec. after the current has ceased to flow.² Although, therefore, the excitation occurs at the moment of opening, the impairment of conductivity persists and delays the propagation of the excitatory state.

In these respects the results confirm those obtained on isolated nerve, though in man they are modified by the diffuse peripolar and intense polar condition previously referred to.

Polar excitation of peripheral sensory organs.—*Taste organs.*—If a current traverses the tongue in man, an acid taste is localised at the contact when the anode is on the tongue, an alkaline or salt taste when the cathode is placed there. The sensations last during the whole time of closure, are reversed on the cessation of the current, and can be obtained with unpolarisable electrodes.³ The susceptibility of the taste organs to such excitation is extremely delicate. The acid anodic

¹ Waller and de Watteville, *Phil. Trans.*, London, 1882; *Proc. Roy. Soc. London*, 1882.

² Waller, *Arch. de physiol. norm. et path.*, Paris, 1882, p. 383.

³ Rosenthal, *Arch. f. Anat., Physiol. u. wissensch. Med.*, 1860; *Biol. Centralbl.*, Bd. vi. S. 120.

effect is appreciated when non-polarisable electrodes are used with a current intensity of only $\frac{1}{156}$ milliampere.¹

The effects may be due to the excitation of specific taste organs, or to the presence of electrolytic products. It is undoubtedly due to the stimulation of the peripheral organ at the pole, and not to excitation of the larger branches of the gustatory nerves, since it is much diminished by the local application to the surface of cocain, which dulls all taste sensations. That it is not the mere effect of acid and alkali, due to electrolytic decomposition, is shown by the circumstance that the sensations are present when no evidence of such chemical products can be found.²

The change in the sensation on the cessation of the current may be caused by the reversed polarisation current coming into play, but in any case it is of the nature of an opening excitatory change. The production of greater instability (dissimilation process) in a peripheral sense organ constitutes an excitation of a specific kind, and the resultant excitatory state, when propagated to the higher centres, is thus the physiological basis of a specific sensation. If the production of greater stability (assimilation process) is also an excitation, it must be of fundamentally different character. Both the propagated nerve states and the result in consciousness will thus differ from those associated with greater instability. The two states are linked together, since the production of either is followed by a rebound into the other condition. This is the view held by Hering in reference to visual contrast, and the taste effects are so nearly parallel, as far as the antagonism of effect with after-effect is concerned, as to fall in with his conceptions.

The visual organs.—If the poles of a galvanic current of sufficient intensity are placed one on the forehead and one on the neck, both the closure and the opening cause an effect which appears to consciousness as the sensation produced by a flash of light. More intense currents produce effects not only at but during closure. These differ with the direction of the current, and are best obtained when one electrode is placed over the shut eyelid.

There is considerable disagreement as to the character of the sensation experienced under these conditions, but the majority of observers concur in the following particulars.³ When the anode is on the eyelid, the flash at closure has the appearance of a violet field with dark centre. This is succeeded by field illumination during the maintenance of the current flow, which slowly subsides, and often appears of a violet or blue hue. On opening the current, there is a bright blue centre with an outside field of yellowish green, or, according to Helmholtz, orange.

With the cathode on the eyelid, the effects are more or less reversed. At the instant of closure the centre is bright and blue, the outside field dark. This persists, but with diminishing intensity, during closure, and, on cessation of the current, is succeeded by opposite effects—the centre being greenish yellow and the external field blue. Hence the centre appears of a hue in contrast with its surrounding, and is, according to Helmholtz, associated as to its peripheral origin with the entry of the optic nerve or blind spot. On this supposition it represents a retinal area which is incapable of appropriate stimulation by the current.

The results as to the visual characters of the field appear to show

¹ Laserstein, *Arch. f. d. ges. Physiol.*, Bonn, Bd. xlix. S. 519.

² v. Vintschgau, see Hermann, "Handbuch," Bd. iii. (2), S. 186.

³ Helmholtz, "Physiol. Optik," 2te Aufl. S. 243 *et seq.*

that during the flow of a current directed through the retina from the layer of nerve cells to that of the rods and cones (anode on the eyelid), the retinal excitation is such as to give the consciousness of bright colour, the flow in the opposite direction is such as to give the consciousness of a dark contrast colour. In such instances the visual characters of the field must be taken as those associated with the retinal excitation, the visual characters of the centre being due to contrast.

These results, although showing discrepancies in the hands of different observers, may be taken as indicating, first, the existence of both initial and prolonged closing and opening excitation effects; and, secondly, the existence of polar excitatory results of opposite kind, but so linked that the production of the one is succeeded by that of the other. They are thus in conformity with the views as to the nature of polar excitation of nerve, which have been set forth in the preceding pages.

ELECTROMOTIVE CHANGES IN UNEXCITED NERVE.

General characters of the nerve current.—It was discovered in 1845 by du Bois-Reymond that persistent electromotive changes might be detected in all nerves.¹ The main features of such changes in an excised nerve may be summed up as follows:—

1. Two symmetrical points on the longitudinal surface of a nerve are equipotential.

2. If one point is nearer a cross-section than the other, a difference of potential is observed, the former being galvanometrically negative to the latter.

3. The maximum difference of potential is observed when one point is the cross section itself and the other the longitudinal surface, the tissue at the section being now markedly negative to that of the surface.

FIG. 269.

The nerve fibres of an excised nerve are thus traversed by axial currents, directed from the cross section along the fibres; and since the nerve is a moist conductor, a closed

circuit for the spread of such currents is afforded by the adjacent nerve fibres and by the moist surroundings. The electrical distribution and direction of the currents are indicated in the annexed diagram (Fig. 269), and since these are present in nerves which may be regarded, at any rate for the present, as unexcited, they may be conveniently described as *currents of rest*.

The amount of the difference of potential varies with the degree of approximation of the terminal contact to the cross section; hence the source of the electromotive change is undoubtedly to be found in the difference between the molecular state of the nerve at any point of its length, and that in the immediate vicinity of the cross section; the critical point is localised in the zone of demarcation between the

¹ du Bois-Reymond, "Untersuchungen," Bd. ii. (1), S. 239.

normal tissue and the altered portion of the actual cross section, the resting nerve current has been therefore termed the demarcation current.

Methods of producing so-called resting or demarcation nerve currents.—*Cross section.*—Every cross section of a nerve brings into prominence the above-mentioned difference. It is, however, somewhat difficult in the case of a small nerve to adjust the contacts, so that one shall be effectively connected with the cross section; a more certain method for attaining the same result is furnished by “thermal section.” This is accomplished by dipping the end of an excised nerve for a brief space into physiological saline at 60° C., so that several mm. of the nerve may be suddenly destroyed; the boundary zone between such a destroyed portion and the normal tissue is practically the same as that present on a cross section, whilst the destroyed end now serves as an indifferent moist conductor to connect the whole of the cross section with the necessary contact.

Localised injury.—Instead of the end, any intermediate portion of the nerve may be similarly injured by local heat, compression, etc.; its boundary zones on each side are demarcation areas between the normal and the injured fibres, and the injured part is thus galvanometrically negative to either portion of the normal longitudinal surface. Partial localised injuries of this kind involving superficial fibres of a nerve trunk may be readily produced by nerve exposure, with the result that, owing to the formation of demarcation zones, the electromotive changes just referred to are now observed.

Temperature.—Localised alterations of the temperature of nerve fibres are accompanied by electromotive changes, even when the temperature change is such as to cause no persistent injury. Thus, with two symmetrical contacts showing isoelectrical conditions, localised warmth to 30° C., in the immediate neighbourhood of one causes the tissue at this point to become galvanometrically positive to that of the cooler region; localised cooling produces the opposite condition.

The methods of ascertaining the characters of the nerve current.—The experimental demonstration of resting nerve currents in the tissue under any of the preceding conditions is one in which the recording instrument may be a high resistance galvanometer, a capillary electrometer, or such a physiological galvanoscope as is afforded by a muscle-nerve preparation. The special precautions attending such demonstration cannot be entered upon here, but some features presented by nerve in common with other moist conductors must be briefly referred to. These are related to the use of the compensator, the restriction of all such investigations to the examination of derivation effects, and the electrical resistance of the nerves themselves.

The compensator is a graduated rheochord of definite resistance, so constructed that it allows the experimental circuit to comprise a known electromotive force, the amount of which can be varied at will. It is thus possible to exactly counterbalance any current in the instrumental circuit due to electromotive changes at the tissue contacts, by means of one of precisely equal amount but opposite sign. The amount of the antagonistic electromotive force which has thus to be employed is a measure of the amount of that present under the tissue contacts. This latter is, in reality, that produced when an electromotive source is surrounded by a moist conductor, and contacts are placed upon two points of the surface of the latter; such a condition, for instance, as is present when two small pieces of dissimilar metals are embedded within a cylinder of kaolin soaked in 0.6 per cent. NaCl. It is obvious that the whole of this moist conductor is now traversed by derivation currents, and

that different points of its surface will show corresponding differences of electrical potential. When a current is obtained in the experimental circuit between any two points of the surface, and is counterbalanced by a suitable external electromotive source, the latter is not a measure of the electromotive change in the interior of the investigated source, but only of the surface differences. Supposing, therefore, that the surface itself is altered, and its electrical resistance changed by increase of moisture, then the current compensation is no longer adequate, since alterations in electrical distribution occur in the new moist envelope. The estimation of the amount of the electromotive force in resting nerve is in like manner that of the amount of surface distribution, and the real value of the change present at the electromotive source is not determined. Other things being equal, the surface change varies directly with that of the interior; but the surface change may be but a fraction of the amount of the electromotive difference present within the nerve fibres. Since the nerve is a moist conductor, its electrical resistance is increased by cooling and diminished by warming. The resistance is very large; in the case of the sciatic nerve of the frog it is about 100,000 ohms for each longitudinal centimetre of nerve; it is also greater to currents flowing across the nerve fibres than to those flowing in the direction of their axis, being five times as great in the former case. The resistance is best determined by balancing the nerve resistance against a variable one, after the method of Kohlrausch. In this a series of alternating induced currents traverse a Wheatstone bridge and a portion of nerve; a telephone suitably connected indicates by its silence when the balance is complete.

The influence of various conditions upon the amount and duration of the resting currents.—The amount of the electromotive difference between the surface and cross section of a nerve, as indicated by the amount of the surface derivation, varies in accordance with the structural character and physiological condition of the tissue.

(a) *The character of the nerve.*—Any mixed nerve, such as the sciatic, will show an electromotive difference between surface and cross section. The amount of this difference does not appear to be entirely dependent upon cross sectional area, although the surface distribution must be largely influenced by this. Thus both the slender nerve of the frog and the larger one of the dog are capable of giving a high difference ($\cdot 02$ D), whilst the large nerve of the horse and the smaller one of the monkey give low differences ($\cdot 008$ D).¹ This is also the case in such a nerve as the large second electrical nerve of *Torpedo*, which, with 24,000 fibres, gives only $\cdot 007$ D.² The amount is thus related to the source of the nerve, *i.e.* the animal from which it is taken, and is probably an expression of the varying susceptibility of the nerve to the particular molecular change which produces the demarcation effect. This is itself dependent upon the extent to which the uninjured surface of the nerve retains its vital properties and still possesses the particular molecular state which characterises the living tissue. All circumstances which impair functional capacity diminish the magnitude of the effect.

The differences just referred to may thus be related to variations in the functional attributes of the nerves of the various animals mentioned. But, in addition to this, the amount of the resting electrical difference is associated with structural peculiarities of the nerve fibres. Thus non-medullated nerves give far larger differences of potential than medullated ones. The fine nerves in such inverte-

¹ See Biedermann, "Elektrophysiologie," 1895, S. 638.

² du Bois-Reymond, *Sitzungsber. d. k. Preuss. Akad. d. Wissensch.*, Berlin, 1883.

brates as the lobster give $\cdot 048 D$,¹ in *Anodon* and in *Eledone* $\cdot 026 D$.² In vertebrates, the olfactory of the pike gives $\cdot 02 D$, whereas medullated nerves from this fish of the same cross sectional area gave only $\cdot 01 D$.³ A still greater contrast is that between the sciatic nerve and the spinal cord; the latter gives a very large cross sectional difference of potential, $\cdot 046 D$ in the cat, and $\cdot 029 D$ in the monkey. These latter differences are not due to the larger cross sectional area, since, on comparing the cord of a small monkey with a sciatic nerve from a large animal of the same species, the cord difference was found to be three times that of the nerve.⁴

Finally, in many nerves, the difference varies with the locality of the cross section. A striking illustration of this is afforded by comparing the lumbar posterior roots with the whole sciatic nerve. In the cat the seventh lumbar root gave $\cdot 026 D$, whereas the whole sciatic nerve gave only $\cdot 018 D$.⁴ It appears, further, that in many purely afferent nerves a more central cross section is more effective than a more peripheral one, so that, on connecting the two cross sections by appropriate contacts, the more central is galvanometrically negative to the more peripheral, and a similar difference is found between two points on the longitudinal surface, when equidistant from their respective cross sections.⁵ On the other hand, in some purely efferent nerves, this relationship is reversed. Thus, in the efferent electrical nerves of *Torpedo*, the increased negativity of a peripheral cross section over a more central one amounts to $\cdot 002 D$.⁶

It is not improbable that these results are, to some extent, associated with the varying susceptibility of the nerve fibres to injury through external agencies owing to differences in the sheaths, etc., of the different regions.

If the phenomena in question are present, the one in all afferent, the other in all efferent fibres, then, in a mixed nerve, the results must vary in proportion as the afferent fibres are more or less numerous than the efferent ones. As a matter of fact, such a mixed nerve as the sciatic gives results which vary with the position of the cross section.

The large electromotive effect obtained with non-medullated nerves shows that the medullary sheath plays little or no part in the production of the difference. If the sources of the change are localised in the axis cylinders, the absence of such an additional moist envelope would serve to bring the experimental contacts into far closer proximity with the electromotive source, and the large difference would be explicable.

It is probable, however, that although the absence of the sheath must be a prominent factor in producing larger effects, it is the electromotive characters of the axis cylinders themselves which are the most potent factor. Hence we are led to infer that different axis cylinders vary as regards the amount of the electromotive change, which can be brought into prominence by their cross section.

(b) *Temperature*.—In any nerve which shows the resting cross

sectional difference, local warming in the neighbourhood of the cross section up to 35° C. increases, whilst local cooling diminishes the amount of the electrical derivation. It is not clear how far such increase and diminution is dependent upon the alteration in the resistance of the moist conductor, with its consequent variation in electrical distribution. There are, however, other considerations in connection with excitatory electromotive changes which afford a basis for the belief that temperature also acts upon the source of the electromotive change in such a way that warmth increases the susceptibility of the axis cylinders to the alterations produced in the neighbourhood of the cross section.

(c) *Connection with nerve cells.*—The functional and structural alterations which follow the severance of their cellular connection cause very marked changes in the nerve fibres as regards the production of the resting electromotive differences. As might be assumed, the onset of the degenerative processes is associated with diminished demarcation difference. It is interesting to note that such difference, although diminished in amount, can be observed in degenerated mammalian nerve after the functional attribute of conductivity has disappeared. The interruption of continuity, which is the cause of the latter, occurs at intervals along the whole course of the fibres, but histological examination in this earlier stage of the process shows that any cross section may comprise fragments of axis cylinders with their medullary sheaths. The existence of the cross sectional difference of potential shows that even in their altered condition such fragments are still susceptible of the change which is the basis of the resting difference.

The electromotive source under these circumstances is presumably localised in the fragments of swollen axis cylinders which happen to be included in the area of the cross section, for, when complete degeneration has been attained, no cross sectional difference is found. Thus, if a portion of a nervous column be completely degenerated, the normal amount of the resting difference of such a tissue is very much diminished. Examples of this are the following: the difference in the normal spinal cord of the cat on the lower dorsal region was found to average .03 D; after section of all the lumbar posterior roots three months previously, the difference was only .012 D; after hemisection above the investigated area three months previously, it was .018 D, and .02 D after degeneration through section of one posterior column below the investigated area.¹ In these cases the lower values are chiefly due to the substitution of some nerve fibres by a layer of indifferently conducting tissue, thus increasing the moist envelope; but it is possible that the remaining fibres, although apparently normal in structure, may have lost their susceptibility to the production of the electromotive effect, and that in addition to the increased connective tissue envelope, there is a diminution in the amount of the electromotive change produced in the apparently sound fibres.

(d) *Arrest of the circulation.*—The arrest of the circulation, or the removal of the nerve from the body, is followed by changes in the amount of the difference, the consideration of which involves the question as to the duration of the change in freshly excised nerves.

The prominent feature exhibited by such nerves is a steady decrease in the amount of the resting difference, this being much more marked in warm-blooded than in cold-blooded animals. In the case of the sciatic nerve of the frog, the difference may in two to four hours sink

¹ Gotch and Horsley, *Phil. Trans.*, London, 1891, vol. clxxxii. B, p. 267 *et seq.*

to half the amount present in the freshly excised nerve, and in twelve hours to a comparatively small amount. This is undoubtedly due to the passing away of the specific change in the neighbourhood of the cross section, since it may be restored to nearly its full amount by a new cross section.¹ The gradual decline is more rapid in summer than in winter frogs; though here also, after the difference has subsided, it can be renewed by a fresh cross section.

The decline and the susceptibility to renewal by fresh cross section are phenomena common to medullated nerves, the spinal cord, and non-medullated nerves. There is thus little ground for the belief either that the decline is due to the gradual physiological failure of the nerve fibres from the point of cross section as far as the nearest node, or that the renewal with a fresh section is due to parts being involved above such nodes. Both the decline and the renewal are rather to be regarded as indicating that the sudden installation of the difference is a functional change, localised to the neighbourhood of the cross section; the duration of this change is determined by the functional capacity of the uninjured nerve and the extent of the alterations produced by the injury.

It often happens that the difference in a freshly excised nerve increases in amount for a short time after its preparation; this might be due to loss of liquid from the nerve through evaporation, thus increasing the resistance, and so altering the distribution of the derivation surface currents, since moistening the nerve always causes the reverse effect.

It is probable, however, that in most instances both the functional capacity of the uninjured tissue and the extent of the reaction of the altered tissue increases for a certain time, since such augmentation is a familiar phase of excitation phenomena in the case of both nerve and other excitable tissues.

An interesting fact connected with the circulation and the maintenance of resting electromotive phenomena is demonstrable on mammalian nerve. The sciatic nerve, or the exposed spinal cord, of the cat or monkey is ligatured and divided, and the end having been freed from the neighbouring structures, is connected with a galvanometer. In this condition a cross sectional difference is obtained which declines very slowly, provided that the few centimetres of exposed nerve are in structural and physiological connection with the deeper undisturbed portions of the same tissue. On the death of the animal, or the complete excision of the tissue, the difference commences to decline with considerable rapidity. It thus appears that the maintenance of a connection with functionally active portions of the tissue, prolongs the duration of the cross sectional difference in the exposed nerve of the mammal.²

Finally, although the resting difference of an excised nerve declines, even in the case of the frog's sciatic, to little or nothing in twenty-four hours, it may be reproduced by fresh cross section several days after excision, provided that the nerve is kept from drying, by placing it in 0.6 per cent. NaCl, containing traces of Ca salts; and the same is true of the excised mammalian nerve. The amount of the resting differences in such stale mammalian nerves is notably less than those of fresh ones, as might be expected from the impairment which has taken place in their functional attributes.

(e) *The influence of previous excitation.*—The gradual decline in the difference which occurs in an excised nerve is greatly modified by

¹ Engelmann, *Arch. f. d. ges. Physiol.*, Bonn, 1877, Bd. xv. S. 138.

² Gotch and Horsley, *Phil. Trans.*, London, *loc. cit.*

previous excitation. These modifications will be referred to in detail in connection with the electromotive phenomena of excited nerve. It will be sufficient, at this stage, to mention that if a nerve is subjected to short periods of excitation occurring at regular intervals, and the amount of the resting difference is noted between these intervals, the difference declines more rapidly than it does if the nerve is left unstimulated. Similarly, if a nerve is subjected to prolonged rapid stimulation, the difference after such excitation is generally found to be more diminished in amount than can be accounted for by the general decline. On the other hand, it occasionally happens that with the fresh nerves of cooled or winter frogs,¹ and with nerves excised and left in a bath of physiological saline,² the after effect of excitation is to cause an increase in the difference. If the diminution is considered as, to a large extent, due to an impairment in the functional capacity of the uninjured surface, then the augmentation is explicable, in cooled frogs, by the greater functional capacity, which is a prominent feature of such nerves.

The whole matter may be complicated by the presence of prolonged excitatory electromotive changes, and the possibility that these are similar or opposed to the difference; if present, they must sum algebraically with the persistent resting difference, thus the decline may, in some cases, be accelerated, in others arrested or converted into temporary rise.

It is clear that there is a most intimate connection between the electromotive changes in resting and in excited nerve. Such a relationship is implied in all theories which have been put forward to explain the electromotive phenomena of nerve, whether the molecular theories of du Bois-Reymond and of Bernstein, or the alteration theory of Hermann, and its modification by Hering. The further consideration of the so-called after-effects of excitation may be thus profitably deferred until the actual excitatory changes have themselves been discussed.

EXCITATORY ELECTROMOTIVE CHANGES OF NERVE.

The excitatory "negative variation."—The discovery of the resting nerve current by du Bois-Reymond was immediately succeeded by that of electromotive changes evoked by excitation. These show themselves when an excised nerve is connected with a high resistance galvanometer by longitudinal and cross sectional contacts, and the distal portion remote from these contacts is stimulated by a rapid series of excitations. If the nerve is the sciatic of the frog, and the excitation consists of a series of alternating induced currents, a fall in the resting difference is observed, which, on the cessation of the stimulation, passes away more or less completely. Such a decline was termed by du Bois-Reymond³ the excitatory "negative variation," the term "negative" being used in its algebraic sense. The decline was rightly considered by its discoverer as due to electromotive changes set up in the tissues which respond to the excitation; these are such that the portion under the surface contact becomes less positive to the cross section than it was in the unexcited state, and currents, termed "action currents," thus flow through the nerve fibres, from the portion under surface contact

¹ Head, *Arch. f. d. ges. Physiol.*, Bonn, 1887, Bd. xl. S. 207.

³ E. du Bois-Reymond, "Untersuchungen," *loc. cit.*

to that under the contact on the cross section. The same result is obtained if the distal portion of the nerve is excited by chemical means,¹ or by a series of mechanical stimuli.² Changes of a similar kind also occur in an efferent nerve left attached to the intact spinal cord whenever a prolonged reflex discharge from the central nervous system is evoked. The efferent medullated nerves of other animals, including those of mammalia, give corresponding effects. In the monkey, cat, rabbit, etc., an excitatory negative variation may be observed in the central end of the divided sciatic, when the nerve, the spinal cord, or the cerebral cortex is roused by either electrical, mechanical, or chemical stimulation.³

The negative variation may be observed equally well in afferent nerves; thus, on dividing a lumbar posterior root in the mammal, and connecting the portion peripheral to the section with a galvanometer circuit by means of contacts on its surface and cross section, the negative diminution of the resting nerve change is observed when distal portions of the sciatic nerve are stimulated by induced currents. So, too, the cross sectional difference in the lower fragment of the divided spinal cord shows a marked diminution when either a posterior root or the sciatic nerve is excited, and since, in the latter case, such diminution is abolished by section of all the posterior roots of the nerve, it is clearly due to the excitation of afferent nerves only.

Just as the negative variation in an efferent nerve can be obtained in consequence of the reflex discharge from the central nervous system, so, too, a similar variation has been obtained in some afferent nerves by the natural stimulus of the peripheral nerve-ending. In the frog, du Bois-Reymond observed the effect in the upper portion of a divided sciatic when the skin was acted on by acids, etc.⁴ S. Fuchs has observed the variation in the peripheral end of the trigeminus of the *Torpedo* divided near its cranial origin, when the skin containing Lorenzini's ampullæ and Savi's vesicles was pressed.⁵ Finally, Beck observed electromotive changes in the occipital lobe of the rabbit when the retina was stimulated by light,⁶ and similar effects have been found to occur in other portions of the cerebral cortex in response to excitation of other afferent nerves.⁷

There can therefore be little doubt that the negative variation is the electrical expression of excitatory changes in the nerves. Further proofs of this are furnished by the following characteristics of the electrical change. It is diminished or abolished by such agents as ether, which lower the functional attributes of excitability and conductivity. It is present during the period of excitation, and disappears when, on cessation of the stimulus, the other indirect signs of functional activity, such as the muscle responses, subside. It is best produced by such stimuli as are found pre-eminently adapted by their character to evoke the functional activity of the nerve, as judged by

the response of the end organs with which this is associated. Thus the non-medullated nerves which innervate the muscles of *Anodon* are excited by the longer galvanic currents far more effectively than by the rapid induced currents, as evidenced by the motor responses, and in these the excitatory electrical change is observed with the former method of stimulation rather than the latter.¹

The discovery of these excitatory electrical effects formed a notable advance in nerve physiology, since their presence affords the only positive data derived from nerve itself as to the characteristics of the alteration which the tissue undergoes when it passes from a condition of rest into one of activity.

It must not, however, be assumed that the electrical change is the whole excitatory alteration; nor indeed, in the present state of our knowledge, are we justified in the less sweeping assumption that it is a complete or absolutely faithful record of such alteration. It has already been pointed out that the arrest of the circulation and the excision of an efferent nerve are followed by profound changes in excitability and conductivity, as estimated by the response of the muscle to which it is distributed. When, in consequence of this arrest, muscular responses have ceased to be evoked by indirect excitation, the nerve will still give the resting difference on cross section; but a more remarkable feature is that, as long as structural continuity is unimpaired, such a nerve may also give the excitatory negative variation. Thus Hermann, Fredericq, and others² found the excitatory electrical change to be present for many hours in the excised sciatic of the rabbit, as indeed is also and more notably the case in the same nerve of the cat.³ Steinach⁴ noticed that the frog's sciatic gave the excitatory effect when, having been dried, it was soaked again in 0.6 per cent. NaCl, and Boruttau⁵ observed electrical changes on mechanical stimulation of the same nerve eight days after its excision, and in the vago-sympathetic of the dog two days after its removal from the body. It must, however, be remembered that the muscular response to indirect excitation requires the functional activity of the nerve-endings. It is therefore not improbable that this manifestation should completely fail, and yet the nerve fibres themselves maintain, to some extent, their functional attributes. Still the facts above mentioned warrant the caution that, although the electrical change is a concomitant of the real excitatory process, the two are not identical, and the former may be perceptible when other evidence of the existence of the latter fails.⁶

In order to accentuate the difference between the *vera causa* and its excitatory electrical concomitant, the latter will in these pages be now referred to as the excitatory electrical response of the nerve.

⁶ Quite recently Gotch and Burch have obtained evidence of the dissociation of the electrical response from the excitatory process. In the sciatic nerve of the frog it is possible with two stimuli in rapid succession to obtain only one electrical response near the seat of excitation which has been cooled, whilst two such responses occur in a more peripheral warmer region.—"Proc. Physiol. Soc.," *Journ. Physiol.*, Cambridge and London, 1899, vol. xxiii.; 1899, vol. xxiv.

Before proceeding to discuss in detail the characters of this electrical response, one other aspect of the negative variation must be alluded to, namely, its relation to the cross sectional difference. The negative variation is dependent not merely upon effective stimulation, but upon the condition of the nerve contacts, and is thus related to the resting nerve current. The larger the demarcation difference, the larger, *cæteris paribus*, will be the negative variation. Most of the conditions alluded to in the previous section as affecting the amount of the resting difference, influence in similar manner that of the negative variation. Thus the spinal cord and those non-medullated nerves which give large demarcation currents give with appropriate stimulation large excitatory effects.

At this stage it will be convenient to anticipate a portion of the subject matter of the succeeding pages, and state in general terms what is known as to those electromotive changes in an excited nerve which produce the familiar negative variation. When the excitation producing this galvanometric deflection is a rapid series of stimuli, each of these evokes an excitatory state of brief duration, with its accompanying electromotive change. A corresponding series of such states and changes will thus be evoked at the seat of stimulation, and be propagated in strict succession along the nerve. The arrival of each member of the series in the neighbourhood of the contact on the longitudinal surface is contemporaneous with a brief electromotive change at this point, such that the tissue there becomes for a short period galvanometrically negative to the unexcited portions. It is the sum of such a series which affects the galvanometer, and if, on the subsequent arrival of the several transmitted states at the cross section, similar changes were produced, it will be obvious that the tissue here would also exhibit the same condition, when compared with any unexcited portions. Under these circumstances the recording instrument would be acted upon by a series of brief currents of alternate direction, one from cross section to surface being in an extremely brief period (less than .001 sec.), followed by one from surface to cross section. It is scarcely necessary to point out that under such conditions there would be no deflection of the galvanometer needle. The considerable deflection which occurs when one contact is upon the surface and the other on the cross section, thus shows that the electromotive change on the arrival of the excitatory state under the former contact is far more intense than that occurring subsequently in the neighbourhood of the cross section, and thus the change resulting in galvanometric negativity of the surface contact becomes prominent. With repeated stimuli the deflection is, in reality, the sum of a series of such electromotive changes under the surface contact, corresponding to the series of stimuli by which they are evoked. Hence the relation of the negative variation to the cross sectional difference must be to a large extent dependent upon the circumstance that, under these conditions, one contact alone is upon tissue which gives the full excitatory response. When both contacts are so arranged on the surface that there is little or no difference, it is obvious that there must be little or no galvanometric indication of negative variation.

The discontinuous character of the electromotive change evoked in nerve by a series of excitations.—Non-medullated nerves are remarkable, inasmuch as the closure or opening of a single galvanic current may cause an obvious galvanometric indication of a diminution

in their resting difference;¹ but in medullated nerves a succession of stimuli must be employed. The proofs that the negative variation produced by such successive stimuli is not a uniform continuous electromotive change, but a series of the same rhythm as the excitation, are similar in character to those which exist in the case of muscle, and differ merely in detail.

Observations with rheotome.—If the differential rheotome referred to in connection with muscle is employed, it is found that when the rate of revolution is 20 per second, a large negative variation occurs if the galvanometric contacts of the instrument are so arranged as to comprise a time of from one to ten thousandths of a second after each excitation; whilst with contacts arranged in any part of the remaining twentieth of a second, which intervenes between the successive excitations, there is no such effect.²

Observations with the telephone.—If a delicate Siemen's telephone is arranged so as to be in metallic contact with the surface and cross section of a large excised nerve or group of nerves, and the nerve be excited near its further end by a rapid series of induced currents (100 per second), a note similar to that of the vibrating exciter is heard. That this is due to the production and transmission of a series of true electrical responses, and not to the physical spread of the exciting induced currents, is proved by observing that it may be augmented or diminished by placing the excited region in the condition of catelectrotonus and anelectrotonus respectively, that it may be blocked by ether, and other agents which impair nerve conductivity, and that it is abolished by destroying the functional continuity between the excited and observed regions.³

Observations with the capillary electrometer.—An instrument combining great sensitiveness and rapidity of movement is highly magnified, and the image of the mercurial meniscus thrown upon a photographic plate which travels at about 50 cms. in 1 sec. When the instrument is connected with the excised sciatic nerve of the frog, a movement of the level of the meniscus is recorded on the plate in response to each single stimulus of the nerve trunk, whether electrical or mechanical. When the nerve is excited by a series of stimuli of 100 per second or less, a movement is shown on the record corresponding to each member of the series of excitations.⁴

Observations with the physiological rheoscope.—The phenomena of secondary tetanus can be obtained when two excitable nerves are in juxtaposition.⁵ Such excitation of one nerve by the excitatory electrical response in an adjoining one was first demonstrated by Hering as follows. In the cooled frog the sciatic branches are prepared near the knee, ligatured and divided below this, and then dissected up a short way. On now exposing and dividing the upper sciatic plexus, the excitation of the lower sciatic branches evokes a tetanic contraction in the adductor muscles. This contraction is not due to an electrotonic escape, such as that which causes the paradoxical contraction of du Bois-Reymond. This is proved by the circumstance that it is evoked with a pro-

portionately weaker stimulus the nearer the excitation is to the ligatured end of the knee branches, and thus to the more excitable end of these nerves. Indeed, the response fails if the stimulus is shifted nearer the muscles, and away from this ligatured cross section. It thus fails if the stimulated nerve is not sufficiently excitable, and it fails also if the excitability of the sciatic plexus is not raised by previous cross section. The group of nerves in the plexus comprises the upper extremities of the fibres which are being stimulated near the knee, and also others which, lying in the plexus bundle, emerge lower down to supply the adductor muscles. Although the two sets of fibres are physiologically and structurally independent, excitation of the latter is produced by the electrical responses occurring in the former. The seat of this excitation is the combined nerve trunk of the plexus, the excitability of whose fibres has been raised by its division, so that the electrical response in the knee fibres, on arriving at the plexus, becomes adequate to arouse other fibres lying in immediate proximity. The fact that the rapid stimulation evokes the secondary tetanus, can only be explained on the supposition that a series of electromotive disturbances are produced and propagated up the primary nerve bundle, and that each member of this rhythmical series is adequate to arouse the fibres of the secondary nerve bundle.

The negative variation caused by repeated stimulation thus comprises a series of electromotive disturbances, each member of the series being transmitted along the nerve, and evoked by a single member of the series of stimuli. The further consideration of the excitatory change resolves itself into that of the electrical response evoked by a single stimulus.

The electrical response of nerve to a single stimulus.—For the reasons already referred to, the simplest mode of investigating this is one in which the electromotive difference between the surface and cross section of a nerve is obtained, and any variation in consequence of excitation observed. The variation is of such brief duration that galvanometric indications of its presence can only be obtained by summing up a number of such variations by means of the repeating rheotome. The capillary electrometer, if constructed so that the surface of the mercury moves with very great rapidity, is, however, able to follow the brief electromotive change. In order to observe the movement, the surface of the mercurial meniscus is projected upon a travelling sensitive plate, so that a quick movement of the magnified image may be recorded, it being impossible to follow the rapid oscillation by the eye. Under these conditions, an oscillation, indicating a rapid electromotive change, has been recorded by the capillary when the nerve is excited by a single stimulus.

The character of the recorded excursion is always such as to show a rapidly developed change, in which the contact nearest the seat of the stimulus becomes relatively negative to that further off. The subsidence of this relative negativity of the tissue under the proximal contact is greatly influenced by the condition of the nerve, but when the distal contact is one involving a cross section of the nerve, it is always somewhat prolonged. This is indicated in Fig. 270, in which the upward movement indicates negativity of the proximal contact. As the moment of the stimulus is indicated on the plate, the time relations of the electrical response to the single

stimulus may be readily calculated. Outlines of such records are shown in Fig. 270, and the results confirm those obtained by means of the repeating rheotome.¹

FIG. 270.—Facsimile curves of the photographed excursions of a capillary electrometer connected with the frog's sciatic nerve. (I), Uninjured fresh nerve; (II), fresh nerve with distal contact on warmed area; (III), excised nerve kept twenty-four hours in 0.6 per cent. NaCl solution; (IV), excised nerve with distal contact on a recent cross-section.—Gotch and Burch.

(a) *Propagation time.*—The interval of time between the stimulus and the appearance of the change under the surface contact is strictly proportional to the distance between the seat of excitation and this contact. Hence, if two seats of excitation are so situated that one is twice as far as the other from the surface contact, the interval in question is in the former case twice as long. In the frog's sciatic the interval is such that at a temperature of 15° C. it is 0.01 sec. for 30 mm. of nerve. The electrical response is thus transmitted at a rate of 30 metres per second, *i.e.* the same rate as the excitatory process, when estimated by the indirect muscle response, according to the method devised by Helmholtz. Further, since the time at which the effect appears is strictly proportional to the distance of the surface contact from the seat of the excitation, it is obvious that the loss of time must be due to transmission and to this only. In other words, there is no delay except that necessitated by uniform propagation at the above rate; there is, therefore, no period of delay or latent time in the electrical response of nerve.² The propagation time of the electrical response varies in any given nerve, when subjected to changed conditions of temperature, etc.; it also varies in different parts of a nerve, in different nerves, and in the nerves of different animals. Thus, in the non-medullated nerves of *Eledone moschatus* the rate of such propagation has been found, in the winter, to be 1 metre per second; in the summer Boruttan³ found a rate of from 3½ to 5½ metres per second, both in *Eledone* and in *Octopus*.⁴

⁴ Boruttan, *Arch. f. d. ges. Physiol.*, Bonn, 1897, Bd. lxxvi. S. 285.

(b) *The duration of the response.*—The electrical change (negativity) under the surface contact reaches its maximum in the frog's sciatic very rapidly, and then subsides; the duration of the whole effect, at 15° C., was found by Bernstein to be as little as .0007 sec. It is probable that this time is too short; Hermann estimated it as .005 sec. at 5° C., and Head as .02 sec.¹ These results, obtained with the repeating rheotome, may be compared with those calculated from the records of the capillary electrometer excursions. From these it appears that at 15° C. the change under the surface contact reaches its maximum in .001 sec. after its first appearance, and subsides in .01 sec. to a small amount, which, however, is followed by a second increase of low electromotive force, lasting several hundredths of a second, this being the so-called after effect. The duration is much prolonged by low temperature (.003 sec. at 5° C.), and diminished by rise up to 30° C. It is probably of different value in different nerves. In non-medullated nerves, such as that of the cephalopod, it has been estimated by Fuchs² as varying between .01 sec. and .008 sec., a result which has been in the main confirmed by Boruttau, though in his observations, carried out upon summer animals, the duration was found to be a little shorter.

(c) *The electromotive force of the response.*—This cannot be accurately determined by the rheotome method; the only reliable estimation is that afforded by analysing the curve of the capillary electrometer variation, as photographed upon a rapidly moving sensitive plate. It is roughly determined by comparing the total deflection obtained in rheotome observations with that produced by a known electromotive force, the currents of which are led through the repeating rheotome contacts. In this way Hermann showed that the excitatory response may in all probability involve an electromotive force, equal to or surpassing that of the cross sectional difference. In some instances in the frog's sciatic, it was nearly twice as great. The analysis of electrometer records appears to show that the maximal electromotive force of the initial change may in the frog's sciatic, at 5° C., amount to .03 volt, whilst that of the more prolonged after effect is only $\frac{1}{10}$ of this, i.e. .003 volt.³

(d) *The character of the response with two surface contacts.*—The rapidity with which the excitatory electrical change is propagated from one part to another of a nerve, renders it difficult to determine the character of the change with two surface contacts. In this case, first the proximal and then the distal contact will be the seat of the same electromotive alteration. The proximal electrode thus becomes negative to the distal, until the change in the latter has developed sufficiently, when it becomes positive to this. Since, however, the distal change in nerve would occur only .001 sec. after the proximal, if 30 mm. of nerve intervened between the two contacts, the experimental demonstration of this diphasic effect is only rendered possible when the rate of propagation is very much slowed. By taking a bundle of six sciatic nerves from the frog and cooling these to 5° C., Hermann has been able to demonstrate the diphasic effects with the rheotome. The proximal surface contact was found to become first negative and then positive to the distal one. As the negative effect under the proximal contact has not subsided when that under the distal contact has commenced, the total result is still

¹ Hermann, *Arch. f. d. ges. Physiol.*, Bonn, Bd. xxiv. S. 246; Head, *ibid.*, 1887, Bd. xi. S. 207.

³ Gotch and Burch, *Proc. Roy. Soc. London*, 1898.

the algebraic sum of two electromotive changes, and the isolated components must be inferred from the time relations of the whole effect.

The curves *a, b, c,* and *d, e, f,* marked by thin lines in Fig. 271, represent the proximal and distal change respectively.

FIG. 271.—After Hermann.

by their combination the observed diphasic effects indicated by the strongly marked lines enclosing the shaded area. In the diagram the abscissæ represent time, and the ordinates the extent of galvanometric deflection when the circuit was closed at different moments after excitation.

It is noteworthy that in all Hermann's results the distal electromotive change and the proximal one are slightly different; these differences are such that the total area of the two curves, *a, b, c,* and *d, e, f,* are the same, but the forms of the two are not absolutely identical.¹

In the non-medullated nerves of *Octopus* and *Eledone*, the slower rate of transmission has enabled Borutttau to observe similar diphasic effects with the rheotome method of galvanometric observation. The

duration of each phase is altered by various nerve conditions, and particularly by low temperature, which prolongs the time relations, and thus increases the effect. The diphasic character of the effect, when the tissue under each contact is susceptible of undergoing the change, is beautifully shown in capillary records.¹ With two surface contacts on an uninjured nerve, the record is of the character shown in Fig. 270, curve *I*, the rapid upward displacement being succeeded by one of opposite direction. If the sciatic nerve is excised and left for over twelve hours in 0.6 NaCl, the subsidence of the injury at the cross section places the whole nerve in the same physiological state, and a diphasic effect may now be obtained wherever the two contacts are placed on the tissue. Propagation being slowed, the effect is more evident than in the fresh nerve. An example is given in Fig. 270, curve *III*. On warming locally the tissues at the distal contact, the record resembles that of curve *II*, the distal tissue being now incapable of responding to its full extent, whilst on making a cross section the records are those of *IV*.²

The influence of various conditions upon the negative variation.—*The intensity of the stimulus*.—The electromotive change increases in magnitude with the increasing intensity of stimulus. The character of the increase is well shown in the photographic records of the galvanometric deflections due to a brief series of successive excitatory changes.³ With one contact on the surface, and the

FIG. 272.—Abscissæ indicate increasing intensity of stimulus. Ordinates indicate magnitude of response.—After Waller.

other on the cross section of the nerve, a short series of about ten induced currents, occurring at a rate of fifty per second, is allowed to excite the excised nerve every fifteen minutes. The intensity of this stimulus is regularly increased, and the resultant deflections are recorded on a slowly moving photographic plate. Within limits the excitatory negative variations, as estimated by the extent of the galvanometric deflections, are augmented in strict proportion to the increase of the stimulus intensity.

² See analysis on previous page (footnote).

³ Waller, *Brain*, London, 1895, vol. xviii. p. 210; Croonian Lecture, *Phil. Trans.*, London, 1896.

If the results are portrayed diagrammatically in a curve whose abscissæ represent units of intensity of stimulus, whilst the ordinates represent those of galvanometric deflection, it will be seen that the curve has three portions (Fig. 272). The first portion, when the stimulating intensity is inadequate to evoke muscular response, is slightly convex to the abscissæ, *i.e.*, the effect increases with increasing increments in the exciting agent. This is succeeded by a portion which is an ascending straight line, the effect increasing in strict proportion to increase in the stimulus. The final portion is slightly concave to the abscissa, the effect increasing less and less in proportion to the augmentation of the stimulus.¹

FIG. 273.—Effect of ether upon the electrical response of nerve. The upper tracing shows the increased response after slight etherisation during period marked *Et.*; the lower tracing shows temporary abolition after more profound etherisation during period marked *Et.* The series reads from left to right. In this and all similar figures the vertical lines are the photographed deflections of a galvanometer needle.

evoked by a series of induced currents, short periods of excitation being alternated with longer periods of repose. The nerve with both its galvanometric and exciting contacts lies in a small chamber, through which the gas is passed, and any alteration in the responses is indicated by a change in the photographic record of the galvanometric deflections.²

Ether, when in very small amount, causes an augmentation in the effects; when a little more pronounced, a primary augmentation is succeeded by diminution and possibly by abolition; when still stronger, the primary augmentation is not seen, and there is complete abolition. All these effects soon pass away if the ether is removed, and even in cases where complete abolition has been produced, the deflections return to at least their original value on the removal of the vapour (Fig. 273).

Chloroform, when very weak, causes primary augmentation, but

¹ Waller, *Brain*, London, 1895, vol. xviii. p. 210.

² *Ibid.*, vol. xix. p. 43.

Temperature.—On warming the nerve up to 35° or 40° C., the duration of electrical response is much diminished; on the other hand, it becomes prolonged in nerves cooled to 5° C. The low temperature acts in two ways, it retards propagation, and it causes a slow rate of development of the response in any one portion of nerve. The total result is thus a marked increase in the negative variation. It is not clear whether there is an alteration in the electromotive force of the response apart from this change in its time relations.

The influence of anæsthetic gases and drugs.—These have been investigated by Waller in much the same way as in the experiments just described.

Negative variations are

this is succeeded by gradual diminution, which is prone to pass into complete abolition with very gradual recovery. These subsequent effects come on even when attempts have been made at quite an early stage to remove the vapour from the chamber. A stronger dose of chloroform abolishes the variations, and on removal of the vapour the electrical effect may never reappear, but even when it does it is liable to be permanently diminished in amount. *Alcohol vapour* causes an augmentation, which persists far longer than in the case of weak ether, and *a fortiori* than in that of weak chloroform (Fig. 275). The augmentation is seen when the vapour is comparatively strong, and depressant effects are only observed as the result of prolonged action. A large number of other gases have been investigated in the same way, the details of which cannot be entered into here. There is, however, one gas the action of which is of great physiological importance, namely, carbon dioxide.

Carbon dioxide.

—The effects of the passage of CO_2 gas through the chamber containing the nerve are as follows. A slight amount causes, during the passage, a primary augmentation followed by a diminution. These effects are succeeded by a marked secondary increase in the negative variations, which continues for some little time

after the cessation of the gas, and then gradually subsides. The effects are well displayed in Fig. 274. If the CO_2 is strong, then the primary augmentation is not observed, and the diminution passes into complete abolition of the electrical effects. The abolition lasts for some little time after the cessation of the CO_2 , and is then succeeded by most marked secondary augmentation.

It will be observed that all the agents above referred to—ether, chloroform, alcohol, and CO_2 —exert both augmentor and depressant effects, possibly related to increased and decreased nerve excitability,

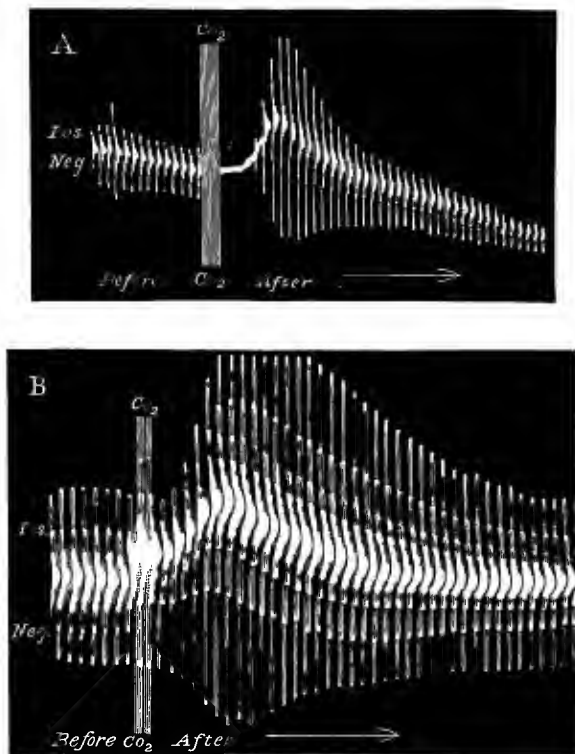

FIG. 274.—The upper record shows the full effect of "much" carbon dioxide on the negative variation. Temporary abolition followed by secondary augmentation. The lower record shows the effect of little CO_2 producing secondary augmentation of negative variation.—Waller.

but obviously due to an increased and decreased susceptibility of the nerve to the production of negative variations. The secondary augmenting effect of CO_2 is so pronounced, that when this gas is combined with chloroform it tends to neutralise the depressing effect produced by that vapour.

Influence of solutions of certain salts.—The investigation of this influence has been carried out by Waller in the following way. The excised sciatic of the frog is soaked in 0.6 per cent. NaCl , and the negative variations produced by short periods of faradisation is recorded by the photographic method previously described. The normal saline is now replaced by solutions containing definite percentages of some other salt.

Neutral salts.—The immersion of the nerve in decimolecular solutions of these salts profoundly modifies the amount of the electrical changes. Potassium salts are markedly depressant; calcium and strontium salts, on the other hand, augment the variations; sodium

FIG. 275.— N =level of normal excitability. O =level of zero excitability. The curves show alteration in excitability, produced by continuance of the three vapours indicated. Ordinates indicate amount of negative variation. Abscissae indicate time after exposure to vapour.—After Waller.

salts are slightly depressant, but the depressing action is in no way comparable with that of potassium. The nature of the acid moiety modifies the result; thus potassium bromide is rather more depressant than the chloride.

Salts of various alkaloids.—Most alkaloids appear to exercise a depressing action upon the negative

variation. Aconitin and veratrin in 1 per cent. solution rapidly abolish the effect; curarin, digitalin, and morphin diminish its amount, whilst strychnin causes an augmentation. The method of soaking the nerve in solutions of the salts produces an alteration in electrical resistance, which need not invalidate the conclusions derived from the photographic records of the responses, since any change due to this cause can be ascertained from the records of excursions caused by a known electromotive force before and after the alteration.

Influence of previous activity.—A short succession of stimuli may be repeated over and over again in the case of the frog's sciatic nerve, without altering perceptibly the extent of the negative variations thus evoked. At the commencement of such a series, comprising short periods of excitation with longer intervals of repose, the effect increases in amount, then it attains a maximum and continues undiminished. The negative variation in a nerve trunk thus shows no sign of fatigue in consequence of the repetition of the external stimulus. This indefatigability has been already alluded to as a characteristic of the excita-

tory process in nerve fibres; it is evidently an equally striking feature of the electrical response.

The initial stage of augmentation is undoubtedly related with the conditions produced in the first few responses, and is thus increased if such changes occur on a more extensive scale.

It will be remembered that nerve excitability, as gauged by the indirect muscular response, is raised by previous excitation; the negative variations show a similar augmentation.

If the nerve is subjected to a prolonged series of rapid alternating induced currents, during the regular and periodic excitation by the shorter series of such currents, then, on the cessation of the prolonged stimulation, the negative variations evoked by the periodic series become augmented in amount (Fig. 276). This augmentation closely resembles that produced

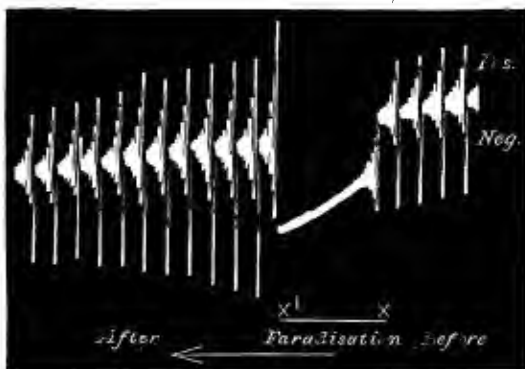

FIG. 276.—Effect of faradisation upon the electrical response evoked by each of a series of stimulations, repeated at considerable intervals. The faradic currents stimulated nerve during period $x x'$, the additional electrical responses thus evoked are fused, and the members of the series are thus masked; on the cessation of the faradisation, the subsequent members of the series are augmented. The series of events is to be read from right to left.—After Waller.

in nerve through subjection to a CO_2 environment. It has been, therefore, supposed by Waller, that the augmentation following prolonged activity is due to the CO_2 set free in the nerve in consequence of its activity. There is, undoubtedly, a close correspondence between the two classes of effect, those of external CO_2 and of internal prolonged activity, which will be made more evident by the facts to be next detailed. The absence of any thermal effects during nerve activity renders it, however, somewhat difficult to accept this explanation of the effect.¹

Negative and positive after effects.—It has been already pointed out that the excitatory negative variation observed in a nerve, when connected by surface and cross sectional contacts with a galvanometric circuit, may exhibit itself as a prolonged change in the resting demarcation current. This is generally of such a character as to cause its diminution, but the presence of effects in the other direction may be detected under certain conditions. The diminution of the difference is termed a negative after effect, the augmentation a positive one, these terms being here employed to indicate a prolonged decrement or increment of the demarcation difference.

It appears from the capillary records previously referred to, that any circumstance causing an impairment in the physiological condition of the tissue under the distal contact (*i.e.* that farthest from the seat of the excitation) produces a negative after effect; as this follows the pro-

¹ Waller, Croonian Lecture, *Phil. Trans.*, London, 1896.

nounced negativity, which is the evidence of the electrical response, it blends with the main effect, and may be regarded as the normal wake of the single response. With uninjured contacts, this wake presumably occurs as the successor of both the change under the proximal and that under the distal contact, and the algebraic sum of the two practically reduces it to nothing. If, however, the distal tissue is rendered less capable of responding (injury, local heat, etc.), the unbalanced effect under the proximal electrode becomes evident. The negative after effect seen under these conditions is thus the tail or wake of the explosion, and occurs under normal conditions as a constant concomitant of this. On the other hand, diminished capacity of the tissue under the proximal contact must allow the wake of the change under an uninjured distal contact to appear. It must show itself as positivity of the proximal contact, and thus give rise to a positive after effect. There are, however, other conditions capable of developing after effects of this type. Thus in the nerves of winter or cooled frogs, the negative variation, as evidenced by the galvanometer, is often succeeded by augmentation of the resting difference. Head, who first drew attention to the phenomenon, considered that the essential condition which favoured its appearance was vital power or vigour. In summer frogs it gives place to the customary demarcation decrement.

Another set of conditions which favours the production of positive after effects has been observed by Waller. He found that the excised sciatic nerve of the frog, if kept for some time in physiological salt solution, responds to electrical stimulation in quite a different manner to that of the freshly excised nerve.¹

In such "stale" nerves, the following electromotive phenomena are observed. After immersion for a few hours, the variation evoked by a short period of rapid stimulation is often of a biphasic character, the deflections indicating surface negativity, followed by positivity. These effects are succeeded by the usual demarcation decrement, *i.e.* decline in the resting difference.

If the nerve has been kept for a still longer time in the bath, the positive phase of the variation becomes still more prominent. The excitatory variation now becomes one in which a positive phase may precede the negative, and may finally be such as to indicate positive phases only.

Photographic reproductions of such positive deflections are given in Fig. 277.

The frequent repetition of the excitation causes a gradual diminution in these positive effects, and thus the most modified condition, in which the variation is purely positive, may become transformed into one showing a positive succeeded by a negative, or into one showing a negative followed by a positive.

There are thus four distinct stages as regards the character of the excitatory galvanometric effects—

First stage.—Each set, with effect - (unmodified nerve).

Second stage.—Each set, first - then + (slightly modified nerve).

Third stage.—Each set, first + then - (more modified nerve).

Fourth stage.—Each set, + only (profoundly modified nerve).

¹ Waller, Croonian Lecture, *Phil. Trans.*, London, 1896.

The essential factor in the production of the modification is the duration of the immersion of the nerve in 0.6 per cent. NaCl.

The modified nerve giving positive variations can be rendered less susceptible to such production by two agents, prolonged activity and CO₂ gas, both of which agents augment the negative variation of the freshly excised nerve. These agencies thus decrease the positive

FIG. 277.—Excitatory variations in fresh and stale nerves. A, Excitatory variation in fresh nerve, large negative (down) effect followed by oscillations and negative after effect; B and C, excitatory variation in early stage of stale nerve, small negative (down) effect, followed by conspicuous positive (up) effect; in C, there is a positive after effect; D, excitatory variations in later stages of stale nerve, the excitatory variation is now positive (up) only. The tracings in the above series are to be read from right to left.—After Waller.

and augment the negative one. If prolonged excitation of a nerve in the fourth stage is interposed among the members of the series of short groups of excitations, then the extensive deflection thus produced is seen to be first positive, rapidly passing into negative. On the cessation of the prolonged excitation, each excitation group evokes an effect of the second stage, being first negative and then positive; this gradually changes into the third, and finally may again reach the fourth stage, *i.e.* + only (Fig. 278).

FIG. 278.—The portion upon the left hand of the figure shows the influence of external CO₂ upon the variation obtained from modified or stale nerve. Before the CO₂ the variations are positive (up), followed by negative (down); after CO₂ they are large negative (down), followed by positive (up). The right hand portion shows the influence of prolonged faradisation upon such variation. The faradisation occurs from *a* to *w*, the variation before is positive (up); after it is negative (down), followed by positive (up).—After Waller.

A nerve in a less modified stage, similarly treated, may give a large negative effect only during the prolonged excitation; on the cessation of this, each group of the responses resembles that of the fresh nerve, being negative only; this gradually gives way to - + and finally to + - effects.

Finally the positive after effect or demarcation increment seems, in many cases, to be similarly changed into the more usual negative after effect, *i.e.* demarcation decrement.

Precisely similar changes are caused by CO₂ gas, the most modified effects being transformed into less modified, and these latter into those of the freshly excised nerve. Examples of both these sets of conditions are given in Fig. 278.

It is thus clear that a close similarity exists between the action of previous activity and that of CO₂ on the electromotive phenomena of stale or modified nerves, and this is the foundation for Waller's view, that the changes following previous activity are caused by the development of CO₂ in the nervous substance, in consequence of the metabolism accompanying such activity.

From these experiments Waller infers that the electrical responses of nerve are in reality the algebraic sum of changes of opposite sign. In the freshly excised nerve those indicating negativity (*i.e.* diminution of the resting difference) are far the larger, in excised nerves kept for some hours those indicating negativity have declined, and positivity may be so pronounced as to swamp the feeble negative changes. The action of prolonged excitation and of CO₂ gas in sweeping away the positive effects, may be due either to their diminishing the molecular change which is the basis of these, or more probably to their increasing the change which underlies the negative effects. If the galvanometric effects are to be regarded as a faithful indication of the excitatory processes, then their twofold character must be interpreted as meaning that, in nerve, two excitatory changes of opposite sign are transmitted along an excited nerve.

It must be confessed that the capillary electrometer records previously described do not support this view, since, whatever the character of the after effect, one change only occurs in kept nerves as the initial effect, *i.e.* relative negativity. The results obtained by Waller may be explained on the view that the positive effects are all effects due to the development of relative negativity of the tissue under the distal contact. The method used by him, unless extended to comprise rheotome observations, is incapable of giving precise information as to the seat of the changes producing the positive effects. This is of essential importance in connection with his conceptions of the excitatory processes, and until we have evidence that the positive change occurs under the proximal contact, the views of Waller, based upon the supposition that it does occur there, cannot be regarded as well founded.

ELECTROMOTIVE CHANGES IN NERVE ASSOCIATED WITH THE PASSAGE OF ELECTRICAL CURRENTS.

Polarisation effects—Electrolysis—External and internal polarisation.—The passage of a galvanic current through a moist conductor is attended by well-known electrolytic phenomena, which subside more or less rapidly on its cessation. The phenomena in question are due to the production of electrolytic changes attaining their maximal development at the points where the current enters and leaves the moist conductor, *i.e.* at the metallic contacts of the battery circuit with this. The electrolytic changes produced by strong currents are such that bubbles of oxygen emerge at the anode, bubbles of hydrogen at the cathode; with feebler currents no obvious evolution of gas takes place, and the products of electrolysis, or electrolytic "ions," are less evident. Evidence of the formation of ions in these instances is obtained, when the moist conductor contains neutral salts, by acidity of the liquid at the anode and alkalinity at the cathode, and an appropriate

dye will change colour in accordance with the reaction. Methylene blue, such as is used for intravital injection, which blanches on reduction and becomes of a more pronounced tinge on oxidation, is a very suitable dye for the purpose; it is observed to blanch at the cathode and become more intense in colour at the anode. A far more delicate proof is that afforded by the fact that the products are themselves electromotive. Thus, if a "polarising" current is passed through a moist conductor by means of metallic contacts, and these are disconnected from the battery and connected with a galvanometer, the anode is now found to be strongly positive to the cathode (Fig. 279). The electromotive changes thus caused are such that a current flows along the moist conductor from the cathode of the battery circuit to the anode; it is thus opposed to the "polarising" current, and is termed the polarisation current. It is sometimes further defined as the "negative" polarisation current in consequence of its direction; the term is a useless refinement, since in all cases the anodic ions of polarisation are galvanometrically positive to the cathodic, and therefore electro-negative to those at the cathode of the moist conductor. The anodic ions being acid are for simplicity denoted in the figures thus, O^- ; the cathodic being basic thus, H^+ .

Internal polarisation.—Since a nerve is a moist conductor, the passage of an electrical current through it, by means of metallic contacts on its surface, must be accompanied by similar changes. The main seat of these, under such conditions, is at the surface junctions of the metals with the liquid of the nerve, hence the polarisation (*i.e.* the electrolytic change) is said to be external.

When non-polarisable electrodes are used, such external polarisation is

reduced to a minimum, but nerve fibres are still polarisable. This is especially the case in medullated nerves, in which there is galvanometric proof of "negative" polarisation, following the passage of a galvanic current. The nerve substance itself is thus polarisable.

Effects very similar in character to those of nerve can be obtained when a current is passed through any schematic arrangement, comprising a good conducting core, surrounded by a moist envelope.

Hermann's model consists of a glass tube, with side openings. The tube contains a thin core of platinum wire, forming its central axis. Both the central and the side tubes are filled with saturated solution of $ZnSO_4$, and into the latter dip amalgamated zinc rods, which serve for the polarising and the galvanometric contacts.

An effectual and simple model consists of a fine copper wire, well covered with cotton. The cotton is soaked in 0.6 per cent. $NaCl$, and the whole plastered with kaolin similarly moistened. It is used in a moist chamber to diminish evaporation, and the contacts are made by non-polarisable electrodes of the usual type.

Hering's model is without a metal core. It consists of a tubular stem of hollow grass, which is soaked in water, and is filled with strong solution of $NaCl$ just before use. The concentrated $NaCl$ in the

FIG. 279.—The polarising current (P) has been led through the moist conductor in the direction of the black arrow by means of metallic contacts from A to C . On opening the circuit and connecting it with the galvanometer (G), polarisation currents are found directed as shown by the dotted arrows.

interior furnishes the good conducting core, the less concentrated liquid in the wall is the moist envelope. All these models give polarisation effects, although external polarisation is eliminated; hence these effects must be due to the surface junction existing between the moist envelope and the internal core.¹ The core is a better conductor than the surrounding envelope, so that the passage of the polarising current is followed by the formation of ions around the platinum wire in Hermann's model, and both around and within the moist core of Hering's model.

Polarisation in Hermann's model.—This is presumed to be of the following character. At the anodic contact

FIG. 280.—Internal polarisation around metallic core of Hermann's model. The polarising current has been led through the model from *A* to *C*. The polarisation after effects are indicated by the ions and lines of current flow.

Hermann's model will traverse the envelope, and leave this liquid to enter the better conducting core. There is, therefore, at this point an internal cathode (Fig. 280) for the liquid envelope immediately around the core, and cathodic ions are thus developed in this region. A similar internal anode for the envelope occurs at

the point where the current leaves the core to enter the envelope (Fig. 281). At both these places, in the neighbourhood of the better conducting core, electrolytic polarisation will be at its maximum, and may be termed, from its position, "internal." The ions of such internal polarisation under the surface anode (*A*), being,

FIG. 281.—Internal polarisation effects around and within liquid core of such a model as Hering's. The polarising current has traversed the complex moist conductor from *A* to *C*.

as far as the moist envelope is concerned, cathodic, will be H, *i.e.* electro-positive to other portions of the moist conducting envelope. Those under the surface cathode (*C*) will, for similar reasons, be O, *i.e.* electro-negative. A current will thus pass through the moist envelope from *A* to *C*, outside the core, and back in this from the portion of core under the cathode to that under the anode as shown in

¹ Hermann, *Arch. f. d. ges. Physiol.*, Bonn, Bd. vi. S. 319; Bd. xxxiii. S. 103.

Fig. 280. If a galvanometer is connected with the surface at or near the polarising contacts, a portion of the surface derivation will pass through the instrument from the anodic to the cathodic contact. Hence the internal polarisation around a central metallic core, lying in a moist envelope, will be evidenced by the fact that on the cessation of the polarising current, the anodic contact is found to be galvanometrically positive to the cathodic.

Polarisation in Hering's model.—In this model both the envelope and the core are liquid, hence the surface junction is the seat of dissimilar polarisation, and ions are formed of one kind in the envelope and of another in the core.¹ The change in the envelope is precisely similar to that just described as occurring in the metallic core model, *i.e.* H ions are found under the surface anode (*A*), where the polarising current leaves the envelope to enter the core, and O ions under the surface cathode (*C*), where the current leaves the core to enter the envelope. These envelope changes must produce a current, flowing from *A* to *C* in the liquid envelope, and from *c* to *a* in the core.

But, in addition to these, the core is itself the seat of ions. Under the surface anode at *a*, the polarising current enters this new liquid, producing O ions; under the surface cathode at *c*, it leaves this, producing H ions. A current thus passes from *c* to *a* within the core, which is the seat of these changes. It leaves this core at *a*, and passes in the liquid envelope from *A* to *C*. It thus augments that produced by the envelope polarisation (see Fig. 281). If the polarising circuit is opened, and a galvanometer connected with the surface at or near the polarising contacts, then a derivation of the current in the moist envelope passes through the galvanometer from the anode to the cathode. The former is therefore galvanometrically positive to the latter.

Polarisation in nerve.—Analogous effects to those just described are observed in nerve. They are far more pronounced in medullated than in non-medullated nerve. It is therefore concluded that the sources are similar to those present in the above models, *i.e.* a two-fold polarisation occurs within the nerve fibres at the surface junction of the liquids of the fibre sheaths with those of the axis cylinders.

On the cessation of a current through a nerve, the anode is found to be galvanometrically positive to the cathode, and it may be thus inferred that the portion of the fibres beneath the surface anode contain basic H compounds in the envelope, and acid O compounds in the axis cylinder, whilst a reversed condition is presumably present under the surface cathode.

Extrapolar polarisation currents.—(*a*) *After effects.*—The passage of a current through either the model or the nerve, is followed not only by intrapolar polarisation currents, but by extrapolar effects. The character of these is due to the circumstance that the part immediately under the surface contact is the seat of maximum electrolytic change. Thus, on the cessation of the polarising current, the portion of envelope under the anode will be galvanometrically positive to all other parts of the whole envelope. A current will therefore flow from this, not only to the intrapolar, but to the extrapolar portions of the envelope. In the anodic extrapolar region, this will enter and return along the core from more remote points to those near the anode. Hence, when

¹ Hering, "Lotos," Prag, 1888, Bd. ix.

two parts of the extrapolar anodic region are connected with a galvanometer, a derivation of the surface effect will pass through it from the contact nearer the anode to the more distant one, *i.e.*, the proximal anodic extrapolar contact will be galvanometrically positive to the distal one, and a current will thus pass in the core from the latter to the former. Similarly, the proximal cathodic extrapolar contact is galvanometrically negative to a distal one. If the direction of the polarising current in the axis cylinder or internal core has been such as to be represented thus \longrightarrow , then, on its cessation, the intrapolar polarisation effect in this will be \longleftarrow ; the anodic extrapolar effect will be \longrightarrow , and the cathodic \longrightarrow , as shown in Fig. 282, I.

As a matter of fact, the above results are complicated when both anode and cathode are present by bipolar electrolytic changes, anodic and cathodic, occurring in close proximity to one another. The effect of the changes in the neighbourhood of any one pole, "idiopolar," can be thus disturbed by the spread of changes from the other pole. In order to simplify the matter, a model may be made so as to be unipolar, one contact only being in connection with the moist envelope, and the

other being attached to the projecting end of the central metallic core.

Under these conditions the idiopolar effects only are seen, and are always those described; *i.e.*, on the cessation of the polarising current, currents flow through the core towards the previous anode and away from the cathode.

With bipolar contacts, the bipolar polarisation effect may swamp the idiopolar. In the intrapolar region the bipolar polarisation is such that the anodic region of the envelope is galvanometrically positive to the cathodic; but if the polarisation has spread along the moist envelope into extrapolar regions, then such region on the anodic side will be also galvanometrically positive to the cathodic, or to all points nearer this cathodic portion. A current will thus flow in the envelope from a distal point of the anodic extrapolar region towards a point nearer the cathodic one, returning through the core the opposite way. Hence, if the direction of the polarisation current in the core is, as before, represented by \longrightarrow , although the intrapolar polarisation after effect is as before \longleftarrow , the anodic extrapolar effect will be \longleftarrow . A similar state of affairs may exist in the cathodic extrapolar region, giving a cathodic extrapolar current directed \longleftarrow . It will be observed that these bipolar effects are in the opposite direction to the idiopolar effects just described (Fig. 282, II).

By the use of very thin envelopes, the resistance offered by the liquid envelope to bipolar polarisation effects is greatly increased,

FIG. 282.—I. Extrapolar polarisation currents on opening a polarising current led through model, with thin envelope from *A* to *C* (idiopolar effects). II. Extrapolar polarisation currents in model, with large envelope and fine core (bipolar effects).

whilst polarisation spread is also altered; hence the bipolar effect is so lessened that the idiopolar one comes into prominence as in the unipolar arrangement, and a turning-point can be found by suitable adjustment of envelope and core.¹ In nerve this thin sheathing envelope exists, so that the extrapolar changes are chiefly those of the idiopolar type. The following table shows the direction of the after effects in various cases of polarisation:—

*Polarisation After Effects.*²

(b) *Effects during current flow.*—All the polarisation currents just referred to are observed on the cessation of the polarising current. They are therefore after effects, but the electrolytic changes, which they represent, commence the moment that the polarising current begins to flow. In the intrapolar region this is evidenced by a diminution in the polarising current; in the extrapolar regions it is shown by the establishment of extrapolar currents during closure. The moment a current begins to flow through any of the models previously referred to, extrapolar currents are observed; the anodic, directed through the core towards the anodic contact; the cathodic, through the core from the cathodic contact; such currents pass through the envelope in the reverse direction in each case. It will be thus evident that during the passage of a current or a series of currents through such a polarisable moist conductor as a medullated nerve, similar changes must be set up outside the line of current flow, so that every point nearer the anode becomes galvanometrically positive to one more remote, and every point nearer the cathode negative to one more remote. If the characters of these changes are compared with those of the excitatory electrical response, it will be noted that since in the latter the transmitted excitatory effect is one in which the point nearer the seat of excitation is negative to one more remote, the character of the excitatory change resembles the polarisation effects produced during closure in the cathodic region. Now, since both polarisation effects, the anodic and the cathodic, extend during closure into the extrapolar regions, electromotive changes of this type might be successively assumed by more remote parts, and possibly be propagated, like those of the excitatory electrical response. Hence the electro-

¹ Hermann, *Arch. f. d. ges. Physiol.*, Bonn, Bd. xxxiii. S. 103 *et seq.*; see also "Biological Memoirs," Oxford, 1887, for translation of Hermann's paper, pp. 312-319.

² Arrows indicate direction in core or axis cylinder.

motive effects produced in nerve by an electrical current or a series of currents may consist of the algebraic sum of (1) the excitatory electrical response, (2) the similarly directed cathodic extrapolar effects, and (3) the oppositely directed anodic effects. The similarity existing between the excitatory electrical response and the cathodic extrapolar change has led Borutttau to frame the hypothesis that the excitatory response may itself be regarded as an electrolytic change of the kind produced at the cathode of a polarising current;¹ the hypothesis will be referred to again later. With regard to the causation of these currents, it is evident that *internal polarisation* (i.e. formation of

FIG. 283.—Spread of current into extrapolar regions during the flow of a polarising current through the model from A to C.

electrolytic products around and within the conducting core) must produce extrapolar currents during the passage of the polarising current. The polarisation operates in two ways—first, by setting up new electromotive sources around and within the internal core, in the manner already described; and, secondly, by bringing into play, through the formation of ions, an increased resistance to the flow of the polarising current through the envelope into the core. This increased resistance causes the lines of current flow to spread more and more into the extrapolar region, in order to enter and leave the core respectively.² The spread is indicated in Fig. 283; it obviously will produce extrapolar surface currents of the same direction as those previously referred to.

In nerve such changes observed during closure in the extrapolar regions constitute the familiar phenomena of electrotonus discovered by du Bois-Reymond in 1843.

The electromotive changes of electrotonus.—On passing a galvanic current through a portion of medullated nerve, the extrapolar regions show an alteration of electrical state; the new condition on the side of the anode is termed *anelectrotonus*, on that of the cathode *catelectrotonus*. As in the polarisable model,

FIG. 284.—The thin arrows (1) represent the electrotonic currents present during the flow of a polarising current through a nerve from A to C; the dark arrows (2) represent the direction of the demarcation currents.

these changes are such that a current flows through the nerve towards the anode and away from the cathode; each part nearer the anode is thus galvanometrically positive to a more remote one, whilst each part nearer the cathode is galvanometrically negative to a more remote one.

If the nerve is an excised one with a cross section at each end, then, as shown in Fig. 284, the anelectrotonic change, being of the same

¹ Borutttau, *Arch. f. d. ges. Physiol.*, Bonn, 1894, Bd. lviii. S. 29.

² Grünhagen, *ibid.*, 1873, Bd. viii. S. 419.

sign as the demarcation current, increases this, whilst the catelectrotonic current, being opposed, diminishes it.

The amount of the electrotonic effects.—The amount of these electrotonic currents varies under the following conditions:—

(a) As the intensity of the polarising current is increased the electrotonic effects are augmented; a maximum can be reached, but this may be as much as twenty times the nerve demarcation current.

(b) The effects vary directly with the length of nerve subjected to the polarising current, provided that the alteration of electrical resistance due to the longer nerve is allowed for or eliminated. In other words, the electrotonic effects increase in proportion as the poles are separated.

(c) The condition of the nerve affects the production of electrotonus. Excised nerves continue to show the changes as long as the structural continuity is maintained, but in diminishing amount. Degenerative changes, which interfere with such continuity, diminish the electrotonic effects.

(d) The polarisability of the nerve. All circumstances which diminish the polarisation constant of the nerve, and thus decrease the susceptibility to electrolytic change, diminish the electrotonic currents. One circumstance of special interest in this respect is the change produced by a rapid series of excitations; the results of such stimulation appear to show that excited nerve is less polarisable, and therefore less susceptible to the production of electrotonic effects.

(e) The effects diminish in amount in proportion as the extrapolar region under investigation is removed from the neighbourhood of the polarising current.

The above conditions affect the changes, not only in medullated nerve, but also in the artificial model; according to Boruttan, even the excitatory changes of a nerve can be reproduced on the model if one end is subjected to a series of alternating induced currents, such as are used to excite the end of the nerve.

One of the most important features of the electrotonic currents is that of their time relations. These present two aspects for investigation, the rate of development at the seat of the change, the pole, and the time of appearance at various distances outside the pole, *i.e.* the rate of extrapolar propagation.

The polar development of electrotonic effects.—This has been investigated by Hermann, Bernstein, and others, by means of the rheotome, which is arranged so that at each revolution both the polarising circuit and extrapolar galvanometer circuit are closed for a short period of definite duration; the time interval between the two closures is, as in all experiments of this nature, susceptible of alteration.

The experiment shows that both in nerve and in the artificial model, extrapolar electrotonus can be appreciated in the neighbourhood of either pole within $\cdot 001$ second after the polarising current has commenced to flow.¹ At the actual poles the electrolytic dissociation probably commences at the moment of closure.²

It will be remembered that in nerve the polar changes in excitability also begin at the moment of closure.³ Pflüger has shown that

¹ Bernstein, *Untersuch. a. d. physiol. Inst. d. Univ. Halle*, 1888, S. 75; *Naturwiss. Rundsch.*, 1887, S. 9.

³ Grünhagen, *loc. cit.*

the anodic lowering of excitability and the anelectrotonic current appear simultaneously,¹ and there is good ground for the belief that the further time relations of these two sets of changes are identical.

The anelectrotonic current, like the anodic fall in excitability, attains its maximum slowly, and subsides but little during closure; the catelectrotonic attains its maximum rapidly, and may subside whilst the former change is still increasing. The time relations of the development of the electrotonic currents in the immediate neighbourhood of the poles were expressed diagrammatically by du Bois-Reymond, as shown in the curves, Fig. 285, where the abscissæ represent time after closure has begun, and the ordinates the intensity of the respective electrotonic currents.² The curves are constructed from a series of successive observations, in each of which the galvanometer was connected with the extrapolar region for a definite period after the closure of the polarising current.

The propagation of the electrotonic effects.—The electromotive changes of electrotonus are undoubtedly present in the extrapolar regions, and there appears to be a delay between the moment of closure and

FIG. 285.—*A* = anelectrotonic; *C* = catelectrotonic effect. T_1 , commencement of closure of polarising circuit; T_2 , commencement of observed extrapolar effect.

the commencement of the electrotonic change, when the distance between the polarising and galvanometric contacts is sufficiently increased. If this delay is referred to the propagation of the state, then, according to Bernstein, the catelectrotonic change is propagated in nerve (15° C.) at a rate of from 9 to 10 metres per second; the rate for the anelectrotonic change varying between 6 and 12 mm. per second.³ These results are rendered inconclusive by the circumstance that the electromotive change at some distance from the pole is much diminished, and thus any comparison between a distant and a near point must be made under dissimilar conditions. The later commencement in the distant region may be chiefly an instrumental lag due to the smallness of the change.⁴ A further complication may be the presence of the excitatory negative variation.

The rate of propagation of the electrotonic change has been investigated also by the response of a nerve muscle preparation used as a galvanoscope. If one of the two branches of the sciatic nerve of the frog is dissected out and divided near its muscular termination, then, on passing a galvanic current through this portion, the other branch is excited, the excitation being indicated by a response in the supplied muscles. This "paradoxical contraction"⁵ is due to the electrotonic

current in the polarised branch spreading to the region where the two branches are in close proximity, at which point it traverses and excites the second nerve. The phenomenon was utilised by Helmholtz for estimating the rate of the electrotonic propagation from the seat of the galvanic current to the point of apposition of the nerve branches (*ab* in Fig. 286). He found that the period of delay of the secondary muscle was identical with that obtained by electrical excitation at a corresponding distance (*bc* in Fig. 286) along the secondary nerve itself, and inferred that the electrotonic change was propagated at about the same rate as the true excitatory process.¹ Hermann has pointed out that the only conclusion to be drawn from this experiment is that the electrotonic disturbance is developed to the same extent in both branches of the nerve.²

The polar alterations in excitability have been utilised as an index, and on the assumption that these are identical as regards origin and time relations with the electromotive changes of electrotonus, the determination of the rate of transmission of the former might throw light on the propagation of the latter. The results have already been referred to in connection with polar changes excitability; it will be remembered that they exhibit considerable discrepancies. Thus, according to Grünhagen, excitability alterations occur in all extrapolar

regions almost instantaneously³; experiments in Hermann's laboratory show that the anelectrotonic decrease in excitability is propagated at least as fast as 165 metres per second,⁴ whilst Asher

FIG. 286.

found a rate of 30 metres per second;⁵ finally, Wundt found that the cathodic increase was transmitted at the same rate as the excitatory state, whilst the anodic decrease was transmitted at 1 metre per second.⁶ In regard to these discrepancies, the most that can be said is that both states are developed at the poles instantaneously, whilst the diminution of the effects in portions far removed from the poles renders all the slower times open to suspicion.

In Hermann's model the rate of propagation of the electrical changes has been estimated by rheotome observations as at least 60 metres per second.⁷ Boruttau, working with polarising currents of short duration and alternate direction, found a rate of cathodic spread in the same model of over 100 metres per second.⁸ In association with Burch, the present writer found a rate of over 100 metres per second for both anodic and cathodic states in a model of similar type, the method used being that of the photographic record of the capillary electrometer excursion produced by an extrapolar effect. Quite recently

Hermann has extended his inquiry to nerve, and has obtained results which lead to the conclusion that the rate of propagation is so rapid as to imply that electrotonus is instantaneously produced in all parts of the extrapolar regions; the only differences between distal and proximal parts being in the amount, not in the time relations of the change.¹

The influence of physiological alterations upon electrotonic currents.—The great similarity between the cathodic electrotonic currents and the currents of action has already been alluded to. The striking experiments of Borutttau with the model bring this similarity prominently forward. He found that when induced currents alternating in direction were passed through a portion of the model, the resulting extrapolar effects on both sides were those of catelectrotonus, *i.e.*, negativity of the part nearest the polarising contacts. This result was not changed when the polarising currents were reversed, and was present when, by means of sinusoidal induced currents, the alternating polarising flow was equal in the two directions.² It admitted of only one explanation: both the anodic and cathodic electromotive disturbances are present in both extrapolar regions of the model, but, owing to their different intensities of development, the algebraic sum of the two opposing effects is one which shows that catelectrotonus overpowers anelectrotonus. It must be remembered that the essential conditions for the production of the result are the short duration of each individual polarising current, the alternation of these currents, and their frequent repetition. An effect can thus be produced in an artificial model closely resembling the negative variation of nerve. In view of this similarity, it is a matter of great theoretical importance to ascertain the extent to which the physiological conditions of a nerve affect polarisation and electrotonus.

Influence of excitation upon electrotonus, and of electrotonus upon the electrical response.—An excited nerve shows a diminution of the

electrotonic currents, and if these are the extrapolar phenomena of polarisation, then during excitation polarisation is apparently diminished.³ The diminution has been deduced from the following experiment:

FIG. 287.

The sciatic nerve (frog) is placed in connection with three independent circuits, the middle set of contacts being that of the galvanometric circuit, whilst the other two are those of the polarising and exciting circuits respectively. As the galvanometric contacts are both upon the longitudinal surface of the nerve, the resting difference and the negative variation due to excitation will be extremely small. The polarising circuit is now closed, so as to obtain an anodic extrapolar effect in the region of the galvanometer contacts. The anodic electrotonic current is thus present in

¹ Hermann and Weiss, *Arch. f. d. ges. Physiol.*, Bonn, 1898, Bd. lxxi. S. 237-295.

² Borutttau, *ibid.*, 1895, Bd. lix. S. 47.

³ Bernstein, *Arch. f. Anat., Physiol. u. wissenschaft. Med.*, 1866, S. 614.

the galvanometric circuit (Fig. 287). If the nerve is excited under these conditions, a perceptible diminution in this anodic, extrapolar current is produced. The reversal of the polarising current causes a cathodic extrapolar effect, opposed in direction to the previous anodic one. On exciting, this is also diminished. The excitatory diminution has been explained on the assumption that during excitation the susceptibility of the nerve to polarisation is decreased, and thus there will be a corresponding diminution in the amount of the electrotonic currents.

The same decrease in the electrotonic currents during excitation may be demonstrated when the galvanometer contacts include the nerve cross section (Fig. 288).

FIG. 288.

In this case the direction of the demarcation current in the nerve may be represented by the arrow 2 of Fig. 288, and the excitatory negative variation by the arrow 3. If the galvanometric contacts lie in the anodic extrapolar region, an electrotonic current during closure represented in the figure by the arrow 1, is produced. This sums with the resting demarcation current, and on excitation a much larger negative variation occurs, since both resting and anelectrotonic currents are diminished, represented by arrows 3 and 4. If, on the other hand, the contacts lie in the cathodic extrapolar region, the catelectrotonic current diminishes that of the resting difference. On excitation, a very small excitatory negative variation occurs, as both the demarcation and the catelectrotonic currents diminish, and, being opposed, their diminutions (3 and 4 in the figure) are counter to one another.

What is the rationale of the apparent excitatory decrease in the polarisation? The excitatory electrical responses, starting from the seat of stimulation, are propagated through the polarised region; they will cause the apparent decrease in polarisation if they should become more pronounced as they approach the anode, less pronounced as they approach the cathode. The result of such alterations would be that the anodic portion of the nerve would tend to become galvanometrically negative to the cathodic portion, and axial currents would thus tend to flow through the nerve, directed from the anode to the cathode, *i.e.* counter to polarisation. There is evidence, by rheotomic observations, that such an alteration in the electrical response is actually present near the poles, and that the polarisation currents, being counter to this, are thus decreased.¹ But, further, the electrical response, when propagated through the extrapolar regions, is profoundly affected. Every point nearer the anode will, owing to the electrolytic change present in its neighbourhood, be the seat of a more intense electrical response than one further off (Fig. 289). The whole anodic extrapolar region will thus become the seat of brief excitatory currents, directed so that the

¹ Hermann, "Handbuch," 1879, "Allg. Nervenphysiologie," Bd. ii. Th. 1, S. 166-167; Fleischl von Marxow, *Sitzungsb. d. k. Akad. d. Wissensch.*, Wien, 1878, Bd. lxxvii. Abth. 3.

point proximal to the pole is galvanometrically negative to the more distal one, these being opposed in direction to the anelectrotonic current.

A similar line of argument applies to the cathodic extrapolar region. In this case the excitatory electrical change gains in galvanometric value as it travels from the cathode, and thus brief currents traverse the nerve from the more distal to the proximal contacts, *i.e.* in the opposite direction to the cathodic electrotonic current (see Fig. 289). By means of rheotome observations, Hermann has conclusively demonstrated the existence of these changes in the propagated electrical response of cooled nerves.¹ Experiments with the capillary electrometer have confirmed and extended this demonstration. It appears that the single electrical diphasic response of an uninjured nerve, having the character shown in Fig. 270 (*I.* or *III.*), is completely altered when the proximal contact, *i.e.* that nearest the seat of excitation, is rendered persistently positive to the distal one by extrapolar electrotonus.² The record under these circumstances is like that produced when the distal contact lies on a warmed or injured region (Fig. 270, *II.*, *IV.*). If the polarisation is of opposite sign, the descending limb of the electrometer curve becomes more extensive as compared with the

FIG. 289.—The upper portion represents the anodic extrapolar effects. The excitatory electrical change is more pronounced under the contact (2), nearer the anode than under the distal contact (1). The lower portion represents the cathodic effect, the electrical change due to excitation being more pronounced at (1) than at (2).

ascending one. Hence relative positivity is associated with greater functional capacity of the tissue, so that, when this is aroused, the state of excitation is of large amount; relative negativity is associated with diminished functional capacity.

Influence of anesthetics.—The natural tendency to regard the changes of electrotonus as states of electrolytic polarisation has been strongly resented by some investigators, and particularly by Biedermann, who differentiates between the “physical” (electrolytic) and the “physiological” factors concerned in the production of the phenomena.³ The theoretical value of the distinction is most certainly open to question, since the electrolytic phenomena displayed by a living nerve are admitted by all to be dependent upon its molecular condition, and as this is one thing during the living and another during the dead state, they must be logically regarded as physiological. In this sense, the

¹ Hermann, *Arch. f. d. ges. Physiol.*, Bonn, 1872, Bd. vi. S. 359; 1873, Bd. vii. S. 349; Bd. x. S. 215; 1875, Bd. xii. S. 157.

² Gotch and Burch, *Proc. Roy. Soc. London*, 1898, vol. lxiii. p. 300.

³ Biedermann, “*Elektrophysiologie*,” S. 694.

only physical phenomena are those due to current escape. The distinction has, however, some practical value, since it brings into prominence other aspects of electrotonic phenomena, which are at any rate not so obviously associated with electrolysis as the preceding. The first of these is that due to the comparison of the extrapolar effects in normal and in etherised nerve respectively.

It has been already stated that the cathodic and anodic electrotonic effects differ in their time relations. In a normal nerve, with extrapolar leads at 1 cm. distance from those of the polarising current, it is notable that the anodic electrotonic effect of a prolonged closure (several seconds) is far larger than the cathodic one, as judged by the galvanometric deflection.¹ Thus in one of Biedermann's experiments the anodic effect gave a deflection of 46, the cathodic only 25; on increasing the intensity of the polarising currents, the anodic gave 96, the cathodic 60. The nerve was now etherised; it gave no excitatory electrical response, and the deflections were, anodic 24, cathodic 24, with the first intensity of polarising current; anodic 68, cathodic 66, with the second one. The inequality between the anodic and cathodic electrotonic effects thus disappear in etherised nerve; but it will be observed that both effects are still present although excitability and conductivity are in abeyance. The explanation given by Biedermann is that in the etherised nerve the condition of electrotonus during closure is a true expression of the polar electrolytic changes, but that in normal nerve, owing to physiological response, a further concomitant effect occurs. This is especially prominent on the anodic side, and spreads from the pole in diminishing amount through the extrapolar region; since it produces electromotive changes of similar sign to those of the anodic electrolytic change, the total anodic extrapolar effect is thus augmented. In the etherised nerve the production of this physiological response is in abeyance, hence the total anodic effect is diminished, and is now nearly equal to the cathodic one. In support of this, he states that etherised nerve shows little or no electrotonic effect at some distance from the polarised region, whilst the normal nerve shows at the same distance the anelectrotonic current due to the physiological response. The anodic electrotonic changes observed during closure in a normal sciatic nerve, within 1 cm. of the polarising current, are thus regarded as the sum of electrolytic spread, and of a physiological response of the nerve at the anode, rendering all parts at or near this galvanometrically positive to those more remote; this response subsides when the polarising current is broken. The basis of the response is a reaction corresponding with an assimilation process in Hering's sense; it is present in diminishing amount through the anodic extrapolar region, and corresponds with greater functional capacity, *i.e.* galvanometric positivity, of the tissue.

Further support for this view is afforded by other facts to be referred to; it must, however, be noted that Waller has found that both the cathodic and the anodic electrotonic effects and their excitatory diminution are influenced by all those agencies which affect the electrical response of nerve. Thus ether and CO₂ may abolish both electrotonic effects, the abolition being succeeded by secondary augmentation. When the gases are weak, an augmenting effect immediately

¹ Biedermann, "Elektrophysiologie," S. 696; *Sitzungsb. d. k. Akad. d. Wissensch.*, Wien, 1888, Bd. xevii. Abth. 3, S. 84.

succeeds an initial slight diminution.¹ It is thus extremely doubtful whether the observations of Biedermann can be taken to indicate a separation between "physical" and "physiological" electromotive factors; if susceptibility to change through the action of ether is to be taken as a crucial test, then we must regard the whole effect as physiological.

The character of the nerve.—The non-medullated nerves of *Anodon*, *Eledone*, and *Octopus*, are readily excited by the passage of a galvanic current, and an electrical excitatory response is propagated at each closure of such a current along the nerve. The electrical response evidently differs in its time relations from that present in medullated nerve, since a single closing excitation causes an obvious galvanometric deflection in a distant portion of the nerve; it is thus far more prolonged than in the case of medullated nerve. It is, however, of the same general character, the proximal surface contact becomes galvanometrically negative to the more distant contact on the cross section.

This initial excitatory effect on closing a polarising current has the same sign whatever the direction of the current, but the subsequent electrical changes differ in accordance as the extrapolar region is anodic or cathodic. On the anodic side it is quickly succeeded and overpowered by an electrical change of opposite sign, the anodic extrapolar electrotonic current; on the cathodic side it is, according to Biedermann, unaltered, being neither augmented nor diminished.² If the galvanometer contacts are both placed on the surface, so that the resting difference and the excitatory electrical response produce but very slight galvanometric effects, then the appearance of the anelectrotonic change and the absence of the catelectrotonic one become very conspicuous. As the galvanometric contacts approach the polarising ones, the anelectrotonic change increases in intensity, although such increase is small when compared with the similar augmentation in medullated nerve. The amount of the effect also increases with that of the polarising current, but a maximum is soon reached, and further increase of polarising intensity does not cause any perceptible augmentation. The structure of non-medullated nerves is not favourable for electrolytic spread, and this factor is therefore reduced to comparatively small proportions. Biedermann thus concludes that the physiological reaction of the tissue at the anode is the chief if not the sole source of the anodic electrotonic current in such nerves. The change spreads with diminishing intensity into the anodic extrapolar region.

These facts have not been confirmed by Borutttau. In the non-medullated nerves of large Cephalopoda, *Octopus* and *Eledone moschatus*, Borutttau observed both anelectrotonic and catelectrotonic extrapolar currents. Thus in *Octopus* the anelectrotonic effect gave a galvanometric deflection of 64, the catelectrotonic one of 49, and, on increasing the intensity of the polarising current, the effects were anelectrotonic 95, catelectrotonic 70, when 18 mm. of nerve intervened between polarising and galvanometric contacts.³ Further, both effects showed the excitatory

¹ Waller, "Proc. Physiol. Soc.," *Journ. Physiol.*, Cambridge and London, 1896, vol. xix.

² Biedermann, "Elektrophysiologie," 1895, S. 635; *Sitzungsb. d. k. Akad. d. Wissensch.*, Wien, Bd. xciii. Abth. 3.

³ Borutttau, *Arch. f. d. ges. Physiol.*, Bonn, 1897, Bd. lxvi. S. 285.

diminution when the nerve was stimulated. Boruttan thus concludes that these non-medullated nerves show electrotonic changes of precisely the same character as those present in medullated nerves, and that such difference as exists is merely a quantitative one, due to the diminished susceptibility to electrolytic polarisation, consequent upon the small extent of the nerve sheath.

Influence of temperature.—The sciatic nerves of large cooled frogs, if kept at a low temperature during the experiments, show results which Biedermann considers to be analogous to those of the *Anodon* non-medullated nerve. If the galvanometer electrodes are connected at a distance of 3 cms. from the polarising, and contacts made with the portion of cooled nerve left in its natural connection with the gastrocnemius muscle, then the resting difference and excitatory electrical response are both so small as not to affect the galvanometer. Under these circumstances an anelectrotonic extrapolar effect is noticed, whilst the catelectrotonic effect is very small. In one of Biedermann's experiments, the former amounted to 6, the latter being absent.¹ On now approaching the galvanometric contacts to 17 mm. from the polarising ones, the anodic effect was 20, the cathodic 2. At 11 mm. the anodic was 34, the cathodic 13. The nerves of the cooled frog are thus in a state which accentuates the normal discrepancy between the amounts of the anodic and cathodic electrotonic effects. This accentuation is regarded by Biedermann as due to increased susceptibility of the nerve to the physiological reaction at the anode. It appears, however, that the influence of temperature is a complicated one. Waller has observed that both electrotonic currents fail when the temperature of the whole sciatic nerve is raised to 40° C. or lowered to 0° C., returning when the temperature is brought back to 15° C.² He observed, also, that after prolonged exposure to these temperatures, electrotonic effects are not produced at ordinary temperatures, whilst after a moderate exposure to 40° C. the effects at 15° C. are perceptibly altered, the cathodic being increased and the anodic diminished so much that the latter may become less than the former.

It is therefore doubtful how far the experimental data brought forward by Biedermann justify the arbitrary division of electrotonic phenomena into two classes. The particular terms employed to describe these two classes, "physical" and "physiological," the present writer is unable to accept. Such a distinction in no way facilitates the physiological conception of the changes in a living nerve. For it is clear that the physiological changes which Biedermann desires to accentuate must have a physical basis as their causative factor. As Boruttan has most pertinently remarked, some physical change must be assumed even by those who take Biedermann's view, and this is presumed to be some chemical rearrangement of a synthetic type at the anode, which is obviously produced by the passage of the current.³ The only known chemical rearrangement at the anode is electrolytic in character. Whether, therefore, electrotonic phenomena have an electro-chemical basis only, or involve, as Biedermann insists, an electro-chemical basis, plus a further "unknown" chemical change, the releasing causative factor is physical, and

¹ Biedermann, "Elektrophysiologie," S. 691.

² Waller, "Proc. Physiol. Soc.," *Journ. Physiol.*, Cambridge and London, vol. xx.

³ Boruttan, *Arch. f. d. ges. Physiol.*, Bonn, 1896, Bd. lxxiii. S. 145, 158.

on either view the resultant phenomena in a living nerve are physiological. Probably the qualifying expression "unknown" is the characteristic which Biedermann desires to accentuate. Those who maintain that the resultant phenomena are in themselves the electrical expression of electrolytic change, are in his opinion open to the criticism that the "vital" character of nerve change is ignored; but surely electrolytic polarisation in nerve must depend upon the chemical and mechanical conditions of the structure, and it is the peculiarity of the living state that these conditions are eminently favourable for its production. Thus the whole group of phenomena remain physiological, and even the use of the term "physical" for the current escape along the nerve is only justified in so far as such escape is independent of electrolytic changes produced in the tissue, in consequence of its living molecular state.

Excitatory after effects—Secondary electromotive phenomena.

—The electromotive changes which follow the passage of galvanic currents through tissues have been termed "secondary electromotive phenomena." These after effects, like those in muscle, are partly the more obvious polarisation changes previously described, and are partly localised excitatory effects produced in the tissue by such changes.

FIG. 290.—In the left-hand portion of the figure the ordinary polarisation after effects, intrapolar and extrapolar, are shown; the flow of the polarising current through the nerve has been from A to C, and has just ceased; the right-hand portion shows the anodic excitatory after effects, the direction of the currents thus produced being indicated by the dark arrows; the polarisation currents are indicated by the dotted lines.

The discovery by du Bois-Reymond that the cessation of the passage of a galvanic current of sufficient intensity and of short duration was accompanied by so-called "positive polarisation," has been already alluded to in the case of muscle.¹ The same phenomenon is readily produced in nerve. The causation is in both instances of the same character. It is a prolonged opening excitation localised

at the anode, and of such character that the nerve at this point is galvanometrically negative. Hence currents flow along the nerve from more distant points to the anode, and these may be so intense as to overpower the proper polarisation effects. The results of this anodic excitatory after effect upon current distribution are shown in Fig. 290.

The proof that the effect is due to a localised anodic effect is due to Hermann.² With a long nerve, and thus a considerable separation of the two polar contacts, galvanometric investigation of the anodic extrapolar region shows that excitatory effects are present, when the polarising current ceases, in sufficient amount to overpower the anodic polarisation change, whilst in the cathodic extrapolar region the polarisation current alone manifests itself. Any localised injury of the anodic region abolishes or largely diminishes the effect. The anodic opening effect is thus explained on the supposition that this region, on opening a current, is the basis of a prolonged localised

¹ E. du Bois-Reymond, *Sitzungsb. k. Preuss Akad. d. Wissensch.*, Berlin, 1883, S. 404.

² Hermann, *Arch. f. d. ges. Physiol.*, Bonn, 1884, Bd. xxxiii. S. 103.

excitation; this prolonged opening response, evoked at the anode, causes anodic negativity such as must occur in consequence of any prolonged excitation. Such an excitation can undoubtedly occur in a muscle, where it is evidenced by an initial propagated twitch and a prolonged localised contraction, the latter being produced on opening intense currents. Both of these opening contractions fail if the anodic tissue is injured.

In nerve, no evidence of a similar prolonged localised excitation at the anode, when a current is opened, had up to the discovery of the phenomena now referred to, been found. Opening tetanus is a proof that a series of propagated excitatory states may be produced, but a localised change without propagation can only be indicated by a localised electrical effect. If the anodic opening after effect is such an indication, the phenomena of nerve excitation are brought into strict accord with those of muscle. In both tissues the excitatory anodic after effect fails, or is markedly diminished if the anodic contact is upon a thermal section,¹ and is decreased in amount if the tissue is in a state of excitation.²

A point raised by the presence of this anodic change has reference to the causation of such opening contractions as are obtained in the second stage of Pflüger's law of contraction.

The discovery of the opening excitatory effect at the anode, renders it difficult to accept the theory advanced by Grützner and by Tigerstedt as to the causation of opening excitation.³ According to this theory, the polarisation current, which comes into full play when a current is opened, is the presumed cause of the anodic excitation, for this is now the cathode of the polarisation counter after effect; hence all excitation is on this view reduced to the production of cathodic changes. It is evident that a prolonged excitation on breaking a current intense enough to cause an anodic excitatory after effect cannot be due to such counter polarisation current, since this is itself overpowered and replaced by an electrical change of opposed sign. Under these circumstances, the anode does not become the cathode of a counter current.

Polarisation and excitation.—It follows from the whole of the facts previously detailed, that the connection between the electrolytic action of a current and its exciting efficiency is, in the case of nerve, a very intimate one. Indeed, the two appear to be so blended that the determination of the conditions which influence polarisation, as well as the character of the polarisation changes, appear to many to constitute the surest road by which the physiologist may reach his goal and acquire more exact conceptions of the excitatory state.

It is therefore a matter of great interest to consider, in conclusion, how far the phenomena of nerve justify the conclusion that the relationship between the electrolytic action and the exciting efficiency of electrical currents is so indissoluble, that the possession of the latter involves, as a necessity, the production of the former, and *vice versa*.

In the first place, what evidence is there that an exciting current

¹ Hermann, *Arch. f. d. ges. Physiol.*, Bonn, Bd. xxxiii. S. 103.

² Stewart, *Journ. Physiol.*, Cambridge and London, 1888, vol. ix. pp. 26 and 199.

³ Grützner, *Arch. f. d. ges. Physiol.*, Bonn, 1883, Bd. xxxii. S. 357.

is one that produces electrolysis? The only absolutely reliable evidence of excitation is the production of an undoubted response in an attached muscle or other recipient organ; the only reliable evidence of electrolysis is the presence of the electromotive state which we term polarisation. That either of these may exist apart from such evidence is by no means improbable; but the present inquiry may be advantageously limited to the indications above mentioned. With this limitation, it will be seen that there is little difficulty in the assumption that, when a current is able to excite, it must have produced polarisation; on the other hand, there are serious objections to the second assumption, namely, that if a current produces polarisation of sufficient intensity, such production must, in an excitable structure, lead to excitation.

It is remarkable what a large number of conditions influence both exciting efficiency and the production of polarisation in a similar manner. The intensity of the current, its duration, the length of the intrapolar region, are all factors the variation of which influence both effects in the same way; and most conditions which increase the rapidity of polarisation development are, *cæteris paribus*, those which increase exciting value. Finally, the nerves most susceptible to polarisation effects (*e.g.* medullated nerves of the frog) are those most readily stimulated by electrical currents.

Against the second assumption is the well-known fact, that currents directed across the fibres of either nerves or muscle are unable to excite, yet, owing to the multiple anodes and cathodes between the poles (there being a pair for each fibre), the polarisation is extremely pronounced. The seat of electrolytic change in nerve must be at the surface junction of each medullated axis cylinder with its envelope, and the counter after effect is a clear indication, both of its existence and of the separation of the two groups of products. Polarisation may thus be produced in large amount, and yet all evidence of excitation may completely fail. A still greater difficulty is the behaviour of nerve when subjected to local change of temperature; local cold increases nerve susceptibility to excitation by galvanic currents and condenser discharges; it decreases such susceptibility for make or break induced currents. Local cooling undoubtedly modifies polarisation, but it is difficult to frame any hypothetical link between excitation and polarisation which may account, on the one hand, for the increased exciting efficiency of prolonged condenser discharges as the temperature falls, and, on the other, for the increased exciting efficiency of rapid condenser discharges as the temperature rises. Finally, the fact that excitation can itself produce electromotive changes of sufficient magnitude to overpower all evidence of polarisation, as in the anodic opening after effect, appears to indicate that the two conditions cannot be connected so intimately that the one is an essential concomitant of the other.

Some of these difficulties have been recognised by Bernstein, who, anxious to bring excitation and polarisation into complete accord, framed an electro-chemical hypothesis to explain the most conspicuous of the difficulties.¹ He supposes that the internal conductor is in reality a discontinuous one, and that electrolytic change takes place both on the surface and in the intervals between the portions of such an interrupted core. Surface polarisation alone does not constitute excitation; it is

¹ Bernstein, *Untersuch. a. d. physiol. Inst. d. Univ. Halle*, 1888 (1); "Lehrbuch d. Physiol.," 1894, pp. 359, 450.

the intermolecular dissociation of oxygen which is the *vera causa*. The hypothesis has been obviously framed to account for the exciting efficiency of longitudinally-directed currents and the inadequacy of cross-directed ones, and is by far the most satisfactory of all attempts to give a picture of the molecular basis of an excitable tissue which shall be in harmony with our modern knowledge. In spite of this, it appears to the present writer to be inadequate, since it explains neither the varying phenomena produced by temperature, nor the still more subtle differences which justify the conclusion that the phenomena of nerve conduction and of nerve excitation are to a great extent independent of each other. The theory would probably need considerable modification in order to embrace these. It has, however, the great merit of accentuating the crux of the present position, namely, that there is no definite standpoint except that which links excitation with polarisation. The latest development of this view has been made by Boruttau. He regards the electrical response of nerve as in reality a catelectrotonic effect; this necessitates the assumption that polarisation and excitation are different aspects of the same state, since catelectrotonus must be understood as the presence of those electrolytic changes which are produced at the cathode of a polarising current.¹ Hermann² has recently drawn attention to the circumstance that in 1872 he framed a conception of the excitatory state in muscle and nerve, based upon the following lines:—(1) Such tissue is excited by the establishment of an adequate cathodic and the disappearance of an adequate anodic polarisation (*i.e.*, electrolytic change of a certain type); (2) the excited tissue becomes at the seat of its excitation relatively negative to those unexcited portions which are in the neighbourhood; (3) cathodic polarisation is thus produced in the latter districts, and on this attaining an adequate intensity, the state of excitation occurs in such districts; (4) this state of excitation must itself similarly influence the neighbouring unexcited parts, and be thus successively assumed by such parts (*i.e.*, it is propagated). The fundamental distinction between the state of excitation and cathodic polarisation is that, whereas the former may be propagated, the latter is not, but is established simultaneously throughout the tissue in a diminishing quantity. A certain intensity of cathodic change is necessary for the production of the state of excitation, and this is only reached in the immediate neighbourhood of the changed tissue; the electrotonic decrement which, in accordance with the laws of electrical distribution, is present in every polarisable moist conductor, thus becomes an important factor in determining the production of a localised state of excitation.

In regard to the whole subject, it must be remembered that the chemical changes which undoubtedly underlie vital activity must, like all others of this nature, be resolved into the interaction of electrolytes. Electrolysis, such as gives rise to the electromotive phenomena of polarisation, is but one result of such interaction, and it is unquestionable that electrolytes may be present although no electrical indications of their presence have been observed. Although, therefore, in our present state of knowledge, the connection between exciting efficiency

¹ Boruttau, *Arch. f. d. ges. Physiol.*, Bonn, 1894, Bd. lviii. S. 51; *ibid.*, 1896. Bd. lxiii. S. 154.

² *Ibid.*, 1897, Bd. lxvii. S. 257; *ibid.*, 1898, Bd. lxxi. S. 277-294.

and such polarisation as we can recognise, may not appear to be so close as to make the two identical, there is sufficient evidence that the relationship is an extremely intimate one. As knowledge increases, the ties of this relationship appear stronger, and a special interest is thus given to the opinion expressed fifty years ago by du Bois-Reymond, that electrical excitation is nothing more than a stage in the process of electrolysis.¹

THE PHYSIOLOGY OF ELECTRICAL ORGANS.

BY FRANCIS GOTCH.

CONTENTS :—General Description, p. 561—Minute Structure in *B. batis*, *Gymnotus*, *Torpedo*, and *Malapterurus*, p. 563—Functional Activity, p. 568—The Electrical Changes of Nerve-Organ Preparations; Activity Effects, p. 571—The so-called Current of Rest, p. 571—The Organ Response, p. 572—Its Time Relations, p. 575—Self-Excitation of the Electrical Organs, p. 579—Effect of Repeated Stimuli, p. 582—Residual Effect of the Response, p. 583—Electromotive Force of the Response, p. 583—Polarisation Phenomena, Secondary Electromotive Effects, Irreciprocal Conductivity, p. 584—The Reflex Response of the Organs, p. 588—The Nature of the Activity, p. 590.

THE possession by certain fishes of a peculiar power, which is now known to be that of giving electric shocks, is such a remarkable phenomenon, that it attracted the special attention of early naturalists, and is referred to in ancient literature. The earliest record is probably the hieroglyphic representation of the *Malapterurus electricus* in the Egyptian tomb of Ti; this fish, belonging to the *Siluridae*, is still found in the Nile, and in the West African rivers. The numbing force exerted by the electric ray of the Mediterranean caused this still more formidable fish to be termed *ναρκη* by the Greeks, and *torpedo* by the Romans. The powers of the electric eel, or *Gymnotus*, found in the branches of the River Orinoco, have always been feared by the inhabitants of this portion of South America; it is in many respects the most remarkable of all electrical fish, since it attains a large size, 8 to 10 ft. in length, and its electric power is thus very great. The shock of all these fish may be sufficient to kill small animals and stun large ones, but although the numbing effects on man were well known, their causation remained a mystery until Dr. Walsh, in 1773, discovered that the power of the *Torpedo* was due to the development of intense electrical currents, through the functional activity of special organs situated one on each side in the lateral mass of the body of the fish.¹ The general structure of the organs in *Torpedo* was described by Lorenzini in 1678, and a detailed account was given by John Hunter, who also described the organ of *Gymnotus*.² Organs of small size have been found in certain species of skate and in the *Mormyrus*, the latter a fresh-water fish found in the rivers of North Africa (Nile, etc.). These organs were termed "pseudo-electric," because, though resembling in general structure those of *Torpedo* and *Gymnotus*, the electric shocks produced by their activity were insufficient to attract notice by their effects upon

¹ Walsh, *Phil. Trans.*, London, 1773, pp. 461-477.

² Lorenzini, "Osservazioni intorno alle Torpedini," Firenze, 1678; J. Hunter, "Works," London, 1835, vol. iv.

man. The term "pseudo-electric" has now been abandoned, and is obviously misleading, since the structures in question, though diminutive and less highly differentiated than those of *Torpedo*, are fundamentally the same as these, both as regards structure and functional activity.

All electric organs possess a characteristic structure which determines the peculiar features of their functional activity, and they all have an unmistakable appearance when examined in the fresh state. This is well displayed in the recently killed *Torpedo*, when the ventral or dorsal skin is removed. Two large masses now come into view placed between the gill slits and the margin of the fish. Each has a concave inner border, and consists of a semi-transparent material, of the consistency of jelly, in which may be seen connective tissue septa and numerous nerve branches. The septa are so arranged as to divide the mass into hexagonal columns, the ends of which lie immediately beneath the dorsal and ventral skin, so that the skin surface of the whole organ presents an appearance resembling the tops of basaltic columns. On making a transverse section of the fish, the organs are seen to extend from the ventral to the dorsal surface, and to contain a number of closely packed columns arranged side by side; as these run from the ventral to the dorsal skin, some of them are displayed in the section, which has cut them in the direction of their length.

In *Gymnotus*, the dissection of the fish shows four such organs, two dorsal and two ventral, the former being the larger. These present a similar transparent appearance in the fresh state, and consist of columns of jelly-like material separated and bounded by connective tissue septa. The organs extend from the neighbourhood of the cephalic to that of the caudal end of the fish, and the columns run for variable distances in the same direction. A section at right angles to the spinal canal thus reveals organs and columns in cross-section.

In *Mormyrus* there are four slender organs situated between the muscles, with their long diameter parallel to the spinal column, thus resembling in general disposition the arrangement present in *Gymnotus*.

The organs found in the skate (*Raia batis*) are situated one on each side of the caudal portion of the spinal column. Each is a slender body tapering at its two ends, and exhibits in the fresh state the characteristic transparent material enclosed within connective tissue septa. A cross-section of the tail at right angles to the spinal column shows that each organ consists of columns which lie closely packed with their long axes parallel to the spinal column; they are thus displayed in such a section as translucent masses, bounded by hexagonal walls.

Finally, in *Malapterurus*, the organ attains a high degree of differentiation. Unlike those just described, it is situated within the skin, which is correspondingly thickened. The organ is imperfectly divided into two halves by a connective tissue septum upon the ventral surface, and enwraps the whole body except the fins and a small portion of the cephalic end. It has not been developed at the expense of any of the muscles used in locomotion, and hence the rapid movements which characterise these fish are in striking contrast with the sluggish motions of the *Torpedo* and *Gymnotus*. The jelly-like organ is bounded externally by the surface layers of the skin, and internally by a strong layer of connective tissue, which is loosely connected with the subjacent muscles. On making sections through the organ, the characteristic

translucent material is seen to be divided up by connective tissue septa, but there is no obvious arrangement of columns.

Minute structure.—The most important features of the minute structure of the organs just described are those of the columnar constituents.

Every column bounded by connective tissue walls, is itself subdivided at regular intervals by connective tissue cross septa, which are fixed at their peripheral edges to the boundary walls; the column thus consists of a pile of superimposed compartments. Further, each of these compartments contains a special protoplasmic mass in which efferent nerves end, whilst the remaining portion of the space offered by the compartment is filled by a transparent material. The protoplasmic mass, with its supporting fibres and nerve terminations, constitutes what is termed the electric plate or disc, and is well supplied with blood vessels.

The structure of the plates differs as regards minute detail in the various groups of fish just mentioned, although all present general features of resemblance. It is best understood by an examination of the least complicated organ, that of the skate.

In the organ of the skate, the columns of which it is composed are divided into the compartments previously referred to; along the connective tissue walls of these compartments run the blood vessels and nerves which enter to be distributed in the plate (see Fig. 291).

FIG. 291.—Electrical organ of skate. Longitudinal section of upper part of organ, as seen under a low power. The arrow indicates the direction of the shock.

The plate or disc is slung across the compartment, being attached by its peripheral edges to the lateral walls, and in contact by its free surfaces with the semi-fluid albuminous material which fills the remainder of the compartment, as shown in Fig. 292.¹ The cephalic border receives a dense network of nerve fibres, the dichotomous divisions of which enter along this surface. Beneath this the nerve branches appear to end in groups of twigs, with terminal knobs lying in a multinucleated layer of granular protoplasm. Immediately beneath this in the protoplasmic layer is a remarkable band of wavy fibres; these are all parallel, and run across the plate between the two lateral attachments, in such a position as to form the most central portion of the disc. These unbranched fibres are quite distinct from one another, and are very prominent in preparations which have been fixed in osmic acid. This

¹ For structure of organ of skate, see Stark, *Proc. Roy. Soc. Edin.*, 1844–45, vol. ii.; Sanderson and Gotch, *Journ. Physiol.*, Cambridge and London, 1888, vol. ix.; Ewart, *Phil. Trans.*, London, 1888, vol. clxxix.; 1892, vol. clxxxiii.; Engelmann, *Arch. f. d. ges. Physiol.*, Bonn, 1894, Bd. lvii.; G. Retzius, *Biol. Untersuch.*, Stockholm, 1898, Bd. viii. S. 83.

meandering layer is probably the vestige of the cross striations of those voluntary muscle fibres which have been transformed into the plates, since in the embryonic stage of *R. batis* and the adult stage of *R. circularis*, the layer can be identified with the materials forming the cross striæ of a slightly modified muscle fibre, and the meandering layer of the organ in adult *R. batis* still possesses those optical properties which characterise striated muscle. The protoplasmic layer on the caudal border of each plate or disc contains many nuclei, and is thrown upon its free surface into a number of projecting processes, upon which extended surface blood capillaries ramify. Every column consists of a series of such compartments, each containing a plate of essentially the

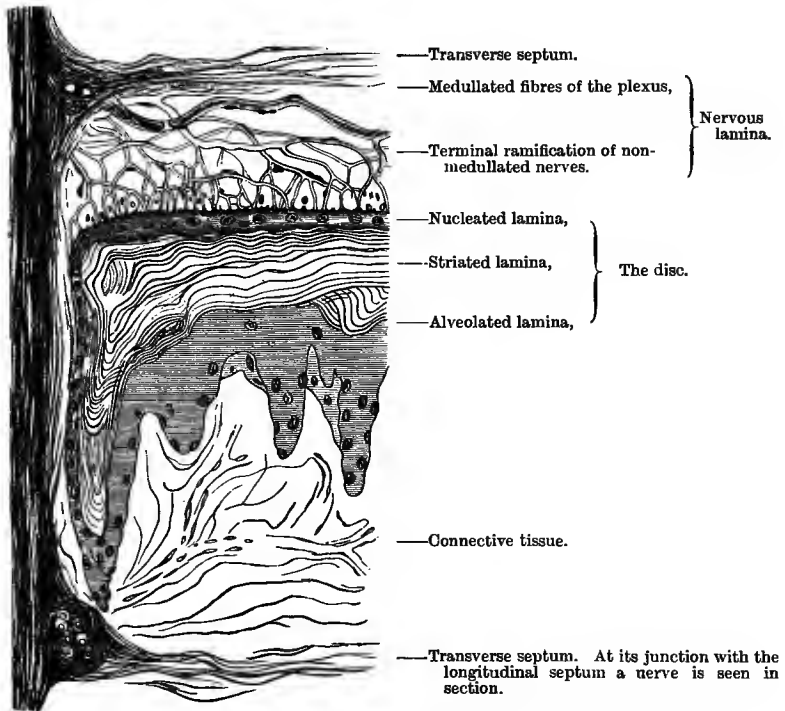

FIG. 292.—Electrical organ of skate. Diagrammatic view to show the structure of a disc.

same structure. As the fish grows in size, the organs also increase, but the number of compartments and plates is fixed at an early stage of growth, and thus the organ of large specimens affords the most favourable specimens for the examination of the plates, since the plates are now some distance apart. The nerves which supply the columns and plates arise from the caudal portion of the spinal cord, and appear to come from special nerve cells situated on the dorsal side of those which give rise to the nerve fibres innervating the muscles. An exception to the structure just described occurs in the embryonic condition of *R. batis* and the adult condition of certain species, e.g. *R. circularis*. Here the compartments composing the columns are irregular, since each contains a modified muscle fibre forming a cross striated multinucleated mass.

This has a flask-like shape, the cephalic extremity being wide and cup-shaped, the caudal long and tapering. The former is seen to be connected with numerous branches of nerve fibres, and corresponds to the nervous layer of the plate just described.

The columns which compose the four organs of *Gymnotus* resemble those of the skate in having compartments, each enclosing a protoplasmic mass which constitutes the electric plate or disc. This presents the same different layers, though with certain modifications. The nerve fibres enter the caudal aspect of each disc, and appear to end in granular protoplasm containing very conspicuous nuclei; this caudal surface is thrown into conspicuous folds with secondary villous projections, all of which are richly supplied with nerve fibres. The meandering layer is not conspicuous, being represented by a few fine parallel lines (Pacini), running through the interior of the whole protoplasmic mass, as in the skate organ; finally, the surface of the cephalic portion is thrown into very prominent papillæ, upon which blood vessels ramify. It is evident that the great difference between this organ and that of the skate is the position of the plate layers with regard to the body extremities, the nerved side being caudal in *Gymnotus* and cephalic in the skate.

A noteworthy feature is the striking difference which exists between different portions of the whole organ of *Gymnotus*. The columns near the tail run somewhat obliquely from the ventral towards the dorsal aspect, are yellowish red in colour, and are subdivided into compartments of very considerable size, in which the protoplasmic plate occupies but a small part of the available space, the clear albuminous substance filling the remainder of the compartment. These columns were supposed by Sachs to be less highly developed; his view is rendered plausible by the microscopic characters of the contained discs, the cephalic surface of each such disc being distinguished by having a large number of long tapering processes, in which may be detected traces of transverse striæ with doubly refracting properties, analogous to those of muscle fibres. All the columns receive nerves from the spinal cord; these emerge from the whole length of the cord, and are the axis cylinder processes of special large cells, the electrical nerve cells. They form a vesicular column on each side, and are seen in any transverse section of the cord to be situated in the grey matter, dorsal and somewhat lateral to the central canal.¹

The organs of *Mormyrus* are in many respects analogous to those of *Gymnotus*, although, owing to the small number of discs and their imperfect development, the total electromotive force of the columns is small. The compartments contain discs athwart the line of the columns, which latter is parallel to the spinal axis. The nerves enter the caudal side of each disc and are derived from special spinal cells like those of *Gymnotus*. A noteworthy feature is that some fibres decussate and supply the half of the organ which is upon opposite side. The nerve cells also are remarkable since their processes join by short anastomoses.²

There are several different varieties of *Torpedo*, all possessing two electrical organs symmetrically placed on each side of the body. The

¹ For structure of organ in *Gymnotus*, see Sachs, "Untersuch. am Zitteraal," Leipzig, 1881; Pacini, "Sulla struttura intima dell' organo elettrico," Firenze, 1852; Schultz, *Arch. f. Anat., Physiol. u. wissenschaft. Med.*, 1858, 1862; Fritsch, "die elektrischen Fische," Leipzig, 1887.

² Fritsch, *Sitzungsber. d. k. preuss. Acad. d. Wissenschaft.*, Berlin, 1891, Bd. xlv.

varieties differ, not only as regards adult size, shape, and skin markings, but also in the number of columns which compose each of the electrical organs. Thus in *Torpedo occidentalis* there are on an average 1069 columns, in *T. californica* 895, in *T. marmorata* 450 to 500.¹

In all varieties the columns are extremely distinct and consist of a series of superimposed compartments, but these are more closely approximated than in the case of the skate or *Gymnotus* organ, and the electric discs which they contain are proportionately thinner. Since the columns extend from the ventral to the dorsal surface of the organ, and the discs are slung athwart the columns, the surfaces of the discs are ventral and dorsal respectively. The nerves enter to be distributed upon the ventral surface, which presents an extraordinarily beautiful example of the dichotomous division of nerve fibres. This is readily demonstrated in the organ of a young torpedo, after fixation in warm osmic acid. If a single plate is stripped off, and spread out with its ventral surface uppermost, microscopic examination shows innumerable nerve twigs, and it may be seen that the twigs of any one branch do not join those of any other. The nuclei of the primitive sheath of the nerve fibres are conspicuous objects in such a preparation, as also those of the granular protoplasmic mass in which the fibres are situated. In cross-sections of the disc the deeper portions of this multinucleated protoplasmic layer exhibit the ultimate endings of the axis cylinder branches, which, according to Ogneff, are groups of nerve twigs with slight bulbous enlargements, each twig being free, *i.e.* not connected with its neighbours. A faint fibrillation running across the disc parallel to the surface probably represents the meandering layer of the skate organ, reduced in the torpedo to very small proportions. The dorsal surface of the plate is not thrown into folds as in the organs just referred to.

The nerves which supply each organ spring from prominent elevations, situated upon the dorsal aspect of the medulla. These elevations, one on each side, constitute the electrical lobes of the medulla, and contain a number of large multipolar nerve cells, each of which has one axis cylinder process continuous with an electrical nerve fibre. The total number of such nerve cells (and thus of electrical nerve fibres) in the case of *T. marmorata* is 58,000 on each side, the fibres being massed for distribution into five nerves, of which the middle are the largest. Each nerve fibre, on entering the connective tissue septa, between the columns of the organ, divides, giving off eighteen branches; this multiple division of the axis cylinder presents an appearance likened by Wagner to a bouquet. Each of the eighteen branches enters the column at one angle of eighteen successive discs, and as there are six such sets of branches coming from six nerve fibres, and entering the angles of each hexagonal disc, it follows that the nerve cells supply three times their number of discs.² The direct enumeration of the discs bears out this numerical relationship, there being about 180,000 discs in an organ of *T. marmorata*, *i.e.* 450 columns, with an average of 400 discs in each column.³

¹ Fritsch, *Arch. f. Physiol.*, Leipzig, 1886, S. 362.

² Fritsch, *Sitzungsb. d. k. preuss. Akad. d. Wissensch.*, Berlin, 1889, Bd. lii.

³ For structure of organ in *Torpedo*, there is an extensive literature comprising among others: Wagner, "Ueber den Bau des elektr. Org. im Zitterrochen," Göttingen, 1847; A. Ewald, "Torpedo," Heidelberg, 1880; Schultze, *Arch. f. Anat., Physiol. u. wissenschaft. Med.*, 1862; Fritsch, "Die elektrischen Fische," Leipzig, 1887, 1890; Ballowitz, *Arch. f. mikr. Anat.*, Bonn, 1893, Bd. xlii.; Ogneff, *Arch. f. Physiol.*, Leipzig, 1897.

As regards *Malapterurus*, it has been already pointed out that there is no obvious columnar arrangement in the organ, but that the connective tissue septa divide it into a very large number of irregularly shaped compartments.¹ Cross-sections made in different planes show that these compartments are more or less lozenge shaped, the acute angle of the lozenge being towards the surface and deep layers of the skin respectively, whilst the obtuse angles are cephalic and caudal in position. These lozenge shaped compartments are dovetailed into their neighbours, and thus practically constitute a large number of columns parallel with the spinal axis. The compartments may be seen with a magnifying lens in a fish 30 cms. in length; they are filled with the usual transparent jelly-like substance, and contain discs slung athwart them. The protoplasmic layer of each disc lies near the walls which form the caudal boundary of each compartment, and the whole organ contains a very large number of such layers, arranged in series from head to tail one behind the other. The nerve fibres enter the compartments at the lateral acute angles, and, running along close to the wall, pass finally to a central stalk projecting from the caudal surface of each protoplasmic disc. Each disc is shaped like a peltate leaf with the central stalk projecting from its caudal surface; the cephalic surface is smooth and has a slight depression opposite the emergence of the stalk from the other caudal surface. The nerve fibre which enters the stalk was formerly supposed to be traceable through this on to the cephalic surface, thus piercing the plate by means of the stalk. Sections show that under the cephalic surface the protoplasm has a punctiform appearance, and this was thought to indicate the section, either real or optical, of the finest divisions of axis cylinder twigs. The observations of Ballowitz do not confirm this view, for the nerve fibre ends in the base of the stalk in free branches with terminal knobs. The actual disc thus contains no nerves at all. The nerve which supplies the organ is probably unique as regards its structure. It consists on each side of one axis cylinder, the process of one gigantic nerve cell, situated in the grey matter, lateral and somewhat dorsal to the central canal, at a level between the exit of the first and second spinal nerve roots. The two cells, one on each side of the cord, were as much as $\frac{1}{2}$ mm. in cross-section, in a specimen of the fish 25 cms. long. They are further characterised by conspicuous nuclei, fibrillæ, and cell processes. The processes are extremely numerous, and those of one cell often join another, but it appears that they do not join the processes either of the other electrical nerve cell or of any neighbouring nerve cells. The cell itself is traversed by special blood vessels, an arrangement which secures an adequate blood supply. The single axis cylinder process of each cell, large in its origin, soon dwindles, and coursing along the inner surface of the organ, accompanied by blood vessels, gives off at regular intervals branches for the supply of the organ. It is surrounded by an extensive connective tissue sheath, consisting of numerous laminae, prolongations of which extend along the subdivisions as far as the angles of the organ compartments. The number of the organ compartments is very large, there being little short of two millions in each lateral half of the entire organ. Since these are all

¹ For structure of organ in *Malapterurus*, see Bilharz, "Elektr. Org. d. Zitterwels," Leipzig, 1857; Fritsch, *loc. cit.*; Ballowitz, *Anat. Anz.*, Jena, 1898, Bd. xv. S. 85; *ibid.*, "Das elektrische organ des Afrikanischen Zitterwelses," Jena, 1899.

innervated by the branches of one axis cylinder, and each compartmental branch itself divides, forming fine terminations in the protoplasmic lining of the compartmental wall, it will be evident that the *Malapterurus* organ affords an instance of the peripheral distribution of a single nerve cell process upon a far more extensive scale than can be traced in any other known structure. It has been estimated that the chief compartmental branches entering the organ have a cross-sectional area 350,000 times that of the axis cylinder process of the nerve cell.

The foregoing brief description of the structural features of electrical organs is by no means an exhaustive one. It is merely intended to portray the most striking of such features, and the reader is referred to the excellent account given by Biedermann in his "Electro-physiology" for other details.¹ The space allotted to the subject admits of but a restricted reference to the chief points in connection with it, and the same is true in regard to the functional activity of the organ. This can only be dealt with in the present article so as to touch upon its most prominent characteristics, but attention will be drawn to such recent discoveries as appear to have a general interest in connection with nerve muscle phenomena.

THE FUNCTIONAL ACTIVITY OF THE ORGAN.

The peculiar features of the structure of an electrical organ, as described in the preceding paragraphs, are the existence of distinct protoplasmic expansions or discs, their situation in separate compartments arranged in series one behind the other, and the presence on each disc of an innervated surface. Such an arrangement is eminently adapted for the functional purposes of an electric organ. For if the functional activity of any one disc is dependent upon the nerve-endings it contains, and displays itself by electromotive changes such that electrical currents traverse the disc from one surface to the other, then, since the liquid contents of the compartment furnish a conducting medium of low resistance for such currents, these must traverse the whole series of superimposed discs. When, therefore, similar electromotive changes are simultaneously established in all the plates of a column, the resultant effects must be summed, and a large total electromotive change is thus produced. The principle upon which each organ is constructed resembles in this respect that of the voltaic pile with columns of superimposed pairs of elements arranged in series; in such a pile the ends of the columns will be the points of maximal potential difference which, with an extensive pile of discs, may be very considerable.

As regards the direction of the electrical currents, which are present during functional activity, the simplest experiments show that this is definite and unvarying for any organ, and that the line of flow is through the discs from one surface to the other. Pacini first drew attention to a supposed relationship between such direction and the minute structure of the protoplasmic disc. In the organs then accurately known, the surface of the disc which receives the entering nerves is so altered during the excitatory state, that it becomes galvanometrically negative to the opposite one, and thus the currents, which during activity traverse

¹ Biedermann, "Electro-Physiology," translated by F. A. Welby, London, 1898, vol. ii. p. 357-407.

the substance of the discs, flow through these from the nerve entry layer to the opposite side. However, Pacini's generalisation obviously breaks down since it is opposed to the condition of affairs in *Malapterurus*.¹ This will be rendered clear by the following table:—

Fish.	Position of Nervous Layer of Disc.	Direction of the Current of the Organ Response through the Body of the Fish.
Skate . . .	Head aspect of each disc.	Head to tail.
<i>Gymnotus</i> . . .	Tail aspect of each disc.	Tail to head.
<i>Malapterurus</i> . . .	Tail aspect of each disc. It was supposed to pierce this and become cephalic, but it really ends in the caudal stalk.	Head to tail.
<i>Torpedo</i> . . .	Ventral aspect of each disc.	Ventral to dorsal surface.
<i>Mormyrus</i> . . .	Tail aspect of each disc.	Tail to head.

These and several other general characteristics of the activity of electrical organs may be readily ascertained, by experiments upon living specimens of fish when the specimen is placed in a suitable experimental tank. In the case of the sluggish torpedo, the fish is allowed to rest with the ventral surface upon a zinc plate, forming the floor of the tank, whilst a second zinc plate is brought into contact with the dorsal surface; if both metallic contacts are connected by means of wires with a suitable galvanometer, a forcible movement of the needle occurs whenever the fish is aroused by mechanical means. The active *Malapterurus* may be caught in an appropriate net, into which two sets of wires have been woven, so that one shall be in contact with the cephalic and the other with the caudal extremity. Finally, in the case of the *Gymnotus*, it is sufficient to immerse two zinc plates or rods at each end of a long narrow tank, along the floor of which the *Gymnotus* lies extended.

In this way it has been ascertained that, when the fish is aroused, intense currents flow through its body, causing strong derivations to pass through the surrounding water and along the wires connected with the metallic contacts.

If the ends of the wires are grasped by the hands, shocks are felt; if connected with a telephone, sounds are heard; if connected with a coil of wire surrounding a soft iron core, this is magnetised (hence an electro-magnetic signal is effected); and if connected with liquid capable of electrolysis, the products of chemical dissociation occur. It is difficult to obtain from even a large torpedo any indication of an electrical spark, for even when the external wires are separated by only .005 mm., no such effect was observed by du Bois-Reymond; but a small spark has been seen on separating the external wires from contact with each

¹ The ending of the nerve in the caudal stalk of the disc of *Malapterurus* organ forbids at present any generalisation from structure to function. The nerved part becomes in *Malapterurus* galvanometrically positive to the unnerved, since the organ shock is from head to tail; it is thus the opposite of the condition in the other electrical fishes. A further difficulty is raised by the localisation of the nerve-endings to the tip of the stalk, the large expanded disc containing no nervous twigs.

other just as the organ discharges. The explanation of this is related to the character and situation of the organ in the fish. This is itself a moist conductor, surrounded by other moist tissues, which afford a perpetual short circuit for any current flow which is caused by electromotive changes in the organ discs. It is impossible, therefore, to completely open the circuit, for the separation of the external wires merely opens one of the derivation circuits.¹

The short circuit afforded by the body and surroundings of the fish inclined the early physicists to dispute the possibility of an external derivation being adequate for the production of the shock-effect on man; but Cavendish demonstrated that shocks similar to those given by *Torpedo* could be easily obtained from a model containing an electromotive source, when immersed, like the fish-organ, in moist surroundings.²

It is obvious that the intense electrical currents produced by the simultaneous activity of the discs in *Gymnotus*, *Malapterurus*, or *Torpedo* traverse the columns, and that the lines of current-flow must comprise the moist-conducting tissues of the body of the fish. These tissues are not only such excitable tissues as muscle and nerve, but the central nervous system itself. In the case of the *Gymnotus*, the head forms, as it were, one terminal of the system of powerful batteries constituted by the functional activity of the very extensive organs, yet although an extremely intense current must traverse the brain of this creature, the vitality of the tissue is not impaired. The excitable structures of such electrical fish as *Gymnotus*, *Torpedo*, and *Malapterurus* thus appear to have become relatively immune to the passage of intense electrical currents.

The simultaneous development of electromotive changes in all the discs causes each column to be transformed into a series of batteries, coupled up in series for intensity, and when, as in the organ of *Gymnotus* and *Malapterurus*, the series of discs is a very extensive one, the arrangement is one eminently adapted for a circuit comprising a large external resistance. Such a resistance is offered by the fresh water in which these fishes live. On the other hand, groups of shorter columns, stacked side by side, afford an arrangement like that produced by coupling up batteries in parallel series, and adapted for a circuit which comprises a low external resistance. This is more or less the case in the organ of *Torpedo*, in which the columns are comparatively short, but so arranged that from 400 to 1000 are placed side by side in each organ; in this connection, du Bois-Reymond pointed out that the electrical resistance of sea water is one million times less than that of fresh water.³

As to the releasing cause of the activity of an electrical organ in the entire fish, it is undoubtedly a central nervous discharge, the excitatory state reaching the organ through the electrical nerves; but, like that of muscle, the activity can be evoked either reflexly in the entire fish, or in separated masses of the organ by excitation of the entering nerves.

A mass of electrical organ, when removed with its attached nerves from a recently killed fish, thus resembles a muscle nerve preparation, inasmuch as it affords opportunities for the study of the response of a

¹ du Bois-Reymond, *Sitzungsb. d. k. preuss. Akad., d. Wissensch.*, Berlin, 1883, 1885.

² Cavendish, *Phil. Trans.*, London, 1776, vol. lxvi. pt. 1.

³ du Bois-Reymond, *loc. cit.*

definite portion of tissue when excited by means of an efferent nerve. The characteristics of muscle activity have been ascertained by noting and recording the changes occurring in isolated nerve-muscle preparations; so also those of the electrical organ are best determined by investigating the response in isolated nerve-organ preparations. The changes which such a preparation undergoes when its nerve is excited, being entirely electrical in character, have to be studied and recorded by appropriate instruments. Such records must form the basis of our knowledge as to the functional activity of the organ when wielded by the living fish, and the study of the nerve-organ response thus has the same importance as that of the contractile process in a muscle.

The electrical changes of nerve-organ preparations; activity effects.—It has already been stated that, when a portion of the electrical organ with its nerves is cut away from a recently killed *Torpedo*, *Malapterurus*, or skate, such a portion responds to excitation of its nerves by the development of the intense electromotive change, for the production of which the tissue is differentiated. In the case of *Torpedo*, the excised organ may be further separated by incisions running from the dorsal to the ventral surface, and a block thus made containing in its interior a number of entire and uninjured columns. If the nerve entering this mass be carefully dissected out, so that its columnar attachments remain intact, a suitable nerve organ preparation is obtained for the investigation of the response. The ends of the strip may be left covered by their portions of dorsal and ventral skin respectively, and brought into connection with a galvanometer, capillary electrometer, telephone, or rheoscopic muscle-nerve preparation.

In an organ preparation, connected with one of these instruments, it is seen that each single stimulus of the nerve evokes an intense electrical response of short duration, the electromotive change being such that a current flows through the organ columns from the ventral to the dorsal skin.

The response is evoked with each excitation of the nerve by an electrical stimulus, whether an induced or galvanic current, provided this is of sufficient intensity; it is also evoked with great ease by even slight mechanical disturbance of the nerve, but is not readily caused by those chemical agents (NaCl, etc.) which so easily excite muscular nerves,¹ although it can be produced by ammonia.

The so-called current of rest.—When connected with a galvanometer, the piece of *Torpedo* organ constituting the preparation generally shows a resting electromotive difference, the dorsal surface being galvanometrically positive to the ventral. A persistent current under these circumstances must be flowing through the excised organ from its ventral to its dorsal surface, *i.e.*, in the same direction as that due to the excitatory response; it was termed by du Bois-Reymond the organ current. The theoretical importance attached by du Bois-Reymond to the existence of such resting electromotive changes, led him to make an extended series of observations on their character.² It appears, however, that the fundamental fact of the existence of this resting difference in uninjured resting organ is problematical.

In an entire *Torpedo*, when quiescent, the difference between the

¹ Schönlein, *Ztschr. f. Biol.*, München, Bd. xxxi. S. 461; also Gotch and Burch, *Phil. Trans.*, London, 1896, vol. clxxvii. B, p. 370.

² du Bois-Reymond, *loc. cit.*

ventral and dorsal skin is extremely small, and only appears as the after-effect of any prolonged organ activity. In the excised organ there is always a difference, but this is dependent upon the extent of the mutilation involved in its excision. The amount is always greatest immediately after the necessary incisions have been made, and then dwindles until in half-an-hour it is comparatively small. It may, however, be renewed by a fresh mutilation, especially that produced by dipping the organ preparation for a brief period in 0.6 NaCl at 80° C.; such immersion causes death of the surface tissue, whilst the internal columns remain uninjured.¹

A piece of organ treated in this way shows a large difference, the dorsal end being galvanometrically positive to the ventral. The sign of the electromotive change is independent of the seat of the injury; it is indifferent whether the sides, dorsal end, or ventral end is the part affected; the resultant effect is always that the dorsal end becomes galvanometrically positive to the ventral. The extent of the change, on the other hand, is definitely related to the amount and position of the injury; it is greatest when the injury involves all the sides of the columns, *i.e.* all the entering nerves; it is small when the ends alone are injured, since under these conditions the mutilation spreads but a short distance along the sides of the subjacent columns. An effective mutilation is thus one which involves local injury and hence excitation of the nerves which enter at the sides of the columns, whilst the resultant electromotive change is always similar, both as regards sign and character, to that of functional activity. It thus seems not improbable that the resting organ current of du Bois-Reymond should be regarded as an instance of that prolonged residual effect which will be described as succeeding every intense organ response, and if so, then no organ current apart from that due to activity has been observed.

This view is confirmed by experiments upon the organ of the skate, where the excitatory response is one in which the caudal end of the organ columns becomes galvanometrically positive to the cephalic end. Here, too, the organ current may be produced by injury, and, when thus caused, is always similar both in direction and character to the residual effect of the response.

In the organ of *Malapterurus*, very little residual effect is observed to follow functional activity, and the response appears to be never succeeded by that prolonged residuum which is so characteristic a feature in *Torpedo*; it is most suggestive that in this fish the resting organ current is either absent or very small, even when excised strips through the entire organ are examined.²

Conditions affecting the magnitude of the excitatory response of the organ.—The functional response of a nerve organ preparation can be evoked by such a stimulus as the passage of a sufficiently intense electrical current, whether this traverse the nerve or the isolated organ. For the present the terminology employed in muscle may be used to denote this distinction, the first being termed a response to indirect, the second that to direct electrical stimulation. Whichever method is employed, the magnitude of the response, as determined by that of either the galvanometric deflection or the excursion of the capillary electrometer, varies under a variety of conditions as follows:—

¹ Gotch, *Phil. Trans.*, London, 1887, vol. clxxviii. B.

² Gotch and Burch, *ibid.*, 1896, vol. clxxxvii. B.

(a) *The number of structural elements.*—This is best illustrated in the case of the torpedo organ preparation. The response is the summed effect of changes of like sign, occurring simultaneously in each of a superimposed series of electrical discs; the number of such discs thrown into simultaneous activity must therefore be a potent factor in determining the magnitude of the total effect. A simple experimental proof is the comparison of the galvanometric effects produced when a portion of the columns and the whole of the columns respectively are traversed by the same exciting current. The exciting current which is thus allowed to traverse the tissue and excite the organ directly, is prevented, by the use of an appropriate rheotome, from entering the galvanometer circuit, which is coupled up with the preparation about .005 secs. after the exciting induced current has been passed through the organ strip. If the portion of organ traversed by the exciting current is small, then the response is small; as it increases in length, so as to include greater lengths of column, the response shows a proportionate increase in intensity.

A further consideration is suggested by this simple experiment. The response is an effect, localised in each transverse disc or plate with its innumerable nerve-endings. There can be no propagation of the excitatory change from one plate to another, for the simple reason that each plate is structurally complete in itself, and is not connected by its differentiated protoplasm with its neighbours. Simultaneous activity is ensured by simultaneous excitation of the nerves to all the plates of the series, and the response of the organ thus differs from that of either a muscle or nerve fibre, since in these the change at the point first aroused is successively assumed by neighbouring portions of the protoplasmic continuum, which have not been the seat of the initial excitatory disturbance.

(b) *The size of the structural elements.*—The intensity of the response increases as the plates increase in size; and since the size is greater the larger the fish, it is always more pronounced in fully grown than it is in young fishes. The increase is too pronounced to be accounted for by the diminution in the electrical resistance offered by the larger organs, for such diminution is small compared with the greatly augmented intensity of the organ response. Further, the capillary electrometer shows a similar increase, hence it is due to the greater capacity for electromotive change possessed by each plate of the adult organ.

(c) *The intensity of the stimulus.*—As in all excitable tissues, so in the electrical organ preparation, a stimulus must be of a certain intensity before it can evoke an appreciable response. When this intensity is reached, the response can be further increased in magnitude by augmenting the stimulation. The minimal exciting intensity of electrical induced currents is much greater than that adequate to evoke a response in a muscle preparation of the frog, whether this is aroused by indirect or direct stimulation. In the case of the *Malapterurus* organ, the ratio between the amounts of such a minimal stimulus as the break-induced current applied, on the one hand to the nerve of the organ, and on the other to the nerve of the gastrocnemius of the frog, may be as much as 100 to 1.

It has been already pointed out that the threshold of exciting efficiency is so high in the case of chemical stimuli, that such reagents as NaCl, etc., evoke no response in the organ preparation, even when

applied to the exposed nerve. On the other hand, the organ readily responds to mechanical stimulation of the nerve, even when this is the mere vibration obtained by Uexküll's nerve-shaker.

The alteration in the magnitude of the response of the organ to the stimulation of its nerve by induced currents, resembles that of a motor nerve with its nerve-endings rather than that of a muscle. Thus the organ response increases with the augmentation of the exciting current, through a much larger range than does that of a muscle, whilst the resemblance to nerve-endings is shown by the circumstance that the organ response is diminished by previous activity. It is true that an isolated piece of organ, if kept cool and moist, can be excited several times before there is any very marked diminution in the size of the response; but such diminution does occur, and has been studied by Schönlein, in torpedo strips repeatedly stimulated by the repeating rheotome; hence fatigue can be produced, and the organ thus resembles nerve-endings as regards fatigability.¹ It should, however, be remarked that the discharge of the entire organ through the central nervous system becomes far more rapidly weakened, unless ample periods of repose alternate with those of activity; this is due to central fatigue.

(d) *Influence of arrest of circulation.*—In close connection with the question of fatigability is the extent of modification which portions of tissues show when kept in the cold and in appropriate moist surroundings for many hours. Such portions may respond even after thirty-six hours to exciting stimuli, but are far more susceptible to fatigue and are evidently in a condition of lowered excitability. This is shown by the small extent to which the phenomena of self-excitation, to be referred to later on, are now observed. The altered condition of the tissue is further shown in *Malapterurus* preparations, by the circumstance that careful analysis of the electrometer record shows the response to be slower in development than is that of the freshly excised organ. In both *Torpedo* and *Malapterurus*, portions of kept organ sometimes exhibit a further phenomenon. A rapid series of responses affecting the recording instruments may suddenly be observed in the absence of any obvious stimulus. This often appears to usher in a gradual diminution and final extinction of excitability; and since the organ is refractory to chemical, but very susceptible to mechanical, stimulation, it is probably due to the nerve-shatter caused by drying, and resembles the familiar muscle tetanus, which is so readily produced by the drying of portions of a motor nerve.

Influence of such drugs as affect muscles and glands.—The comparative indifference of the organ to such drugs as curari and atropin is a remarkable and suggestive fact. Torpedoes can be curarised by placing them in salt water containing the alkaloid, until they are quite immovable, yet, when touched, they give violent shocks, showing that the functional activity of the organ is still at the beck and call of the nervous system.² The organ of *Malapterurus* with its nerve, can be soaked in 1 per cent. curari solution, without undergoing any appreciable alteration in its susceptibility to respond to nerve excitation.³

It has been recently found that when large doses of curari (15 c.c. of

¹ Schönlein, *Ztschr. f. Biol.*, München, Bd. xxxi.; Bd. xxxiii. S. 408.

² Moreau, *Ann. d. sc. nat.*, Paris, 1862, tome xviii.; Gotch, "Proc. Physiol. Soc.," 1888, p. 6, *Journ. Physiol.*, Cambridge and London, vol. ix.

³ Gotch and Burch, *loc. cit.*

4 per cent. solution) are injected into the blood stream of *Torpedo*, there is a final diminution in the organ response to both indirect and direct excitation.¹ In this connection it is interesting to note that Waller has observed a diminution in the nerve electrical response to follow the action of large doses of curari. It thus appears that, unlike muscle, the nerve organ mechanism is one in which there are no connecting links between nerve-endings and organ to be affected by curari, and that no distinction between direct and indirect excitability can be brought out in the case of the electrical organ by the use of this drug.²

The same is true of solutions of atropin, which paralyse many of the neuro-muscular and neuro-glandular mechanisms. Portions of *Malapterurus* immersed in such solutions are as readily excited, and give as intense responses, as they did before the immersion.

Experiments made by the author show that when portions of *Malapterurus* organ are submitted to chloroform and ether, the responses fail; in the case of ether, recovery may follow the removal of the vapour.

It will be clear from this brief description of the influence of various conditions upon the excised organ, that the response presents far more striking analogies to that of efferent nerves and nerve-endings than to that of muscle, although the plates of which the organ is composed appear to have been developed by the transformation of muscle. With reference to such transformation, it should be remembered that the essential elements are nervous and that these are the processes of central cells, which do not correspond in position with those innervating the muscles. The difficulty thus offered to those who would view the organ as a transformed muscle, has not so far received the attention it merits.³

The time relations of the organ response.—The most interesting features of the response are undoubtedly those brought to light by the study of its time relations. In the first place, the response is so intense, even in isolated portions of tissue, that its commencement can be ascertained with more precision than that of the excitatory electromotive change in other forms of excitable tissue. In the second place, the analogy between the pronounced organ response and the comparatively feeble nerve excitatory change makes the precise determination of the former most suggestive in regard to the characters of the latter.

The time relations may be most easily determined by photographing the excursions of a known and accurately calibrated capillary electrometer, but, owing to the difficulties in getting fish, in suitable condition, to laboratories containing photographic appliances for this purpose, this has at present been done in the case of one organ only, that of the *Malapterurus*.

The time relations of the response have been determined in the case of the organs of *Torpedo* and of *Raia* by means of rheotome methods, the galvanometer, a special telephone, or the nerve muscle preparation of the frog, being used as the recording instrument. A convenient rheotome is that of the spring myograph, or pendulum, which at each passage opens three keys. The opening of the first key (K_1) causes an exciting break-induced current; that of the second (K_2) opens a short circuit,

¹ Schönlein, *Ztschr. f. Biol.*, München, Bd. xxxi.

² Gotch and Burch, *loc. cit.*

³ See Fritsch, "Die elektrischen Fische," Leipzig, 1887, 1890.

and allows any electrical effect in the organ to traverse the galvanometer; that of the third (K_3) breaks the galvanometer circuit, and hence the instrument is only influenced by electromotive changes occurring between the opening of K_2 and of K_3 . By suitable arrangements, the time between K_1 and K_2 may be varied, whilst that between K_2 and K_3 remains always of some fixed short duration, such as $\cdot 001$ sec. or less.

By moving K_2 and K_3 towards or away from K_1 before each passage of the traveller, and noting the galvanometric deflections produced by such a passage with its consequent excitation, data are obtained from which the total development of the response may be inferred. The repeating rheotome has also been used in the Naples laboratory, by Schönlein, for the same purpose.

The first and most obvious fact is the existence of a period of delay between the excitation and the commencement of the response. Every preparation shows such a period of delay, the so-called latent period. If the preparation is excited by the stimulation of its nerve, then the delay is in the case of *Torpedo* perceptibly increased, in proportion as the seat of the stimulus is removed from the nerve termination in the organ. The increase has been shown to be accounted for by the propagation rate along the nerve of the excitatory state thus aroused, which, in the case of the electrical nerves of *Torpedo*, may be as little as 9 metres per second at 5° C., although at 20° C. it is 30 metres per second. At 15° C. a rate of from 15 to 20 metres per second has been observed.¹

In *Malapterurus* preparations, on the other hand, change in the delay, due to the seat of the nerve excitation, is far less marked, and the propagation rate in the electrical nerve of this organ is, at 12° C., at least as fast as that in the motor nerve, *i.e.* 40 metres per second. But even when the nerve is excited close to the organ, a distinct delay occurs, and a fact of great significance is the remarkable circumstance that, when the exciting current is allowed to traverse the organ itself, the duration of the period of delay is not perceptibly different.² It will be remembered that in frog's muscle a very appreciable diminution, amounting to $0\cdot 003$ second, at a temperature of 15° C., occurs in the delay to direct, as compared with that to indirect, excitation.

The absence of any such diminution in the case of the electrical organ is in favour of the view that the organ response is that of a structure which cannot be separated from the nerve-endings. These are excited whether the stimulus is applied to the entering trunk of the nerve, or to the nerve fibres contained in the discs. It follows from this that the organ owes its susceptibility to excitation entirely to the nerves which it contains, and that, apart from these, its substance is inexcitable. A further inference may be hazarded. If the plates, apart from the nerve-endings, are inexcitable, then the seat of the excitatory change, that is the electrical response, being localised in the nerve-endings of the plate, the function of the protoplasmic substance remains at present unknown. An additional confirmation of the view that the discs apart from the nerves are inexcitable, is furnished by the observations of Garten on the result of nerve section. *Torpedoes*, the electrical nerves of which had been previously divided on one side, showed, nineteen days after section, complete inexcitability of the organ of this side to both

¹ Schönlein, *loc. cit.*; Gotch, *Phil. Trans.*, London, 1887, vol. clxxviii. B.

² Gotch and Burch, *loc. cit.*

indirect and direct excitation.¹ A suggestive fact in connection with the delay which occurs in the response of the organ to the passage of an exciting current through its substance, is the minimal duration of the period. This, in *Torpedo*, *Malapterurus*, and skate, is .003 sec., a time identical with the nerve-ending time in motor nerves, as ascertained by Bernstein. The delay is prolonged by lowering the temperature, the minimal limit of .003 sec. at 30° C. being in all the above organs increased, until at 5° C. it may amount to .01 sec. Here, again, the alteration is one which affects almost equally the delay to the so-called "direct," as that due to indirect, stimulation. From the above remarks, it will be clear that the writer considers the term "direct," as applied to the stimulation of a portion of organ by the passage through it of an electrical current, to be inappropriate; the passage of a current through the substance of the organ acts by exciting the contained nerves.

When the response begins, it develops in *Torpedo* organ with great rapidity, reaching its maximum in 0.003 sec. under favourable conditions.² The rate of development is accelerated by warmth, and slowed by cold. This is seen by the curves given in Fig. 293, which are plotted from a number of rheotome observations obtained in the organ of *Torpedo* by myself. In *Malapterurus* the development may be completed in less than 0.002 sec. at 30° C. The magnitude of the change in this organ is increased by cold, and diminished by heat (see Fig. 294).

The subsidence of the electromotive change of the response is slower than the development, occupying 0.005 sec. at 15° C., and 0.01 sec. at 5° C. In the final stages it is generally much prolonged, each response being thus accompanied by an after-effect, having the same sign as the response itself.

It is for this reason that, after a rapid series of responses, a more or less persistent electromotive change presents itself, having the same sign as that of the response, the so-called organ current of du Bois-Reymond. Attention may here be drawn to the fact that the subsidence is not caused by any counter-effect, due to changes occurring in more remote parts. In both muscle and nerve, with contacts on uninjured tissue, the change under the contact proximal to the seat of excitation having been propagated to the distal region, is counteracted by a second change of like sign under this distal portion. The total effect under any one contact in these tissues is thus diphasic, *i.e.* the response is one in which the initial change rapidly subsides through the development of one of opposite sign counteracting it. In the electrical organ there is no such counter-effect, because there is no protoplasmic continuum along which the excitatory change can be propagated, and

FIG. 293.—The ordinates indicate the galvanometric deflections when the galvanometer was connected with a strip of torpedo organ for 0.002 sec. at various intervals after the excitation of the strip, which occurred at 0.

¹ Garten, *Centralbl. f. Physiol.*, Leipzig u. Wien, 1879, Bd. xiii. S. 1.

² Schönlein has found that the development of the change in the organ of vigorous Torpedoes may take place in less than 0.002 sec. (*Ztschr. f. Biol.*, München, Bd. xxxiii. S. 408).

the change is thus strictly monophasic. This is well shown by the character of the single excursion of the mercurial meniscus of the capillary electrometer, produced by a single response of the excised organ of *Malapterurus*, when in a low state of excitability. An examination of this excursion, as photographed (see Fig. 294, A), shows that, after the application of the stimulus at the time (X), a period of delay occurs

FIG. 294.—Outlines of records obtained by photographing the capillary electrometer. A, *Malapterurus* organ strip of low excitability; electrometer connected with caudal and cephalic ends of strip, with short circuiting shunt of 80 ohms. Temperature of strip = 5° C. The nerve was excited by a single induced current at the moment marked x. The single monophasic response commences at 0.01 sec. and is fully developed by 0.02 sec. B, Same strip as that used in A, but connected with a pair of condenser plates; the electrometer was connected with another set of plates at 3 mm. distance. The change in the organ commences at 0.01 sec. after the excitation of the nerve producing a condenser charge; it ceases at 0.016 sec., producing a discharge of opposite sign. Temperature of organ strip, 5° C. Condenser 537 C.G.S. units. C, Same as B, but temperature of strip 30° C. Time of commencement of response after excitation of nerve, 0.006 sec.; cessation of response indicated by discharge of opposite sign at 0.008 sec.

rise being succeeded by a sudden fall, which brings back the level of the meniscus. The records A and B are both those due to responses of the organ at a low temperature; in C, Fig. 294, the record obtained from the same organ at 30° C. shows that the response culminates in $\frac{1}{1000}$ sec. after its commencement.¹

¹ Gotch and Burch, *loc. cit.*

Self-excitation of the electrical organ.—In the excised *Malapterurus* organ it is but seldom that the response to a single stimulus is the single monophasic change indicated by such electrometer excursions as are outlined in Fig. 294. It generally happens that the subsidence of such an effect is succeeded by the development of a second one, this by a third one, and so on. This tendency of the organ to respond to a single excitation by a rhythmical series of changes, although apparently most marked in *Malapterurus*, appears to be a property of all electrical organs. In the *Torpedo* it is demonstrable by a sufficiently wide range of rheotome readings, when the galvanometer is used as the recording instrument. In the portion of organ investigated a series of electromotive changes are now found, occurring one after another at definite intervals, which at 5° C. are $\frac{1}{100}$ sec. (see Fig. 295). A more striking demonstration of the same characteristic is afforded by the photographic records of the capillary electrometer, when connected with the excised *Malapterurus* organ. A series of from ten to twenty monophasic changes is now seen to be evoked by the single stimulus. In consequence of the slow subsidence of the meniscus, the successive fresh developments are superimposed

one upon another, but the rhythm may be made plainer by converting each monophasic change into diphasic condenser discharges, through the interposition of the condenser plates alluded to in the preceding paragraph. Two illustrations, with the organ at different

FIG. 295.

temperatures, are given in Fig. 296. The extent of this "peripheral organ rhythm" varies with the temperature, the state of excitability of the organ, and the intensity of the individual responses which compose it.¹

The multiple response is evoked by a single stimulus of either the nerve trunk or the organ strip. This discovery, made by me in 1886, was confirmed by Schönlein, working with the repeating rheotome, who termed the phenomenon, *Selbsttetanisierung*. The essential factor concerned in its production is undoubtedly the passage through the tissue of the intense current due to the response; this excites the tissue again, and the same effect is repeated. The following facts, among others, prove that the phenomena are due to such auto-excitation.² If two strips of *Malapterurus* organ, A and B, are arranged as in Fig. 297, and the nerve of one, the primary strip, excited by a single stimulus, then the current due to the activity of this primary strip A will traverse the secondary strip B. By placing the secondary strip B the opposite way round to A, it is easy to see whether it responds to the current produced by the functional activity of A, for if B responds, the electrical effect of its

² Gotch and Burch, *loc. cit.*

FIG. 296.—Outlines of excursions of capillary electrometer records when the capillary is connected to one pair of condenser-plates, and another pair, at 3 mm. distance from these, is connected with the two ends of a strip of *Malapterurus* organ. In A the organ was excited by stimulating the nerve with a single induced current at the moment marked x. The temperature of the strip was 15° C. The secondary responses occur at an average interval of 0.0076 sec.; initial period of delay, 0.0080 sec. In B the organ strip was excited directly by an induced current (heterodromous); the temperature of strip was 25° C.; initial period of delay, 0.0035 sec.; average interval between secondary responses, 0.0045 sec.

response passing from the head to the tail end of the strip must be of opposite sign to that of A. When the two strips, A and B, are successively connected with a capillary electrometer, records of their

FIG. 297.

primary one A, in having an extra period of delay. It is clear, there-

responses are obtained, of which the curves A and B in Fig. 298 are an illustration. It is obvious that the lower curve is the response of B, due to the excitatory change of A traversing its substance. The response of the secondary preparation B, differs from that of the

fore, that the electrical current of an active strip is fully capable of exciting another strip, but it can also excite the nerves of its own plates. This is demonstrated by section of the single nerve which lies upon the under surface of a *Mala-pterurus* strip, so that one end only is left with its nerve fibres in connection with the nerve outside the organ, as in Fig. 299. On exciting the nerve of the preparation, and connecting successively the two halves, proximal and distal respectively, with the electro-meter, responses are obtained in both, but the record of the distal one differs from that of the proximal in having an extra period of delay. Thus, in one instance, the two periods of delay were .01 sec. and .04 sec. respectively.

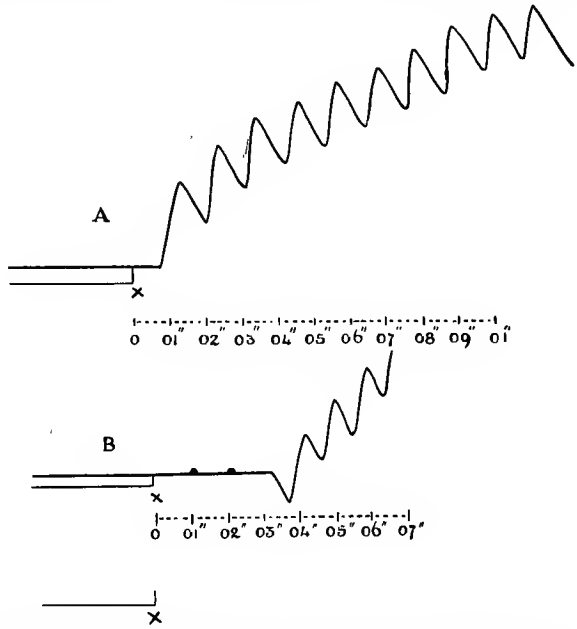

FIG. 298.—A, Outline of electrometer excursion obtained from primary strip of *Mala-pterurus* organ in response to a single excitation of its nerve. $T=15^{\circ}C$. First response occurs 0.008 sec. after excitation. B, Outline of excursion obtained from a secondary strip, through which current produced by A has been led. The secondary strip, having been arranged the opposite way round, will show, when excited by the current of A, a response of opposite direction to that of A. First response 0.03 sec. after excitation of A at moment x. The derivations of two of the responses of A are seen in front of the response of B at 0.01 sec. and 0.021 sec. respectively.

The successive responses in *Mala-pterurus* follow one another with the utmost regularity, the rapidity of the succession being influenced by temperature. Thus at $30^{\circ}C$., a rate of succession of 300 per sec. was recorded; whilst at $5^{\circ}C$. it sank to 100. The state of excitability of the tissue has a great effect upon the production of the phenomenon. A freshly prepared organ strip and the organ in the living fish always show the multiple effect, but it is possible by keeping excised strips in

FIG. 299.

0.6 per cent. NaCl to obtain a lowered state of excitability, in which the initial response alone presents itself. Even then any circumstance raising the excitability may develop the normal multiple effect, such, for instance, as section of the nerve near the organ. Schönlein has observed an interesting instance of the abolition of the multiple response, when the excitability is sufficiently lowered; this occurred in *Torpedo* on exciting the nerve trunk by an ascending galvanic current, the lowered excitability being in this case that of the anodic extrapolar region of the nerve extending to the nerve-endings in the organ discs.

The members of the whole multiple response become feebler as they are successively evoked, and when the intensity of one sinks below the threshold of exciting efficiency, the reduplication of the effect ceases. The duration or number of members is thus very variable, being increased by great intensity of initial effect and high organ excitability. In the living *Malapterurus* such a rhythmical response may last 0.5 sec., and comprise 150 individual members, but as a rule the multiple effect only lasts 0.2 sec., and seldom has more than fifteen members.

Similar auto-excitation has been observed in motor nerve, when rendered highly excitable through cold,¹ and in the sartorius muscle when locally squeezed;² in these instances, the causation of the phenomenon is of the same character, the electrical change of the active tissue exciting it to renewed activity, but in no structure is the production of secondary, tertiary, etc., effects so marked as in the electrical organ. In *Malapterurus* this is so pre-eminently the case, that the efficiency of the organ, as a weapon for protection and attack, is thus enormously increased.

The effect of repetition of the stimulus.—It does not appear possible by rapid repetition of the stimuli to evoke responses which shall be superimposed upon their predecessors. Probably the tissue change, which is the basis of the response, cannot be reproduced until the electromotive effect, which is its objective sign, has more or less subsided. The presence of the change would be then associated with a period of diminished excitability. It appears probable from recent researches by Gotch and Burch, that nerve shows a similar incapacity for the production of a second electromotive change whilst that of a precursor is still in progress.³ The potency of the organ discharge, when wielded by the fish, is thus not increased, like that of a muscle, by such summation of mechanical effect as exists in the fused tetanic contraction. It is modified by the magnitude of the initial effect, which is itself dependent upon that of the exciting stimulus, by the extent of the auto-excitation which causes a repetition of the effect, and by the number of the successive central discharges which reach the organ.

The gradual diminution in the magnitude of the response, when the organ is excited many times at such intervals (say five times per sec.), as to insure its excitation, has been already alluded to. In *Torpedo* preparations, Schönlein⁴ found that a rheotome experiment, involving at least 500 excitations, could be repeated about ten times when the tissue

⁴ Schönlein, *Ztschr. f. Biol.*, München, Bd. xxxiii. S. 408.

was fresh, although only two or three times when it had been kept for over twenty-four hours.

The residual effect of the response.—In *Torpedo* the electromotive changes, due to the excitatory explosion, are followed by others of the same sign; these may be termed residual effects, and are not improbably strictly analogous to the negative after-effect observed in both muscle and nerve. In the organ of *Malapterurus* they are of small amount, and it is of interest to note that, in this fish, the so-called resting current of du Bois-Reymond is also inconsiderable. In the organ of *Torpedo* and in that of the skate, such residual effects are far more marked.¹ The simplest experiment suffices to show the change. A strip of organ with its attached nerve is connected with a galvanometric circuit, and any existing difference of potential is carefully compensated. The galvanometer circuit is now disconnected, and the organ excited several times by stimulating its nerve. On again connecting the galvanometer, although the excitatory explosions have had ample time to develop and subside, the dorsal end of the *Torpedo* columns is found to be galvanometrically positive to the ventral. This wake or residuum of the excitatory disturbance slowly subsides; it resembles the initial response in sign, but is unlike it in other respects, since the change is of comparatively low electromotive force, and subsides slowly. It is of interest, not merely because it accounts for the so-called resting difference, but also because its presence shows that the molecular disturbance, which is the basis of the pronounced shock, is such that the tissue does not completely regain its poise for some considerable time. It must be remembered that, since the residual effect is present in every disc, the change observed in a preparation is the sum of such effects in all the discs constituting the columns. In any one disc it is thus of very small amount, but is magnified into a distinct effect by the pile arrangement of the tissue.

The electromotive force of the response.—Various methods have been employed for this interesting determination. These have been chiefly concerned with the electromotive force of the discharge which is obtained from an uninjured electrical fish, but it is probable that the intermittent character of the effect in such cases only allows of an approximate determination. In *Torpedo* the telephone results of Schönlein gave an electromotive force of 30 volts, or over;² in *Malapterurus* the total electromotive force must certainly be at least six times as great as this. With the excised organ the electromotive force of a single response may be ascertained within certain limits, either by balancing the effect, when a known rheotomic fraction of the response is permitted to traverse a galvanometric circuit, or by analysing the photographed curves of the excursion of the capillary electrometer produced by such a response. If the strip of organ stimulated is subsequently prepared for microscopic purposes, the number of discs placed in series in the strip can easily be counted, and thus the electromotive force of the change in any one disc can be calculated, on the supposition that all such discs are the seat of similar changes. In this way it has been found that in the comparatively feeble organ of the skate the change in each disc amounts to about 0.03 volt, in *Torpedo* to about 0.04 volt, in the powerful organ of the *Malapterurus* it may reach as much as

¹ du Bois-Reymond, *loc. cit.*; Gotch, *loc. cit.*

² Schönlein, *Ztschr. f. Biol.*, München, Bd. xxxiii. S. 408.

0.045 volt.¹ In regard to the physiological effects produced by the electrical discharge of an entire fish, it must be remembered that the small quantity, the rapid character of the development, and the sudden cessation, causes the physiological effects of the high potential upon the tissues of other animals to be of a different order to those produced by a similar voltage of longer duration; and since the seat of electrical production, the discs, is set in the moist tissues of the organ, only a derivation of the currents produced by the electromotive changes will pass through such external conductors as are supplied by the tissues of any other animals which chance to be in the neighbourhood.

Polarisation phenomena in electrical organs.—The peculiar structure of the electrical organ must undoubtedly complicate the production of such polarisation effects as are demonstrable in nerve, during and after the passage of electrical currents. The main features of polar changes in nerve are those associated with alterations in the excitability and in the electromotive conditions of the tissue respectively. Evidence of similar effects is not wanting in the case of electrical organs, but this evidence can be only rendered intelligible after a brief consideration of the polarisable media presented by such a series of compartments as exist in these structures. Each compartment has a protoplasmic disc, with a dense array of nerves, both being polarisable structures; it is bounded on both sides by a more liquid mass, the electrical conductivity of which is on a par with that of 0.6 per cent. NaCl solution.² The disc thus offers to the passage of currents along the column length a thin central plate of higher resistance, and when non-polarisable electrodes are used for the passage of a current from an external source through the length of a column, the polarisation interfaces will obviously be situated on each surface of each disc. In a column, therefore, there will be, as far as the discs and the contained nerves are concerned, multiple anodes and cathodes, an anode and a cathode being present in each disc. The polar changes in excitability, if present, will thus resemble those produced when a current is directed more or less transversely through a series of nerve fibres lying side by side. We know that the more the direction of a current is transverse in these latter structures, the less becomes its exciting efficiency, and the less, therefore, any evidence of polar interference with such excitability, in consequence of reversal of the direction of the traversing current. We should not, therefore, expect, on *a priori* grounds, any pronounced change in the response of an electrical organ, dependent upon altered direction of a polarising current, when this is allowed to traverse the plates in the direction of the columns. On the other hand, if the polarising current is applied to the trunk of the electrical nerve, then the nerve divisions in the plate will be the seat of extrapolar changes, and the response of the organ should be affected in much the same way as is that of a muscle under similar conditions.

¹ Recent observations by Gotch and Burch, made in 1899, have enabled an accurate calculation of the electromotive force of the effect obtained from a strip of *Malapterurus* organ 15 mm. long. The electromotive force of the strip reached a maximum of 26 volts, giving for the whole fish a maximum of 200 volts, and for each disc a maximum of 0.044 volt, since the strip contained 500 discs in series (*Proc. Roy. Soc. London*, 1899).

² Recent experiments on *Malapterurus* organ, made at Oxford, show that the resistance for currents directed longitudinally through the columns is four times as great as that offered to transverse currents. The greater resistance in the former case is an indication of that of the discs. The resistance to transverse currents was found to be the same as that of 0.6 per cent. NaCl. (*Proc. Roy. Soc. London*, 1899).

In the case of polarising currents which traverse the discs, the most appropriate nomenclature for indicating their direction is that first employed by du Bois-Reymond, who termed all currents traversing the discs in the same direction as those produced by the functional organ response, *homodromous*, whilst those of opposite direction were described as *heterodromous*.¹

In *Torpedo* organ it is found that homodromous currents excite a response, on the whole more effectually than heterodromous ones; with the former the trunks of the nerve fibres entering the discs, to be distributed on its ventral aspect, are evidently in the region of the anodic polarisation, whilst the terminations of such nerves in the disc would lie in regions of cathodic polarisation.² The reverse will be the case with heterodromous currents, the nerve-endings being now anodic rather than cathodic. Any increased exciting efficiency of homodromous currents may be thus reasonably supposed to be related to cathodic polar changes in the nerve-endings contained in these. It appears, however, from recent experiments by Schönlein, that there is considerable variation as regards exciting efficiency, and it is extremely doubtful if any definite augmentation of excitability can be produced by homodromous currents.

In *Malapterurus* organ the present writer has always observed that the heterodromous current excites better than the homodromous. It must be remembered that the discs in this organ are peculiar, since the nerve fibres end in the caudal stalk and do not ramify in the expansion of the disc. The current due to functional activity is directed through the discs from the cephalic to the caudal aspect; this would therefore be the direction of homodromous exciting currents. On the passage of such homodromous currents, the nerve-endings would, owing to their position, be in an anodic region, whilst, with heterodromous currents, the nerve-ending layer would, for similar reasons, be within the cathodic region. We should therefore expect, provided these regions are the seat of polar changes in excitability during the flow of a current, that the heterodromous would be more effectual for evoking the response than the homodromous. Such results as are definite both in *Malapterurus* and *Torpedo* are thus consistent with the view that polar changes of excitability may occur in the nerve-endings of electrical organs.

This is confirmed by observations upon the exciting efficiency of currents applied to the nerve trunk outside the organ. It has been found by Schönlein that an ascending galvanic current (directed up the electrical nerve) evokes a response in *Torpedo* of much less marked character than one directed down the nerve.³ In the former case, the peripheral nerve branches are in the region extrapolar to the anode (anelectrotonic), in the latter catelectrotonic, and the nerve-endings undoubtedly share in the extrapolar state. The augmented response to the descending current, and the diminished response to the ascending one, appear to indicate that the excitability of the nerve-endings in the supplied discs is augmented in the one case, diminished in the other. The result might be due to polar changes in the nerve outside the organ, interfering with the adequate propagation of the excitatory state along the nerve trunk; but such interference is insufficient to account for the difference in the organ responses, for the following reason. The response to the nerve excitation by the descend-

¹ du Bois-Reymond, *loc. cit.*

² Gotch, *loc. cit.*

³ Schönlein, *loc. cit.*

ing voltaic current is not merely augmented but shows self-excitation, whilst that due to excitation by the ascending current is a single small effect. Since self-excitation occurs when the excitability of the nerve-endings is high, it appears most probable that we have in this experiment a demonstration of the establishment of extrapolar changes in excitability along the nerve trunk to its ending in the organ.

The second great feature of the changes caused in nerve by the passage of currents is the production of secondary electromotive effects. The simplest experiment upon this subject is the familiar fact that the passage of a galvanic current is succeeded in polarisable media by the establishment of counter-electromotive changes. In strips of organ this is readily demonstrated, provided the galvanic current used be not intense enough to excite. If, however, it should excite the strip, then the intense current due to the response must obviously sum algebraically with any polarisation after-effect. For this reason, homodromous polarising currents, though followed by opposite, *i.e.* negative, polarisation effects when weak, are, when stronger, followed by a marked positive or similarly directed change, that of the response itself. On the other hand, heterodromous currents, which when weak are followed by the counter-current of negative polarisation, are, when stronger, succeeded by counter-effects of very great intensity, since the excitatory change, being of like sign with that of polarisation, now sums directly with this.

The presence of the response appears to have been overlooked by du Bois-Reymond, who considered that two sorts of polarisation effects, negative and positive, could be produced in the electrical organ.¹ There seems little doubt that when experiments are so arranged as to exclude the strong excitatory effect which immediately follows the cessation of a strong current, but little evidence of such doubly directed polarisation exists.

Excitatory and Polarisation After-Effects in Torpedo Organ.

The particular positive after-effect, or positive polarisation, was admitted by du Bois-Reymond to occur, as a secondary phenomenon, only in the case of homodromous polarising currents. This in itself suggests that the change is due to an excitation, since the response is always in one direction, however aroused. It will be remembered that a similar positive polarisation, declared by the same authority to exist in muscle and nerve, has been shown to be due to local polar

¹ du Bois-Reymond, *Arch. f. Physiol.*, Leipzig, 1885, S. 86; 1887, S. 51; *Sitzungsber. d. Akad. d. Wissensch.*, Berlin, 1888, Bd. xxii. S. 531.

excitation. The present writer, working with strips of *Malapterurus* organ, in 1894, convinced himself that if the strip was narcotised or otherwise altered, so that the excitatory response failed, no homodromous after-effect occurred on the cessation of the homodromous polarising current. Indeed, even in perfectly excitable strips of *Torpedo* organ, it is possible to do away with the homodromous after-effect by very simple means. For if the polarising current is not too strong (maximum, 7 Groves), although a short closure of $\cdot 005$ sec. to $\cdot 01$ sec. is succeeded by an homodromous after-effect, due to the excitatory response overpowering negative polarisation effects, yet, on lengthening the period of closure to 1 sec., the negative polarisation is sufficiently increased to swamp the excitatory change, and the usual heterodromous after-effect appears. This will be made clear by the above example.

The failure to recognise excitation phenomena involved du Bois-Reymond in a further unwarrantable statement, namely, that the electrical conductivity of an organ strip was very much less for homodromous than for heterodromous currents. The evidence for such irreciprocal resistance is quite as unconvincing. Many of the observations were made with induced currents, which were allowed to traverse both the organ and an appropriately arranged galvanometer. If this current was homodromous, the galvanometric deflection was large; if heterodromous, small; but rheotome observations have shown that, under these circumstances, the former large galvanometric effect was due to the summed effect of the homodromous induced current and the homodromous excitatory response, whilst the small effect was the algebraic sum of the dissimilar heterodromous induced current with the homodromous response. In regard to the observations with voltaic currents of long duration, such interference of the excitatory effect is not so obvious. The subject has been reinvestigated by Schönlein, who used Kirchoff's well-known methods for estimating electrical resistance and Kohlrausch's bridge.¹ He found that when a current of from 20 Daniells or more was led through the excised organ for 30 secs. in either direction, the tissue lost its excitability, and did not respond to ordinary excitation. Accompanying this failure is a diminution of the living electrical resistance. When such currents were led through the tissue for only 0.1 sec., the tissue showed most irregular results. At one time the homodromous, at another the heterodromous, appeared to have the advantage. There is thus no evidence of such marked irreciprocal resistance as du Bois-Reymond imagined to exist, an irreciprocity so great as only to be accounted for, in his opinion, by assuming an electromotive force of over 30 volts, due to a particular arrangement of those hypothetical molecules with which his name is identified.

The refutation of positive polarisation and of marked irreciprocal conductivity may seem a matter of small moment, but as their existence was considered by du Bois-Reymond as almost a *demonstratio ad oculos* of the existence of those special electromotive molecules which form the basis of his theory, it is really of some little importance. It cannot be said that the great electro-physiologist contributed much towards the elucidation of the functional activity of electrical organs, and it was the error of ignoring the true excitatory response which appears to have barred his progress. The phenomena of electrical organs may seem somewhat inexplicable, on any present conception as to the source of

¹ *Ztschr. f. Biol.*, München, Bd. xxxiii. S. 408.

vital electromotive changes, but they appear to the author to be far more in harmony with the alteration theory than with any other; and if, as experiments seems to show, the change is that of nerve-endings magnified by the peculiar symmetry of their arrangements, this theory can embrace them as harmoniously as it does those of nerve itself.

The reflex response of the organ.—The nerve fibres which supply the electrical organs are in all cases the axis cylinder branches of special nerve cells. In *Gymnotus* and *Mormyrus*, these cells form a vesicular column on each side of the spinal cord, but in *Torpedo* they are massed into special lobes of the medulla oblongata. In the case of *Malapterurus*, there being only one nerve fibre for each lateral organ, there is only one giant nerve cell in each half of the cord; this is situated between the exit of the first and second spinal nerves. In all these fish the organ can be made to respond reflexly to special sensory stimulation, the most efficient being electrical or mechanical excitation of the skin. Mechanical pressure appears to be a particularly efficacious means of evolving the reflex. Thus in the skate, a reflex response of the organs in the tail is readily evoked by rubbing the rough spines upon the dorsal surface. *Torpedo* and *Malapterurus* discharge when the surface is pressed. The telephone forms a convenient mode of ascertaining the presence of the response, the fish being placed in a suitable tank and connected by means of either plates or an appropriate net with the necessary metallic leads. The reflex responses are enormously increased by the action of strychnia, the organ like the muscles being thrown into a series of prolonged intermittent phases of functional activity; they are diminished by narcotisation and by prolonged cold.

In the case of the active *Malapterurus*, discharges of the organ often occur when it is swimming about, and the same appears to be true of *Torpedo*. The *Gymnotus*, kept in a tank, will discharge when small live fish are placed in the water. The discharge stuns a certain number of the fish, and the sluggish eel is thus able to devour them at his leisure.

These natural discharges present two points of interest. In the first place, the discharge is a succession of organ-effects; thus the electro-magnetic signal vibrates, and a singing sound is heard in the telephone. In the second place, both the rate of succession and the intensity of the organ responses are extremely variable. The writer recorded with an electro-magnetic signal a torpedo discharge of 110 successive electrical changes in the second. At Naples, working with the recording telephone, Schönlein found a maximum of 187 in the second. This rapid succession cannot be kept up for any length of time, the longest period of rapid discharges observed at Naples was only 0.896 sec., but in this time ninety-two separate responses occurred.¹ It appears also that the responses of both organs are evoked simultaneously, so that the numbers just given must indicate the rate of discharge of each of the organs.

A special interest attaches to the study of the reflex organ response, in consequence of the light which it may throw upon the working of the central nervous system. For if, as seems probable, the organ response is due to the functional activity of nerve-endings, then the reflex discharge should give a tolerably faithful picture of the character and rate of the outflow from those nerve cells with which the nerve-endings are structurally continuous.

¹ Schönlein, *loc. cit.*

In the case of both *Torpedo* and *Gymnotus*, there is apparent evidence that a succession of excitatory states leaves the electrical nerve cells at a rate which may be at least 100 per second. It would be rash to assume that this rate of outflow occurred from each central electrical nerve cell, for in both these fish there are a large number of such cells. But in the case of *Torpedo* the nerve cells are all definitely localised in a portion of the medulla oblongata, and thus form as a whole the efferent cells of one nerve centre; the whole centre may possibly discharge at this rate. It is, however, not clear in either *Torpedo* or *Gymnotus* what share the self-excitation of the organ takes in the production of the rapid succession of responses. Until the organ discharge has been recorded by means of such an instrument as the capillary electrometer, the responses evoked by fresh central nervous impulses cannot be separated from those of the organ rhythm. At present, therefore, any such rapid rate of central outflow of nervous impulses is not proved, and is on *a priori* grounds improbable.

The most interesting case is undoubtedly that of the *Malapterurus*, for, as each organ is innervated by the terminal branches of one axis cylinder, the character of the reflex response in this fish must indicate that of the efferent output of the single nerve cell from which the axis cylinder springs. The reflex response of the organ of *Malapterurus* has been studied in the living specimen by the aid of the capillary electrometer, and the following characters have been thus determined.¹ When the skin of the fish is excited, either mechanically or electrically, a reflex response is evoked after a comparatively long period of delay. This delay may be as little as 0.023 sec., or as much as 0.5 sec. The smaller number, after deduction of the transmission time along the main nerve-paths, and of the delay in the organ itself, leaves a remainder of 0.008 sec. for the central time. This duration, 0.008 sec., is thus the time occupied by the transmission of the excitatory state through the central arc.

As regards the character of the response itself, a difficulty arises, due to the capacity for self-excitation previously described; from the absolute regularity of the effects produced during this peripheral organ activity, it is, however, easy to distinguish, in the photographic records of electrometer excursions, between the results of such auto-excitation and the arrival at the organ of a new excitatory state along the efferent nerves.

This distinction is further facilitated by the circumstance that, in *Malapterurus*, whereas the separate responses due to auto-excitation occur at rates of from 100 to 300 per second, those due to a fresh central outflow are of a very different order. The shortest interval between two separate responses of a reflex character yet observed was $\frac{1}{12}$ sec. (0.085), and the average interval was as much as $\frac{1}{4}$ sec. (0.25). Even this slow rate of central discharge could not be maintained, the maximum number in any series being only five, and the average number two to three. If the reflex organ response, when evoked by impulses reaching it through its efferent nerves, gives a true picture of the central discharge, then in the *Malapterurus* a second excitatory state cannot emerge from the single cell at an interval of much less than $\frac{1}{10}$ second, whilst the cell itself, after two or three such displays of activity, is fatigued. The same susceptibility to central fatigue occurs in both *Gymnotus* and *Torpedo*, and hence it is not improbable that the so-called immunity of

¹ Gotch and Burch, *loc. cit.*

electrical fish to their own discharges is only relative. It seems far more likely that the discharges, if forcible or prolonged, exercise deleterious effects upon both central and peripheral parts of the nervous system. In confirmation of this is the observation of Schönlein and others, that after repeated reflex discharges of a violent character, the excised organ is in a far lower state of excitability than it is when repeatedly excited by stimulation of its nerves.¹

THE NATURE OF THE ACTIVITY OF ELECTRICAL ORGANS.

A few remarks may be made, in concluding the present article, with reference to the question as to how far the activity of electrical organs is to be regarded as based upon changes which are *sui generis*, rather than upon those present in other excitable structures such as muscle and nerve. The great electromotive force of the change is, at first sight, only to be accounted for on the supposition that the organ is the seat of special processes unlike those present in muscle or nerve; it has, however, been insisted upon in this article, that the extent of this electromotive force is due to the disposition of the elements in series, and that in each element of the series no such enormous development occurs. The columnar structure of the electrical organ thus modifies rather than determines the characteristics of the activity. The separate elements constituting the essential structural features of the organ, have in the case of *Torpedo*, *Mormyrus*, *Raia*, and *Gymnotus* been developed from neuro-muscular elements, and whereas the nervous part persists, the muscular part has been transformed. It is thus not unreasonable to consider, in the first place, how far the activity of the organ can be viewed as in its essence of the same nature as that which produces the electromotive changes accompanying muscular activity. Although there is no disparity between the electromotive force of the change in an organ element and that of such a muscle as the *sartorius*, there are very serious objections to any causal connection between organ and muscular electrical effects. In *Malapterurus* the morphological evidence tends to show that glandular elements have been utilised in the evolution of the organ, not muscular ones. Further, the multinucleated protoplasm which constitutes the greater part of the disc of *Raia* and the whole of the *Malapterurus* disc is homologous neither with muscle nor with gland, but with the protoplasmic sole of the nerve end-plate. The whole question, therefore, is narrowed down to the two following possibilities:—(1) Is the disc the effective part of the organ element? If so, then the change, though analogous with that presumably present in nerve end-plates, is in reality something *sui generis*, for no electrical effect has been observed in such end-plates. (2) Is the disc merely a means for reinforcing electrical changes occurring in the nerves themselves? If so, then the effective part of the organ-elements is nervous, and the change is based upon the same processes as are present in nerve when roused to activity. (1) The view that the disc is an excitable structure responding to nervous impulses which reach it through its nerves, is contradicted by all experimental observations. Drugs, such as curari and atropin, appear to have no specific paralysing effect upon the organ, unless such doses are employed that the nerves themselves are affected. There is no evidence that the discs can be excited apart from their contained nerves; all agents which annul the excitability of the electrical nerves annul at the same time the response of the organ to electrical currents which traverse its substance. One of the most suggestive facts bearing on this point is the complete inexcitability of an organ when deprived of its nerves through nerve degeneration in consequence of previous section. Direct excitation of the organ is direct only in appearance, not in reality; there is always nerve excitation, whether the

¹ Schönlein, *loc. cit.*

excited nerves lie outside or inside the organ columns. In one organ, that of *Malapterurus*, the expanded disc has no nerves in its substance, these all ending in the slender stalk which projects from the disc; and the disc expansion itself affords no structural differences to account for corresponding electromotive differences between its surfaces.

(2) The only excitable structures in the organ are thus the nerves and their fine terminations, and since these are known to be the seat of electrical changes during activity, it seems more reasonable to presume that the organ change is in reality closely related to the production of molecular disturbances in its contained nerves. Apart from the consideration that the nerves are the only structures present which we know to be capable of developing such electrical changes, there are other circumstances which favour this view. The time relations of the organ shock and those of nerve closely correspond; it is true that the organ shows a period of delay, but this can be accounted for by transmission time either along nerve trunks or fine nerve-endings. There are in fact only two discrepancies of moment; the organ can be fatigued by activity, and the electromotive force of the change in each organ element is greater than that present during nerve activity. With regard to organ fatigue, it may be pointed out that this occurs even in nerve as far as the finer terminations are concerned, and as regards the electromotive force discrepancy it has been recently shown that the sciatic nerve of the frog can develop a change of more than $\cdot 03$ volt in response to a single stimulus.¹ The electromotive force of each organ element varies between $\cdot 03$ and $\cdot 05$ volt; the discrepancy is thus not so great as to offer any insuperable objection to the view that the organ effect is essentially that of active nerve. It is not fanciful to imagine that the disc itself may play somewhat the same secondary part in regard to the primary and essential nervous disturbance, as a resonator can play in the case of sound, or an electrophorus in the case of the electrified body which charges it.²

But whether the protoplasmic expansion of the disc plays such a reinforcing rôle or not, the clear fact remains that the essential primary disturbance which constitutes the organ shock is a nervous one; without nerves, the discs, having nothing to reinforce, would be impotent and absolutely inexcitable. The primary cause of the organ shock is thus in all probability a change identical in nature with that producing the electromotive phenomena of nerve, and if so, then it will be interesting to see how far the various theoretical explanations of these phenomena can be extended so as to comprise those of the electrical organ. One such hypothesis can undoubtedly be so extended—the alteration theory, as given either by Hermann or by Hering. It is far more difficult to extend any molecular theory in this direction, or indeed any view which involves the pre-existence of electromotive elements. Electrical organs show no resting electrical effects; all the effects are connected with excitation and its concomitant alteration. This may be produced by the sudden stimulus of electrical currents or the prolonged one of a persistent localised injury of nerve trunks. In all cases the alteration in the nerve is accompanied by the rapid development of electrical changes, whilst the structural disposition of the organ is such that the changes present in each group of nerve terminations can, by summing with those in the neighbouring groups, become conspicuous.

¹ Gotch and Burch, *Proc. Roy. Soc. London*, 1898, vol. lxiii. p. 300.

² Compare Kühne's views on the causative value of electrical changes in motor nerve-endings for the production of indirect muscular contraction. The above interpretation of the phenomena of the electrical organ undoubtedly supports Kühne's suggestion that "a nerve throws a muscle into contraction by means of its currents of action." Kühne, Croonian Lecture, "Ueber die Entstehung der vitalen Bewegung," *Proc. Roy. Soc. London*, 1888, vol. xlv. pp. 429-446.

THE NERVE CELL.

BY E. A. SCHÄFER.

CONTENTS.—Classification of Nerve Cells, p. 592—Theory of Isolated Units (Neurone Theory), p. 593—Structure of Nerve Cells, p. 594—Changes in Nerve Cells as the result of Excitation, p. 599—Changes resulting from Section of the Nerve Fibre Process, p. 600—Conduction in Nerve Cells, p. 605—Time lost in Transmission from Cell to Cell, p. 608—Refractory Period, p. 614.

NERVE CELLS may be broadly classified into—(1) *afferent cells*, which receive impressions at the periphery, and convert such impressions into impulses which pass towards the central nervous system; (2) *efferent cells*, which send out nervous impressions towards the periphery; (3) *intermediary cells*, which receive impressions from afferent cells and transmit them directly or indirectly to efferent cells; (4) *distributing cells*, which occur near the periphery, and, receiving impulses from efferent cells, distribute them to involuntary muscles and secreting organs. The cells classed under (1) and (2) are also known as *root cells*. The greater number of the nerve cells of the brain and cord belong to the intermediate class; they serve the purposes of association and co-ordination, and afford a physical basis for psychical phenomena; the cells classed under (4) belong to the so-called sympathetic system.

Originally the afferent or sensory root-cell is situated at the periphery, in some part of the integument, and is connected with the central nervous system by a process (nerve-root fibre) which ramifies amongst the nerve-cells of the central organ. This primitive condition is found in the earthworm, and it is also persistent in the olfactory cells of all vertebrates. In the process of evolution the peripheral cell sinks below the integument, leaving a process at the surface. Ultimately the body of the cell is found close to the central nervous system (in the spinal ganglion), and the peripheral process is found to have developed into the peripheral sensory nerve (Fig. 300). The typical efferent root cell is the cell of the anterior horn of the spinal cord, which sends out a nerve fibre directly to one or more muscle fibres or gland cells.

Every nerve fibre is a process of a nerve cell. As was first made clear by the researches of Deiters,¹ most nerve cells have, besides the nerve fibre or axis cylinder process (neuron,² axon), an uncertain number of other processes (dendrons),³ which differ from the nerve fibre process

¹ "Untersuch. u. Gehirn. u. Rückenmark," Braunschweig, 1865.

² From *νευρον*, a nerve. This term was suggested by me (*Brain*, London, 1893, vol. xvi. p. 134) to denote that the process in question is a nerve fibre, and I regret that only one or two prominent neurologists have employed it in this sense. The terms *neuraxon*, *neurite*, are also used by authors to express the same idea.

³ *Dendrites* of some authors.

in certain details of structure, and also in the fact that at once on leaving the cell body they begin to branch dendritically, and the resulting branches terminate in arborisations in the neighbouring grey matter. The dendrons of some nerve cells are beset in their whole course with short and minute processes which have been termed "thorns" or "gemmulæ."¹ Many nerve cells possess no dendrons; this is the case with the typical cells of the spinal ganglia, and with those of the corresponding ganglia of the cranial nerves, but it is doubtful whether any nerve cell possesses only dendrons, and is destitute of a nerve fibre process.² On the other hand, a nerve cell may possess more than one; thus the bipolar cells of the spinal ganglia of osseous fishes and the cells of the

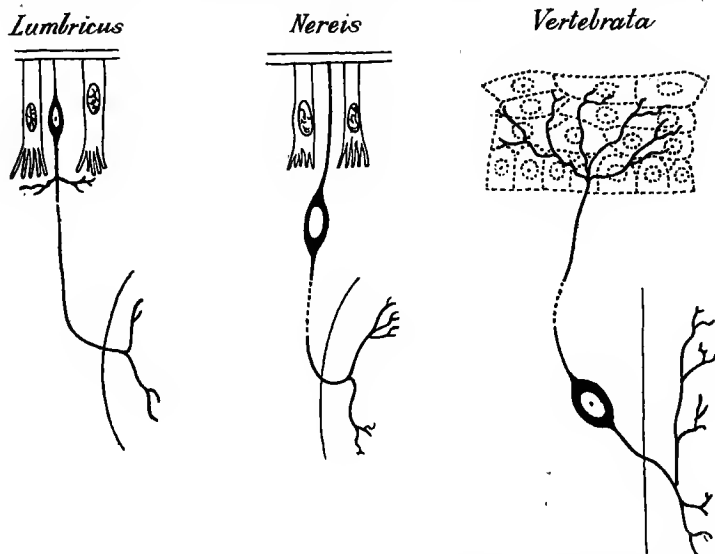

FIG. 300.—Diagram to show the primitive condition of the afferent nerve cell, and the manner in which it has become altered in the process of evolution of the nervous system.—G. Retzius.

ganglion cochleæ possess two, issuing from opposite ends of the cell (bineural cells); and cells have been described by Ramón y Cajal in the molecular layer of the cortex cerebri which have three or more (polyneural cells).

Cajal³ distinguishes nerve cells into those with a long axis cylinder process (type 1 of Golgi), and those with a short axis cylinder process (type 2 of Golgi), but it is doubtful if these types represent any physiological distinction, as supposed by Golgi, or if, indeed, they are morphologically distinct from one another.

Theory of isolated units. Neurone theory of Waldeyer.—Each nerve cell, inclusive of the nucleated body and all its processes, irrespect-

¹ See on these structures, A. Hill, *Brain*, London, 1897, vol. xx. p. 131.

² The "amacrin" cells described by Ramón y Cajal in the retina, may be an exception to this rule. See Quain's "Anatomy," vol. iii. pt. 3.

³ *Rev. de cien. méd. de Barcelona*, 1891.

ive of their number, length, complexity, character, and position, forms a distinct unit, which is believed, as the result of the employment of the chromate of silver methods introduced by Golgi, to have no structural continuity with any other unit. This "theory of isolated units," which is often spoken of as the "neurone¹ theory," from the name "Neuron" having been applied by Waldeyer² to the nerve cell as above defined (including all its processes), is not conclusively proved, nor is it accepted by some prominent histologists, including Golgi himself. But it is supported by the anatomical observations which have just been referred to, and is found to fit in with many known physiological facts, and to lend itself better than the "continuity theory" of nervous elements, which it has in large measure supplanted, to the explanation of phenomena which were previously obscure; on this account it has been widely adopted by neurologists, many of whom, following the example of Waldeyer, habitually speak of nerve cells as neurones, although the term is quite synonymous with "nerve cell"; nor has the newer name any advantage either on the score of brevity or of etymology over the older and more general expression. Strong reasons, moreover, as will presently appear, have lately been urged against the acceptance of the theory which is associated with the newer name, so that it would seem wiser to retain the term "nerve cell." The practice of restricting the use of "nerve cell" to the body of the cell ("perikaryon" of some writers) should for obvious reasons be dropped.

Structure of nerve cells.—The structure of nerve cells has of late years been the subject of numerous researches.³ The general result of these may be shortly given as follows:—The nucleus of the nerve cell is characterised by its large size, and the fact that its chromatin is in relatively small amount, except in the nucleolus, which is large.⁴ The protoplasm of the cell body resembles that of other cells in exhibiting a reticular or sponge-like structure (spongioplasm), with a clear or finely granular substance (hyaloplasm) in its meshes.⁵ But there are two points in which it is peculiar. One consists in the occurrence of fibrils which run through the protoplasm. Such fibrils were observed by Max Schultze,⁶ who found them in both fresh and osmic preparations of nerve cells (Fig. 301), and described them as passing into and out of the cell by its processes, and as having the same finely varicose character as the fibrils which he had also found in the axis cylinder and its terminations. Of late years there has been shown a tendency to doubt the existence of such fibrils, as structures distinct from the general reticulum of the protoplasm. For it is obvious that the elongation of the meshes of a reticulum in definite directions might simulate fibrils, as indeed is probably the case in many elongated cells, such as columnar epithelium, and smooth muscle. This view of the matter was taken

¹ Often erroneously written "neuron." Gr. *νευρώω*.

² *Deutsche med. Wchnschr.*, Leipzig, 1891.

³ A concise account of these researches, with very full bibliography, is given by W. Ford Robertson in *Brain*, London, 1899, vol. xxii. pp. 203–327.

⁴ The structure of the nucleus is dealt with by Levi in various papers in the *Riv. di patol. nerv.*, Firenze, for 1896, 1897, and 1898.

⁵ Like other cells, it contains a centrosome (v. Lenhossék, *Arch. f. mikr. Anat.*, Bonn, 1895, Bd. xiv. S. 345). The protoplasm (interfibrillar substance) of the axis cylinder is somewhat different chemically—as shown by its reaction to certain stains and to osmic acid—from the protoplasm of the cell-body and dendrons (Mönckeberg and Bethe, *ibid.*, 1899, Bd. xlv. S. 135).

⁶ Stricker's "Histology," vol. i. *Syd. Soc. Translation*.

originally by Frommann,¹ and adopted by several recent writers, such as Ramón y Cajal,² v. Lenhossék,³ v. Gehuchten,⁴ Held,⁵ and Marinesco.⁶

Others, such as Flemming,¹ Lugaro,² Dogiel,³ Levi,⁴ Cox,⁵ Mann,⁶ and Bethe,⁷ have, on the other hand, insisted upon the existence of fibrils, distinct from the reticulum, running through the protoplasm from and into the several processes, and this view is now generally held, and has been adopted even by those who until quite lately were of the opposite opinion.

FIG. 302.—Nerve cells of *Hirudo*.—*A*, Unipolar motor nerve cell; *a*, network of neuro-fibrils in cell body near surface; *b*, network near nucleus, *n*; *c*, afferent neuro-fibrils; *d*, efferent neuro-fibril. *B*, Sensory nerve cell, bipolar; *a*, body of cell; *n*, nucleus. A neuro-fibril is seen passing from its ramification between the epidermis cells, *ep*, close to the cuticle, *cu*, to form a network within the nerve cell, before passing on to the central nervous system.—Apáthy.

While it is easy, by certain methods and in certain cells, to show a fibrillation both in the cell body and in its processes, with other cells it is more difficult on account of the complexity of course of the fibrils within them. The axis cylinder of a nerve is an especially favourable object for the observation of nerve fibrils, and they become naturally dissociated at the termination of nerves, where in some cases, as in the cornea, the axis cylinders break up into pencils of fibrils. It must be noted that these terminal fibrils are almost invariably branched, and sometimes even form a network; which appears to indicate that there may be lateral communications between them, and that they may not be always entirely distinct even throughout their course in the nerve fibre.⁸ Such lateral communications are sometimes apparent in the fibrillations of the dendrons, as well as in those of the cell body, and although less obvious in the course of the axis cylinder process, they may not be altogether absent in this. Nor are there any physio-

logical facts which would lead to the belief that nervous impulses are conducted within the nervous units by isolated fibrillæ.

The question of the existence or non-existence of fibrillæ may be now regarded as having been settled by the discovery by Apáthy⁹ of definite fibrils, entirely different from any spongioplastic reticulum, in the nerve cells of annelids. The fibrils form a network with com-

paratively open meshes in most parts of the cell, but sometimes more closely arranged immediately around the nucleus. The cell network is continuous with fibrils in the cell processes (Fig. 304).

Apáthy¹ has shown that cells which are apparently unipolar (unineural), may show, when appropriately stained, a central fibril in the centre of the nerve fibre process, which is traceable from a network of fibrils encircling the nucleus, and two or more fibrils situated peripherally in the process and connected with another network, intercommunicating with the first, and situated at the periphery of the cell (Fig. 302 A). He suggests that the central fibril is efferent, the others afferent in function.

A fibril network of a somewhat similar character has also been demonstrated by Golgi² in various cells of the central nervous system and in the cells of the spinal ganglia of mammals, so that the existence of such a network is probably to be looked upon as of general occurrence. Apáthy's observations in annelids go, however, further than this, for he has been able to show that the fibrillæ which he describes are not only continuous throughout the whole of any one nerve cell and its

FIG. 303.—Spinal ganglion cell, showing intracellular network of fibrils.—C. Golgi.

processes, but exhibit continuity from cell to cell, and form a network in the intercellular substance, or grey matter, of the nerve centres. If this should prove to be the case in vertebrates, as Nissl inclines to

FIG. 304.—Nerve cell of annelid, showing neuro-fibrils within the cell-body. *df*, fibrils of dendrons; *mf*, fibril of axon. The two sets of fibrils form a network within the cell.

believe,³ our conception of the nervous system must undergo important modification. At any rate, it appears clear that, at least in annelids, the neurone theory will not hold good, although the structure and

arrangement of their nervous system was at one time regarded as affording one of the surest bases for its foundation; and we must find some other reason than want of continuity of the fibrillæ for the explanation of the fact that, in preparations made by the chromate methods of Golgi, the nerve cells always appear distinct from one another and never actually united. But if we hold with Leydig (see below, note 4) that the fibrillæ are not the true conducting material, but merely supporting structures, and that the conducting function is carried on by the perifibrillar substance, which, it is possible to suppose, does not share the continuity of the fibrillæ, we can, whilst accepting the conclusions of Apáthy regarding the continuity of the nerve fibrils, still hold the neurone theory, so far as concerns the perifibrillar substance. According to Mönckeberg and Bethe,¹ the perifibrillar substance is discontinuous at the nodes of Ranvier.

There is some reason to believe that nerve fibrils are tubular. The fact that they are prone after death and under the influence of reagents to become varicose, is an indication of such a structure. Mönckeberg and Bethe² account for the varicosities by supposing that the interfibrillar substance may form droplets around the fibrils. But in sections of nerve fibres, the axis cylinders of which have not undergone any marked shrinking in the process of preparation, the fibrils, when examined or photographed with a very high magnifying power, have a distinctly tubular appearance.³

It is generally assumed, the existence of fibrils in the nerve element being presupposed, that these are the parts of the element along which the conduction of nerve impulses actually takes place.⁴ If this is so, we can conceive that the nervous impulses might pass along such minute tubes, in the form of a chemical change propagated from molecule to molecule, or as a physical change in the form of waves, started either by external mechanical means (tactile nerves, auditory nerves), or by contraction of the body of a nerve cell (motor nerves (?), olfactory nerves (?), visual nerves). The fact that nerve fibres are practically unfatiguable is in favour of a purely physical explanation of their peculiar manifestation of activity; moreover, no chemical change and no development of heat⁵ can be shown to occur in them as a result of their excitation. This is not the case with the body of the nerve cell, for the grey matter of the nerve centres does tend to become acid and also warmer⁶ after excitation. The fatigue of nerve centres is in fact a matter of every-day experience, and it has also been shown by Mosso⁷ that such fatigue, produced by mental strain, is accompanied by the development of fatigue products, which cause, through the circulation, fatigue effects on the voluntary muscles. It must, however, be conceded that both the unfatigability and the absence of demonstrable chemical change in nerve fibre does not necessarily prove that no chemical changes are occurring; for such changes may be so slight as to be entirely beyond our means of observation, owing to the very small

¹ *Loc. cit.* According to Engelmann, this discontinuity at the nodes of Ranvier involves the nerve fibrils of the axis cylinder (*Arch. f. d. ges. Physiol.*, Bonn, 1880, Bd. xxi.).

amount of true conducting matter within the nerves, and there may besides be a rapid process of reparation going on at the same time. There is, indeed, insufficient basis upon which we can at present found a probable theory as to the mode of origination and conduction of nervous impulses, or as to the exact nature of these impulses.

Another point of peculiarity displayed by the protoplasm of many nerve cells, is the existence within it of peculiar angular granules having a special affinity for basic aniline dyes, such as methylene-blue and toluidin-blue. The demonstration of these granules and the evidence of their importance in the physiology of the nerve cell we owe to Nissl,¹ and they are usually called after him the "Nissl bodies": they are also known as "chromatophil" or "tigroid" granules. They occur scattered in variable amount in all parts of the cell body and in its dendrons, but they are absent from the axis cylinder process and also from the part of the cell body to which this process is immediately attached. Their disposition within the cell body varies. In some cells they are chiefly disposed in the neighbourhood of the nucleus, whereas in others they are uniformly distributed or are more numerous at the periphery, but whether this implies differences in function or in the functional condition of the cells, is uncertain.

The most important physiological fact regarding these granules is that, under certain conditions of either normal or abnormal activity of the nerve cell, they undergo a change which has been termed by Marinesco *chromatolysis*, and which appears to consist in a gradual disintegration of the substance of the granules, and its diffusion in the juices of the protoplasm: this change is at first accompanied by a swelling of the cell, together with a displacement of the nucleus to one side; subsequently the cell may diminish in size, with disappearance complete or partial of the chromatophil substance.

The structural changes in the nerve cell which result from its excitation, whether this be direct excitation of a ganglion, or indirect by means of a nerve passing to it, have been studied by Hodge,² Vas,³ Mann,⁴ and others. Hodge has also studied the changes which result from natural excitation of nerve cells in the motor ganglia of insects, and in the cerebellum, cerebrum, and spinal cord of birds, both before and after a period of prolonged activity; and observations of a similar

character have been made by Mann upon the motor nerve cells of the brain and spinal cord, and the nerve cells concerned in visual perceptions (in the retina and the occipital lobe). Hodge did not examine the condition of the Nissl bodies, but notes that active nerve cells, as compared with those at rest, show a diminution of volume and a lessened power of reducing osmic acid, the nucleus also becoming shrunken and showing a tendency to stain more deeply. Vas¹ and Lambert² described the stimulated nerve cell as becoming clear in the centre and chromophil towards the periphery, and Pognat³ found that, with more prolonged stimulation, the Nissl bodies disappear entirely. Mann described the cell body and nucleus as becoming at first somewhat enlarged as the result of activity, but with fatigue there succeeds diminution in bulk of both nucleus and protoplasm; he also noted a diminution in the chromatic substance of the cell protoplasm. Nissl⁴ himself, in repeating these experiments, was unable to obtain such marked results.⁵ Nevertheless, it appears clear that the effect of activity is to induce certain chemical changes within the body of the nerve cell, its functional activity being attended with a diminution in the amount of chromatic substance in the cell protoplasm.

Much more definite effects are obtained as the result of section of the nerve fibre process. The first study of these effects we also owe to Nissl;⁶ his observations have been confirmed and extended by many others, and especially by Lugaro,⁷ Marinesco,⁸ and v. Gehuchten.⁹ Their results may be briefly summarised as follows:—When a motor nerve is cut, the cells from which its axis cylinders are derived begin, within from twenty-four to forty-eight hours after the lesion, to show indications of chromatolysis. The granules of Nissl become less defined, and the neighbouring portions of the protoplasm diffusely coloured. Concomitantly with, or soon after this, the cell body becomes swollen and the nucleus is often displaced to one side. This process goes on for about fifteen days, at the end of which time most of the cells of origin of the nerve are converted into rounded bodies, staining nearly uniformly with methylene-blue and showing no Nissl granules or only small ones, and these confined to the periphery of the cell. The change begins apparently at the place where the axis cylinder leaves the cell, and invades first the perinuclear portion of the protoplasm, and then its successive layers, the peripheral being last affected. It also extends gradually into the dendrons. After fifteen to twenty-four days the process of chromatolysis is at an end, and a process of reparation begins; this proceeds very slowly, so that it may take three months to be completed. At the end of that time the cells have for the most part resumed their original appearance, even although the cut nerve may not have undergone regeneration.

The corresponding changes in sensory nerve cells after section of the peripheral nerve, have been studied by Lugaro,¹ R. Fleming,² Cox,³ and others; partial atrophy and chromatolysis in the spinal ganglion cells having been noted by them.⁴ Lugaro failed to find any definite changes in the posterior ganglion cells on cutting the root between the ganglion and the spinal cord, or at most a very slight amount of chromatolysis. This is in accordance with the observation that in tabes, with complete atrophy of the fibres of the posterior columns of the cord, the spinal ganglion cells may be intact. van Gehuchten,⁵ with Nélis, has pursued similar investigations upon the effects on the cells of the ganglion of the vagus, of cutting that nerve peripherally to the ganglion. These observers find that changes, quite comparable to those above described for motor nerves, proceed in the cells of this ganglion, but that the process of disintegration is not replaced by a process of reparation, so that at the end of three months the cells have almost all disappeared. The complete disintegration of some motor cells, as a result of division of motor nerves, has also been affirmed by Nissl. I have found a similar change to take place with the cells of Clarke's column of the spinal cord, after section nearer the bulb of the afferent (cerebellar) tracts. The cells on the side of the section undergo chromatolysis, atrophy, and ultimately almost disappear.⁶

In all cases the nerve fibres cut off from the cell body undergo disintegration and disappear in a few days. In the case of the medullated nerves, their section also involves a breaking up and gradual removal of the substance of the medullary sheath, accompanied by multiplication of the nuclei which are embedded in this sheath. This is the well-known *Wallerian degeneration* of nerve fibres,⁷ and the first signs of it appear about twenty-four hours after section of the nerve, in the commencing fragmentation of the medullary sheath. This in two or three days is broken up into segments of variable size, and these, as the degeneration progresses, become gradually resolved into drops and droplets of myelin. Simultaneously with or immediately before these alterations in the myelin sheath, a change in the chemical constitution of the fibrils of the axis cylinder appears, as shown by an alteration in their capacity for staining,⁸ and it is about this time that the peripheral part of the nerve ceases to be excitable by electrical stimulation, although for the first few hours its excitability was increased. The fibrils next become wavy and varicose, and soon break up into isolated portions (granules), which break up still further, so that they are soon indistinguishable from the perifibrillar substance. Similar changes occur for a certain distance along the central part of the cut nerve. The degenerated axis cylinder may show complete
