TRANSLATOR'S PREFACE.

THE acknowledged fame of the celebrated author of these Tracts, and the importance of his numerous discoveries, are too well established to require any additional confirmation here. His name has justly been inrolled with that of the most illustrious European physiologists : and his works will ever remain an emblem of genius and research. All bear indisputable evidence of profound investigation into the phenomena of nature, and of the most comprehensive and enlightened understanding. Probably the following treatises on the *Natural History of Animals and Vegetables* will rank with the first of his productions ; for the new, singular, and interesting matter they contain will be an equal source of pleasure and admiration to the philosophic reader.

The unaccountable theory of spontaneous generation made great and rapid progress towards the middle of last century : it was even embraced by naturalists of no inconsiderable merit. Mr Needham, in supporting a system which he firmly believed, attacked or misconstrued some of the author's principles, who, in his turn, retorted with uncommon severity. This controversy occupied a considerable portion of the first Tract, but part of it is here omitted ; for it is certainly needless to revive any thing concerning a doctrine now totally exploded. Whoever beholds the animalcula of infusions, either with the naked eye or a microscope, in my opinion, can demand no other evidence of their animation, which was the principal point in dispute. All the other Tracts are preserved entire as in the original.

Several notes are subjoined, chiefly in illustration of general points, and sometimes in explanation of the text. But this is not a mode of writing to be recommended ; for it distracts the attention from the subject, and too frequent opportunities occur of making useless remarks. Perhaps it will always be preferable, if possible, to connect observations of this kind in such a manner as to form a brief dissertation, which is a much better way for a commentator to illustrate. The preliminary remarks will in a certain degree
supply

supply the place of other elucidations. But an ample field will be found for many more than are there.

I must acknowledge, that I have sometimes been at a loss to discover the exact species of seeds which the author used for infusions. He seldom or never gives specific names; and in Scotland little is yet known of Italian botanical synonyms. However, it is of less importance, as many different infusions will produce the same animalcula. In my own observations on these singular animals, during several years, I believe I have discovered almost the whole which have been the subject of the author's consideration. A few I have not found, or have been unable to recognise.

It will easily be perceived, that the Treatises on Animal Reproduction originally formed no part of the Tracts. Therefore the reader may reasonably inquire, why he finds them here.—Such investigations may properly constitute a sixth subject, on which as great learning and ingenuity are bestowed as on the rest. This is a study which seems to have made less progress in Britain than on the Continent; there are few or no original experiments in English, and some of the following tracts are difficult to be procured: therefore

it appears right to convert what may be obtained to use. There is complete evidence that a decapitated snail will acquire a new head, notwithstanding the numerous discordant opinions and experiments. For this celebrated discovery we are indebted to Spallanzani, who has considered the various reproductions of animals more profoundly and comprehensively than any other author: indeed, a very great portion of what is known concerning them we owe to him. The first Memoir on snails is entire; but the second, where the author enters copiously into his own defence, is much abbreviated. It is true, all the matter is preserved, but the keenness and redundancy, which ever attend controversy, can give no pleasure to those whose more useful researches are directed to facts. For of what avail are opinions unless established on facts? Even the foundest analogical reasoning is too often to be distrusted.

In these Memoirs, several redundancies will occur, but it was impossible to avoid them. M. Bonnet's whole treatise may appear in this light. However, in one respect, it may be useful, namely, from the apparent correctness of the engravings. It is by figures chiefly that we are more easily enabled to understand such intricate subjects of natural history; M. Bonnet's are more diversified

fied than those of the other two Memoirs; and as this Memoir was added to the last edition of the Tracts, independent of the excellence of the matter which it contains, the reader will not be displeas'd to see it reprinted. Although Spallanzani makes repeated allusions to an extensive work on animal reproductions, he never published any thing respecting the reproductions of water newts, except what is in his PRODROMO. The author of his *Literary Life* informs us, that he considered the defect had been fully supplied by M. Bonnet, and he therefore abandoned the design of publishing his Researches on Animal Reproductions;—a determination deeply to be regretted by every philosopher. All that is contained in these volumes on this subject, was at first intended for a separate publication.

It may safely be affirmed, that we are indebted to the friendship subsisting between the two philosophers for whatever portion of this work is written by M. Bonnet. Their esteem was mutual. Spallanzani translated *La Contemplation de la Nature* into Italian; and propos'd to translate *La Palingenesie* also. However, I believe, the Inquisition oppos'd it: at least, it is said, that the translation of the work was prohibited by this formidable tribunal.

The difference between the style of Spallanzani and Bonnet is inconceivable. In general, that of the former is natural and perspicuous: the meaning is easily comprehended, for it is in a manner analysed. Bonnet, on the other hand, is commonly prolix, and very often obscure; and it is sometimes with extreme difficulty that his real sentiments can be discovered. Several of his writings seem never to have undergone correction; and a literal translation, even abridging the innumerable tautologies and redundancies, sounds uncouth in English. Notwithstanding these imperfections, he is unquestionably a great philosopher; he has profoundly investigated nature, and his authenticity is unchallenged.

Although Spallanzani was reputed the first physiologist of the age in which he lived, in one respect he was certainly most unfortunate. The truth of his experiments was disputed; nay, his veracity itself was called in question. Nor was this done by the ignorant, weak, or malignant, who are usually the first to labour for the discovery of error, but by philosophers of established credit, learned and liberal. Not only has the author's own defence elucidated any doubt that attended his principles, but the latest experiments on the same abstruse and difficult subjects have
tended

tended to prove them true, and given them additional weight.

In his whole writings, the author uniformly testifies the utmost contempt of nomenclators. Yet we must allow that nothing is more useful than correct nomenclature; for it rests both on description and physiology. This second qualification, it is true, has not met with sufficient attention; and the extraordinary anxiety of most modern naturalists for classification, from external appearances, has occasioned the neglect of real physiology; therefore, the consequence has been continual alterations. Indeed, if both are to be observed, they will sometimes be at variance with common understanding. Such as placing bats, whales, and dolphins, in the same class with mankind. These arrangements, however just, are at first repugnant to received opinions; and many will feel the same repugnance at admitting medusæ, actiniæ, snails, and animalcula, into the class of vermes.

It has often surpris'd me very much, that so few foreign works of high authority are translated into English, and almost never until a considerable interval after publication; nor do I think that any good reason will easily be assigned. Assuredly it is not because they are found prefer-

able in the original, because they are very seldom to be procured in that state ; and this difficulty of procuring the foreign authors is undoubtedly very detrimental to the literature of the nation : for discoveries and observations, well known on the continent, are frequently a long time dormant here. But the intercourse of countries, and the rapid progress of civilization, will tend more and more to the diffusion of science.

PHYSIOLOGICAL REFLECTIONS

ON THE

NATURAL HISTORY

OF

ANIMALS AND VEGETABLES.

I. ANIMALCULA OF INFUSIONS.—Even in this advanced stage of science, we are intimately acquainted with the natural history of only a few of the larger animals which are daily in view. The particular age when they begin to generate is known; we can calculate the period of gestation; we have learned what food is unfuitable to their nature; and sometimes it may be discovered whether they are healthy or diseased. These general facts have been attained by reiterated and evident observation.—Yet of the secret vital phenomena,

X INTRODUCTORY OBSERVATIONS.

nomena, and of the life of a savage animal, our knowledge is limited indeed.—The original cause of existence is in the most profound obscurity; we are in the utmost ignorance why the offspring of an animal assumes a determinate figure; why the increment of one part is more rapid than that of another; and why the size of the whole is at last confined within certain bounds. No satisfactory reason has hitherto been assigned, why the capacity of either sex to generate does not arise until a certain age; for the very different duration of gestation by different females, or the variety in the time of incubation. And although we contemplate the progress of a disease that ends in death, it is seldom that we can either tell what is the real origin of it, or the cause why existence ceases. Most of the animals, which have been the subject of observation, we have endeavoured to domesticate, but those that roam in the desert, dwell on lofty mountains, are hid in the earth, or concealed in the recesses of the ocean, are hardly known to us by name.—Is there any wonder, therefore, that so many centuries have passed away, before the properties of beings, almost as minute as we conceive the particles of matter, have been investigated?

The animalcula of infusions constitute a class in the animal kingdom, on which the learning
and

and ingenuity of philosophers have been equally exercised. Their infinite multitudes, their varieties, the places of abode, and above every thing, their extreme minuteness, have all conspired to retard our inquiries into their real nature. Let one conceive himself, in a moment, conveyed to a region where the properties, the figure, and motion of every animal are unknown, and he will be able to form some idea of what infusion animalcula are. The amazing variety of figure beheld at once, and their motions, will first attract his attention. One is a long slender line, another is an eel or a serpent. Some are circular, elliptical, and globular, others cylindrical or triangular. One is a thin flat plate, another like a number of articulated reeds. Several have a long tail, almost invisible, or the posterior part is terminated by two strong horns. One is like a funnel, another like a bell, and many cannot be referred to any object familiar to our senses. Certain animalcula can change their figure at pleasure. Sometimes they are extended to immoderate length, then contracted almost into nothing; sometimes curved like a leech, stretched or coiled like a snake. At one moment an animalcule is inflated, and the next it is flaccid. Some are perfectly opaque; some scarcely visible, from extreme transparency. Numbers have no apparent organs; and many are covered with tubercles or bristles.

bristles. No less singular is the variety of motion peculiar to each. Several species swim with the velocity of an arrow; the eye can hardly follow them. Some drag the unwieldy body along by painful exertion, and others seem to persist in perpetual rest. An animalcule will revolve on its centre as the axis of motion, or the anterior part or head is made that axis by another. Some move by undulations, by leaps, or incessant gyration. In short, there is no kind of animal motion, or any other mode of progression, that is not practised by animalcula. The manner in which they propagate is as remarkable. In general, they produce eggs, many, a living foetus, and others, like a few of the larger animals, both; some multiply by a part of the body detaching and becoming a new animal; some by a transverse or longitudinal division of the body, and others, by the mother bursting to allow her offspring to come into the world.

Compared with the rest of animated nature, the number of infusion animalcula surpasses all belief: they are surely the most numerous. Next are worms, insects, or fishes; amphibia and serpents, birds, quadrupeds; and last, is man. The space he occupies on earth is small, and the propagation of his species goes slowly on. The human female produces only one at a time, that
after

after a considerable interval from birth ; and but few during her whole existence. Many quadrupeds are subject to similar laws ; some are more fertile, and their fecundity is little, if at all, inferior to that of certain birds, for they will produce ten or twenty at once. Several birds will breed frequently in a year, and have more than a single egg at a time. How prodigious is the difference, on descending to fishes, amphibia, reptiles, insects, and worms ! Yet, among them, the numbers cannot be more different. According to naturalists, a scorpion will produce 65 young ; a common fly will lay 144 eggs ; a leech, 150 ; and a spider, 170. I have seen a hydrachna produce 600 eggs, and a female moth 1100. A tortoise, it is said, will lay 1000 eggs, and a frog 1100. A gall insect has laid 5000 eggs ; a shrimp 6000 ; and 10000 have been found in the ovary, or what is supposed that part, of an ascarides. One naturalist found above 12000 eggs in a lobster ; and another above 21000. An insect, very similar to an ant, has produced 80000 in a single day ; and Læwenhoeck seems to compute four millions in a crab. Many fishes, and those which in some countries seldom occur, produce incredible numbers of eggs. Above 36000 have been counted in a herring, 38000 in a smelt, 1000000 in a sole, 1130000 in a roach, 3000000 in a species of sturgeon, 342000 in a carp,

carp, 383000 in a tench, 546000 in a mackrel, 992000 in a perch, and 1357000 in a flounder. But of all fishes hitherto discovered, the cod seems the most fertile. One naturalist computes that it produces more than 3686000 eggs; another, 9000000; and a third, 93444000. Here then are eleven fishes, which, probably in the course of one season, will produce above thirteen millions of eggs; which is a number so astonishing and immense, that, without demonstration, we could never believe it true.

Perhaps the innumerable multitude of animals in existence is less influenced by the numbers produced at a time than by frequent and early propagation, by the hazard of destruction to which the young are exposed, and also, it is possible, by some females being more numerous than males. Many insects generate but once in their whole lives. It has been calculated, that two females, of the animals most loathsome and disgusting to the human race, may see ten thousand descendents in eight weeks; that above fourteen thousand may, in the second generation, come from a spider; and a common flesh fly have seven hundred and forty thousand young in the third month. None of these animals are at first very fertile, compared with others. But what are all their
 their

their numbers in comparifon to invifible animalcula and vermiculi? One hundred and fifty millions have been computed in the milt of a fingle fifh.

How does it happen that the earth is not overrun by animals, and that they find food fufficient for the prefervation of life? In a day, an immense legion will fometimes arife, carrying famine and defolation along with it.—To preferve the requifite balance, there muft be deftruction proportioned to propagation; and the wifdom of Nature feems to have provided for it in a certain degree. The animal, its egg, or the young, are all liable to perifh; and the more ftages it has to pafs through before maturity, the greater hazard does it undergo. Many females produce thoufands of eggs, without any commerce with the male: it often happens that thefe are never fecundated, or a very fmall portion of them, if external fecundation fhould take place. The young, in their tender ftate, may either be deftroyed by the elements, or become a prey to thofe ftonger than themfelves. From their various metamorphofes, they are liable to perifh by difeafe, or from unfuitable fituations. Therefore, comparatively fpeaking, few come to maturity. The number of butterflies is very inconfiderable, in proportion

to

to the eggs : few frogs are found near a pool which has been black with tadpoles. Let a leaf, or a particle of animal substance, fall into a little water, myriads of animalcula will be produced ; but simple evaporation of the water, an event that must ensue, is inevitable destruction to the whole. Although the period of existence is limited, few animals die a natural death. The war, which incessantly rages among the whole, is a never failing source of destruction. The stronger prey on the weaker ; and these on animals that are less powerful than themselves. The justice of Nature might be arraigned : Why are some provided with horns, tusks, or poison, while others have no such means of defence ? Thousands of animalcula are apparently but a simple vesicle, without visible organs external or internal : they burst on contact with the air alone. All this destruction is necessary ; the earth would be overstocked ; and even those animals, now living in amity, would make each other a prey. Death must thus be the indispensable attendant on life, unless propagation were to cease.

The structure of some animalcula, such as it appears to us, cannot be more simple ; but the organization of many is certainly very complicated, no less so than that of animals a thousand
times

times their size. Several naturalists have assumed the *simplicity of organization*, as the means of explaining different phenomena exhibited by animals. To me this seems most fallacious reasoning. The organic structure of one animal is simple, only when compared with another known animal. If it lives, it is perfect in its kind. Because no heart, lungs, brain, or nerves, are visible, we can seldom positively affirm either that these organs do not exist, or that there are no other parts which perform the functions belonging to the most important of them. Indeed, in the simple animals before us, they may be so diversified, disguised, and incorporated or partitioned into its substance, as, separately, to be invisible or irrecognisable, but, collectively, capable of performing every vital function. Some may have less necessity for the important organs which we behold in the larger animals. A muscular heart is not equally essential to all that even have one. In general they instantly die, when deprived of it; but the life of several, thus mutilated, endures longer than that allotted to certain animals in their most perfect state. The pulsation of one heart will cease the moment that it is wounded; another will beat long after being torn from the body. Some agents, destructive of life, will destroy its irritability; others will produce no sensible effect. Penetration of the

brain will often occasion instant death ; but various animals will live long, not only after the whole has been scooped from the cavity of the skull, but after the head itself is cut off.

In the larger animals, where dissection may be used, it is in the power of the anatomist to lay every muscle, tendon, and blood vessel, bare. In those so minute as infusion animalcula, where, instead of each part, the entire whole is in general hardly visible, the philosopher must sometimes be satisfied with the most rational inductions from what he beholds, and analogical reasoning, if that is ever to be admitted.—The different functions of animalcula are probably performed by means analogous to those of other animals. The course of some, which are without perceptible external organs, proportionally exceeds the swiftest flight of birds ; consequently, they must have considerable strength. Whether their motion proceeds from curvature, leaps, or undulations, it can only be effected by impulse against the water ; and we may reasonably infer, that some muscular movement is the principle ; or that the strength proceeds from something corresponding to muscles. The great source of motion among worms and aquatic animals, destitute of feet and fins, is undulation. In this manner is the progression of all serpents, eels, and many other

other reptiles. No evident curvature is seen in the body of a snail; but in the belly are successive undulations, by which its peculiar progression is performed. It is more convincing, that animalcula have muscular parts, and perhaps joints formed of membrane, or a similar substance, when we can actually observe fins, feet, or fibrilli. Many which we suppose deprived of them, really are not so; and in others, they are so minute, slender, or transparent, or so much of the same colour as the fluid they inhabit, as seldom or never to be visible. Indeed we often see particles, in an infusion, carried along, at a distance from the animalcula, by some invisible hair.

When an animal is called imperfect, we mean, that it wants organs with the use of which we are acquainted. External impressions are certainly the origin of ideas; and there is reason to believe, that mind originates entirely with the use that can be made of the senses. Undoubtedly we can form no conception of any object, without the intervention of some of the senses: and, although the mind may wander through all the immeasurable field of imagination, still it can invent no new idea that is without any chain or link to what is suggested by the senses. Thus, if it is possible to conceive that a

man might be born without any of the senses, we cannot figure how he could have mind, or be capable of distinguishing objects. But there are many animals which want some of the known senses, and are still capable of volition, choice, and several of those sensations which we ascribe to the most perfect. It is not evident that they labour under much inconvenience, where certain organs are entirely wanting, or derive equivalent advantage, where they abound. The variety of organs is more essential than the number.—The flight of an insect is as rapid with two wings as with four: vision is as acute with two eyes as with eight: progression is as quick with six or eight legs as with an hundred. Indeed it is difficult to say what is the use of such a redundancy of organs, at least, if we judge from simple appearances. Some animals, which have only six legs at first, acquire an additional pair every year of their lives. There is one species with eight legs, when full grown, in which the third pair is wanting at first; and another, with six pair originally, and a seventh is afterwards acquired.

More than five senses may exist; nor is there any absolute necessity for limitation to that number. In various animals, there may be others so complicated or uncommon, as to be totally incomprehensible by the human mind; and they
may

may be transmitted through channels very different from those known to us for the transmission of sense. Hearing and sight are very uncertain in whole classes of animals; the ears of very few insects have been discovered; some molluscæ and worms seem hardly to be sensible of sound. In insects, which form so great and beautiful a part of the creation, vision is undoubtedly very obscure. No organs of vision are found in an infinity of worms; and those that have eyes seem to make very little use of them. Although many insects are sensible of the impressions of light, I doubt whether they are capable of the perception of objects, or guided towards them by vision; even the wonderful operations of the bee are performed in utter darkness. There are some insects, however, that are sensible of the presence of adjacent objects, and actually recognise them as I have demonstrated by experiment. One sense may certainly supply the place of another, which we see in the larger animals. A bat, deprived of sight, will traverse the same course, and avoid the same obstacles as before. These creatures fly through openings, nay, discover new ones, and without any embarrassment, pass through them. Some naturalists thence concluded, that bats had a sixth sense; some from experiment asserted, they were guided by hearing; and others, that excessive delicacy of feeling rendered them sensible of

the presence and direction of objects. Innumerable instances prove, that one sense, either in a natural state, or well practised, may supply the place of another.

Thus, apparent simplicity of organization can neither be an argument for explaining the phenomena presented by animalcula or the similar classes of animals, such as propagation by shoots or division, resuscitation, reparation of the lost parts, as has been supposed peculiar to certain animalcula. But with all this apparent simplicity, they possess every characteristic requisite to entitle an animal to be called a living being. A slight investigation of their nature is alone sufficient to establish the fact; for there is scarcely any phenomenon among known animals, that does not exist among them; and they exhibit many which seldom or never occur in any other race.

It is a prevalent opinion, that animalcula may be discovered in rain water with the microscope, or in that of the purest fountain. This is an error. I have never once found them in the course of innumerable observations; and the great animalculist MULLER himself says, they are very rare. That they may exist in these situations, is by no means impossible; they may be invisible in air, and become

come visible in water. Though imperceptible by our senses, they may be suspended in the air as their native element; and, if it was not for the excessive delicacy of their parts, and the difficulty of observation, they might be rendered visible by the interposition of different mediums;—and here imagination may figure beings of another kind, which, by an interposing medium, may in the same manner be brought into view. Some animalcula of considerable size are seen with the utmost difficulty, from extreme transparency; it is only an accidental inflection, or an alteration of the usual direction of the rays of light, that renders them visible.

II. SEMINAL VERMICULI.—Three great and important points are to be considered in animated existence; the mode of an animal's origin and introduction into the world; the duration of life; and the manner of it's death. What we daily behold, events and objects continually familiar to us, make little impression; and, if there is any novelty at first, it soon wears away. If we reflect on the phenomena of nature, and inquire into the original cause of life, its preservation and end, an infinite and unaccountable variety is presented; and although we may be inclined to give physical reasons in explication, or feel an internal conviction that none other will apply to certain

cases, it must be acknowledged, that the boundless empire of nature has neither been completely explored, nor reduced within determinate limits by human understanding, and perhaps never will.

Seminal vermiculi are a race of animals whose origin, existence, and use, if they are of any, are all equally mysterious. Their origin is even more wonderful than that of the numerous other worms inhabiting the bodies by which they are nourished. Every thing contributes to the difficulty of investigating their nature. The termination of life, or the cruel mutilations that must be employed to view them in their native abode; the ravages and disorder that such operations must occasion; and their extreme minuteness (for it has been computed that the diameter of some does not exceed one hundredth part of the thickness of a human hair) render it surprising how so much of their history has been discovered. But the period is yet distant, when every kind of propagation shall be known. Two thousand years ago, the generation of eels occupied the attention of naturalists, and it is still obscure.—The chief difficulty which attends our comprehending the origin of seminal vermiculi is their appearance only at a certain age. Where do they exist before this term arrives? The germ or
 primordium

primordium may constitute a part of the animal itself: it may remain entire, though incapable of expansion, and not be liable to decay for a series of years; then, when the fluid which it should naturally inhabit is secreted, some of the numerous germs, which we may well suppose disseminated throughout the body, will be unfolded there, though the circumstances necessary for their development are seldom or never found elsewhere. In the same manner, it is not improbable, are the numerous worms inhabiting the human body produced. The egg is conveyed into the body, or transmitted by the parent; and, when in a suitable situation, it expands. Yet this reproduction is mysterious, when compared with that of other animals.

The same rules, with little variation, regulate the propagation of mankind, quadrupeds, and birds. Fishes and amphibia in general generate in a mode peculiar to themselves. Insects approach in some respects to the higher orders of animals; but descending to the innumerable and various classes of worms in all the branches, nothing can be more diversified. Some divide into pieces, and each becomes a new animal; others send forth buds, which grow complete like the parent, and thus perpetuate the species; some produce living young; some eggs; and a few, both eggs and young.

The theories of generation which these peculiarities have created are various; and all, even the most inconsistent and chimerical, have had partisans. Perhaps the same difficulty does not attend a probable conjecture, not to go so far as *explanation*, of that generation, which is effected by means of a fluid and of eggs. When the female approaches maturity, and often long before it, substances resembling eggs, or which really are so, appear; and in the male is secreted that particular fluid which is peopled by numberless vermiculi. Immediately after they were discovered, the charge of perpetuating animated beings was committed to them: it was generally believed that every animal originated from a vermicule. But it is now universally known that the foetus belongs to the mother alone; that it pre-exists fecundation; and lies dormant until it is called into existence. Eggs have been rendered prolific; and animals, which require copulation to propagate their young, have been artificially fecundated, that is, without interposition of the male. It is even said that this strange experiment has succeeded in mankind. Still it is to be explained, why of twenty or thirty eggs, as in the human female, only one is impregnated at a time, and why ten or fifteen may be impregnated in a female quadruped; more especially, if generation is effected by absorption,

forption, as it is most natural to believe. Is it because only one ovum is in a state to be impregnated in the one case, and almost always more than one in the other? Whatever is the truth, it is evident that feminal vermiculi have no concern in generation, both because it appears that some feminal fluids are entirely destitute of them, and not the less fecundative on that account; and although the whole are dead, their native element has lost none of its prolific virtue. Since indisputable observations prove, that various animals actually exist in the mother before fecundation, how do they originate there? Does every germ include another germ; that a smaller one; and in this manner involving successive germs to infinity; so that a thousand years ago, beings which have now passed through a thousand generations, then existed, though the term of evolution could not arrive until a thousand changes were undergone? Can we conceive, that at a time beyond the power of imagination to reach, a germ existed; that we ourselves, the present generation of mankind, were in being, under any figure, however minute; that, until the maturity of the preceding generation, our bodies could never expand into perfect shape and organization.—Or, is it more rational to suppose, that at the age of puberty, something is secreted by the mother, that there is some assimilation of parts which will form a fœtus;

tus; that there is some generative power developed with age, which can produce a germ capable of being fecundated by the male. Discordant opinions like these have divided the most celebrated philosophers; ingenious arguments have been given for each; and if infinite involution is the more generally adopted, perhaps it is because the expansion of parts in miniature is less repugnant to the mind than creation.—Yet changes certainly take place in the bodies of animals, which may almost be called creation. New parts are acquired; though these may be derived from other existing substances, still they form a part of the body. The cartilages of a foetus undoubtedly do not contain principles exactly the same as the bones of an adult. Solids may be involved in other solids; but it was never said that fluids could be involved in fluids. The blood, the milk, the bile, urine, and the numerous other fluids in the human body, must be derived from other substances, because the quantity of any one is so small in the foetus; not to name that prolific fluid which does not exist before a particular state at which the body arrives. The solids must also acquire new parts; increment in size may be effected indeed, by expansion alone, but no additional weight will be gained.—But this is entering on the profound theory of increment. These facts bear some distant resemblance to creation, notwithstanding they are only the assimilation of one substance

stance

stance into the parts of another. Every system of generation is accompanied by difficulties almost insurmountable. We have penetrated some of the mysteries, but the veil is not entirely removed.

Though the germ belongs to the female alone, the male has an active share in the expansion and modification of its parts. The eyes, the voice, the colour, nay, the whole appearance, often resemble the father much more than the mother. However, in considering this matter on a great scale, and neglecting the peculiarities of individuals, all animals have a greater resemblance to the mother. The flat nose, the woolly hair, and thick lips of a negro will be transmitted to his offspring by a European woman: and the high features, long hair, and light colour of a European father will be transmitted in some measure to the child of an African mother. The active part of the father is more conspicuous in the generation of hybrids. In the offspring of the ass and the mare, the goldfinch and canary, or the canary and linnæus, some of the parts peculiar to the female are altered, while those belonging to the father are preserved almost entire. He communicates something, whatever it may be, that awakens existence in the germ, is assimilated into itself, and regulates the formation and appearance
of

of its body. But the greatest singularity is, that certain parts should be received, and others rejected: that although the father is deprived of those very parts which prove the offspring his, it will have them all. Notwithstanding both parents should be maimed or mutilated, the germ is perfect, and the embryo will exhibit none of their imperfections. What an immense fund for experiment and observation is here! Sometimes imperfections are hereditary; but these are rare and uncommon cases: and it is much more remarkable when an existing imperfection passes one generation and affects the next. Deformity of the person is often transmitted to a succeeding race: we have known a vice in the conformation of the organs of hearing and speech in a whole family, and sometimes several children born blind. These imperfections, on investigation, are frequently found in the relations of the parents.

Considering the little progress of knowledge, and the rude hypotheses of generation, it is not at all surprising that the origin of animals was ascribed to feminal vermiculi when they were first discovered: and this would have acquired additional credit had it been known there were pores in the integuments of the germ or egg which vermiculi might penetrate.—Let us consider an impregnated egg. It consists of a transparent

transparent viscous fluid, surrounding a yellow liquid contained in another envelope; nothing more is visible. If the egg is exposed to heat, it is of no importance whence derived; if attaining a certain degree, appears an irregular vermicular figure, without any determinate parts. But this is the rudiments of the chicken. A red point next becomes visible, which is the heart: then the eyes and the bill are unfolded: the embryo gradually increases; it grows a perfect animal, and bursts the shell. In a manner nearly analogous are the original evolution and increment of the human living foetus. A transparent vesicle is detached from the ovary by impregnation; it is deposited in the womb; all the parts of the human body appear; and what is in one and twenty days accomplished in the chicken succeeds in nine months: the perfect foetus is formed. How this could be effected without any sensible primordium, confounded naturalists, (for then it had not been proved that the germ belongs to the female) and when they saw a living animal furnished by the male, they eagerly adopted it as the principle of existence.

III. DEATH OF ANIMALS IN STAGNANT AIR.—Long before philosophical experiment, it was probably well known, that the life of an animal confined where there is no admission of fresh air,

air, or where the circulation is impeded, will be destroyed; and that plants in such a situation will droop and die.—Late researches in chemistry have discovered various invisible fluids produced by different substances, which are fatal to the animals that respire them. Some are so destructive as to occasion instant dissolution; in others, an animal may linger long, though it will at last perish under their deleterious influence. Nay, eminent philosophers have fallen a victim to hazardous experiment on themselves: and several have escaped after the most imminent danger.

So useful is atmospherical air to the conservation of life, and so dependent is life on its influence, that none of the animals, with whose nature we are acquainted, can exist without it entirely: and if some do support privation of air better than others, still they languish, and at length will die. Those inhabiting waters, and seldom come to the surface for respiration, perish when the water is deprived of the pure air which it contains.

Atmospherical air is not a simple fluid; it is a combination of various fluids; some of which, in a decomposed and separate state, are better calculated to support life, at least for a certain time, than the rest, but none except itself has yet been
found

found perfectly innoxious, nor any one equally beneficial. The principal ingredients are said to be azotic gas, oxygen, carbonic acid, and water. Azotic gas and carbonic acid are most pernicious to animals, and the former constitutes two-thirds of the whole. By respiration, a chemical process takes place, both in the system of the respiring animal and in the air. A change is produced in the blood, and animal heat is promoted. But the alteration that succeeds in the fluid respired is of greater importance, for it is that which occasions death in whatever manner it may operate. The oxygen, or pure vital air, is consumed; an addition is made to the carbonic acid gas, and almost all the azot is left. Such are the principal changes effected by respiration. When this goes on in the open air, the continual renewal of the pure parts, and the purification of those unfit for use, the emanations and combinations of what arise from the substances in which analogous operations are maintained, render it again capable of being respired without injury. When the vital air is consumed, and the noxious part remains behind, the pernicious effects immediately become visible. The manner in which death ensues, like most profound investigations, has divided the opinion of philosophers.

Various gases produce an alteration in the state of the blood: experiment, it is true, has been chiefly directed to blood after proceeding from the body of the animal, and the difficulty of the subject has hitherto prevented a full consideration of what are the principal phenomena on that which still continues to flow during life. Whether or not the change there produced is sufficient to destroy the animal, the operation of gases on the muscular and nervous system is very conspicuous, and especially on the former, perhaps, because it may then be more easily recognised. Animals, at the same time, in some instances certainly die from absolute suffocation; for the excessive irritation produced by gases will close the entry to the lungs, and death ensue before one inspiration is completed. The general operation is most probably on muscular irritability and the nerves, more especially when we reflect that the animals respiring so very little, as some are known to do, can not escape the pernicious consequence of respired air. Yet we must admit, that if they respire at all, which it is most likely they do, by absorbing air from water, if they are aquatic animals, they will also absorb exhalations, and thus be destroyed.

Drowning and strangling are equally fatal to life as suffocation in mephitic vapours; but the
irritability

irritability of the heart is much longer preserved in drowned and strangled animals than in those that have perished in gases. Much light has been thrown on muscular irritability since the discovery of Galvanism; for by that means a spark of life has often been found when it was thought totally extinct. The loss of irritability depends in a great measure on the nature of the fluid in which the animal has died. By some, it will be altogether destroyed, and others will only weaken its power. Drowning an animal suspended by the feet, is entirely destructive of irritability, also the vapour of charcoal and other gases; but azotic gas and atmospheric air only diminish, they do not extinguish it; and the heart of an animal, killed by its own respiration, beats long afterwards. Thus the difference is very great both in the suddenness of death and the effect upon its body, according to the medium where an animal has perished. But it should be considered, with the utmost attention, whether any of the characteristic symptoms precede, accompany, or follow death.

From numerous experiments, it appears that death, in stagnant air or in mephitic gases, may proceed from suffocation, from injury of the muscular fibre, from affections of the nerves, or all three combined, or perhaps from the chemical

change produced on the blood by respiration being obstructed ; but it is not evident that conclusions from experiments are coincident, or that the real cause is fully established.

IV. ANIMALS KILLED AND REVIVED.—We are lost in astonishment while we contemplate the nature of LIFE : the deeper our inquiries go, the farther does the object seem to recede from us. We can account for the destruction of life, when the reciprocal harmony of the parts of an animal is deranged : the functions of the most important organs are interrupted, and death must ensue ; but how life is maintained is a profound mystery.—An animal originates, its parts unfold, and it visibly lives. At first, the interposition of a parent is necessary to administer the nutritive matter, for its own organs are too weak and imperfect. At length, they acquire sufficient power to receive nutriment ; the animal is detached from its parent, and lives for itself. It gradually approaches to perfection, new parts are expanded, and thus may it remain for years with little or no sensible alteration. Then the organs begin to evince perceptible symptoms of decay : certain parts increase, change, or diminish : they become deranged, and incapable of performing their respective offices : life grows feeble, the animal languishes and dies ; and what constituted its personality

nality vanishes in air. Such is the termination of existence by age : but how small a portion of the animated creation attain the time ! Often, during the vigour of youth, in the height of activity and sensation, the chain will be dissolved without any external cause ; the thread is cut ; something seems to depart ; and the most beautiful work of nature hastens into hideous corruption.

To affirm that a being, whose animation has been suspended for an immoderate length of time, even for years, can, in virtue of certain conditions, be revived, has so singular and paradoxical an appearance, that reason finds it repugnant to admit the fact. But to produce an animal which has been stiff and motionless, withered, disfigured, and contracted ; utterly incapable of any corporeal function, and the operation of its organs at an end ; to produce this animal, and, by a particular treatment, to make it renovate every action that it could perform before ; to see nutrition, digestion, and generation carried on, not only will it bear perfect conviction to the mind that it has come from a state which, if it was not death, certainly cannot be called life, but that it again lives as completely as before its animation was suspended or destroyed.---Some animals in the world enjoy this wonderful prerogative. They originate, arrive at maturity, and maintain the vital functions:

their native element is a fluid, and they are naturally moist ; but deprive them of this element, or allow them to dry, they become motionless, they contract, wither, and die. Thus may the animals remain one year or ten ; then let moisture and the other requisites be supplied, their members swell, life returns, and the animals become as lively and vigorous as ever.

It is reasonable to expect that so remarkable a deviation from the course of nature should be limited, and the privileged animals uncommonly few. Still they are not so rare as to prevent the truth of the phenomenon from being amply established. Hitherto none of the larger animals have been found which are endowed with this singular property.—Nature, as if to veil that which is so fondly cherished in idea by mankind, seems to have bestowed it only on the most minute of her creatures.—The wheel animal, various microscopic eels, and the sloth, may all die and be revived. The excessive scarcity of the last has prevented naturalists from investigating the utmost limits of its resurgent faculties. No one, except Spallanzani, so far as I know, has ever been able to discover it. In this remote kingdom, where the study of animated existence is yet in infancy, I have found three, perhaps four varieties of the sloth, all evidently belonging to the same genus of this wonderful animal, or of a race analogous ;

analogous ; but whether possessing the same prerogative I have not yet been able to ascertain. Of the fourth, I speak with diffidence ; for, without long investigation, we must hesitate in ascribing animality to a being whose length does not equal the thickness of a human hair, which scarcely ever exhibits perceptible motion, and is not once to be found in a thousand observations.

Whether an animal may actually die, and afterwards be revived, has been the subject of much controversy ; equally so as the symptoms preceding and attending death. Putrefaction is, by common consent, regarded as the most infallible sign of dissolution, though it will sometimes commence during life. But many animals dry up, and wither, and become as hard as wood without putrefaction ever appearing in the slightest degree. Next to this, the want of irritability is considered certain evidence of death. Yet the absence of it will not always prove an animal dead ; for life often remains when there is no sensible irritability ; and one stimulant will awaken vitality, while the use of all others is vain.—In the same manner as particular stimulants are incapable of awakening dormant animation, neither can methods destructive of it, in its utmost vigour, in one instance, affect it at all in another. Undoubtedly we should suppose the most efficacious methods of destroying animals, are depriving them of nutriment, or de-

priving them of some organs which seem most important in executing the vital functions. Whether life is in these situations extinguished by the same means, or whether it is extinguished in every case, by exciting a cause that will impair existing irritability, is left to greater physiologists. But until the principle of life is discovered, which, according to some, is the union and reciprocal action of the parts in resisting dissolution; or consists in the blood; in a particular aura, like the imaginary aura seminalis; in something resembling electricity; in irritability, or the existence of nerves; all reasoning on what affects its creation, preservation, or destruction, must be unsatisfactory. One thing is certain, that the death of one part is often the necessary consequence of that of another; that the death of the heart may occasion the death of the brain; and the lungs will die when the heart is dead.

Mankind can ill support the privation of food. It is true there are some wonderful stories of abstinence, in the records handed down to our own time; however, these in general may be rather ascribed to the love of imposture, and that anxiety to deal in the marvellous, which so eminently characterised the darker ages. Still, abiding by authentic information, and trusting to veracious accounts of modern date, men have subsisted on a quantity of food small beyond belief; and have even existed
incredibly

incredibly long without any at all. Captain Bligh of the *Bounty*, failed near four thousand miles in an open boat, reduced to the utmost extremity for want of provisions : sometimes a bird, not many ounces in weight, was the only food for seventeen people in a day. Fourteen men and women of the *Junö*, wrecked on the coast of Arracan, lived twenty-three days without a morsel of food. On the fifth day after the shipwreck, two people first died of want.

Animals, Redi observes, do not perish from hunger so soon as is generally believed. The period of their death is very various. House and field rats never lived with him three days ; capons lived seven, eight, or nine ; a civet cat lived ten ; wild pigeons, twelve and thirteen days ; an antelope, twenty, and a very large wild cat, the same time. A royal eagle survived twenty-eight days without food. Buffon mentions one that lived five complete weeks. A badger lived a month, and several dogs thirty-six days.—When we consider total abstinence from food for such a length of time as thirty-six days, it is truly wonderful that the animal could exist. But accounts still more surprising are given by naturalists of undoubted credit. A crocodile will live two months without food. Leeuwenhoeck had a scorpion that lived three. A bear is said to have

have lived six, and vipers the same time. However, allowances must be made, if this happens in winter, during extreme cold, when the digestive and secretory powers are feeble, and if the animal, of whatever kind, is liable to torpor. A common garden snail lived eight months on a pane of my window, nor do I know that it was then dead. Redi had a cameleon that lived eight months without food, and vipers ten. Vaillant had a spider that lived as long; nay, its strength was at that time sufficient to kill another, put under the receiver where it was kept, as large as itself, and quite vigorous. According to different authors, some of these animals, suffering long abstinence, have not become much emaciated. Mr John Hunter inclosed a toad between two stone flower pots; it lived fourteen months, and was then as lively as ever. M. Sue quotes instances of the same animals living eighteen months without either food or respiration, because they were closely sealed up in boxes or vessels. M. Herissant confined three toads in a box, and then covered the whole with a coat of plaster: the box was opened in eighteen months, and one of the toads was still alive. Land tortoises lived eighteen months with Redi; Muller kept hydrachnæ equally long. But Baker had a beetle that lived three complete years without food, and then escaped; and Virey cites Plempius for leeches

leeches surviving three years in water without any visible food. This instance, and that of the hydrachnæ, indeed, are different from total abstinence; for birds which drink seldom, and even carnivorous animals, have subsisted on water alone for a very considerable time. Whether invisible animalcula might be the aliment of those animals, I cannot tell, but I have seen snails, which were kept months in water only, void very sensible excretions, and increase the size of their shells, though these continued uncommonly transparent, nor could the excretions be the remains of food in the stomach, for the snails had never ate; they were young; and I had bred them from the egg. However, this is little more surprising than that plants should vegetate and attain considerable size in water, for both they and animals extract some nutritive part, which, by various decompositions, secretions, and assimilations, is converted into their own substance. Now, indeed, it is supposed that the excretions of plants are discovered.

If daily experience did not testify the reverse, it might reasonably be conceived that all the parts of an animal were of equal use to it; and that privation of one would be as injurious as privation of any other. But we are acquainted with some animals which can lose a portion of
the

the body, and be as healthy, lively, and vigorous, as before ; and we continually witness this in the amputation of limbs. Nay, so far from mutilations being fatal, several of the lost parts will be repaired, as the branches of a tree are renewed.

The most dreadful wounds, that imagination can figure, hardly seem to accelerate death. M. Riboud stuck different beetles through with pins ; he cut and lacerated others in the severest manner ; yet all lived nearly, if not quite, as long as those that were entire. One, with a pin through the body as thick as its thigh, survived fourteen days. I have seen a caterpillar still alive, though shrunk to one third of its original size ; and the body of a butterfly manifest animation, when the wings were dry and shrivelled up. I have seen a butterfly live a month after being stuck through with a pin, and after I conceived its life had been destroyed by the fumes of sulphur ; for such cruel experiments were not purposely made. Leeuwenhoeck, I think, had a mite which lived eleven weeks stuck on a point before his microscope. Vaillant, intending to preserve a locust of the Cape of Good Hope, took out the intestines, and filled the abdomen with cotton, and then fixed it down by a pin through the thorax ; yet, after five months, the animal still moved its feet and antennæ.

In the beginning of November, Redi opened the skull of a land tortoise, and excavated the whole brain. The tortoise did not seem to suffer: it moved about as before, but groping its way; for the eyes soon shut after losing the brain, and never opened again. A fleshy integument formed, which covered the opening of the skull; and in this state the animal lived until May, that is, six complete months. Spallanzani deprived four frogs of the brain: two lived till the fifth day. He also deprived three newts of the brain: they suffered violent convulsions; their eyes closed; they hardly moved from one place to another; and expired about the middle of the third day.

He cut the heart out of three newts: they took to flight, leapt, swam, and executed the same functions as before; however, all died in forty-eight hours. Four frogs, deprived of the heart, kept their eyes open, and preserved the use of their limbs. They survived thirty-six hours.

Privation of these organs, and even of those far less important in the organic system, would occasion immediate death to innumerable animals. But it does not appear that the tenacity of life is uniformly dependent on the same principle, or
absolutely

absolutely of the same kind; at least, we cannot affirm that it is entirely so.—Eels, it is well known, exhibit symptoms of life in the various divided parts. They are killed by dashing against the ground. Osbeck says, the greater dog fish will move about, though the head or tail is cut off; nay, that it lives more than an hour after the intestines are taken out. Lyonet saw motion in the abdomen of a wasp, three days after separation from the rest; and a caterpillar crawled about several days after the head was cut off. From these and other experiments, he remarks, that the soul of animals, if they have any, is extended over the whole body; and every part seems capable of evincing consciousness and sensation. The headless caterpillar endeavoured to escape; it had the same motions as before decollation. The anterior half of a divided wasp bit every thing presented to it. The middle part of an earth worm, deprived of both ends, expeditiously moved away when touched. The same conclusions are made by Sue, in his *Researches on Vitality*. A decollated turkey seemed to have spontaneous motions. The body of a butterfly continued to fly as usual, among the flowers, twenty minutes after the head was cut off. A decapitated beetle will advance over a table, groping its way, and recognize a precipice on approaching the edge. Reversed on its back, it will

will endeavour to recover the natural position equally as before. Similar motions are exhibited by decollated snails and other animals. Cuvier, indeed, an eminent naturalist, seems to consider the head or brain as the only seat of sense and reflection. But this can hardly be admitted, from the numerous instances which appear contradictory; and the reason of so prevalent an opinion, in all probability, arises because the principal organs, for conveying external impressions, are usually situated in the head. If more animals were subjected to experiments of this kind, and if it could be performed without such terrible concussions of the brain and spinal marrow, we should be more able to reason upon it. Labillardiere remarks, that the turtles of Waygiou, weighing above two hundred pounds, would continue to crawl several hours after being deprived of their heads. Redi decapitated four tortoises, and all the blood was discharged. On opening the body twelve days afterwards, the heart was perceived to beat. He decapitated another large tortoise; it lived twenty-three days; but Broussonet affirms, that this animal will survive during two months without the head. Colonel Pringle decapitated several libellulæ. One lived above four months, and another nearly six; and a singular occurrence in his experiments was, that
those

those unhurt, which were kept in the same situation as those decapitated, never survived above a few days.

There are many other examples of animals living in a condition, where it is scarcely to be imagined how any principle of life could remain. Swammerdam had a larva that seemed to live as well in salt water as fresh, which Lyonet quotes; and Reaumur had another that lived twenty-four hours in spirit of wine. De-Geer, proposing to kill a lobster, put it in vinegar: in five hours, it was as lively and vigorous as ever; and, then being put in spirit of wine, it died in an hour.

I have purposely avoided illustrations from the animals that repair their lost parts, at least illustrations relative to them, and reproduce the head when cut off, as snails, leeches, and several worms; for there is a certain vegetative process there going on. At the same time, the suspension of most, or all the organic functions, during six or even twelve months that it takes to be renewed, renders it wonderful that the animal is not altogether destroyed.

All this violence is committed on animals in their utmost vigour, when pulsation is strong, digestion powerful, and sensation exquisite. The
very

very shock would seem sufficient to extinguish life. But existence will continue two years, while an active and voracious caterpillar, which perhaps ate its own weight in a day, is shut up in the chrysalis, and incapable of feeding; perceptible motion is its only function; digestion is at an end. Motion, in other animals, is the first sensible function. The eggs of the common water snail are at first transparent globules; then a speck appears, which is the fœtus. It continues to increase; and, long before bursting the integument, it moves about within the egg.

If the whole of these facts are considered, and due weight allowed to each, it may not appear so very far beyond belief, that all the vital functions of an animal may be suspended without death for a long time, and that they may be again awakened when its organs are brought into a suitable situation. What is the state of an unimpregnated germ?—Certainly it does not live: Though it proceeds from the mother even at the appointed time, it corrupts, unless the prolific liquid is applied. Let us consider the consequence. Is there a creation of life, or only the awakening of that which is dormant?—Assuredly the creation of life does ensue. The fecundative liquid alone can produce so wonderful an effect; it does not awaken dormant life, for there is no

I INTRODUCTORY OBSERVATIONS.

evidence, not even a distant probability, that any exists to be awakened. If life consists in irritability, or without going so far, if it is true that it is not extinct, where irritability is manifested, what else is requisite, than that the animal shall be put in a situation where its dormant irritability may be re-excited, that some stimulus, capable of awakening the susceptibility of its muscles, shall be applied? This, however, generally speaking, is only a case of suspended animation; undoubtedly, it is not death, which occasions a most difficult and delicate distinction; for by admitting it, almost every criterion of real dissolution is rejected. Suspended animation may degenerate into death, without any evident external change. A man has been revived who was forty-five minutes in water; two minutes more, or a little accidental delay, might have rendered all efforts to resuscitate him ineffectual. The muscles might have lost that property which rendered them susceptible of a certain stimulus. There may be, nay, it is likely, there are stimulants, with which we are unacquainted, that will rouse the vital powers into action, after a much longer period than has hitherto been witnessed. The condition of an animal suffocated in mephitic vapours, or half strangled, is the same; life may be recalled by particular stimulants. When torpid from cold, the simple application of moderate

derate heat will revive the animal. Where is the term at which death begins, when every spark of life is extinct, and all endeavours to restore suspended animation will be ineffectual? Though the great physiologist of Berne fixes it in man when the irritability of the heart is destroyed for ever, we must necessarily admit that it is still unknown. But that vigorous life may be suspended for a long interval, is a fact not to be called in question. Sleep is a temporary suspension of the active faculties; still all the organic functions are going on. Torpor is a greater suspension. Some of the functions are interrupted, and others imperfectly executed. It bears the nearest resemblance to the state of the resurgent animals under our view, because it may be protracted to an immoderate length by the simple continuance of cold. The life of insects in the chrysalis, of birds and reptiles in the egg, may also be long protracted, or the production of the perfect animal accelerated. The chicken exists in the egg before incubation, but it depends entirely on heat whether it shall ever be unfolded.

Suspension of animation, without becoming death, is less repugnant to the mind, when an animal is presented that will feed voraciously, and then abstain from food for eighteen months

or three years. An animal that can lose its blood, its heart, or its brain, without immediate death, and one that exhibits voluntary motions after decapitation, nay, which will live thus a year, and the head then grow to the place from which it was taken.

Socoloff remarks it as a singular circumstance, that an insect, immersed in spirit of wine a quarter of an hour, will revive. He threw a number of flies, that had been accidentally drowned, among wood-ashes, and was surprised to find them alive. He repeated the experiment, and the flies revived. He had equal success with some small beetles. The experiment was repeated five times within three hours on a small spider, which so much weakened it at last, that it could scarcely recover. Common bugs revived, but they required to be longer among the wood-ashes. Millipedes would not revive. Earth worms immersed nineteen hours in oil, which is a fluid most destructive to all their race, revived when Spallanzani put them in humid earth. Dr Franklin affirms, that flies drowned in Madeira revived after six months. Mr Gough made a number of experiments on drowned insects. None revived, if immersed longer than two or three minutes, except the nut-weevil, which was in brandy seventeen hours. He quotes instances
of

of these animals living *torpid*, and not destroyed, though bottled up in a phial of brandy many weeks. It is rational to suppose that some animals may suffer very long immersion in water without the vital principle being extinguished; at least, not nearly so soon as has been supposed.

The success of naturalists in reviving the wheel animal has been very various. Muller never saw it recover after being two minutes dry, unless involved in some terrestrial substance. Fontana revived it after being dry two years. Virey thinks no organised being can dry without death, nor that the complete desiccation of animalcula can happen, unless to their destruction.—Is it possible to conceive, that any portion of humidity remains when an animal has been a-year out of water, its native element, and the whole organic functions interrupted, or that its own fluids are not contracted, hardened, and dried up. Yet, in addition to the instances of animals that have remained dry two, six, or twenty-seven years, and then come to life, it is confidently asserted that the hair worm will revive after long desiccation; and there is an account tolerably well authenticated, though I do not consider it absolute proof, of snails reviving when put in water after they had been kept in a cabinet sixteen years.

From observations made by myself, I have great reason to suppose some species of snails are resuscitant, and that several infusion animalcula enjoy the same privilege.—Plants are undoubtedly a kind of organised beings, whose life and propagation bear the nearest resemblance to those of animals. In a late experiment, the water lentil revived thirty-three months after it was dried. Mosses, it is said, have revived after an hundred years desiccation, and seeds preserved their vegetative faculty two hundred years.

Those who have been unsuccessful in reviving resurgent animals, have either neglected the necessary conditions, in the same manner as the use of one stimulant will excite vitality, while the want of it, or employment of another, will allow suspended animation to terminate in actual death; or they have not attended to the proper species of animals. But we are safe to conclude, that the vital functions may be suspended incredibly long, and the animal still revive, and that there are animals which may exist years in complete desiccation, without the principle of life being lost. All this is only suspended animation; it is not death. May there be such a thing as a second creation of life? If the life of the impregnated germ is created, perhaps the same creation, if such an idea can be

be

be admitted, happens to the animals whose animation we conceive to be only suspended.—Should it actually be so, their state is absolute death.

Where is the immaterial and sentient principle during this long interval of corporeal repose? Is it annihilated and again renewed, or does it exist totally independent of the state into which the material part of organization may be brought?

V. ORIGIN OF MOULD.—The obscurity which reigned over the origin of animated nature has been dissipated by the penetration of philosophers. Absurd and contradictory ideas were formerly embraced by those who called themselves learned. Adopting a hasty opinion from a cursory glance, and without time for investigation or judgment to discriminate, they hurried on into error; and at length became so deeply entangled, that to be extricated was impossible, unless by totally abandoning received theories, and entering on experiment, which is the only infallible guide to truth.

The uniformity beheld in the generation of the larger animals, the mutual intercourse of sexes, and particular periods of gestation, were facts so evident and undeniable, that any doubt or question concerning their existence proved itself false. But it was different with animals more minute. Butterflies and bees appeared without any producing parent; myriads of wasps and flies were

seen about the mud of rivers and putrid carcases ; whence, then, did they originate ? Some supposed them to come from one thing, some from another, from mud, lime, shells, or, as it would seem, whatever the animals were nearest to at the time ; but the great source of all was believed to be putrefaction ; that, by general concurrence, was admitted to be the origin of insects, and many other animated beings. It is inconceivable how long this opinion was maintained. Ocular demonstration of the reverse was hardly judged conviction, and treatises were even written in its support. Others, more watchful of the progress of nature, saw an egg produced by an insect ; they kept it till a worm came forth ; and preserved the worm until, by a complete metamorphosis, it changed into a winged animal. Thus was the real origin of an immense part of the creation ascertained.

It is not so surprising that the spontaneous generation of plants also gained credit in the fullest extent. The seeds were either so minute or so difficult to be found, that they eluded the most accurate search, and in this manner gave foundation to conclude that there were none. Now is it universally received, that the origin of every plant must be from some part of another plant ;
and

and it was probably the inability to discover that part, or to recognise the seeds, that allowed the belief of spontaneous generation. All this was applied to the very minute plants of mould. The seeds were invisible, or not recognised: eminent philosophers of modern date thought they had none, and advanced cogent arguments for spontaneous production of the plants. It is, indeed, very difficult to account for the existence of seeds in certain situations, unless by admitting that, like the germs of animalcula, they are universally dispersed, and, falling every where without any law, expand in those situations only which are congenial to their nature. One of the nicest points to be investigated in the natural history of mould consists in examining the places where seeds are found.

When a minnow or a leech dies under water, even several inches from the surface, and has seldom or never come there but for the purpose of respiration, it will soon be covered with a peculiar kind of long slender mould, while lying at the bottom, as I have repeatedly seen. Various species, some thicker, others more bushy and shorter, grow on different animal or vegetable substances also under water: it then seems more luxuriant, which is a general remark to be made of
mould

mould where it imbibes most nutriment. Whence does this mould originate? Does the fish, or whatever it is, receive the seeds of the plant the moment it comes in contact with the air? Do they adhere to it without being washed off by the water, until the conditions necessary for their expansion concur in its death and tendency to putrefaction?—Is it more reasonable to suppose the seeds are dispersed through the water, continually ready to be attached to the substances presented, to expand and produce their plant. Philosophic botanists may decide which of these opinions is the more probable. But it would rather appear; that the seeds of mould are dispersed in water; for I have kept many aquatic animals, which I can hardly think came to the surface during a long time, and if they required air, perhaps extracted or received it from the surrounding water: and, after death, luxuriant mould grew upon them. The thickness of this aquatic mould has been considerable, but never equally so as mould growing in the open air, which, it may be, arises from the difference of species more than from privation of circulating air. There is no reason why mould should not thrive in water just as well as many plants, whose natural aliment is there, and absorb air in the same manner; because there are facts which seem to prove the existence

istence of certain species of aquatic mould that are not to be found on terrestrial substances.

Mould is sometimes seen in nuts and other shell fruit, without any visible opening. In this case, it has, perhaps, penetrated the parts of fructification in an early stage, or while the plant was in flower; for it is unlikely that the seeds, however minute, will penetrate a thick shell where pores do not abound. They may lie in the fruit till an opportunity occurs for their development. These examples, it is true, are attended with great difficulty; but there are certainly methods of explaining them, though still undiscovered, unless we recur to equivocal generation, which is absurd.

Another theory may be conceived, which is the most probable of any. The seeds of mould may be disseminated in such abundance as to enter into the composition of all animal and vegetable substances. They find a receptacle in the external pores, or enter within the body itself. If a slice of moistened bread is put under a very small receiver, it will soon be covered with as many plants as would require millions of seeds for their origin. Six square inches of flour and water boiled into paste, and put under a receiver, not above eleven or twelve inches in capacity, have
shown

shown a vast variety of mould both in colour and species. Some long slender filaments crowned by a globule, some thick bushes with fruit on every branch, some very short, and consisting almost of dust. Then in one place a green spot; in another, lead colour, blue, red, or yellow. Whether is it more probable, that all the seeds, producing this infinite variety, have fallen from the air of the receiver, that they are communicated by the moistening liquid, or form a part of the bread and flour; the last supposition is not the most difficult: it is the readiest method of accounting for the extraordinary abundance and universal existence of mould.

But wherefore all this anxiety for framing theories. Let us be better acquainted with the kingdoms of nature; and, by deep investigation, endeavour to become intimately acquainted with the real properties of plants and animals.

To describe the prodigious variety of mould would require a volume: it would be a methodical system of botany. A fleece of long white mould will cover one substance; and it is sometimes so short as to have hardly any sensible length. The stalk of a few species is articulated like a stalk of corn. In general, it is straight, slender, and transparent. Sometimes it consists
of

of alternate angles, and at each is a globule; or it is intricate and confused below, but with fruit surrounding the extremities. The figure of the globule is various; some are spherical, some flattish, and others a perfect cone.

All mould certainly ought not to be classed among fungous plants. I have seen several species which rather appeared to belong to grasses: and oftener than once, I have thought flowers were perceptible. The Cryptogamia formed an immense pit, into which every plant of obscure origin, little known, or imperfectly described, was thrown. It only requires attention and experiment to discover the real properties of bodies, and thus to assign them their proper place. It appears indubitable that some kinds of mould belong to genera of plants whose larger species are well known; but there may also be many which exhibit peculiarities to be found in none other. The knowledge of this beautiful part of botany is in its infancy: diminutive objects are too apt to be considered as undeserving of notice; but to the philosopher all the works of nature are pleasing and interesting.

ANIMAL REPRODUCTION.—In all the field of natural history there is no subject more extraordinary than animal reproductions. Ge-
neration

neration itself is hardly so wonderful. There, indeed, by the laws of organization, the germ of an impregnated egg unfolds. Nutrition is supplied, and all the parts expand until the final term of increment arrives. This is an immutable ordination, and belongs to every animal alike that propagates by a foetus or eggs. If a limb is destroyed after attaining its full size, in numberless instances, it is lost for ever; nay, the remaining trunk in general withers and decays.—But there are some animals singularly privileged by nature. Let a member be torn off; the wanting limb is in the same state as before the act of the parent animals in generating and fecundating the germ: it is even less in existence; for the original germ of the defective part is also destroyed. Yet, not only will a new generation ensue, the amputated portion be produced as complete and entire as what was taken away, but, unlike the first evolution, which was of all the parts, this will acquire the size, figure, and motion, peculiar to itself, independent of the rest of the body.

In whatever lives there is a powerful tendency to vegetation, and heat is one great source of existence. Animals are more lively, their increase is more rapid, and eggs more numerously hatched, according to the external heat that prevails; and the reverse succeeds with cold. The same

same is an invariable rule with the reproductions of mutilated members.—Two general classes of animals are the cold and warm blooded. The latter always remain nearly at the same degree of heat, that is, commonly between 96° and 104° ; though the surrounding medium should be very far above or below these limits. Those with cold blood are not far from the temperature of the surrounding medium; and if it increases to a great degree, or falls very low, a material change is produced on their system. These animals seem to enjoy several eminent prerogatives respecting their individual safety; and among others, that of reproduction. Few material parts of warm blooded animals are regenerated; while of some cold blooded animals, there are few that are not reproduced. But heat is equally essential to this regeneration as it is to propagation and exclusion. Although we divide animals into cold and warm, *cold* is but a relative expression; for, in the total absence of heat, life would be extinct; and we always see it destroyed by a considerable degree of cold.

Even in warm blooded animals, there are important reproductions continually going on, perhaps from the moment of birth until death. The fluids are continually wasted and repaired. The
 insensible

insensible parts, the hair, the nails, the skin, are constantly falling off and produced again. Some parts regenerate only once or twice during life; others hardly cease before the reproductive faculty is lost for ever.

Several parts of the body are acquired after birth. Then the teeth of mankind seldom exist. In a few years, those first expanding are lost and replaced by others, which remain serviceable until decayed by time. Sometimes, at a very advanced age, a new set appears, even at an age which few live to attain; and these, whose *germs* have existed a century in the person, (if germs or organs are not created,) are as found and entire as in the most vigorous and youthful. The hair grows rapidly after birth; it is continually destroyed and constantly reproduced, and in such a manner that it will frequently branch afunder. This is the common course repeatedly in a year; but it is very remarkable, that, after ten or twelve years, it begins only then to grow on particular parts of the body: and after it springs, there seems to be very little reproduction. The nature and properties of this substance are as yet but imperfectly understood. The renewal of the skin is almost insensible; it comes off in minute scales. One instance occurred where the whole skin of both hands, up to the wrist, was thrown
off

off like a pair of gloves, frequently in a year, without any material inconvenience attending the change.

Were it possible to ascertain the fact, I should suppose that many parts of the human body would reproduce. The sides of a wound unite, and pieces of flesh are always regenerated. There is much reason to think that some part of a mutilated limb might be reproduced, was it not from the methods practised in healing the wounds. Examples of human reproductions are numerous. An instance lately occurred of a child born with two thumbs on one hand, and each with a perfect nail. When the child was three years old, the supernumerary thumb was amputated; however, it grew again, bearing a nail. It was cut off a second time, yet a third thumb like the first was reproduced.

The ends of fractured bones will grow; nay, entire bones have sometimes been regenerated. The head, neck, and part of the os humeri, we are assured, have been repaired. The complete bone of the leg, between the joints, was extracted by an operation; it was afterwards fully repaired. The whole has been cast off by expoliation, and a new bone grown in its place.

There is a remarkable sympathy often beheld between some parts of animals that are continually reproducing, and those which never regenerate. No part is more constantly reproduced than the beard ; its progress is frequently perceptible in a few hours ; but castration puts an end to it for ever. Many animals reproduce the horns every year ; but castration of the animal without them prevents their growth : and it is said, the castration of an adult male prevents them from falling again. This operation produces a singular effect on the frame : a visible change ensues ; the increment of certain parts terminates, while others extend to an immoderate size. Even the mind is materially affected.

Throughout most of the animal scale, there is a general reproduction of the parts which are of a similar nature. The skin, nails, hair, feathers, horns, and scales, have a great analogy to each other. Some of these, which, in particular animals, are renewed by a partial and continual change, are lost and repaired by others all at once. Serpents and caterpillars cast the whole skin. A caterpillar will in a short time reproduce six or seven,—within a few months. The lobster annually throws off its shell, and acquires a new one ; and, with the shell, it also loses the stomach. The feathers of birds are changed
once

once a year ; but feveral males acquire a long and beautiful tail only during the feafon of their amours, which afterwards falls off. The hair of thofe quadrupeds that inhabit the northern climates grows in much greater quantity as the rigours of the feafon become more intenfè. The fcales of fifhes, according to fome naturalifts, are yearly renewed ; but, in the opinion of others, they only acquire an additional ring. Certain horns alfo grow by an additional fheath periodically acquired.

In moft of the warm blooded animals, the inevitable confequence of mutilating important organs is death ; even unfkilful treatment of thofe that appear of lefs confequence is generally attended with pernicious effects. The flock fuf- tained, the pain they endure, and the lofs of blood, all combined, have a fatal tendency, which ends in total deftruction. The difference is incredible in the mutilations of animals which do not poffefs much internal heat. Not to fpeak of the polypus, which is well known to enjoy the property of living though cut in pieces, and each becoming a new and complete animal, there are fome other animals that enjoy prerogatives nearly as great ; and many which furvive the utmoft violence committed on the body. The claws of lobfters torn off will grow again. The legs

and tail cut off a water newt will be reproduced. Losing the head is not a mortal mutilation. I have seen one of the *planariae* regenerate a new head in fourteen or sixteen days; and the severed head acquires a new body. Indeed, the reproductive faculties of this animal are almost equal to those of the polypus, and perhaps will prove a more interesting subject for experiment. Indisputable evidence proves, that the snail will acquire a new head in place of the old one cut off, and that it regenerates almost every other part of the body. Certainly it is a most extraordinary property, to reproduce one of these organs commonly reputed the most important in the preservation of animal life. But we have already seen, that those organs which are of the utmost consequence to one animal are not so to another; and that they may be wounded, mutilated, or destroyed, without death infallibly following. The reproductive faculty is not exhausted by a single regeneration: if the second head is severed, a third will come in its place; and if this also is cut off, another will grow.

The sea anemone, some species of which are several inches in diameter, and which realises the ancient fable, applied to another animal, of producing its young by the mouth, possesses the reproductive property in a degree little inferior to the polypus. If the earth worm is cut in pieces, each
will

will live and produce a new worm. Some singularities arise from these mutilations. If the two ends are cut off a worm, the middle piece will become a perfect animal; but the head will not germinate from what we should suppose the natural place, that is, the anterior part; on the contrary, it proceeds from the portion that was next the original tail; and the new tail will grow from the anterior part of the trunk. It has been supposed, that the difficulty of eradicating that terrible scourge of mankind, the tenia, is owing to the prompt and sudden reproduction of mutilated parts. Numbers of marine animals, such as *asteriæ*, *medusæ*, even fishes, enjoy this property; and it is thought that it descends to the animalcula of infusions. In short, there is every reason to believe that it is widely diffused through the animal scale; and, if experiments could be made without endangering life, or inducing disease, that its empire would be found far more extensive than possibly can be conceived.

The first observations on animal reproduction were readily credited, because they related to parts without which it was known an animal might exist; but when such observations were extended to the organs most material and important to life, and when the loss of these daily testified that the animal inevitably perished, an un-

fual

sual degree of surprize and distrust arose. When the head was severed from the body, either intentionally or by accident, every known animal was destroyed. Therefore, the assertion that a new head would grow in place of the old one, naturally met with discredit. Intelligent persons reasoned from what had happened, and not from what might ensue. Certainly we can hardly call their hesitation culpable : and it has tended to one good consequence, namely, the establishment of the fact without dispute. But, in the prosecution of these experiments, distrust will gradually wear away : when we see the fins, flesh, bones, claws, feet, eyes, and jaws of an animal regenerated, and behold an animal survive after being divided in pieces, it is not so repugnant to think that it may reproduce the head.

If there is any reason why certain animals enjoy this singular prerogative in its full extent, it is yet unknown. Those hardy philosophers, who are irresistibly impelled to account for every phenomenon they behold, are continually deceived ; and in nothing is it more eminent than their arguments, once esteemed plausible, for the reproduction of lost parts. Here there is an immense source of information to be laid open to physiologists, both with regard to the regeneration of
important

important organs, and the discovery of facts respecting the mental powers. But in all experiments and reasoning, it will be found that nature pursues a certain determinate course; if there are deviations from it, they are accidental; and the same uninterrupted and invariable line will be resumed, whenever the cause obstructing it is removed.

TRANSLATOR.

OBSERVATIONS AND EXPERIMENTS

ON THE

ANIMALCULA OF INFUSIONS.

CHAPTER I.

WHETHER, ACCORDING TO A NEW THEORY OF GENERATION, ANIMALCULA ARE PRODUCED BY A VEGETATIVE POWER IN MATTER. INFUSIONS AND INFUSED SUBSTANCES EXPOSED TO HEAT.

Nothing is more common with philosophers who have invented any theory, or given a new form to one already established, and universally known, than to republish it on some other occasion, corrected, improved, or illustrated, with additional information. If we would review our discoveries, if we would examine them profoundly and with impartiality, we should in general find defects unnoticed before, which arise from

the want of connection in sentiment, from the want of a necessary and laudable perspicuity, or because they are discordant with more recent discoveries.

A certain vegetative power some have conceived to reside in matter, appropriated to the formation and regulation of organised existence; that by it are the numberless combinations of the animal machine effected; the operation of nutrition and perspiration, the variety of constitution, the animal appetites and dimensions of the human frame. By the same means has it been explained why a blind or a maimed person may have children vigorous and entire; because the vegetative power will restore to them the members defective in the parent.

Not only has it been supposed to be destined for the organization of matter in animated beings, but that it might change an animal to the vegetable state, and the vegetable again to an animal; that it acts on plants while living, and when dead regenerates them in new beings; these are the animalcula of infusions, which cannot strictly be called animals, but beings simply *vital*.

One proof adduced in support of this hypothesis, is derived from the origin of animalcula. We are told they must either come from specific seeds, or be produced by the vegetative power; that

that the first cannot take place, because they are found in close vessels subjected to the action of heat, equally as in open vessels, whereas the included germs, if there were any, ought not to survive. Therefore, they must originate from the vegetative power alone. Nothing has been omitted to obtain favourable arguments for this opinion, and to give it that clearness, elegance, and simplicity most likely to gain converts.

Nineteen vessels, containing infused substances, were hermetically sealed, and kept an hour in boiling water. Being opened at a proper time, not a single animalcula was to be seen (1). To this experiment of mine, it was objected that the long continuance of heat had perhaps entirely destroyed the vegetative power of the infused substances, or materially injured the elasticity of the air remaining included in the vessels; thus, it was not surprising if animalcula did not appear.

To estimate the weight of these objections, I conceived an experiment apparently decisive; which was, to make nineteen infusions, and boil some of them a short time, others longer, and the rest very long. If it was founded, the number of animalcula would be less according to the duration of boiling, if not, the number would be alike in all cases.

A 2

Vegetable

(1) Saggio di osservazioni microscopiche.

Vegetable seeds, being the most fit for producing animalcula, were preferred to other substances, and those that never failed to produce them though they had experienced the influence of heat. White kidney beans, vetches, buck-wheat, barley, maize, the seeds of mallows and beets were infused; and, that the experiment might be the more accurate; I endeavoured as much as possible to take each species of seed from the same plant. As the yolk of an egg in maceration abounds with animalcula, one was also infused.

Experiment has demonstrated, that the heat of boiling water is not always the same, but greater, if the atmosphere is heavier; and less, if lighter: therefore, water will acquire more heat at one time than another, which will be proportioned to the state of the atmosphere. In this, and my other experiments, the seven different kinds of seeds, and the yolk, were all boiled an equal time, that they might acquire the same degree of heat. Here the experiment was diversified, by boiling a certain quantity of each infusion half an hour; another quantity, an hour; a third, an hour and a half; and a fourth, two hours. Thus, four classes of infusion, and the egg, could be formed. The same water, in which the seeds had boiled; was taken for the infusions, and what had boiled half an hour alone taken for the
the

the seeds that had boiled half an hour. The like proportions of time were preserved in the water for the other three classes of infusions; that is, an hour, one and a half, and two hours.

Each of the four classes was marked with a different number, to avoid all hazard of confusion or error: and, because an equal temperature was most essential, all were deposited in the same place. The vessels, containing the infusions, were not hermetically sealed, but loosely stopped with corks; the only object of this examination being to discover, whether long protracted ebullition would prejudice or destroy the property of infused substances in producing animalcula; if it did, there would be no difference whether the vessels were open or close.

The examination of one, or of few drops, will often induce an observer to suppose the infusion quite deserted, or very thinly inhabited, while the observation of many drops proves it to be otherwise. I was not content with one drop only, but uniformly took a considerable number from each infusion.

The surface of infusions is generally covered with a gelatinous scum, thin at first, and easily broken, which, in process of time, acquires consistence. Here, animalcula are always most numerous, as may be seen by a method I have

constantly practised, examining with a magnifier a portion placed in a strong light.

Where the animalcula are minute, or rare, the thickness of the infusion often prevents the observer from distinguishing whether any are there or not. It is then necessary to dilute the drops with water. Elsewhere it has been remarked, that distilled water was taken to make the infusions; common water might introduce some latent animalcule (1). In the course of these observations and experiments, distilled water has also been employed for dilution, when required; and, for greater security, examined with a magnifier before being used. In particular cases, the accidental concealment of a single animalcule might vitiate the truth of the experiment.

I conceive it my duty to mention precautions so essential, and to put it in every individual's power to judge not only of the experiments and observations themselves, but of the mode of conducting them in matters so nice and important.

On the 15 of September, I made thirty-two infusions; and on the 23 examined them for the first time. Animalcula were in all; but the number and species different in each. In the maize infusions, they were smaller, and proportionally more rare, according to the duration of boiling.

From

(1) Saggio o dissertazione citat. Cap. 4.

From this it may seem, that although long continued heat had not prevented the production of animalcula, it had contributed to diminish the number, or alter the kind. But with the rest of the infusions it was otherwise: the kidney beans, vetches, barley, and mallow seeds, were in a better condition, after sustaining the violent impression of heat two hours, than those that had been exposed to it less. Let us enter on that detail which the subject merits.

In the infusion of kidney beans, boiled two hours, were three species of animalcula; very large; middle sized; and very small. The figure of the first, partly umbellated and attached to long filaments dragged along in their progress; the second were cylindrical; and the third, globular. All three were incredibly numerous.

In the infusion boiled two hours, were animalcula of the largest and smallest class, but few in number; still fewer, in that boiled an hour; and fewest of all, in that boiled half an hour.

The infusion of mallows, boiled two hours, produced middle sized circular animalcula; and some very large, with the head extremity hooked. In two infusions, boiled an hour, and an hour and a half, the number and species were the same: and though they might be surpassed by those of the infusions boiled two hours, still they

were much more numerous than in those boiled half an hour.

In vetches, boiled half an hour, was an immense number of semicircular bell-shaped animalcula, all of considerable size, while in those boiled an hour and a half, they were small and rare. Some bell-shaped animalcula might be seen in an infusion boiled an hour, but it gave the eye pain to discover a few, and these most minute, when it had boiled only half an hour.

Those in a barley infusion boiled two hours were numerous beyond description, and large; part of an elliptic figure, others oblong (1). The infusions boiled an hour and a half had but a moderate number of animalcula very minute; and some appeared when boiled half an hour.

There was no fixed rule with the remaining infusions. In buck-wheat boiled an hour and a half were many more animalcula than in any other infusions of it. This also happened in the egg and beet feed boiled an hour; but it is to be remarked, that fewer animalcula were in these two infusions boiled half an hour than in any of the rest.

Hitherto, the figure of these legions of animalcula has been curiously alluded to. A circumstantial

(1) Probably the author means different kinds of ellipse. At the same time, there are animalcula, though few, nearly of an oblong figure. Most of the descriptions in all this Tract are so general, that it is difficult to ascertain the exact species of animalcula.—TRANSLATOR.

stantial account is in my Dissertations, and it will be spoken of more at large in the course of the Tract.

Thus, it is clearly evident, that long boiling of seed infusions does not prevent the production of animalcula; and, notwithstanding the maize does not seem to favour it, four infusions strongly corroborate the fact.

What is the cause that infusions boiled least have fewest animalcula? I cannot think myself mistaken in assigning the following reason. That animalcula should appear, it is necessary that the macerating substances give some indication of the dissolution of their parts; and, in proportion as dissolution advances, at least for a limited time, the number of animalcula will increase. The uniformity of this has been shewn in another place, and would be confirmed, was it requisite, by further experiments and observations, in these new inquiries. Now, as seeds have boiled a shorter time, so are they less invested and penetrated by the dissolving power of heat; therefore, when set apart to macerate, they are not so soon decomposed as those longer boiled. Thus, there is no occasion for surprize if some infusions swarm with animalcula while others have very few: And this I do believe the reason why, when two infusions are made at the same time, one of unboiled, the other of boiled seeds, animalcula are frequently

quently observed much sooner in the latter than in the former. A little boiling will not decompose vegetable feeds, for decomposition is effected by slow and gradual maceration.

Some days after these experiments, the number of animalcula always became greater; and towards the middle of October increased so much, that each of the thirty-two infusions was equally swarming. The only difference was in size, figure, and motion: I enjoyed this pleasing microscopic scene uninterrupted until the 10 of November; and it might have amused me longer had I continued to examine the infusions.

It ought not to be omitted, that experiments exactly similar were soon afterwards made with pease, lentils, beans, and hemp seed. Except in the beans, the result so far corresponded, that a greater number of animalcula appeared in the infusions that had boiled most.

It is a fact established by the universal concurrence of philosophers, that, after water has come to the state of ebullition, it cannot acquire a greater degree of heat, however much the action of the fire may be augmented, provided it can evaporate. Therefore, when I say the feeds boiled longest have acquired greater heat, I mean it to be understood in *time* and not *intensity*, by supposing that the duration of boiling encreased the

the intensity of heat the seeds would be exposed to.

Recourse was had to another experiment to learn whether an encrease of heat would obstruct the production of animalcula. The eleven species of seeds were slowly heated in a coffee roaster till they became pretty well roasted, and eleven infusions formed of them with water previously boiled as usual. But this heat, so much more intense, neither prevented the origin of animalcula nor lessened the number. They were rare at first; but about the middle of October, that is, twenty days after making the infusions, the fluid was so full as absolutely to appear animated.

The constancy of their appearing even here, excited my curiosity to augment the heat still more. The seeds were burnt and ground the same as we burn and grind coffee. Of the dust, which resembled soot, I made as many infusions as different kinds of seed: likewise, an infusion was made of the yolk of an egg, which by the thermometer had suffered 279° of heat (1). What followed?

(1) The author used Reaumur's thermometer in all his experiments. As Fahrenheit's is the only thermometer used in this country, the degrees of heat are here reduced to his standard, 2.25 of Fahrenheit being equal to 1° of Reaumur. The fractional parts of the former are not given, both because experiments can seldom be made with-
in

followed? Animalcula equally appeared in these infusions, only a little more time elapsed before they became so numerous, because the weather was colder; and they uniformly inhabit infusions sooner or later according to the temperature of the atmosphere.

Vegetable feeds were exposed to trials more severe: they were exposed to the greatest heat that can be excited by common fires, or fire augmented by art. Burning coals, and the flame of the blow pipe, were the two agents exercising their power on them. And, in the first place, I kept them on an iron plate above burning coals until entirely consumed by the violence of the flames, and converted to a dry cinder, which was reduced to powder, and as many infusions formed as there were feeds. A cinder was also made by the blow pipe, which, besides excessive aridity, had acquired considerable hardness. I must acknowledge I did not in the least expect to find animalcula in this new infusion. After viewing them once and again, hardly able to credit my eyes, I repeated the experiment twice. Some suspicion arose that the animalcula might come from the water used rather than the burnt feeds; therefore, on repeating the experiment, the same
as

in parts of a degree, or thermometers to agree exactly, and because the difference here, where there is any, never exceeds .25 of 1°.—T.

as what formed the infusions was put in other vessels. Both times, however, they re-appeared in the burnt feeds, while not one was seen in the water.

These facts fully convinced me, that vegetable feeds never fail to produce animalcula, though exposed to any degree of heat; whence arises a direct conclusion, that the *vegetative power* is nothing but the work of imagination; and if no animalcula appear in vessels hermetically sealed and kept an hour in boiling water, their absence must proceed from some other cause.

CHAP. II.

WHETHER THE INFLUENCE OF HEAT DIMINISHES THE ELASTICITY OF AIR INCLUDED IN VESSELS HERMETICALLY SEALED; AND IF IT WOULD BE AN OBSTACLE TO THE PRODUCTION OF ANIMALCULA.

THIS inquiry may be reduced to two heads: *First*, By subjecting a given number of vessels hermetically sealed to heat so regulated that they might suffer different degrees, and observing if the production of animalcula is obstructed or altogether

altogether prevented, by increasing the heat. *Secondly*, Whether the increments of heat prove the diminished elasticity of the air.

For convenient examination of both, eleven vessels, containing eleven kinds of the same vegetable feeds as before, were hermetically sealed. But, to proceed with due caution, it was essential that the included air should undergo no sensible rarefaction in sealing with the blow pipe, and not lose its elasticity, which would assuredly happen if the vessels were sealed without any further preparation, by the flame surrounding and softening the neck: for such powerful heat, after communicating from the neck to the belly, could not but expel great part of the included air, whence the part remaining behind would become more or less rarefied, and more or less elastic accordingly. Indeed, when the hermetic seal is broken, after the vessel cools, a faint hissing is almost always heard, which proceeds from the air escaping by the orifice: and that this is the fact is certain, by applying the flame of a candle near the seal; when broke, the flame is driven from the aperture, and sometimes actually extinguished. If the seal is broken when the vessel is inverted in water, the water suddenly rises above the level of what surrounds the vessel; a most satisfactory proof of the internal air being more rarefied than the external. To avoid this inconvenience, the
neck,

neck of the vessel was drawn out at the lamp almost to a capillary tube: the smallest part was then instantaneously sealed, so that the internal air could suffer no alteration, as was evident from no hissing being heard on breaking the vessel.

After ascertaining that the included air was of the same density as the atmospherical, it was necessary, before exposing the vessels to heat, to investigate, whether simple inclusion of the seeds would obstruct the production of animalcula: Was it so, it could be ascribed neither to heat nor air, but the closeness of the vessels alone. Other experiments had rendered me cautious here(1). They had taught me, 1. Infusion animalcula are not produced in vessels hermetically sealed unless the vessels are capacious; 2. They are not always produced; 3. They are never so numerous as in open vessels. I now felt the necessity of such circumspection, and although it was used, two substances, kidney beans and pease, ceased to produce animalcula. The other nine seeds produced a moderate number. To these nine only, I confined myself, and subjected each to heat in the following manner. Nine vessels, hermetically sealed, containing seeds, were immersed in boiling water half a minute; other nine, a minute; nine more, a minute and a half; and nine, two minutes. Thus I had thirty-six infusions,

(1) Dissert. Cap. 10.

fusions, the seeds in which were exposed to the heat of boiling water. To discover the proper period for examining the sealed vessels, similar infusions were at the same time made in open vessels; and, when animalcula abounded there, those sealed up were visited. In eleven days, the nine open infusions being full of animalcula, it seemed fit to examine the others. On breaking the first hermetic seal, a faint hissing was heard, not unlike that mentioned above. Then it did occur to me that heat had truly injured the elasticity of the internal air, and excited me to observe, with the utmost attention, what happened on breaking the seal. The hissing was obvious in all; but I soon discovered it arose from an opposite cause, namely, increased elasticity of the air. In the first place, the flame of a candle was driven from the orifice; secondly, on just touching the sealed part with a file, it twice sprung more than a span from the vessel; in the third place, on making the infusion flow towards the seal, and then breaking it, the infusion violently spouted out; fourthly, the seal being broken under water, instead of running into the vessel, the water was forced away. Reflecting on the nature of macerating substances, I saw it could not be otherwise. Vegetable seeds are well known to contain a great quantity of air. During

ing their dissolution by heat it must be extricated, and in this way render the portion included more elastic. I do not deny, however, that this encreased elasticity may partly arise from an elastic fluid, discovered in vegetables, of a nature different from the atmospherical fluid.

To return to my microscopic examination of the sealed infusions. It gave me great surprize to see heat, so very far inferior to that mentioned in the preceding chapter, had obstructed the origin of our animalcula. Some infusions were an absolute desert, and others reduced to such poverty as only to afford so many wandering animalcula like points, and hardly perceptible (1). Let the reader figure two lakes; in one, are fishes of every size, from a whale down to the smallest; while in the other are a few minute fishes, not larger than ants, and he will have a sensible idea of the animals appearing in the open infusions and those that appeared in the close. I was particularly surprized how the heat of half a minute had been as injurious as the heat of two minutes. Those inexpressibly

B

minute

(1) *Monas Termo*. MULLER, *Animalcula Infusoria*, p. 1. Hauniae, 1786.—This is a systematic work on the animalcula of infusions, where the indefatigable author has described 378 species of these singular beings. The reader will find a number of synonyms, preceding each description, if the animalcula has come under the view of other authors.—T.

minute animalcula were produced from beans, vetches, buck-wheat, mallows, maize, and lentils. Whatever attention was bestowed on the other three infusions, I could never discern the least indication of animation.

From this series of experiments I concluded, that the heat of boiling water half a minute was fatal to large, middle sized, and small animalcula, which, to adopt the energetic expression of my illustrious friend M. Bonnet, I shall term animalcula of the *higher class*; while the same heat, protracted two minutes, did not affect the infinitely minute animalcula, which I shall term the *lower class*. Here two problems occurred: Whether the continuance of boiling longer than two minutes would prevent the origin of the lower class; or, if diminishing the boiling less than half a minute, would admit the existence of the higher class. As no two problems could be more important, I endeavoured to solve them in the following manner.

I began with the first; and, using the method already observed, kept vessels with six kinds of feeds, producing the lower class of animalcula, in boiling water, some two minutes and a half, three minutes, three and a half, and four minutes.

The hermetical seal of twenty four vessels was broken at a proper time; though the higher class of animalcula was wanting, it was not so with
the

the lower; some were in all the infusions. In general, the hissing was heard on breaking the seals, which proceeded from the violent efforts of the air, rendered more elastic, to escape, as the proofs already given convinced me, and an additional one occurred, than which nothing could be more decisive. A small barometer was included in a receiver full of common air; whenever the neck of a sealed vessel introduced by the top was broke, the mercury rose in the barometer. To avoid redundancy, I may now remark, that condensation of the internal air almost uniformly manifested itself in the other experiment with heat yet to be narrated.

Vessels were immersed seven minutes in boiling water; animalcula of the lower class appeared in all six; and they constantly originated though the infusions remained twelve minutes in boiling water.

Perhaps it may be imagined that some optical illusion deceived me; that I was induced to suppose the lower class of animalcula what arose only from the particles of the infused substances. That it might be the consequence of decomposition by gradual fermentation, or by their lubricity occasioning locomotion on the least shock or agitation; or of an active and volatile spirit penetrating and putting them in motion; from a great evaporation, or one less copious; from

a powerful attraction or repulsion, by which the particles of the substances were forcibly attracted or repelled, or from any other accidental cause deceiving the eye. But in the same manner as these, and so many other fallacious appearances, may impose on him who is only beginning the difficult art of experiment and observation, so can they be properly appreciated by one well accustomed to microscopes, and who has made the history of these infinitely minute beings his long and particular study.

Notwithstanding the lower orders of animalcula are incomparably smaller than the others, they are not so very minute as not to differ in figure and size. But I shall not tire the reader with descriptions.

I would willingly have protracted the heat by continuing the immersion longer in boiling water, but the nature of the glass prevented it; for, after being a few minutes immersed, all the vessels burst in pieces, and of a sufficient number for my experiments I am sure two-thirds were lost. Therefore it became necessary to procure glass that would sustain heat better; which was effected by putting only a small quantity of water in the vessels with infusions. Omitting this precaution, I was certain to see them fly in pieces. It is needless to descend to minute details: the result of experiment proved, that boiling
ing

ing half an hour did not prevent the origin of the lower animalcula. Boiling three quarters, or a little less, rendered the whole infusions sterile.

We know the heat of boiling water is about 212° . The infusions had evidently acquired this degree at least, from their ebullition, while the surrounding water boiled. I say at least, for philosophers know, that water boiled in a close vessel acquires more heat than boiled in an open one.

The first problem being solved, which was to ascertain how much longer than two minutes infusions must boil to obstruct the production of the lower animalcula. The second, which was the inverse of the first, remained for solution, how much within half a minute, boiling would admit the origin of the higher class. A second watch was used; and the vessels were immersed a certain number of seconds, beginning with twenty-nine. In a word, boiling for a single second prevented the appearance of the higher class. Thus I had to take a less degree of heat, as 209° , 207° , 205° , 203° , until arriving at that which did not obstruct their existence. To be absolutely sure the heat had time to penetrate the infusions, the water was gradually warmed, till attaining the requisite degree, which was indicated by a small thermometer also immersed.

But to recede by such small differences would have been extremely tedious and troublesome; and receding by great intervals, as for example, from 212° to 167° , 122° , might produce inaccuracy, and admit that animalcula had appeared, not only at that degree, but at one much inferior, therefore I thought of adopting a mean temperature, which would both diminish the labour, and liberate me from the imputation of an unexact observer. The reduction proceeded by 11° , descending from 200° to 189° , 178° , 167° ; whence I had four classes of experiments corresponding with the numbers 200, 189, 178, 167. Each class had nine infusions of the seeds before named, which made thirty-six vessels, whose seals were broken, when the time necessary for producing animalcula had elapsed: but not a single animalcule was in any one of the thirty-six vessels. Whence I concluded, that none of the higher classes could appear at 167° , which is 45° less than the heat of boiling water. Continuing to descend by 11° from 156° , I came to 111° ; whence I had five classes of infusions, and forty-five vessels.

My surprize has already been expressed at seeing such abundance of animalcula of every description, in substances openly infused, after exposure to the violent flame of the blow-pipe: but it gave me no less astonishment not to find
a single.

a single one of the higher class in infusions hermetically sealed, though they had suffered only the moderate heat of 111° .

This was done in the middle of July; and the thermometer in the shade stood at 88° . Eighteen vessels were put to the test: nine suffered 99° ; and nine 88° . No animalcula of the higher class were produced at 99° ; but the whole nine infusions produced them at 88° . Animalcula, the same in number and species, were in each vessel, as in the close infusions not subjected to heat. From this fact, it was easily discovered, that the degree of heat fatal to these animals was between 99° and 88° ; and I found it to be 95° : at 93° , a few of the higher class appeared; at 95° , only those of the lower.

The method of opening the infusions has been described towards the beginning of this chapter. When close infusions were made, I also formed open ones: and both being put in the same place, to have an equal temperature, when the open infusions abounded with all sorts of animalcula, I examined the close. Such a plan always seemed the best; nevertheless, if disappointed of seeing animalcula, I changed it oftener than once: sometimes the vessels were opened sooner, sometimes later; and though frequently delayed very long, the fact was uniform. In short, I remain under the most absolute conviction, that

the non-existence of these animalcula does not depend on the duration of time, but entirely on the action of the heat to which infusions have been exposed.

Before terminating the experiments before us, and making the reflections which they merit, let a word be said, in passing, of the death of animalcula, after speaking so largely of their birth. We have seen the lower class originate, in close vessels, at 212° ; while the higher scarcely can at 93° . It would therefore appear, that, on exposing both to heat, the lower class should resist it much better than the higher: however, the same degree that is fatal to the one, is fatal to the other; and both constantly die at 106° , or, at most, 108° .

Two important consequences flow from these experiments: First, The efficacy of heat in rendering close infusions barren of an infinity of animated beings. In open infusions, are an incredible number and variety; while in the close, subjected to the action of fire, one seeks in vain for an animal which he can call even the smallest in size. We cannot affirm, that simple inclusion occasions such devastation, since, in other cases, it only diminishes the number: therefore, we must conclude, that heat truly does it. But how can it operate? Can we think it is by rendering infused substances unfit for producing animalcula?

animalcula? The insufficiency of such a supposition has already been seen. Neither can heat impair the elasticity of the internal air: because, from the precautions taken, there was not the least difference between the state of the internal air and the external; and attending to what happened on opening the vessels, so far from that within being less elastic, it is even more so than the other. It is impossible to conceive the increased elasticity is prejudicial to the origin of our animalcula, as I have seen them where the air was condensed twice or three times more than its natural state. The conclusion will then subsist, that when the higher class does not appear, it is because heat has vitiated or injured the productive principle. The force of this conclusion will afterwards be better comprehended. The second consequence is the inverse of the first, and respects the constancy or rather certainty of animalcula appearing in boiled close infusions. And this result is no more favourable to the reason assigned for none originating in infusions boiled an hour, because too great heat had destroyed the vegetative power, or impaired the elasticity of the air; nor with the time I ought to expose infusions to heat, and still see animalcula, which has been prescribed to be as much as will destroy the eggs of the silk-worm-moth, that is, 135° , or 138° , or 140° , the same as we shall soon

soon see that renders their eggs unfit for exclusion. But I have not only found the lowest animalcula at that degree, but at 212° continued fully half an hour.

These are the facts I have deemed it necessary to collect for estimating the weight of the two objections to my experiment: and we readily see how discordant they are. If, in the heat experiment mentioned in my Dissertation, I found no motive inducing me to admit an imagined vegetative power, I have now the strongest reasons for rejecting it as inconsistent and chimerical. And as I could not then conceal my propensity to believe, that infusion animalcula originated from germs, neither do I hesitate here to say, propensity has become perfect conviction(1). If the animalcula, in close vessels subjected to heat, do not originate from the vegetative power, I do
not

(1) In the course of this work there are many allusions to germs. The great dispute concerning the generation of animated beings seems to resolve into the question, Whether there is a preorganized principle continually involved in another preorganized principle, and so on, by successive involutions, from all eternity, and this, by the concurrence of peculiar circumstances, expanding into the complete animal; or if it is more probable, that by the intercourse of the sexes, or otherwise, some change or creation is effected, which gives birth to a new animal or a wanting part: Both hypothesis are attended with infinite difficulty.—T.

not see how we can ascribe their origin to any thing but eggs, seeds, or preorganized corpuscula, which we understand and distinguish by the generic name of germs. That such is the real origin of animalcula will be directly proved, in the course of this Tract, by incontrovertible facts. An objection, it is true, here presents itself, which impartiality will not permit me to conceal. Speaking of germs that develop into the lowest order of animalcula, we must admit, that these germs have resisted the heat of boiling water, and that for three quarters of an hour; for it cannot be supposed they have passed from the air and insinuated themselves through the pores of glass, after cooling of the vessels. Such suppositions, if not impossible, are certainly very difficult to be comprehended. However this should rather be called a doubt or difficulty than a real objection; since, when well weighed, it may be reduced to the consideration, whether we can conceive germs of animals in nature, whose extreme subtilty permits their passage through glass, or whose constitution allows them to withstand the heat of boiling water. As to the first hypothesis, though I do not find it absolutely repugnant, because we know there are animals so very minute that their existence never would have been credited but for the microscope, I cannot admit it for the following reasons. In the *first* place,

place, because the size of germs is proportioned to the size of animalcula, as I have seen in more than one species; and, on the other hand, the lower animalcula, considered in themselves, being of some sensible size, so should their germs be of some sensible size, such, at least, as prevents them from penetrating glass; particularly when we know, that other corpuscula apparently more minute, as the particles of air and water, of the most acute and penetrating odour, cannot do it (1). In the *second* place, these animalcula are produced not only in glass, but even in metal vessels sealed with metal, immersed above half an hour in boiling water, as I have twice had occasion to experience, notwithstanding the greater narrowness of the pores, or more irregular and tortuous position, made it impossible to conceive the germs would penetrate the sides of the metal. Finally, Was the hypothesis true, animalcula of the lower class should originate equally well, whatever is the duration of boiling; for, in both cases, the passage of the germs through the sides of the vessel should be equally successful. On the contrary, not one appears after boiling three quarters of an hour.

Thus we are led to ascribe their origin to included germs, which for a limited time can resist the

(1) *Academ. del Cim.*

the influence of heat, but at length yield under it. As the higher class does not originate unless at a much more moderate degree of heat, there is a necessary inference, that the germs of this class are much sooner affected than those of the lower ; whence we must conclude, that the amazing multitude of animalcula in the infusions of open vessels exposed to boiling heat, and the intense flame of the blow pipe, do not appear because their germs have resisted so great a degree of heat, but because other germs have come to the infusions after cessation of the heat.

But is there any proof, or any forcible argument, to remove or lessen our natural repugnance to suppose that germs of the lower animalcula can resist the heat of boiling water? To speak of the germs or eggs of animals known to us, are there none of this nature? Undoubtedly, as far as our knowledge extends, we are unacquainted with any of that description. Something has been said on the subject in the ninth chapter of my Dissertation, demonstrating how the eggs of various insects, as well as those of birds, perish at a degree of heat considerably less than that of boiling water. It is further shown, that this heat injures the seeds of plants, even those with the hardest shell. A greater number of seeds and eggs, indeed, might have been subjected to experiment : and some may be found capable of standing the
trial.

trial. With regard to feeds, hope should not be abandoned from reading in Duhamel, that he succeeded in the germination of wheat which had suffered 234° in a stove; and it is very probable this feed is not unique. So many analogies existing between feeds and eggs, I indulged the hope of finding something similar in the latter. These facts were sufficient inducements to make new experiments on feeds and eggs, to which I was additionally incited by the most singular phenomenon of the lowest animalcula originating in boiled infusions: and, in case eggs and feeds should not withstand the heat of boiling water, it would still be useful to ascertain what they could support, by passing through various degrees to that which was fatal to them. But there was one particular inquiry not to be omitted, namely, whether animals and plants were more easily destroyed than their eggs and seeds, and in what proportion, the same as animalcula of the lowest class can support heat less than their germs. As all such investigations would greatly elucidate the present researches, I endeavoured to realize them by experiments, which will afford matter for the subsequent chapter.

CHAP. III.

EGGS AND ANIMALS, SEEDS AND PLANTS, EXPOSED
TO DIFFERENT DEGREES OF HEAT.

IN the month of May, I fished up the eggs of frogs, which had a few hours before been deposited in the water of ditches. The quantity was divided into equal portions, and each exposed to a different intensity of heat, in this manner. The eggs were completely immersed in water, where I had put the ball of a thermometer. The vessel was then placed on a slow fire; and, when the thermometer had attained the requisite height, the eggs were taken out, and each portion put in a vessel of cold water. I had ten vessels, because there were ten portions of eggs that had experienced different degrees of heat, as 111° , 122° , 133° , 144° , 155° , 167° , 178° , 189° , 200° , 212° .

The eggs that suffered 111° , 122° , 133° , produced young, but with some difference. Almost all those at 111° were fertile; fewer produced at 122° , and the number extremely small at 133° . The whole that were exposed to greater heat became corrupted.

corrupted. The heat neither accelerated nor retarded the exclusion of the eggs, for tadpoles were hatched in the same time as in those not exposed, which had been reserved for the purpose of comparison.

Having ascertained the heat which the eggs of frogs could suffer without injury to the tadpoles, I had to examine what heat the tadpoles produced by them could bear; however, they were unable to resist as much, for all died at 111° .

These experiments were repeated on adult frogs. Although I had several species, I preferred those that had produced the eggs. They inhabited the ditches of plains, were rather small in size, and greenish on the back. Being put on the fire, they had all liberty in the water; they could swim at pleasure, and come to the surface to respire: but a covering prevented them from escaping. The whole perished at nearly about 111° .

I know there are frogs that live in warm springs, though the heat is greater than 111° . Thus, the illustrious Cocchi relates, they are not injured in the warm baths of Pisa, where it is 111° by Fahrenheit, which corresponds with 37° of Reaumur's thermometer (1). But we must either say they are of a different species, or, being long accustomed

(1) There seems to be some error here: 37° of Reaumur's thermometer corresponds with 115° of Fahrenheit.

tomed to that degree, suffer no injury, though at first it would have been fatal to them. And we know, that men who can hardly endure the vapour bath six minutes, and are covered with profuse perspiration, can, in process of time, remain fifteen minutes without any sensible inconvenience (1).

(1) Both man and animals can bear an incredible degree of heat without perishing, and even without any sensible injury. Not that the living body will become heated to a high degree; it always preserves a temperature near what it should have in a natural state. In a memoir on this subject, it is said that a girl supported 284° , in an oven without inconvenience. Those serving the oven bore 257° a quarter of an hour, and perhaps could have endured 212° half an hour. *TILLET sur les chaleurs auxquels les hommes sont capables de résister. Mem. de l'Acad. Roy. 1764.* Several persons bore a room heated to 198° . 210° . 211° . The same persons could just bear cooling spirits at 130° , cooling oil at 129° , and cooling quicksilver at 117° . They could not suffer the heat of water at 125° ; *Philosophical Transactions*, 1775, p. 117, 120. Different persons at Liverpool bore the heat of an apartment at 224° ; and Sir Charles Blagden bore one at 260° . *Philos. Transac.*

A dog has been in the heat of 236° without inconvenience; and a species of tænia has been found alive in a boiled carp.

In Russia, the vapour bath is said by Storck to be generally 133° . according to D'Auteroche 167° ; and Acerbi observes, that those in Finland are from 158° to 167° .---T.

I could have wished, when my experiments were made on other animals, to have also made them on their eggs; but it was not always as convenient for me to procure the latter. Thus when, at one time, I had abundance of larvæ of muskitoes, water fleas (1), rat-tail worms (2), and other aquatic insects, I never could succeed in finding the eggs whence they originated. However, it did not appear that my labour would be lost in making experiments on the animals. The nymphs and larvæ of muskitoes (3) died at 111° ; rat-tail worms and water fleas, at 106° ; water newts and leeches died at 111° ; the eels of vinegar, at 113° .

In my experiments on silk-worms, the caterpillars of elm butterflies, and the worms of the large flesh fly, I was more successful, as I had both the animals and their eggs. Until 93° , silk-worms did not appear affected; at 95° , and particularly

(1) No name is more incorrectly applied in general than *water flea*; almost every small aquatic animal, even *squillæ* and *gyrini*, have been so designed. It is most likely the author means the *monoculi* of Linnæus. There is a complete systematic history of these, and many other minute aquatic animals, by Muller, *Entomostraca seu Insecta Testacea*, 1785, 4to.—T.

(2) Reaumur so denominates certain white worms from the resemblance of their tail to a rat's.

(3) It is uncertain whether the author may not mean tipulæ.—T.

particularly at 97° , they became restless; at 99° , they ceased to move; and at 108° , all had perished. The eggs producing these animals long resisted the influence of heat: at 88° , they produced the greatest possible number of worms; at 99° , many, but fewer than before; and the number always diminished as the heat encreased: at 144° , not one was fertile. The eggs and caterpillars of the elm butterfly perfectly corresponded with the silk-worms. It would be superfluous to say more of them; and I pass to my experiments on the large fly.

The species was that which deposits the eggs on flesh either putrid or tending to putrefy. Until 124° , a great many produced worms; at 135° and 138° , very few; and all were sterile at 140° . The larvæ of these eggs, at 88° , began to be restless, and endeavoured to escape: their agitation encreased at the subsequent degrees; and at 108° all had perished. Full grown worms of the same kind died at 108° also; Changed to nymphs and flies: the latter bore the heat worst of all; 99° degrees killed them. Flies came from nymphs at 104° and 106° ; but none at 111° : having opened them, I found the heat had entirely dried them up.

And this much being said with respect to animals, and their eggs, exposed to different inten-

fities of heat ; let us next narrate what happened to plants, and their feeds, in a similar situation.

The feeds I used were grey pease, lentils, wheat, lintseed, and trefoil : each, as usual, was exposed to a different degree, 167° , 178° , 189° , 201° , 212° , and then sown in a small distinct space of earth, so prepared that each space might contain an equal number of feeds.

Their germination was not injured by 167° : 178° began to be prejudicial ; very few succeeded : at 189° , there were no more than eleven plants of trefoil, and only ten at 201° : of those exposed to 212° , only three germinated. Thus none of the feeds but trefoil could sustain the heat of boiling water.

The five feeds had been subjected to heat by means of a sand-bed. In a second experiment, they were kept in water that was gradually heated, till as hot as required, in the same manner as before with feeds and eggs. Heat operated more powerfully on them here : at 167° , pease and trefoil germinated plentifully ; but very little lintseed, lentils, or wheat : at 189° , were only seven stalks of trefoil ; and at 212° none.

My curiosity being satisfied with regard to feeds, I had still to satisfy it concerning the plants sprung from them. Growing plants, thirteen days old, were subjected to 167° , 178° , 189° , 201° , 212° , dipping the roots in water gradually warmed.

ed. Though immediately replanted in moistened earth, all died. As 167° was too powerful for these young plants, the heat was reduced to 156° and 144° ; and this was not prejudicial to them, for the whole grew when replanted.

I had already subjected feeds to the influence of heat, but did not then think of doing the same to their plants. The feeds were beans, barley, white and black kidney beans, maize, vetches, parsley, spinage, turnips, beets, radishes, and mallows. They were heated to 167° , in sand, after the manner above described; and all germinated. At 178° , some began to perish; at 189° and 201° , very few succeeded; and at 212° , only one plant of kidney beans. The experiment was repeated at 201° and 212° , on all the feeds, but not one germinated.

My first experiment having proved, that trefoil had resisted heat better than the rest, it occurred to me, that, it being the smallest seed, the size might perhaps concur towards the cause. Whether more heat could be sustained as the feeds diminished, could have been ascertained by instituting a series of experiments on a given number of vegetable feeds gradually decreasing in size. But beans, and kidney beans, which are incomparably larger than trefoil feeds, had supported heat as well: and this induced me to abandon the idea, and spare myself useless trouble.

It may be proper here to recur to the seeds composing several infusions, mentioned before, exposed to the heat of boiling water in vessels hermetically sealed. Two minutes immersion admitted of full germination, but it ceased if the heat continued longer : and the like happened in open vessels, only, these could scarcely bear two minutes, and the others could bear a little more.

At first sight, the experiments before us seem discordant with the former, indicating the vegetative faculty is lost when seeds in water are exposed to 212° , or the heat of boiling water. By attending to the different modes of conducting the experiments, all inconsistency disappears. In the former series, the water was heated till beginning to boil ; here, on the contrary, that in which either the sealed or open vessels were immersed two minutes, did not give the least sign of ebullition, and the included water would have required at least four or five minutes longer for it ; that the seeds vegetated is not surprising, while those named before did not, since the one suffered more heat than the other.

Such have been my experiments on animals and their eggs, and on seeds and their plants ; which, although not very numerous, seem to bring certain laws of nature in view, whence we derive some elucidation of this subject. We collect, in the first place, that the eggs of the animals examined

ained were more able to withstand heat than the animals themselves. Tadpoles and frogs died at 111° , while their eggs became sterile at 133° ; and some even not so soon. Silk worms and the caterpillars of the elm butterfly died at 108° : their eggs did not produce at 133° . Large flesh flies perished at 99° , their nymphs at 111° , their larvæ at 105° , and eggs at 140° . Secondly, There is much the same relation between plants and seeds as between animals and eggs. Some, as trefoil, beans, and kidney beans, are fertile, after having been exposed to 212° , or the heat of boiling water, while their plants cannot support 167° . Thirdly, The seeds of plants are more adapted for resisting the violence of heat than the eggs of animals. All the seeds my experiments were made on by dry heating germinated, though they had suffered 167° , and some 212° , but no egg was hatched after 144° . Lastly, It is to be remarked, that heat is more noxious when acting along with water. None of the seeds in water at 212° afterwards germinated.

I am very far from pretending to give reasons for all these results. I feel the difficulty of the enterprise, and at most shall only hazard some conjectural explanations, allowing whatever weight they merit, and permitting every one to think as he judges best. It may not be difficult, if we take the first appearance only, to comprehend why

plants and animals do not sustain heat so well as seeds and eggs; and it would seem, because they receive the immediate impressions, which is not so when included in the seed or egg. But was the difference only a few degrees, which the animal could sustain in the egg and out of it, and the same will apply to plants, this reason might be good; however, when that difference reaches 22° , nay 31° and more, who does not perceive the insufficiency of it? Besides, we should necessarily have to admit, that the integuments of eggs, which in many insects are but as points in matter, would be able to protect them against 22 or 31 additional degrees of heat, which is very improbable, when we consider its extreme facility and activity in penetrating substances so pervious. Neither do I think the minuteness of the germ in the egg a satisfactory reason why it should be less sensible of the impressions of heat; for, however small it may be, the particles of heat are incomparably smaller, and they will therefore invest and penetrate it on all sides, the same as they invest and penetrate it when developed. A complete refutation of this imaginary reasoning is in the ninth chapter of my Dissertation.

Before we are able to conceive why an animal in the egg is not so easily destroyed by heat as after it is produced, we must take an accurate view of what constitutes life in both these situations.

tions. But, if the life of animals in existence is so little known, notwithstanding all the efforts of modern physiology, much more obscure must be the life of an animal concealed or concentrated in an egg. Certainly we may conclude, that the life of an animal in the egg is most feeble compared with that of the animal produced. During the first hours of incubation, the animation of the chicken is indicated only by the beating of the heart. Life before this is still more feeble: it is a lesser life, doubtless such as that in the germs of insects eggs previous to their having experienced the degree of heat necessary for exclusion. Can this most faint and feeble animation be any reason why it may endure more heat than after it is developed? Certain it is, that animals, when in a state of very feeble life, which hardly merits the name of animation, do resist external injuries with much greater impunity than when most vivacious (1). Thus, if we cut off
the

(1) This certainly depends very much on the nature of the injury to which the germ or animal is exposed, for the imperceptible agency of particular substances, whose nature we are little acquainted with, are noxious. Thus Michelotti inclosed a number of eggs in glass vessels, some of which admitted the rays of light, and others excluded them. Few or none in the former were hatched; whence, from a series of experiments, he concludes that light is prejudicial to the development of all the germs of animals, and the same with respect to vegetable germs.—T.

the head of a frog, toad, lizard, snake, or viper, or take out the heart, or deprive them of some member during winter, while torpid with the cold, and apparently more dead than alive, they survive the operation much longer than if they undergo it in summer, when in the vigour of life. I have often admired this fact; and that insects immersed in water in winter live longer than if immersed in summer.

There is no doubt that the life of plants is weaker while included in seeds than after they are produced; and why may not this lesser life, as with the germ of an animal in the egg, render them less sensible of the impression of heat? In winter, when plants are surely less alive than in other seasons, are they not less liable to perish on being rooted up, wounded or mutilated, than on doing this during summer?

I should not suppose that the reason why eggs are more unfit for supporting heat than seeds is from the greater softness of the former, because there are seeds not nearly so hard as the shell of an egg, and still capable of supporting the heat of boiling water, as trefoil seeds, but from fluids being more abundant in the egg, by means of which heat has more influence in destroying the germ. Experiment renders it undoubted, that the fluids of eggs, and consequently of their germs, are more abundant than in vegetable seeds.

That

That this excess of fluid contributes to destroy the germ more readily, appears to happen from the heat expanding the fluids, and putting them in motion; thus they must violently strike against the very subtile filaments of the germs, and occasion their rupture and destruction. This we have actually witnessed in the seeds that become sterile with less heat in water than if dry. For a similar reason does a piece of ice melt sooner in warm water than in air of equal temperature.

But let us leave these intricate researches, which are in some measure foreign to our inquiries, and compare the results concerning seeds and eggs with those concerning infusion animalcula. If we mean to assume a standard of the heat which the germs of the lowest class of animalcula can support, from that which eggs withstand, we cannot be divested of a natural repugnance to suppose them capable of enduring boiling water, when eggs are incapable of doing near so much. If, instead of comparing the germs with eggs, we compare them with vegetable seeds, our repugnance is wonderfully diminished; for, besides Duhamel's wheat, we have seen other seeds, as trefoil, beans, and kidney beans, resist heat as great. However, in pursuing this analogy, we incline more to compare them with the germs of eggs than seeds. At the same time, there are eggs that may most properly be compared

pared to seeds, since, like them, after becoming dry, and remaining long in that state, they are excluded on application of moisture. Such are those of certain pennated polypi, discovered by M. Trembley (1). Why may not the germs of the lowest class of animalcula be of this kind? The possibility becomes probability, and this advances a step still farther, by our finding that the germs or ovula of similar races of infusion animalcula, possess the qualities nearly of vegetable seeds and the Trembleyan polypi.

If the example of vegetable seeds resisting boiling heat would induce us to believe that the germs of our animalcula might do the same, the supposition is singularly strengthened by other arguments, the most immediate and direct, deduced from the animals and eggs themselves. Duhamel observed, that a beetle, which feeds on grain, did not die at the heat of boiling water; and Schaeffer found one species of caterpillar that supported as much. The assertion of such celebrated naturalists deserves all credit.

If from animals inhabiting climates so temperate as ours, we pass to the consideration of those that live in the warmest regions, and confiding in the most credible histories, they certainly multiply, and are most numerous, notwithstanding the excessive heat. Apamea and the Cape
of

(1) Bonnet, Corps Organises, Tom. 2.

of Good Hope abound with animals of every size and figure, though the thermometer, in the shade, rises to 111° (1). Equally abundant is Carolina, where it also rises in the shade to 122° , and higher. It has been demonstrated, that the direct heat of the sun is twice that of the shade, and sometimes thrice in the hottest countries, therefore this heat in Apamea and the Cape of Good Hope should be at least 189° , and in Carolina will exceed 212° (2). If animals live at such heat
as

(1) Haller, *Physiolog.* T. 2. It is not clear what country the author means by Apamea; several regions have that name.—T.

(2) Assuredly this is an error; for it is very much to be doubted, nay, I incline to deny altogether, that in any part of the globe the heat of the solar rays is nearly double that of the shade. By the few experiments made in hot countries, the difference is not many degrees. In Scotland, I have seen a thermometer, in an ordinary situation, exposed to the sun, rise to twice the heat of the shade. But that was from reflection, and the heat that the surrounding substances had acquired. It has ascended to 118° or 120° , which was from the same cause, as experiments demonstrated.

The author is not the only person who supposes the direct heat of the sun is twice that of the shade. Haller, an illustrious physiologist, and other naturalists, think it may even be more. At Montpellier, he says, it has been so great as to roast an egg, *Physiologia, tom. II. p. 32.* which would be between 150° and 160° at least.

as in Carolina, will surpass that of boiling water, and their eggs suffer no injury; and if there are animals

At Benares, when the thermometer in the shade stood at 100° , it rose only to 110° in the sun. When it stood in the sun-shine at 113° and 118° , exposed to a hot westerly wind, it was 104° and 110° in the shade, *Philosophical Transactions*, 1793.—In Caffraria, when the heat was 102° in the shade, it was 106° in the sun, *Barrow's Travels in Africa*.—At Goree, in the shade, it was 86° , in the sun 99° , *Memoire, Journal de Physique*, 1788, p. 224. *Annales de Chimie*.—At Gondar, in Abyssinia, the thermometer rose from 81° or 82° , in the shade, to 113° in the sun; it is not improbable from some disturbing cause, *Bruce's Travels*.—But the most surprising accounts of solar heat are that in Paris 1793, while the thermometer in the shade was 94° , it stood at 144° in the sun, *Annales de Chimie*, tom. 18.—At Montpellier, in the year 1705, in the shade it was about 100° ; exposed to the rays of the sun twenty-eight minutes, it rose to 212° , the heat of boiling water, *Memoires de l'Academie Royale*, 1706, p. 12. 13.—I cannot avoid suspecting that the conclusions from both these instances have been erroneous; that the heat has, in the former case, been owing to some surrounding objects, or the reflection of a neighbouring wall, and in the latter case that the instrument has been imperfect. Thermometers it has been thought were then open at the top; but it was certainly otherwise in general. However in each of these cases, the heat might be very great. There is much reason to believe, that, except the observations made at sea, most of all we have are erroneous.

The heat of many climates would be to us almost intolerable. The greatest custom can hardly reconcile the inhabitants of northern regions to the burning heat of the south-

animals in our temperate climates that can also sustain it, what difficulty is there in admitting, that

ern. In a warm country, the negroes could not sleep for cold when the thermometer was at 68° . *Park's Travels*.—The heat in Cayenne is from 70° to 93° . *Prelong, Memoire*. In the town of Batavia in Java, while the last Chinese embassy was there, between 88° and 92° , *Macartney's Embassy*, v. 1. p. 251.—During Peroufe's voyage, the thermometers, when highest, stood at 95° , *Voyages*.—They were in the ships; and it is to be remarked that cold is greater at sea. The greatest heat in Japan, while Thunberg was there, was 98° , *Travels*.—In one excursion in the Cape of Good Hope, it was 100° , *Sparman's Voyages*.—At Aleppo, 101° , *Ruffel's Natural History of Aleppo*.—At Fort George, on the coast of Coromandel, the thermometer stood at 104° , *Philosophical Transactions*, 1780. It was equally high in Paris 1720 and 1793, *Kirwan on the Temperature of different latitudes*, p. 75. *Annales de Chimie*, Tom. 18. In Goree, the heat was from 104° to 106° , *Prelong, Memoire*.—In the interior of the Cape of Good Hope, 108° , *Barrow's Travels*.—At Pekin, 1773, from 108° to 110° , *Kirwan*, p. 93, *from Mem. de Scavan. Etrang.*—At Pondicherry, 1769, the heat was from 111° to 117° , *Gentil Voyage dans les mers de L'Inde*, tom. 1. p. 490. 495. 505. Browne one day saw the thermometer at 116° , *Travels in Egypt and Syria*. Bruce saw it stand at 114° in Sennaar, and 119° at Chendi. M. Monneron told Prelong, that at Mafulipatam, he had seen the thermometer at 118° , in the shade: and an officer assured him, that he had seen it rise to 131° at Podor. During a voyage there, the thermometer, in the cabin of a vessel, stood at 133° , *Adanson Histoire Naturelle du Senegal*, p. 81. And this is the greatest

that the germs of animalcula of a similar constitution may exist. In confirmation of all this,
I may

est degree of heat in the shade that I have yet met with well authenticated.

Although the direct rays of the sun are not so powerful as the author supposes, the heat which various substances, from their peculiar nature, receive from them, is greater than can easily be imagined: and there may actually be countries where the heat of certain spots does equal that of boiling water. We read of the sand so hot that the feet can hardly be borne upon it. In Senegal, it was 168° ; and Adanson supposes, that the thermometer might have rose higher had the tube admitted; and eggs hardened in it, *Hist. Natur. p. 131*. At Marseilles, it is said, Dr Raymond found the earth heated to 170° , *Kirwan on different Temperatures, from Mem. de la Societ. Med. de Paris, 1778*. But it depends entirely on the substance what heat it will receive. The sand of Goree, which consists of broken shells, was heated only to 113° , *Prelong, Memoire*; and we have seen that the thermometer in the shade rises almost as high.

Some persons have imagined, I know, that if the heat was as great as the author admits, all the rivers would boil. This by no means follows, for one substance is not only more easily heated than another, but will receive more and retain it longer; and at Marseilles where the earth was heated to 170° , the sea was only 45° . The like has been found in other instances, and is daily evinced in water in particular.

From all these facts, we are warranted to conclude that there may be places in the world, where in particular situations, and aided by collateral circumstances, some animal eggs or vegetable seeds may be exposed to heat not inferior

I may relate an observation by M. Sonnerat, correspondent of the Academy of Sciences, concerning the heat of certain waters in Luçon, one of the Philippine Islands. They were so hot he could not bear his hand in them, and the thermometer rose to 187° . Yet, to his great astonishment, were fishes swimming there (1).

I am constrained, by philosophical sincerity, now to think otherwise of the germs of certain infusion animalcula than I did at the time of publishing my Dissertation, when it did appear to me possible their germs in general could resist the heat of boiling water. This was a deduction from vegetable seeds and eggs perishing at that heat: but the facts narrated here, which were then unknown to me, have induced me to alter my opinion.

Though the germs so often referred to are not destroyed, at least for some time, by boiling heat, the animalcula thence produced perish at 108° , a degree remarkably inferior. This has been already observed, and not without surprise, but none will remain on bringing the example of plants

VOL. I.

D

and

inferior to that of boiling water; it may even surpass it; but it is a very different consideration whether these eggs and seeds will not lose their fertility; eggs undoubtedly will when they are in that state, if they have the various parts commonly ascribed to an egg.—T.

(1) Observations sur la Physique, par M. Rozier, tom. 3.

and animals into consideration, as they can sustain so much less heat than seeds or eggs. However, the rule has an exception in the germs of the highest animalcula; for, whatever may be the cause, they can support less heat than the animals themselves. The animalcula die at 108° , but the germs are not developed after 95° . We are under the necessity of admitting, therefore, that the nature of the germs of the higher and lower classes, is very different relative to their faculty of resisting heat; which is fully coincident with all I have said of vegetable seeds, and what succeeds in eggs. Pease, lentils, wheat and lintseed, for the most part, became sterile at 189° ; trefoil vegetated at 212° ; and M. Duhamel's wheat at 234° : and although the difference has not been so sensible in the eggs of the animals mentioned above, it is sufficiently perceptible in those of another kind. The eggs deposited by certain butterflies on the under side of leaves, as well as those that some insects deposit to a northern aspect, perish at 79° . Twenty degrees more will hatch the eggs of other insects; and that heat even seems necessary for their exclusion. Such are those inserted by asili in the hard hide of oxen, cows, or bulls; of particular flies, that insinuate them into the nose or frontal sinus of sheep, goats, or deer; and of others, which deposit

deposit them in the rectum of the horse (1). The same may be said of several species of worms breeding in the human body, and in calves, where the heat is about 99°.

If there is so much similarity in the powers of animalculas germs, and the eggs of other animals, in resisting heat, there is still more relation between animalcula and the animals themselves; for the same heat is fatal to both, or they die at degrees not much different.

Though these connections between germs and eggs, between infusion animalcula and other animals, afford additional conviction, that all the operations here are according to the known and ordinary laws of nature, without recurring to imaginary forces, still we want further information to acquire more particular, more enlarged, and more correct notions of a class of beings, which their wonderful minuteness has removed to such a distance from us. Yet our curiosity is singularly excited concerning them, from the famous systems of generation to which they have given rise, by their mysterious mode of reproduction, and the uncommon qualities connecting them with the rest of animated nature. ‘ Here

‘ another universe begins,’ says M. BONNET,

‘ of which we the Columbus and Vespuccius have
‘ but distinguished the shores, and describe them

D 2

‘ not

(1) Vallinieri.

‘not unlike the manner of the first American navigators.’(1). After Mr Needham, I have attempted to make little excursions in this universe. I have endeavoured to penetrate the Continent, to view the inhabitants, and have not failed to give naturalists a faithful account on my return. But from new excursions, and by exploring the country with greater diligence and leisure, I perceive my narrative is very superficial to what may be given. This is what I have begun to communicate to the reader in the preceding chapters, and which shall be prosecuted in the subsequent.

What above all should be investigated is the nature of the inhabitants of this microscopic world. The nature of an object is discovered from its properties, that is, its relation to other beings. The more analogies there are, the greater scope is there for comparison; and the more comparisons we can make, our knowledge of it acquires greater extent. My principal purpose in these new researches should therefore be, to institute the greatest possible number of comparisons between animalcula and other animals. I have already made some experiments on them with heat, and I shall now proceed to speak of others; and first of what is directly the reverse of heat, namely, the influence of cold.

CHAP.

(1) *Corps Organises*, T. 2.

CHAP. IV.

INFUSION ANIMALCULA AND THEIR GERMS EXPOSED
TO VARIOUS DEGREES OF COLD.

ANIMALCULA were transported from the heat of the atmosphere to the cold of an ice-house. It must have been a severe change, in the heats of August, to be removed from 84° to 36° . The only alteration I could perceive was some relaxation of motion; but they did not seem to suffer farther, though they remained there several days.

The experiment was diversified by exposing them to the cold of freezing, which I did by burying the vessels of infusions in ice. Considerable part of the animalcula died on the fourth day: of twenty-two infusions, those of seven only were alive. These seven were kept buried in ice, and visited from time to time. In eleven days, the animalcula of two had perished, but those of the other five were still living at the end of two months; nay, one species seemed more numerous. Besides the seven infusions already full of animalcula, two, which were yet sterile, from being lately made, had at the same time been put among the ice. In some days, I know not

how many, they produced a legion of most minute animalcula.

In the course of the following winter, animalcula were exposed to new trials, and the result corresponded with that formerly obtained. Though under the freezing point, the infusions continued fluid, from the vegetable oil they contained, and not a particle of ice was to be seen : yet the animalcula of many died, except some more robust species; on which I determined, for that reason, to make further experiments. During this winter, I put the animalcula that the cold had not been able to kill without the window in an excessively cold day. The thermometer fell to 19° ; and the infusions, hitherto preserving their fluidity, were covered with a thin crust of ice. Breaking this crust, and applying some particles to the microscope, in the parts not completely hardened, I saw animalcula still alive, immersed in little caverns of ice (1) : but in the portions absolutely frozen and dry, they were dead and motionless; nor did they revive after melting the ice. Where the water was perfectly fluid, the animals were quite vivacious (2).

This

(1) The author means, he took the pieces when beginning to freeze; for water exposed at 19° would very soon become a solid lump of ice.—T.

(2) The illustrious Muller of Copenhagen has met with some

This was not enough. I was eager to see what happened as the water gradually froze.—A large drop of infusion being prepared, it was adjusted to the microscope. The circumference, that is, the thinnest part, froze first. The animalcula retreated from the edge to the interior of the fluid. As the freezing advanced, they still receded, until collected in a mass in the middle of the drop, where it was yet fluid. When this also froze, the life and motion of the animalcula ceased.

On repeating the experiment, they again fled to the centre, and died there as the drop hardened into ice. Two other glasses being filled with similar infusions, they took an hour to freeze; and this infinite army of animalcula had so concentrated

D 4

trated

some species that have survived the congelation of infusions;—a fact which it has not been my fortune to witness: and I must suppose, he convinced himself the infusions were perfectly frozen. *Quaedam (i. e. Animalia Infusoria) rigorem frigoris sustinent aquaque gelu soluta, eodem numero, vigoreque pristino circumnatant, alia gelu affecta periere.* Thus does he express himself, in his Treatise on Infusion Animalcula, Leipzig, 1773, 1774. I regret that this work did not come to my knowledge until too late to use it in the text of my manuscript, which was already transcribed. The loss can only be repaired by notes; particularly as the author and myself have frequently remarked the same facts, or discussed analogous problems.

trated in the middle, that very few were frozen in the rest of the infusion.

What I have hitherto related proves that these species of animalcula do not perish at 13° under freezing: but do they perish because cold has destroyed them, or because the infusions have lost their fluidity, for I have uniformly found, when infusions dried up, the animalcula were irrecoverably dead? The matter was dubious, nor could it be elucidated unless by farther experiment. It was necessary to augment the cold below 19° , and at the same time prevent the fluid from freezing. Both the one and the other were easily accomplished, by means of artificial cold, or a mixture of salt, snow, and common water, in which animalcula that had died at 19° were put. It is well known to philosophers, that water does not lose its fluidity at 20° , nay, at 21° below freezing, if at perfect rest, which is attained by inclusion in a vessel, and removal from all external motion. Thus I discovered that 19° had not been fatal to the animalcula but the freezing of the infusions, since at 12° all were alive and swimming about, though with much less velocity than usual. Some species could support no more, for they died at 12° , though the water was not frozen, but began to be covered with a thin film. Two species still survived, and perhaps, or even without perhaps,

might

might have supported a greater degree, had I been able to keep the water longer fluid (1).

The germs of the animalcula were likewise exposed to cold. New infusions being made, and the vessels hermetically sealed, I exposed them to most intense cold produced by a mixture of finely-pounded salt and snow; the thermometer fell 2° below 0. The infusions were frozen so hard as to require above half an hour to melt where: the temperature of the air they were removed to surpassed the temperate degree (2). But the germs had not suffered the smallest injury, as all the infusions, though constantly remaining in vessels hermetically sealed, produced every species of animalcula at the proper time.

Little is said of cold in my Dissertation, but it has been observed, that the cold of snow, or, which is the same, that of freezing, killed infusion animalcula. It is confirmed by the facts stated here: and we see in addition, that all animalcula do not yield to that degree, but some can bear 14° and others more. These things completely quadrate with

(1) Dr Blagden cooled boiled distilled water to 20° without freezing. He does not seem to consider that keeping it at perfect rest is the cause of fluidity. *Philosophical Transactions*, 1733.—T.

(2) The temperate degree in Reaumur's thermometer. I can neither procure one of them marked with the temperate degree; nor can I discover from the Author's own memoirs what it is. Probably it may be between 51° and 56° of Fahrenheit.—T.

with the animals bearing the greatest analogy and the nearest to animalcula, I mean insects. Some races do not die at 11° below 0, while others perish at 10° , or at most at 7° . Many cannot support simple freezing, and others cease to live at cold far inferior (1).

There is this difference between infusion animalcula and insects exposed to cold; the former are sufficiently lively to preserve the action of their members; the latter at freezing, and some before it, lose all vivacity, and assume the appearance of dead bodies. However, there are a few insects which, in this respect, may be compared to animalcula; besides the podura of Linnaeus, which inhabits the snows of Sweden (2), I have seen the eels of vinegar retain motion at an intense cold. Vinegar does not freeze so soon as water; some kinds did not freeze at 16° ; others more spirituous at 7° ; and the anguillae always moved while it remained fluid. Eels, like animalcula, insensibly become motionless on encreasing the cold; they still move while a thin crust covers the vinegar; but the freezing being augmented, motion ceases, and they are extended in a straight line, or in one a little curved. If sudden aid is brought, by melting the ice, they will certainly recover; but if the ice is allowed to harden more, melting will not bring them to life (3).

The

(1) Reaumur, *Memoires sur les Insectes*, tom. 2. 5.

(2) *Fauna Suecica*.

(3) Dr Power observes, that the eels of vinegar may be
frozen

The relation between insects and animalcula extends to the originating principles of both. Intense cold neither destroys the germs of animalcula nor the eggs of insects. The year 1709 is celebrated for its rigour, and the fatal effects it had on plants and animals. The thermometer fell to 1° . Who can believe, exclaims Boerhaave, that the severity of this winter did not destroy the eggs of insects, especially those exposed to its influence, in the open fields, on the naked earth, or the branches of trees? Yet, when the spring had tempered the air, these eggs produced as after the mildest winters (1).

I

frozen and thawed several times, and they will still be as lively as ever. Fischer has seen a species of taenia resist freezing eight days, and the *hydatis cellulosa* has survived it as long; *Virey sur les Vers*. Muller exposed a glass vessel of water containing various minute animals to the cold of freezing for twenty-four hours. The ice was then melted, and the bodies of the animals appeared dead during twenty-four hours longer than they were examined. But on the following morning he saw the *Cypris pilosa*, a small shelled insect, and the *Cyclops quadricornis*, which is one of the monoculi, as lively as ever both males and females. Some small water beetles also recovered. *Entomostraca seu Insecta testacea quae in aquis reperiuntur*, p. 5, 6.—T.

(1) Since that period, there have been winters more severe. In France, during December 1788, the thermometer fell considerably lower, and in several other temperate European climates. There is a memoir on the subject also containing some judicious remarks on thermometers by M. Gaussen.—*Memoires de la Societe des Sciences Physiques de Lausanne*, tom. 3.—T.

I have exposed eggs to a more rigorous trial than the winter 1709. Those of several insects and among others of the silk-worm moth, and elm butterfly, were inclosed in a glass vessel, and buried five hours in a mixture of ice and sal gem; the thermometer fell 6° below 0. In the middle of the following spring, however, caterpillars came from all the eggs, and at the same time as from those that had suffered no cold.

In the following year, I subjected them to an experiment still more hazardous: A mixture of ice and sal gem, with the fuming spirit of nitre, reduced the thermometer 22° below 0, that is 23° lower than in 1709. They were not injured, as I had evident proof by their being hatched.

Combining all these facts, we conclude that cold is less noxious to germs and eggs than to animalcula and insects. Germs in general can support 2° below 0: whereas of animalcula, some die at freezing, and some about 20° . The eggs of many insects continue fertile at 22° below 0, while the insects die at 16° and 14° . This I have seen in silk-moths eggs, and those of the elm butterfly; and although there are caterpillars and chrysalids able to resist great cold, I have uniformly found it to be in a less degree than their eggs. What can be the cause of such a difference? The question has already been agitated when speaking of heat; and in the same manner

manner as infusion animalcula and insects can resist cold less than their germs, so do they less resist heat. A cause for the difference has also been attempted to be assigned, and what has been said will apply to the present case, which the reader may see by resuming the passage. There is still a more obvious cause: insects killed at 16° and 14° are so penetrated and frozen by the cold, that their members do not yield to the pressure of the finger, and seem perfect ice under the knife. This does not happen to eggs, though subjected to a much greater intensity. Their humours remain fluid, even at the greatest cold, as may be seen by crushing them with the nail. Perhaps this is derived from constituent spirituous or oleaginous parts, or from some principle adapted to abate the power of cold (1). If eggs do not freeze, it is probable the included embryos do not freeze. Is there any thing wonderful, therefore, that they then survive cold which is fatal to them when produced? Probably for the same reason, (and I see no objection

(1) To understand this in its full extent would be erroneous; for an egg will freeze by a great degree of cold: at the same time, there seems to be a living principle which enables it to support cold without destruction; and when once that principle is destroyed, cold more easily operates. An egg was froze by the cold of 0; after thawing, it froze seven minutes and a half sooner. A new laid egg took half an hour to freeze in 15° and 17° ; but when thawed, it froze at 25° in half the time. *Hunter on the Animal Oeconomy.*—T.

tion that can apply) animalcula concentrated in the germ, support a degree of cold they are incapable of when developed.

Before terminating the chapter, some reflections should be made on the smaller species of animalcula which originate at freezing,—a phenomenon not remarked in my Dissertation, when occasionally speaking of the season most fit for their production, either because I had not adverted to the fact, or had never observed it. We must admit, that the germs of these most minute animalcula expand when no eggs will produce; for there is no instance of any being hatched at the freezing point. But there is nothing singular in it, if we consider what is the temperature we denominate *freezing*. The ancients believed it the greatest possible degree of cold: modern experiment has demonstrated how much it may be augmented, either naturally or by art; and the facts we just now relate are an incontestible proof. They shew, that the cold of freezing is never separate from a considerable portion of heat. Can we desire any thing more convincing? If the ball of a thermometer is transferred from a mixture of snow and salt to plain snow, it will rise from 22° or 27° below zero to the freezing point again. Is not this a clear indication of the thermometer passing from a cold to a warm situation, or, to speak more philosophically, from a
place

place where there is less heat to one where there is more. If the temperature of freezing retains a portion of absolute heat, Why should it not develop the germs of the most minute animalcula? It is needless to say we are unacquainted with any species of eggs that may be hatched by so little heat; had we never seen any but those of birds which require 104° , we should undoubtedly suppose all others require the same. A little initiation into the study of minute animals teaches how many kinds produce at heat infinitely less: Such are the eggs of butterflies and many other insects, of frogs, toads, lizards, tortoises, down to some, as those of toads, which I have seen produce at 45° . If these eggs hatch at 59° less than those of birds require, what repugnance will there be to suppose that at 13 degrees less, or the cold of freezing, may hatch the eggs of other animals? Nor should it surprise me to be told of animals, whose eggs would produce at much greater cold, after knowing there are plants, beings so similar to animals, and many of them, which, amidst the rigours of winter, flourish, are impregnated and fructify, as winter aconitum, liverwort, (*epatica nobile*) narcissus, black hellebore, terrestrial mosses, and corallines (1).

Among

(1) It is uncertain what the Author means by Corallines.—T.

Among the germs producing infusion animalcula, there is one species that does not perish at boiling heat, whence the smallest animalcula originate, or, as we have termed them, of the lowest class. The resemblance in minuteness of such animalcula, and those originating at freezing, made me suspect, that the germs resisting boiling might be the same with those expanding at freezing. Rigorous experiment was necessary to ascertain whether it was actually so. While several new infusions were buried in snow, others hermetically sealed were exposed to boiling heat; and I examined both at a proper time, but I never could discover any sensible difference in the figure, size, organization, or motions of the respective animalcula; whence I think there is sufficient reason to conclude they are identically the same species. The identity of the animalcula establishes the identity of the germs. Two most singular properties, therefore, exist in these minute animated beings; one the power of resisting the heat of boiling water; the other the peculiarity of originating at freezing.

CHAP. V.

MORE ACCURATE AND EXTENSIVE CONSIDERATION
OF THE EFFECT OF HEAT AND COLD ON ANIMALS.

HEAT and cold, we have seen, are two agents destructive of animals, when extended to a certain degree. We have also observed, that all species do not perish at the same intensity; but some can support more, and some less, according to the hardiness of their constitutions. All this, however, has been viewed only on a narrow scale, and in a limited number of animals, and even those occupying the lowest rank in the scale of animation. Let us generalise our ideas, and consider the facts more at large. Let us run over the different classes and orders of animated beings, beginning with man, the most noble, the most sublime, and most perfect of all.—Such considerations will afford an agreeable interlude, and lessen the ennui which attends the sameness of a subject.

Though man, like other animals, being subject to physical laws, must necessarily be liable to perish from excess of heat or cold, he can sustain a degree of heat that might be supposed insup-

portable. Coinciding with Boerhaave's sentiments, it is commonly believed, we cannot exist in an atmosphere warmer than blood-heat. So that illustrious philosopher concluded, because he saw certain birds and quadrupeds die at 149° , which is 50° more than human blood (1). This opinion is ill founded; since there are countries inhabited where the atmospherical heat is greater than that of our bodies. Thus, in Apamea and the Cape of Good Hope, it is 113° in the shade (2); to which the natives must be exposed. In Carolina, it surpasses that of the human body; for the thermometer falls when taken from the air in the shade and put in a person's mouth (3). In warm baths, we are sometimes subjected to more heat than in the hottest climates. Certain waters are 113° , and others so much as 120° (4).

There is the same similarity in the facts related of cold to those related of heat. Boerhaave thought the utmost degree of cold that could happen was zero in Fahrenheit's thermometer, or $14\frac{1}{2}^{\circ}$ below freezing by Reaumur's; at which, he remarks, men, animals, and vegetables soon perish. Experience proves that, in different parts of the globe, cold is greater. According to what the Parisian academicians relate,
in

(1) *Chemia*. Tom. 1.(2) *Cap.* 4.(3) *Haller, Physiolog.* T. 2.(4) *Haller, ibid.*

in some winters at Peterburgh, the thermometer fell 29° , and once 33° below 0 (1). The cold at Quebec exceeded it, for the thermometer fell to 42° (2). That at Torneao, observed by Maupertuis, was still greater, as it fell to 51° (3). But this which appears extreme, compared with what we witness, cannot bear comparison with that sometimes felt in many parts of Siberia, as Tomsk, Kirenga, Jeniseik, where the thermometer has been seen at 90° , 128° , and even 178° below 0 (4).

Such dreadful cold, we cannot deny, was pernicious, nay fatal. In Peterburgh, at -29° , the face could not be kept uncovered above half a minute (5): and at Torneao, where the thermometer fell -51° , those exposed to the air felt the breast as if lacerated. Nor is it uncommon for the inhabitants of these cold climates to lose some member, as a leg or an arm, during winter (6). Similar and more terrible are the effects in Siberia: yet, in other parts of the earth, cold is perhaps more intense. Such may Captain Middleton have experienced in Hudson's Bay, as he has communicated to the London Royal

E 2

Society.

Society.—All the liquors, not excepting brandy, froze within their houses, and the beds in their apartments were covered with a coating of ice three inches thick,—though the walls of the dwellings, where they had buried themselves, were stone, and two feet thick,—the windows very small, and closed with strong boards most part of the day,—and they had great fires continually burning. The Dutch suffered equal cold in Nova Zembla; where the rigour of the weather was such, that, in a close hut, and with a constant fire, it was with great difficulty they could keep their feet from freezing. Their cloaths were always covered with ice; and their wine, though very strong, was dealt out in lumps of ice (1).

The

(1) Here the author's deductions are from erroneous experiments made by others; because cold so very intense has never been witnessed by modern philosophers. It is not impossible, indeed, that there are countries where it is really as great, but they are yet unexplored.

It was long believed, that no natural degree of cold existed which would congeal mercury. It was artificially frozen, and the thermometer fell several hundred degrees below the freezing point. Therefore, when travellers in the northern regions saw it stand at— 100° or 200° , they concluded that to be the real degree of cold: but the mercury in the thermometer was already frozen, and rapidly contracting into less bulk. The freezing point of mercury, it is now ascertained, is under— 40° : but if the cold exceeds

The effects of cold to that degree too clearly demonstrate, that it would be fatal to the human race, if unprotected against it. I do not mean,

E 3

. it

exceeds this very little, it will descend the scale some hundred degrees. In an experiment, where the cold was only a few degrees more than 40, the thermometer immediately fell to—450° and 490°.—*Cavendish's Observations on Mr Hutchin's Experiments, Philos. Transac.* 1783, p. 23, 25.

The greatest cold that Acerbi observed in his travels in the north, was—13°. Mackenzie experienced 16°; but his thermometer was then broken.—*Travels over the N. Continent of America.* The greatest cold at Montreal in North America was—16°. 18°.—*Philosophical Transactions.* That experienced by Captain Cartwright, on the coast of Labrador,—25°.—*Journal of a Residence on the Coast of Labrador.* On the same coast, by M. de la Trobe,—30°.—*Philos. Transf.* 1782, p. 198. The cold at Petersburg and Moscow has been from—30° to 39°.—*Acta Petropolitana, Nov. et Vet. var. loc.* Mercury has froze at Prince of Wales Fort, Hudson's Bay, and Albany Fort.—*Philos. Transf.* 1793, p. 368. 1770. M. Patrin suffered—35° in Siberia; and quicksilver froze.—*Journal de Physique*, 1791, p. 88. But even these degrees have been far surpassed at Oustioug Velikoi, in the government of Vologhda, lat. 60°. 50. N. where the thermometer fell 83° below Zero, in December 1787; and, in January the same year, so low as 103°.

The sensations excited by such excessive cold are inconceivable to us, who live in temperate climates. "I cannot express the pain of respiration at 35°," exclaims M. Patrin: "boiling oil seems to fill the lungs. Even in the
" closest

it will be so absolutely, but only relative to the condition of the persons exposed. With regard to what was suffered by Middleton and the Dutch in Nova Zembla; shut up in huts, they led a quiet and sedentary life, which undoubtedly promotes the action of cold; I do not think myself mistaken in affirming, that, well cloathed, and taking plenty of exercise in an open country, they might have braved as intense cold without danger. In the winter nights of our temperate climate, it is sometimes much more than freezing, and one exposed to it without any motion would really die; but preserving sufficient motion, we might suffer a greater degree. Thus, the Paris academicians, though accustomed to a climate

“closest carriages, one is suffocated by this piercing cold.” Its other effects are no less terrible: rocks and trees are split with reports like cannon. There is a perfect calm, and so thick a mist prevails, that nothing can be distinguished a few paces distant. Magpies, crows, and sparrows fall dead to the earth; nor are quadrupeds and the human race secure from danger.

The pernicious consequence of cold is visible in all animated nature. Plants are neither so abundant nor luxuriant as in the warmer regions. Animals are fewer; they are less diversified; and, in general, their size is smaller. Something is wanting to expand the organic system; nay, to create that beauty and variety which are found in the genial temperature of the South, and which it is so pleasing to behold.—T.

climate as temperate as ours, began their astronomical observations amidst the woods or mountains near Torneao, before the snow lay deep upon them, and the intense cold had not encreased to---51°, as it afterwards did; however, it was such, that all liquors excepting brandy froze, and a vessel could not be taken from the mouth without drawing blood, for the frost had glued it to the lips.

The savages of the most northern climates continue to hunt during the coldest weather; and so true is it, that motion alone preserves life, when any misfortune threatens destruction, they accelerate death by rest(1). There can be no better proof of the efficacy of motion against cold than the narrative of the Dutch who wintered at Spitzbergen, a country situated in 78° of north latitude, and by common consent allowed to be the coldest in the world. Those who had shut themselves up in a hut, in the beginning of the season, died one after another. The cold was so excessive that no fire could warm them; whereas those who had gone into the open air, and employed themselves in the chase, in carrying wood, or any other corporal exercise, preserved health and vigour (2).

E.4

From

(1) Boerhaave, Praelectiones. Haller, Phys. tom. 2.

(2) The same has invariably been proved by the accounts of those unfortunate persons condemned to winter

From what has been said may be judged the variety of heat and cold that man can suffer, beginning with heat equalling or surpassing blood heat, and descending to the horrors of cold so far exceeding freezing, which shews that man is not necessitated by nature to inhabit certain determinate parts of the globe, but to live, multiply, and exercise his sovereignty over all, without finding an obstacle in climate. It is otherwise with quadrupeds. They are dispersed over the earth ; so that some are limited to warm climates, some to temperate, and some to cold ; nor has any species yet been found adapted to live in all indifferently. The lion, elephant, tiger, leopard, and panther, inhabit only the warmest regions ; when transported to the temperate, they become incapable of propagating, and soon perish in the cold. Although the domestic animals, so useful to us, are not injured by warmer climates, they cannot live in colder. Such are the horse, ox, and sheep. The elk, rein-deer, and ermine, inhabitants of the north, are never found in southern countries ; and so far from being able to exist there, they do not live in temperate climates. At least this has
been

ter in such inhospitable regions. Air and exercise always preserved health, while inactivity uniformly subjected them to disease. However the death of a great many seems to have ensued from improper food.--T.

been found with the rein-deer ; its naturalization has often been attempted in France and Germany, but instead of multiplying they always perished(1).

The law restraining quadrupeds to their native countries is liable to modifications ; for there are some that can exist and multiply in temperate though originally from warm climates. The rabbit and guinea-pig are instances of the former ; the beaver and lynx of the latter(2).

Birds may in this investigation be considered as divided into two classes : Of those inhabiting cold, temperate or warm countries, some do not wander far from their native place, or do not change their climate. Others have no fixed abode, but change according to the different seasons, being necessitated to it either by the scantiness

(1) Buffon Histoire Naturelle, tom. 14.

(2) It is very true, that the animals which have been removed all at once from cold to warm climates, and the reverse, have ceased to propagate their species. However, there are several exceptions, and more will be known in proportion as natural history continues to be further cultivated. Perhaps the cessation of multiplying their species arises from the great and sudden change : but if one generation was removed two degrees farther north or south, propagation would most probably continue. If their progeny were removed two degrees more, and so proceeding by short distances, every generation, there is great reason to suppose, would continue fertile, and the animal be naturalized in any climate.—T.

ness of food, or from inability to bear the winter, or even a slight degree of cold.

We have said that Boerhaave thought 149° immediately killed certain birds and quadrupeds. Surely 50° above blood heat is very great, and cannot but be intolerable to many races of animals; yet we must acknowledge it may be borne, and that it is so by many species inhabiting the torrid zone, and other very hot regions. And it appears to me, that we should reason on heat which birds and the rest of animals can support as we reason on the cold. As those in the northern climates can sustain excessive cold, so can those in the southern sustain excessive heat.

It is easy to ascertain the greatest cold that either cetaceous or squamous fishes suffer: it will always equal that of the water which they are in, consequently in fresh water less than freezing, else it would not continue fluid. Those inhabiting salt waters, as the sea, will suffer a little more. Thus fishes are secured against the rigour of cold to which innumerable animals are so much exposed. No less are they sheltered from the burning heat of the atmosphere, excepting those living in shallow waters, and on that account more or less subjected to the influence of the air from the predominating seasons or the climate.

From some observations, we know there are carp living in warm springs that experience blood heat

heat (1). I took several river carp for experiment. When the water they were in had been heated to 106° , they exhibited no sign of uneasiness. At 109° , they began to struggle, and died at 116° . Experiments were made on other fishes, as eels, tench, lampreys, but none could bear so much heat. Whence, by analogy, those inhabiting warm springs should support greater heat: and of this the fishes we have just mentioned afford ample evidence (2).

But of all known animals, reptiles and insects stand in greatest dread of cold, and seek heat the most. The heat of the sun may be called their soul. Then they are full of sensation and motion; and as that luminary is more powerful, so do their activity, vivacity, and boldness increase. The venomous kinds, as snakes and scorpions, are more formidable, and their poison more dangerous. But cold produces an opposite effect. Innumerable insects perish on the approach of winter, and most of both them and reptiles that survive would encounter the same hazard, if not protected against it. In temperate climates, all seek a safe retreat when winter comes. Some, as scorpions, and many species of flies, retire to the rents of walls, or under the tiles of houses; others are concealed in the midst of stones, the
cliffs

(1) Haller, *Physiol.* Tom. 2.

(2) *Ibid.* Tom. 4.

clifts of trees, or holes in their trunks, as vipers, snakes, cantharides. Some are secured in the caverns of mountains, in subterraneous abodes and the cellars we make, as spiders, flies, muskitoes, naked snails, and beetles. Others find a genial warmth in dunghills during the rigour of winter. The bottom of waters, and the bowels of the earth above all, give shelter and retreat to most reptiles and insects. Yet, in the whole of these asylums, though sufficiently defended from the fatal effects of cold, they suffer from its influence in the most sensible manner. Their limbs become torpid, and they remain in a lethargic slumber the whole winter.

But among quadrupeds, birds, nay, perhaps, among fishes, there are some that experience a kind of lethargic torpidity not unlike that of reptiles and insects. To say nothing of frogs, toads, lizards, and the like, among quadrupeds which dwell in water or in the earth all the winter, hedgehogs, land tortoises, several rats, the marmot and dormouse, are also overcome by lethargy. Some in society, and some in solitude, conceal themselves in the trunks of trees, or are hid in the earth. Cold has the same influence on bats; they are found stiff and motionless in hollow trees, or the rents of walls, or hanging to the vaults of subterraneous caverns.

Some

Some birds are also subject to torpidity. At the end of summer, hundreds collect, cluster together, and plunge into water, where they remain the whole winter in heaps, and shrunk within themselves. The learned reader already anticipates that I speak of swallows. The fact is too well circumstantiated, too well authenticated, for any one to be hardy enough to call it in question. Many respectable and credible persons declare, they have not only beheld flocks of swallows collect and plunge into pools on the approach of winter, but oftener than once have seen clusters of them taken out of water, and even from beneath ice. The doubt therefore is, whether the swallows of which these respectable authorities speak are ours, that is, those constructing an earthen nest in our houses, and residing with us during summer, or whether they are strange swallows, by which I mean a bird similar in colour, figure, and size, but of a different nature and species. For many years I have endeavoured to solve this question. Experiment has taught me, that animals which are torpid in winter become lethargic also in other seasons, if subjected to the requisite degree of cold; so that, on exposing a frog, a dormouse (*forcio moscardino*) or a lizard, to the cold of freezing, in summer, while most vivacious, it soon becomes torpid, and is in a state of torpor till the cold ceases. Supposing the swallows of
our

our country were those drawn torpid out of water, and from beneath ice, I imagined they might become torpid and motionless if subjected to the same degree of cold, and thought of exposing some to the temperature of an ice-house, gradually bringing them from warmer atmospheres, as of a cave or an apartment adjoining to the ice-house; for, during the month of August, to carry them all at once to such cold might be too sudden a change. But all the swallows in the adjoining chamber died in three hours, without my being able to discover whether they had first fallen into a lethargy. The cold was not great, as the thermometer stood at 43° . Other swallows had the same fate. Whence I may conclude, that the swallows found in water or under ice are of a species specifically different from ours, because they perish at a small degree of cold (1).

This

(1) Since the author wrote this, he made the following experiments on swallows, which may tend in some measure to elucidate the natural history of these birds, which has hitherto been so obscure.

‘ August 23. 1792, the thermometer being at 76° , four house swallows, (*hirundo domestica*) confined in a glass vessel, were buried in snow. In an hour, they had not suffered in the least, and flew about the apartment. They were returned to the vessel, and the cold increased. In

This experiment, which is mentioned in my Annotations

124 minutes, the thermometer stood at 9° ; they were very feeble, but kept their eyes open: they moved when touched, and endeavoured to escape. The thermometer fell no more. In 60 minutes, some signs of animation were indicated by two, but the others appeared dead. However, this was only asphyxy, for the heat of the atmosphere re-animated them, and in 68 minutes they had recovered their natural vivacity.

‘ Of two swallows exposed to 1° , one died in ten, the other in fifteen minutes.

‘ Two window swallows (*hirundo urbica*) exposed to 2° and 3° of cold, died in 21 and 40 minutes.

‘ Six martins (*hirundo apus*) were exposed to 8° for three hours. The first hour they were restless; the second their motions less frequent; the third they seemed motionless though without lethargy. Their eyes were open, and they moved on being touched. Exposed to the atmosphere at 74° , they recovered.

‘ In another experiment with the same martins, the thermometer fell to 3° ; one died in six minutes, two more in twenty-five; the other three appeared dead, but revived on exposure to the atmosphere an hour: however, they died irrecoverably when returned to the vessel ten minutes longer.

‘ Some naturalists think, that the bank swallow (*hirundo riparia*) conceals itself in holes during winter; and the error ascribing the same to window swallows, arises from confounding

notations on *La Contemplation de la Nature*, a
work

confounding the one with the other. Montbeillard conceives, that instinct may induce them to conceal themselves in the earth during winter.

‘ Achard, coming down the Rhine in 1763, procured some birds, evidently swallows, quite torpid and inanimate, drawn from their sandy holes. Being put next his skin, they recovered, and flew away. But this observation only proves, that there exist swallows subject to real lethargy without determining what species. Therefore, notwithstanding all that has been written on it, the question is still dubious. In two years, I opened above fifty swallow holes on the Banks of the Po, without finding any thing but their nest or its remains, which demonstrates that the owners had gone to winter in other climates. This recalls an observation by Collinson, who did the same, and he discovered nothing.

‘ On the 15 of June four swallows confined in a glass vessel were immersed in a mixture of soda and ice. The thermometer fell to freezing without affecting them; I confined them again, and the thermometer fell to 10°. In twenty minutes they were taken out. They could scarcely move, or stretch their wings; their eyes were shut, nevertheless they gradually recovered, and in half an hour flew about the apartment.

‘ The experiment was repeated; they lived thirty minutes at the same degree. Put on their backs on a table, they were motionless at first; then after many efforts they recovered

work translated by me (1), I find confirmed by M. De Buffon, in his first volume on birds, published

covered their natural position, and walked about the chamber, but had not strength to fly. As the animal functions returned, respiration gradually became more sensible and quicker; the eyes opened, motion and life were re-acquired. In three hours the swallows could fly.

‘ They were again exposed to the cold of o twenty minutes. Two expired; the other two revived in five hours, but were unable to use their wings. Is this torpor a real lethargy similar to what is most improperly called the sleep of many animals? Immobility of the body, almost extinguished respiration, suspension of the senses, and recovery of them are strong presumptions. But the same symptoms may attend real asphyxy, similar to that of animals immersed a certain time in water, or brought within the sphere of some mephitic gas: an asphyxy essentially different from lethargic sleep, which may be continued several months without injuring the existence of the animal, while the other will soon deprive it of life.

‘ To ascertain this point, I entered with greater eagerness on new experiments, as they afforded me an opportunity of correcting an error, when formerly speaking incidentally of the lethargy of swallows. In one of my notes to *La Contemplation de la Nature*, I said, several swallows which were kept in an apartment adjoining to an ice-house, where

(1) First printed 1769, 1770. The experiments were made five years before.

lished 1770; where he observes, that, with the same design, he confined several swallows in an ice-house,

where the thermometer stood at 43° , died without becoming lethargic; whence I concluded, that these birds were incapable of supporting cold. In my *Opuscoli di Fisica Animale e Vegetabile*, I repeated the same remark: the fact was true, but I deduced a false consequence; for they bear a much greater degree without inconvenience.

‘ Several species were shut up in wicker baskets, covered with wax-cloth to preserve the humidity, and buried in snow. In twelve hours, they were still vivacious, and crept close together to secure themselves as much as possible against the cold. The next twelve hours, they were in the same state. Two could fly languidly about the ice-house. In thirty-five hours four were dead, two house swallows, a bank swallow, and a martin; the rest were so weak, that they could neither stand nor fly, neither did they make any effort to escape. Still, these symptoms rather indicated infirmity than lethargy: their eyes were not shut, and they resembled dying birds in every thing. Not one was alive in ten hours more. All perished in 48 hours in another experiment.

‘ It was necessary to cover the baskets with wax-cloth, for two swallows, exposed without this precaution, died in two hours and a half, and were as wet as if they had been drenched in water; which has certainly been the case with those mentioned in my note on *La Contemplation*, as I recollect perfectly well that they were very humid.

‘ Nine

ice-house, but without ever seeing them become torpid; and they uniformly perished on remaining exposed any considerable time. He thence concludes it impossible that this bird becomes

F 2

lethargic

{ Nine more were confined in an ice-house: they languished without becoming lethargic, insensibly lost their strength, and died in 41 hours. These animals did not perish from hunger, for others lived without food three days, three and a half, and five days, while the most vigorous in the ice-house lived only 48 hours. Thus, the acceleration of death can only be ascribed to privation of heat.—A.

These experiments very much elucidate the nature of swallows in one respect, but they are not quite satisfactory. The author seems to think that intense cold does not actually produce lethargy. If this is the case, it must be admitted, that all the swallows named here leave Britain in autumn and return in spring; and that we have no proof as yet, that any birds taken torpid from the earth, caverns, rocks, or walls, were really swallows.

It is not evident whether the author retains his opinion in the text, that swallows have been drawn torpid from water. This has been supported by learned men. It is admitted in a late tract by Fabricius on the winter sleep of animals.

All the experiments on swallows are related in the author's history of these birds. Neither that, nor his history of Owls and Eels, in the same volume, are yet translated into English, so far as I know.—T.

lethargic in winter; so much the more, as he learns from M. Adanson, that common swallows constantly appear in Senegal during autumn, and disappear in spring: and he conceives the European swallows, and those subject to lethargy, of different species, though they have hitherto been esteemed the same.

Neither are some wanting in the immense tribe of fishes on which cold produces a similar effect. Tench, if we may credit Pechlin, as quoted by Haller, are of this description (1). In the beginning of winter, he has observed them bury themselves in the mud, just as we have seen many reptiles and insects do in the earth. Speaking in general terms, fishes are a class of animals enjoying the privilege of preserving action and vivacity, however cold the atmosphere may be, not only because fluid water can never acquire a great portion of cold, but because they may retire still deeper and deeper whatever is the cold it acquires (2).

Whence

(1) Ad Praelection. Boerhaav. T. 4. Haller, Physiok. T. 5.

(2) The possibility of fishes becoming torpid has been doubted. A few experiments which I have made on several small fishes seemed to indicate torpor. When exposed to considerable cold, though less than freezing, they sunk motionless to the bottom of a vessel, and immediately

Whence does it happen that almost all reptiles and all insects, at a certain degree of cold, lose their whole vigour; their motion ceases, and they assume the appearance of death; while man, and the most part of quadrupeds and birds, at an infinitely greater degree, retain their original strength and vivacity? What can be the proximate, the immediate cause of this apparent death in the former animals, and that it is not so in the latter? No one that I know of, before M. de Buffon, set himself seriously to consider this singular phenomenon. According to him, the animals that become torpid are cold blooded. Such had he found the greater dormouse (1), the common dormouse, land hedgehogs, and bats, which of themselves have no internal heat, and only that of the atmosphere. Their blood refrigerates in proportion as the atmosphere refrigerates, which cannot take place with warm blooded animals from their internal principle of heat. Torpidity must ensue from this refrigeration, because the use of the senses and limbs is

F 3

lost;

ly revived on removal to a milder atmosphere. Some, however, preserved a languid motion while the water was about 32°. La Cèpede appears to consider fishes, in general, subject to a degree of torpor; and he says, the deeper the lethargy, the less of their substance is lost.—*Histoire des Poissons*, T. 1. Discours, p. 132. 133.—T.

(1) By him called Lerots.

lost, and because the blood probably circulates in the larger vessels only. Such does this author suppose the immediate cause of torpidity in these four animals; and he extends it to marmots, and all others subject to torpor, as he is convinced their blood is cold (1).

I could have wished that so plausible an hypothesis had been true; but I have never found it accord with facts. In the first place, it is not the case that every animal becoming torpid has cold blood. Hedgehogs, marmots, and bats certainly are not so. Haller, who has dissected several hedgehogs, says positively, he has always found their blood warm. Lister, Robinson, and Lancisi affirm the same (2). I most fully assent to the opinion of these illustrious physiologists. The blood of three hedgehogs dissected by me was warm; so have I found that of bats. M. de Buffon's method was used to ascertain it. He introduced the ball of a small thermometer into the body of dormice by the mouth. He never saw the fluid rise: On the contrary, it sunk sometimes one and sometimes two degrees; an evident sign that the blood was cold. But whenever I introduced the thermometer into the mouth of hedge-hogs and bats, the fluid rose to 99° , and even 102° , if kept eight or ten minutes, which demonstrates

(1) Histoire Naturelle, Tom. 16. 17.

(2) Phys. Tom. 2.

demonstrates the heat of both to be the same as our own (1.)

As it was not then in my power to have marmots at pleasure, I desired a much respected friend, who could easily obtain them, to undertake similar experiments (2). He did so; and the result proved, that marmots are not cold blooded, as M. De Buffon had supposed, but are endowed with an internal principle of heat, equalling that of other animals. He was positively assured of it, by keeping the thermometer in the axilla of two marmots. The heat of one raised it to 90° in eight minutes, 20° above the temperature of

F 4 the

(1) Hunter found the heat of a dormouse 80° and 85° , when the heat of the atmosphere was 50° or 60° ; when the animal was lively, 91° or 93° . A thermometer introduced within the body and applied to the pelvis rose to 99° , the atmosphere at 66° . The mouse being put an hour in an atmosphere of 13° , it rose to 83° .

In hedge-hogs, he observes, Mr Jenner found the heat 48° , when they were torpid or the atmosphere 44° , and the heat only 30° in an atmosphere of 26° . But exposed to this cold two days, the heat in the rectum was 93° . So far from being torpid a hedge-hog was lively, and the bed on which it lay felt warm. Whence he concludes that excessive cold rouses the vital powers.—*Observations on the Animal Economy*—T.

(2) Sig. Giannambrogio of Milan an able chemist, already well known in the republic of letters, by a most elaborate

the atmosphere at the time ; and in fifteen minutes, that of the other raised it to 93° (1).

Some

laborate and learned dissertation on Fox-tail, (Covetta) and ammunition bread.

(1) It will be observed, that, in the course of this work, much is said of cold and warm blooded animals, and some important conclusions thence deduced. Notwithstanding all that has been written on animal heat, the cause is undoubtedly very obscure. Experiments and reasoning have neither sufficiently coincided, nor been so generally adopted, as to entitle us to form positive opinions on the subject, more especially when philosophers do not agree whether the living body has the property of producing heat or cold.

Amphibia, reptiles, fishes, insects and worms, are generally believed to have cold blood. However, there are experiments on all but the last that seem to indicate a principle of internal heat independent of the atmosphere ; so that the thermometer will ascend when removed from the open air into their bodies. Yet many naturalists deny that they have any principle of heat ; and think the temperature of their bodies must always be exactly the same as that of the surrounding medium. But, in my opinion, sufficient accuracy in experiment has been neglected, and due attention has not been paid to the state of the medium where the animals previously were. A few experiments which I have made on the subject, even with those precautions, have been discordant ; one thing how-
ever

Some time afterwards I succeeded in procuring two marmots.—The experiments made on them completely corresponded with those of my learned friend. In the open air, the thermometer stood at 66° ; when introduced within the throat, it rose to 102° : therefore the fact, with respect to all these animals, cannot be more decisive (1).

How, in contradiction to the facts before us, which admit of no reply, can Buffon's assertion subsist, which is in express terms—that he has found the blood of hedgehogs and bats cold? Without supposing his animals of a different species from mine, and much less not to allow his

his
 ever is certain, namely, that all insects are not cold; and although the heat of one singly is not sensible, the heat of a number collected is very considerable. I kept a thermometer in a bee hive; it sometimes stood between 90° and 98° . The height did not seem entirely regulated by the temperature of the atmosphere, for it has been 80° and 90° in the hive, while 55° and 51° in the shade. When 62° in the shade, it has been as low as 82° in the hive. A number of bees collected do not become torpid during winter. When the atmosphere was at 25° , which is cold weather in Scotland, I reversed a hive, and introduced a thermometer among the bees, it immediately ascended to 71° , and would perhaps have rose higher.—T.

(1) I believe that the author afterwards made a series of investigations concerning marmots, but I have not been able to procure the work.—T.

his experiments credit, there is an easy method of conciliating the differences : It is, That the French naturalist has made his experiments in winter, when the animals are deprived of sense and motion, and actually are not different from cold-blooded animals, because inclemency of the season has exhausted every principle of heat. Experiment had taught me, as reason itself would do, that neither bats nor hedgehogs become lethargic unless their internal heat is diminished.

From the whole it is evident, that, notwithstanding M. De Buffon's idea is ill founded, it is indubitable that refrigeration of the blood takes place in all animals experiencing lethargic sleep. Shall we hence conclude the lethargy an immediate consequence of this refrigeration? Let us consider the incipient torpor of an animal.—The influence of cold begins : it acts not only on the exterior, but also internally. Application of the thermometer will not allow me to doubt it ; and evinces, that the action of the cold is equally communicated to the sanguinous fluid and the solids. Yet I am left in doubt, whether torpidity proceeds from refrigeration of the blood, of the solids, or of both. I try to analyze the fact ; and reflect whether there is any animal, among those becoming torpid, which, after privation of its whole blood, will, for a considerable time, preserve its original vivacity and vigour.

Such

Such a one may perhaps ascertain the truth. If, after being deprived of the blood, this animal does not become torpid on exposure to cold, then the sole cause of torpidity lies in the refrigeration of the blood: if torpor does ensue, we cannot recur to the refrigeration of the blood, but to that of the solids, or to the influence that cold has on them. An animal of this kind is not only possible, but it exists,—there are several, as, frogs, toads, tree frogs, and water newts. In my experiments I have observed, that all the blood being discharged from the opened heart or divided aorta, these animals still leap for many hours, run, dive in water, and swim to the top, retain a lively sense of sight and feeling; in a word, continue the exercise of every corporal function that they had before (1). I now repeated the experiments, and began with frogs.—Several very vivacious were buried in snow; part were untouched, and part of the number deprived of the blood, by endeavouring to evacuate it completely from the heart and large vessels. In eight or ten minutes, some were examined: the blooded and those entire were exactly in the same state, that is, half dead, and not attempting to escape, though at liberty. In fifteen minutes, I
drew

(1) These experiments are spoken of in my work, *De Fenomeni della Circolazione*.

drew others from the snow, some entire, and others deprived of blood; they appeared motionless, and as if frozen. All were replaced in the snow, and in a few hours removed to a warm situation. I attentively considered what happened. By degrees, the contracted ones stretched, their eyes opened, they shook themselves, began to leap and escape. Being again consigned to the snow, and taken out after a certain interval, all exhibited the same phenomena. There was not the smallest difference at whatever season the experiments were made. I found a remarkable correspondence between tree frogs, toads, and water newts: the whole became lethargic in the same manner, by the cold of snow,—and returned to their former animation when removed from it.

The coincidence of these facts obliges me to say, that the failure of sense and motion does not arise from refrigeration of the blood, for it cannot take place where there is none, nor from the relaxed circulation of this fluid, but depends entirely on the solids, which, being powerfully attacked by cold, are in a condition very different from the natural state. What the new condition is, may be discovered from the phenomena of lethargic animals. They appear contracted, the muscles have no longer their natural softness and pliancy, but become hard and withered.

Thus

Thus there is absolute proof that the muscular fibre acquires great rigidity, and it is such as must materially prejudice its irritability: This is evident from the most active stimulants not occasioning the slightest contraction or corrugation. Irritability is commonly believed the origin and principle of life: when it is so much injured in the animals of which we speak, it must occasion that lethargy, that similitude to death which is manifested.

If this is the real and immediate cause of torpor in these animals, I cannot see any reason why it should not extend to all others subject to torpidity. It is impossible, indeed, to deprive the warm blooded animals, liable to torpor, of what Buffon supposes the efficient means, for their nature does not admit of them living without blood. But their muscular rigidity, also, is certain; and it renders them insensible to every stimulus while in the lethargic slumber. I have seen it in bats. I sprinkled them with salt, bathed them with warm water, pricked them with needles, and laid open the pectoral muscle, methods most powerful to excite irritability, but all were ineffectual, while they were oppressed by profound lethargy. The electric spark, so fit above all stimulants to awaken irritability, was equally ineffectual. If the irritability of warm blooded animals is suspended by means of cold the same as that of the cold blooded, and if the cessation of this power, as far as appears

pears to me, is the only and immediate cause of lethargic sleep in the latter, I do not see why it may not also be extended to the former.

The same degree of cold does not occasion torpidity in all the animals subject to it. Very little is necessary for some; others require considerably more; and others an excessive degree (1). What we design temperate, which is so mild to our sensations, occasions torpidity in dormice; a little more affects bees, snakes, vipers, and many species of bats. What affects frogs, toads, newts, and others, approaches freezing, but this is far from operating on marmots, as they require 11 degrees below freezing (2). The difference

(1) Réaumur Memoires sur les Infectes.

(2) At different seasons, however, the same cold seems to produce different effects. On the 18 of July, when the heat is generally between 60° and 70°, I cooled the water with six Hydrachnae down to 38°. They all sunk to the bottom, and remained completely torpid. In general, they yielded to 42° or 40°, except one, called, by Muller, a variety of the Papillator (but apparently constituting a particular species in Scotland), which resisted 38° a long time, and then sunk down along with the rest. All revived at a moderate heat.

On the 5 of December, I took five hydrachnae from water at about 44°, and put them into water at 36°. They became more languid. The thermometer gradually

ference of cold required to occasion torpor, must arise from the different nature of the muscular fibre, which in some animals is more susceptible of it than in others. If the power of cold is encreased, torpor degenerates into death.

The reason assigned by physiologists for the death of man and animals from cold, is certainly very plausible. The contraction of the cutaneous vessels forces a reflux of the blood to the internal parts of the body; whence is occasioned the insensibility and stiffness of our fingers and the extreme paleness of the body. Cold becoming more intense, the internal and large vessels contract, and the reflux of blood is greater; but those of the brain, being better defended by the cranium from the injuries of the air, are not so liable to contract. Blood flows copiously in the

ly fell to 32° ; and a crust of ice, a quarter of an inch thick, formed on the top. Still the animals could move, though languidly, and a very faint motion was perceptible in the legs of one. Thus the water remained some hours. In twenty hours after the experiment began, the thermometer stood at 36° . None of the hydrachnae were torpid.

Experiments were at the same time made on several other aquatic animals. Squillae and gyrini did not become torpid at 32° . Perhaps this subject deserves further consideration.—T.

the arteries, covered and protected from the atmosphere, while the jugular veins being contracted, it is with difficulty returned to the heart. A sensible relaxation in the circulation will ensue, which, encreasing as the intenseness of the cold advances, will end in rest, and the animal will die.

In the northern countries, it is not unusual that a *coup de froid* kills men on the spot. The cause has been supposed nearly the same. The lungs, exposed to the immediate action of the cold air, are suddenly contracted, and impede the passage of the blood from the right to the left ventricle of the heart. Thus, according to those authors, death proceeds from obstructed circulation (1).

I am fully convinced this may be the real reason why numberless animals die, that is, all those necessitated to perish when the circulation is stopped; but there are many that live, at least some time, when the circulation of the fluids is suspended, or even when they are entirely taken away. The death of animals by cold must therefore

fore

(1) According to the most authentic accounts, when men are exposed to intense cold, an irresistible desire to sleep ensues, which ends in death. Thus, it is not improbable that men may be in a degree of torpor and revive.
—T.

fore be ascribed to some other cause than obstructed circulation (1).

To discover the immediate cause of death, I made observations on animals killed by cold similar to those I had made on animals becoming lethargic at a small degree. The phenomena attending death are these. Rigidity of the muscles gradually encreases until the whole body hardens and freezes. Freezing first appears at the extremities, whence it extends to the centre. If taken to thaw in milder air, the parts acquire their former pliancy, but the animal will not revive. Its death is in consequence of having been frozen, but we cannot say it is from freezing of the blood: first, from the reasons above given; secondly, because several animals being exposed to cold, some deprived of blood, and others untouched, all died in the same time. Thus, death of this kind proceeds from the solids being frozen. At a certain degree of cold, the muscles grow rigid, and the irritable power is destroyed; thence proceeds their apparent death. Cold more intense freezes the muscles; freezing destroys the power

VOL. I.

G

of

(1) In my work *De fenomeni della Circolazione*, I have demonstrated, that many animals live a considerable time after privation of the whole blood, also when circulation is suspended, by tying up the aorta. I have since observed this in reptiles, as vipers, serpents, eels, &c.

of irritability, and real death is the consequence. The muscular fibre is contracted by cold; the liquid, rendering it moist and pliant, is inspissated; but freezing vitiates the use of this fluid, by changing it into so many icicles, whose sharp and cutting points lacerate the finest and most delicate parts of the fibre. The muscular flesh is then discovered to be full of these icicles; and, when one attempts to twist or bend it, fracture ensues, as of a friable substance.

CHAP. VI.

INFUSION ANIMALCULA EXPOSED TO VARIOUS ODOURS
AND LIQUORS; TO ELECTRICITY AND A VACUUM.

CERTAIN odours are to insects the most virulent poison. Such has Reaumur found the oil of turpentine, and the fumes of tobacco. The odour of camphor, according to Menghini, has the same effect; and its vapours are still more efficacious when burnt (1). In my investigation, I proposed to institute the greatest possible number of comparisons between known animals and those so remarkable as the animalcula of infusions, the better to penetrate their origin, nature, and

(1) Commentar. Acad. Bonon. T. 3.

and properties, which induced me to resolve not to neglect trying the effect of odours upon them. I began with that of camphor: the result was precisely the same as has been observed in insects. The vapours of this resin occasioned sudden agitation and discomposure in the animalcula: they endeavoured to retreat from the malignant fumes, by retiring deep into the infusions. If the vapour was rare, they were long of dying; but when dense, it immediately became fatal. The odour of the oil of turpentine killed them, but not so soon as camphor. The fumes of tobacco were not fatal for some hours: but those of sulphur, instantaneously (1).

The liquids used in my experiments were chiefly oleaginous, because these are mortal to insects: they were no less so to animalcula. I omit the spirituous or corrosive, which killed them in a moment; as also salt water, vinegar, ink, brandy, and spirit of wine.

We could hardly believe that human urine produces animalcula, after standing a few days, as Hartsoecker has observed, if the same phenomenon was not daily observed in vinegar, which is full of microscopic eels, though a fluid equally destructive to animalcula as urine. Repeating

G 2

the

(1) Odours penetrate deep into water, but to a very different degree: Some will traverse several inches, others not one. There are a few curious experiments on the subject. *Senebier Physiologie Vegetale*. Tom. 5. chap. 6.—T.

the experiment, I found it perfectly true. A dark cineritious pellicle covers the surface of urine that has been some time at rest; and here are the animalcula generated. They are of a roundish figure, and in size like animated points (1). The same race of animalcula always continues in urine, kept several months; but no new species ever appears. One might suspect, that they are produced after the urine has lost its acrid and corrosive principle: but, besides retaining the characteristics of real urine, it is still fatal to other animalcula; nor do those of stale urine die when put into that which is recent. Therefore this species must be essentially different from common infusion animalcula.

It is well known, that the electric shock kills animals; and as they are smaller, so are they more easily killed. A battery ten feet square with difficulty kills a cat or a dog (2); but very few feet is enough for a pigeon; less for a goldfinch or canary; and thus diminishing as the animals are smaller. It appeared that a shock of moderate strength would destroy animalcula; but not being possessed of an electrical machine, I availed myself of the assistance of Sig. Pietro Moscati, then my colleague in the royal university of Pavia, who,
in

(1) Leeuwenhoeck thinks he saw animalcula in the recent urine of a mare, *De certu et defluvio capillorum*.—T.

(2) Prictley. History of Electricity.

in addition to skill in electrical experiments, had a machine of considerable power. He was so obliging as frequently to comply with my philosophical request, and subject infusions full of animalcula to the electric shock. They were invulnerable, and as lively after receiving the shock as before; nor was there any difference, though two, three, or more sparks were drawn from the infusions. The weakness of the shock cannot be objected, as two or three killed a leech, newt, or similar small animal.

I was accustomed to communicate the result of my experiments to M. Bonnet before publishing them, because this illustrious naturalist seemed to wish to partake of my little discoveries. Among the rest, I mentioned that which Dr Moscati had made. He answered, that he had shown M. de Sauffure my letters, who had repeated our electrical experiments, but with opposite effects, which he ascribes to the great humidity of the air of Lombardy preventing electricity from being so powerful as at Geneva. He adds, that M. de Sauffure would himself inform me of his results, which he did very soon; and I transcribe them here, such as M. Bonnet sent to me, in the following letter (1):

G 3

“ My

(1) M. Bonnet afterwards published a collection of his letters to his learned correspondents. I have collated all that are quoted here with those in that collection, and corrected any errors or inaccuracies.—T.

‘ *My Solitude, 15 February 1772.*

‘ It was but lately, my celebrated friend, that
 ‘ M. de Sauffure transmited me his experiments
 ‘ on our animalcula. Certain of the pleasure
 ‘ you will derive, I do not delay a moment in
 ‘ sending them. You will judge of my opinion
 ‘ by your own; and I have no doubt will be as
 ‘ well satisfied. This is a subject equally new
 ‘ and curious for the meditation of philosophers;
 ‘ nor is it to be questioned, that in future we shall
 ‘ be able to diversify and extend this new kind
 ‘ of *physico-electricity*. But a plan must first be
 ‘ pointed out; and there is no small merit in
 ‘ opening up the unknown sources of truth,
 ‘ which experiment is to accomplish. I can-
 ‘ not retard the pleasure you will have in M. de
 ‘ Sauffure’s letter.

“ *Geneva, 8 February 1772.*

“ I return, Sir, with a thousand thanks, the
 “ letters you had the goodness to send. I have
 “ perused both with extreme satisfaction, but re-
 “ gret that you transmitted my letter on the
 “ *transparency of germs* to Sig. Spallanzani, for
 “ it is not worthy of that honour, and still less of
 “ your eulogium on it (1). Behold where you
 “ have conveyed that trifling epistle; being in
 “ your’s, it will also be published by Signior Spal-
 “ lanzani;

(1) Vide M. Bonnet’s second letter at the end of this
 Tract.

“ lanzani, though I never thought it would have
“ been printed, which it little deserves.

“ At another time, I have told you, Sir, but it
“ cannot be repeated too often, my extreme plea-
“ sure in perusing the beautiful series of Signior
“ Spallanzani’s experiments and observations.
“ He is fit for your friend and fellow labourer.
“ With him are found that order, that analysis,
“ that just and rigorous logic, of which your own
“ writings afford an example.

“ You know that I also have been occupied
“ with infusion animalcula; and you yourself
“ have honoured me by inserting some of my re-
“ sults in the republication of your Palingenesie.
“ It has pleased me to observe, that my experi-
“ ments entirely coincide with Signior Spallan-
“ zani’s observations.

“ I had attempted, as he did, to repeat
“ Mr Needham’s singular experiment, which
“ consists in introducing the halves of corn
“ pickles into slices of clay, that they might ger-
“minate at the surface of water. I also saw ani-
“ malcula originate as in common infusions; but
“ neither discovered those zoophytes, nor vege-
“ table roots producing animalcula, which Mr
“ Needham had seen rather with the eyes of an
“ imagination heated by the love of theory, than
“ with the calm senses of a philosopher.

“ I had seen the minute round heads which
“ terminate the filaments of mould burst when
“ moistened, and discharge a globular dust. I had
“ communicated it to Baron Haller, who speaks
“ of it in the article *Mucor*, in the new edition
“ of his history of Swiss Plants ; but I had nei-
“ ther witnessed nor suspected the surprizing in-
“ destructibility of this dust, which Signior Spal-
“ lanzani justly supposes the seed of the plant.

“ I had long endeavoured to kill infusion ani-
“ malcula by electricity, and without better suc-
“ cesses than Sig. Moscati and Spallanzani ; but
“ more exact observations have at last given op-
“ posite results. You may communicate them
“ to the latter if you think proper.

“ Some drops of rice infusion, full of animal-
“ cula, were put on a glass slider four inches
“ long and one broad, with the rounded point
“ of a quill, and the drops drawn out so as to
“ form an uninterrupted line from one extremity
“ of the glass to the other. When the slider was
“ applied to the machine, so that the electric
“ fluid passed continually, and without shocks
“ and sparks, they moved about, and did every
“ thing as usual. In general, I have observed,
“ that simple electricity, that is without shocks
“ and sparks, never produced the least effect ;
“ but, when the slider was so disposed that a
“ strong

“ strong spark suddenly passed from one end to
“ the other, the whole were killed almost instan-
“ taneously, and any that survived died very
“ soon. The Leyden phial was not required ; a
“ spark from the conductor, without any more
“ apparatus, was sufficient.

“ I was curious to learn what happened at the
“ moment of the shock, and disposed my slider
“ so as to observe the animalcula. After a vio-
“ lent shock, they were always in agitation.
“ Some were immediately reduced to granuli, a
“ mode of death to which you know these ani-
“ mals are very subject : Polypi, which in the
“ manner of multiplication resemble them so
“ much, often perish in the same way. The ani-
“ malcula remaining entire, revolved a few se-
“ conds in the liquid, then stopped at the bot-
“ tom, and died on the spot, without any change
“ of figure.

“ The spark is fatal, though they are in a
“ greater quantity of water. I filled a glass tube
“ two lines in diameter and four inches long with
“ water full of animalcula. Five or six very
“ strong sparks drawn through it killed them all.
“ But the consequence was different, on taking
“ tubes four or five lines in diameter. The
“ electric fluid, dispersed in so great a space, is
“ not of that density to lacerate the body of ani-
“ malcula.

“ One

“ One fact has to me appeared most singular. You know, Sir, that the sparks, which we wish to direct through a substance, often glide over the surface rather than penetrate it, even where the substance is very permeable by electricity. Matters may be so arranged, that such a phenomenon will infallibly succeed; and I have frequently prepared a basin of water so as the sparks would pass over a surface a foot long without penetrating the water. This I found to have the same effect on animalcula as when the sparks passed through the water itself. While my eye was applied to the microscope, the moment superficial sparks were drawn, I saw the whole animalcula in agitation; some reduced to grains, and the rest immediately die.

“ Do not imagine the possibility of my being deceived, by supposing the spark glided over the surface, when it in reality penetrated the water, for the difference is too sensible. That which glides appears most brilliant over the whole surface; that which penetrates passes without being seen. Perhaps you will say one portion of the electric fluid passes within while the remainder passes without. Doubtless this may be; was it so, it seems that such a division should weaken the spark; whereas it appears more brilliant and sonorous than usual.

“ These

“ These superficial sparks do not go deep :
“ they have no effect on animalcula swimming
“ five or six lines from the surface : only few are
“ killed, which certainly are near the top when
“ the spark passes : the rest remain vivacious and
“ well. At this depth, a very strong shock, such
“ as is capable of melting an inch and a half of
“ iron wire one twelfth of an inch in diameter,
“ has not the least influence on them.

“ These, Sir, are the results of my most interest-
“ ing experiments on electricity operating on ani-
“ malcula. I wish they may satisfy you and Sig:
“ Spallanzani, if communicated to him, or that
“ you will tell me what more I ought to do. Two
“ circumstances should be mentioned ; one that
“ the experiments were made on the infusion
“ animalcula of wheat, hempseed, and maize,
“ and the result has always been uniform ; the
“ other, that the animalcula were of the largest
“ size that infusions produce.”

M. de Sauffure's experiments besides being ingeniously conceived, and happily executed, appear decisive ; and they induced me to suppose, some unforeseen accident had opposed Sig. Moscati's ; and perhaps that the excessive humidity of the air of Pavia, as the Genevese professor had thought might be the cause, particularly as our experiments were made in winter ; I wished to repeat them in a more favourable season, but
that

that became impossible, as Sig. Moscati was soon afterwards re-established in Milan, his native place. However, in two years, having procured an excellent machine, I repeated them myself, and the consequence could not correspond more with M. de Sauffure's results.

The animalcula were first exposed to the discharge of the Franklinian battery. Upon it was put a little spot of pitch, with a very small hole through the centre, full of infusion; the spark was drawn through this hole. Not one animalcula of thousands in the liquid survived the shock a moment; many were wounded and reduced by the electric vapour, and many appeared untouched. The shock was diminished by charging the battery less, but the effect was the same. The quantity of liquid exposed to the shock was increased, by drawing a right line on the spot, two thirds of an inch long, and two lines broad, proceeding from the central hole. Then the shock was transmitted through the whole fluid. It was a real thunderbolt to the animalcula; all immediately died. If the breadth of the line was increased but not the length, a change ensued. So long as only two lines broad, none escaped, but when more than that, the animalcula either were not injured or did not die for some time. Those within the limits of two lines were stunned, and continually revolved on themselves; the vertiginous

ous motion diminished by degrees, and in a quarter of an hour entirely ceased. Those not so near as two lines survived longer; the activity and liveliness of the most distant evinced they were not effected by the electric fluid. If, instead of increasing the breadth of the liquid more than two lines, it was produced from the centre of the spot, so as to reach the circumference, which made full five inches in length, the shock equally killed the animalcula throughout the whole. Such were my experiments with Franklin's battery.

Let us now speak of a simple spark drawn from the conductor. Here I used the same spot of pitch which was put on the conductor. The spark drawn through the central hole seemed more brilliant and sonorous. The central hole alone was filled with fluid, or a little channel was added of various dimensions on the spot. Every time the spark was drawn through the hole, all the animalcula perished, but three or four were required to kill them in the little channel.

Many substances are better conductors of the electric fluid than water; and where the shock was weak, I was unable to direct it through the channel, especially if very long and narrow. But the fluid did penetrate and act upon it, as appeared from the crackling when the conducting rod was applied; and this trifling electricity was
sufficient

sufficient to kill animalcula, which I could not have believed.

To learn whether the electricity dissipated by metal points, fixed to conductors, would destroy animalcula, I applied a drop of infusion to one, and found it to be so only if the electric fluid passed for some time from the point.

It was evident, in short, that every shock, however feeble, was always fatal. But simple electricity, that is which operates silently, had no effect, as M. de Saussure also observed. As to the kind of animalcula, I can freely affirm that experiment has been omitted on none of the vast variety, and electricity has been alike fatal to all.

The perfect coincidence of my experiments with M. de Saussure's leads me to publish them; but the friendship I had always borne to Sig. Moscati, imposed the duty of first inquiring whether he had repeated our experiments as he promised, when I communicated them to the Genevese naturalist. I transcribe his answer, as he seemed to wish it should be published. It both proves that he kept his promise, and obtained new results, which cannot but do great credit to truth.

‘ In your last letter, you inquire whether I
‘ have repeated the experiments which we made
‘ some years ago on electrifying animalcula,
‘ which

‘ which were then neither injured nor killed;
‘ More than once they have been repeated, with
‘ different and even opposite results, which I have
‘ also discovered did not arise from the weakness
‘ of my machine, since fulminating electricity is
‘ not necessary to kill them, but to the method
‘ employed. When we made the experiments,
‘ we used a little brass cup; and, towards its cen-
‘ tre, endeavoured to direct the flock of the jar
‘ where the cup was fixed. We never killed one
‘ animalcule by this method; nor was I more
‘ successful on repeating the experiment alone, at
‘ the most favourable periods for electricity. But
‘ as you informed me that M. de Sauffure, whose
‘ merit and accuracy in experiment I know and
‘ highly esteem, had seen them die; and as it had
‘ also appeared, that the spark, instead of com-
‘ ing from the liquid with the animalcula, escap-
‘ ed from the circumference and sides of the ves-
‘ sel, I began to suspect that, instead of passing
‘ through the fluid and striking the animalcula,
‘ it came directly from the metallic cup to the
‘ conductor, gliding over the surface of the in-
‘ fusion. I therefore changed the plan. On a
‘ polished crystal plate, well wiped, I put a little
‘ hollow piece of wax, and fastened two brass
‘ wires, with obtuse points, from two opposite
‘ extremities near the surface; one communicat-
‘ ed within, and the other without, the jar. This
‘ apparatus

‘ apparatus was placed before a compound micro-
‘ scope, made by Cuff, which his Excellency
‘ the Conte di Firmian had presented to me.
‘ The hollow was filled with liquid, containing
‘ lively and vigorous animalcula; and I kept my
‘ eye intent on them, while another person work-
‘ ed the machine: I succeeded thus in killing
‘ them with a shock of no great strength, and
‘ with a small jar. The animalcula suffered ei-
‘ ther by receiving the shock or being in the vi-
‘ cinity when it passed; those at the bottom of
‘ the hollow remaining alive. One thing I re-
‘ collect to have particularly remarked, that the
‘ animalcula killed assumed a bristly appearance,
‘ like a microscopic sponge, and were more
‘ opaque than the rest; from the superficial as-
‘ perities occasioned by the shock, they seemed
‘ larger than when alive. I was in this manner
‘ convinced of the truth of the experiment; and
‘ being afterwards engaged in other matters, as
‘ I still am, thought no more of it. Excuse the
‘ brevity of the recital and the dryness of the sub-
‘ ject; it does not arise from indifference to such
‘ agreeable studies, but the necessity which you
‘ well know I am under of applying to subjects
‘ less interesting. I have the honour to be, with
‘ the utmost esteem and friendship, your most de-
‘ voted, obliged servant and friend,

‘ Milan, 6 Jan. 1774.

PIETRO MOSCATI.’

I have still to speak of animalcula included in a vacuum, which is the last subject that I proposed to discuss in this chapter.—The consequences were different according to the difference of species; a vacuum was very soon fatal to some, and others lived in it very long. Let us enter on detail.

Several small glass tubes, close at one end, were filled with various infusions. The tubes were very small, and the glass extremely thin, so that applying the magnifier I might see what passed within when appended to the inside of a receiver. Some open tubes, full of the same infusions, were kept in reserve for the necessary comparisons. Sixteen days privation of air did not injure the animalcula; on the twentieth day, they began to die; and on the twenty-fourth, all were dead. Those in the open air still survived, otherwise one might say the natural term of life was expired (1).

The experiments were repeated on more infusions of a different kind. Of some the animalcula lived a month in vacuo, and even thirty-five days: those of others died in fourteen, eleven, and eight days: and some lived only two. The infusions mentioned in my Dissertation were si-

VOL. I.

H

milar

(1) Nearly a century ago, Derham observes, that he kept the animalcula of pepper water twenty-four hours alive in vacuo. Some naturalists have erroneously cited this passage, as if the animalcula lived a month. *Physico-Theology*.—T.

milar to these; their animalcula died in about two days (1).

The nature of certain animals is wonderful. They continue their ordinary corporal functions in vacuo a considerable time. Vipers and snakes will creep, and leeches swim in fluids. Some insects feed, and others perform, the work of generation (2): Such is the nature of animalcula. In a vacuum, they preserve their wonted motions, ascending or sinking, darting to the surface of the infusion, and diving into its deeps, or driving before them the floating particles on which they feed. I shall afterwards speak of their singular modes of propagation; and this also succeeds for several days in vacuo. In process of time, and according to the strength of the animalcula, motion relaxes and ends in death. It sometimes happens, but rarely, that, being taken from the receiver, and left exposed to the open air, they revive.

These experiments have confirmed two observations in my Dissertation; the usual sterility of infusions in vacuo; and their fertility when the air was only rarified. No animal or vegetable substance macerated in vacuo ever produced a single animalcule: the reverse uniformly happened, on leaving a portion of air in the receiver. As much as keeps thirteen inches of mercury in
equilibrio

(1) Capítolo, 10.

(2) Sperienze del Cimento,

equilibrio is most advantageous for them to originate.

Similar phenomena have occurred with the eggs of animals. I have repeatedly put those of terrestrial and aquatic insects in the receiver of an air-pump, but none were ever hatched, though they had all the requisites necessary except air.

From these and other analogous facts is deduced the necessity of air for the developement of every animated being. While the animal is concentrated in the egg, it enjoys the beneficial influence of air by an infinity of minute pores throughout the egg, which have not escaped the notice of naturalists: when liberated from it, or the involucre by which it was concealed in the womb of the mother, it receives the benefit of the air by other more evident ways. An immense number of animals respire by the mouth, and many by apertures in the sides of the body, by the extremity of the abdomen, or by other parts. The breath enters the mouth of numerous channels at the surface, which conduct the air by ramifications into the interior of the body. The animalcula of infusions, notwithstanding their apparent simplicity of structure, exhibit an organ which we are strongly induced to conceive is intended for respiration. And in this case, they more than ever stand in need of the aerial fluid, which is evident by depriving them of it. There

are some that die very soon after privation of air, others after a longer interval, and the length of it is according to the nature of the animalcula. A sparrow, a nightingale, and in general other birds, quickly die in vacuo. A lizard, a frog, or a reptile, remain some time alive; insects, usually much longer. As there are distinctions among infusion animalcula, there is a difference in their ability to support a vacuum; and those that do so longest, seem of all animals, the most capable of living without air, at least we are unacquainted with any species that exist a month in that state, as we have seen some animalcula do. Though they can long support privation of air, they at last sink under it and die, which is proved by the animalcula living in the open air above two months. And this confirms the general rule, that all animals require air.

I know there are instances given of some which are said to have lived without this element; such as the famous stories of frogs found alive in the middle of the hardest substances, and living toads discovered in the centre of stones, or of entire trees, where not a particle of air could penetrate into their hidden recesses (1). But I am also aware, that such histories are more the object of the admiration than belief of persons who have made any progress in experimental philosophy; because
they

(1) *Melanges d'Histoire Naturelle.*

they are not corroborated by that authenticity which is essential in a case so strange and paradoxical, more especially as the pulmonary structure manifests that they are adapted for respiration. Therefore, until facts are produced to the contrary, more credible and better proved, we have sufficient reason to assert, there is no living animal in nature, limiting ourselves to those already known, that can exist without the benefit of air (1).

H 3

CHAP.

(1) There are numerous accounts, unquestionably very singular, of animals found alive in solid masses; and several intelligent and reputable persons have gone so far as to affirm that they have seen them. It is very difficult to conceive how an animal formed for breathing can live deprived of air: but it seems little less difficult to reject the testimony of the most creditable men. Every day, we discover new singularities, which would be absolutely incredible without authentic information. This is a fact in which more than usual evidence is required; for without that, nay, without ocular demonstration, we find it incomprehensible. Yet I can never understand why the toad is almost always selected for these wonderful preservations, and seldom any other animal. There is an extract from a late Memoir on the subject by Murhard, *Philosophical Magazine*, vol. 3.—T:

CHAP. VII.

SINGULAR MODE IN WHICH MANY SPECIES OF ANIMALCULA PROPAGATE.

IF we observe two animalcula united, the first idea which arises is, that they are occupied in the work of generation; and we cannot avoid it, though the animals exciting the idea are infinitely minute, because uniform example proves this to be the usual position of animals for propagating the species. Hence the actual copulation of animalcula has been supposed from seeing them united in pairs. Such is the opinion of Ellis, and the celebrated Father Beccaria, as he informs me in a letter, written many years ago, concerning my first observations on infusion animalcula. The whole is here transcribed, as it is particular on this phenomenon, and alludes to other important points.

Turin, 11 September 1765.

‘ If your excellent experiments required any
‘ support from the testimony of another, I could
‘ afford it: for, twelve years ago, when the Duke
‘ of Savoy called me to see Mr Needham’s ex-
‘ periments on microscopic animals, I thought it
‘ my

‘ my duty to present him a long treatise with this
 ‘ motto, *Si parva licet componere magnis*,—in
 ‘ which I demonstrated, from analogy, the fallacy
 ‘ of the opinion advanced ; and then pointed out,
 ‘ that it was not the consequence of experiment.
 ‘ Besides, I employed most of my leisure hours,
 ‘ for two years, in experiments on what seemed
 ‘ so interesting a subject ; and succeeded in dis-
 ‘ covering, 1. How infusions dissolved the fixed
 ‘ salts of the substances, carrying them to the
 ‘ edge and dissipating the volatile part, as is evi-
 ‘ dent by the taste and smell, and leaving a gela-
 ‘ tinous matter well adapted to collect and feed
 ‘ animalcula ; 2. That animalcula have a proper
 ‘ internal and spontaneous motion, in addition to
 ‘ the characteristics of avoiding obstacles, chang-
 ‘ ing their direction, and passing above them ; also,
 ‘ the two following, thus described in my Treatise,
 ‘ *Lucem refugiunt, paulo vividiores, putrem ma-*
 ‘ *teriam appetunt, quasi ut vescantur.* A singular
 ‘ fact, relative to the multiplication of animal-
 ‘ cula, cannot have escaped your penetration. I
 ‘ have often remarked, that at full size they
 ‘ seemed in copulation. Two animalcula are fre-
 ‘ quently seen at the circumference of a drop of
 ‘ putrid matter, one supported by a particle or
 ‘ joined to it, or, to speak more certainly and
 ‘ adhering to appearances, in contact with it, and
 ‘ continually vibrating or oscillating in the direc-

‘ tion of a straight line uniting the centres of the
‘ two bodies ; and the oscillation is particularly
‘ manifested by the motion of some internal parts
‘ near the line of direction. But some reserve
‘ has probably induced you, as well as myself,
‘ to be silent concerning this most simple obser-
‘ vation.’

In my answer to the polite and learned letter of this celebrated philosopher, I had the honour to inform him, that I had several times seen the phenomenon of two animalcula united, which was expressly mentioned in my Journals,—and had even sketched the figure ; but, to confess the truth, although it did appear that this union might be a real copulation, I could not resolve to advance it in my Dissertation from the fear of being deceived. Animalcula are a part of the creation as yet little known to philosophers ; and it is easy to be mistaken by applying our ideas of large animals to them. Thus was I induced to leave the matter in obscurity ; and only desirous that some more fortunate or more acute observer would promote the interesting subject, on which my poor abilities had thrown any additional illustration. Happily my wishes were not vain. My observations came into the hands of M. De Saussure, who, among other phenomena, having fallen on this supposed copulation, made it the subject of long, nice, and minute discussion ;
and

and he at last discovered, that it was not the copulation of two animals, but one animal which multiplied by a division into two parts. His observation was communicated to M. Bonnet, who transmitted it to me.

My Solitude, 27 January 1770.

‘ I have hazarded some conjectures on infusion
 ‘ animalcula, and their mode of multiplication,
 ‘ in the first volume of my *Considerations sur les*
 ‘ *Corps Organisés*, chapter 3.; and it is there
 ‘ said, “ Let us prefer conjectures founded on ob-
 ‘ fervation or experiment.—Let us compare these
 ‘ animalcula to polypi, and other insects, multi-
 ‘ plying by sections.—Let us suppose they pro-
 ‘ pagate by natural division, similar or analogous
 ‘ to the cluster polypus; or, by breaking or se-
 ‘ parating with extreme facility, like the fresh
 ‘ water anguillae, spoken of in my *Traité*
 ‘ *d’Insectologie*, Observat. 21. part 2. By such
 ‘ suppositions, we may explain the chief pheno-
 ‘ mena presented by animalcula—that singular
 ‘ diminution of size and encrease of number.”

‘ I do acknowledge, that I had no great hopes
 ‘ that these conjectures would one day be veri-
 ‘ fied, nor was I very sanguine in their favour.
 ‘ Animalcula are so minute, that it was not easy
 ‘ to presume the mystery of their reproduction
 ‘ would be inveiled. But it is now accomplished;
 ‘ and we owe it to a naturalist, who, although
 ‘ experienced

‘ experienced in the rare and uncommon art of
 ‘ interrogating nature, is restrained by modesty
 ‘ from making his discoveries known, lest they
 ‘ may not be sufficiently comprehended. A work
 ‘ containing excellent observations on the *Petals*
 ‘ *of Flowers*, a subject but little understood, has
 ‘ already spread his name among the limited
 ‘ number of his equals. It is evident I mean M.
 ‘ de Saussure, who, at an age when men only be-
 ‘ gin to think, already fills one of our philosophi-
 ‘ cal chairs with credit. His affectionate attach-
 ‘ ment to me, which is merited but by a reciproc-
 ‘ al sensation, would not permit him to let me
 ‘ remain ignorant of his discoveries concerning the
 ‘ mode of animalcula propagating. These are re-
 ‘ lated at large in the following letter, which well
 ‘ deserves the attention of observers (1).

“ *Geneva, 25 September 1769.*

“ You have great reason, Sir, to suppose, that
 “ animalcula of infusions may multiply by con-
 “ tinual division and subdivision like polypi. You
 “ state it only as a suspicion ; however, my ob-
 “ servations, on many species of these singular ani-
 “ mals, convince me that we may regard it as a
 “ fact. Animalcula of a roundish form, without
 “ beak

(1) This and M. de Saussure's letter are inserted in the republication of *La Palingenese*.

“ beak or hook, divide tranversely in two. A
 “ contraction appears at the middle, which gra-
 “ dually increases until the two parts are attach-
 “ ed only by a thread : the animal, or rather two
 “ animals, make violent efforts to complete the
 “ separation ; and, after it is effected, seem stun-
 “ ned for some seconds. They afterwards begin
 “ to traverse the liquid as the entire animal did.

“ You will easily conceive, that, in the first
 “ movements of their new life, they are smaller
 “ than the animal they composed, each, in reality,
 “ is only one half, but it soon acquires the size
 “ of the whole, and, in its turn, divides into
 “ animalcula that rapidly become equal to it.

“ Mr Needham has done me the honour to
 “ commend this observation in his notes on the
 “ translation of Signor Spallanzani’s excellent
 “ performance ; and employs it in support of his
 “ theory, which is, that the smallest animalcula of
 “ infusions, those that seem points before the most
 “ powerful microscopes, are produced by continu-
 “ al divisions and subdivisions of the large species.
 “ Undoubtedly, in four years which have elapsed
 “ since I communicated this observation, he must
 “ have forgot that I constantly observed the
 “ parts of the divided animalcula in a short time
 “ became as large as the whole to which they
 “ had belonged. Therefore, in their propaga-
 “ tion, we find the same constancy and unifor-
 “ mity that is seen in the rest of nature. Per-
 “ haps

“ haps I did not insist with Mr Needham on this
 “ peculiarity ; perhaps I did not inform him
 “ that, to remove every possibility of doubt, I
 “ put a single animalcule in a drop of water ;
 “ that it divided in two before my eyes ; that
 “ next morning these two had become five, and,
 “ during the day, sixty ; and on the third day
 “ were so numerous, that it was impossible to
 “ count them ; and all, except these just produc-
 “ ed, of equal size to the animalcule from which
 “ they came.

“ When, for the first time, you see the animal
 “ dividing, you will think it the copulation
 “ of two. I was completely deceived ; and
 “ thought, like Micromegas, that I had caught
 “ nature in the fact : nor was I undeceived
 “ until one had, in the space of twenty mi-
 “ nutes, successively passed through all the de-
 “ grees from the most imperceptible contraction
 “ to full separation (1).

“ What is most remarkable in the instinct of
 “ these animals is, when they observe or discover
 “ two

(1) Muller ingenuously acknowledges, that the first
 animalcula he had seen united seemed to him in copula-
 tion : and this seductive phenomenon may impose on any
 one ; whence Father Beccaria's innocent mistake was not
 surprising : and there is no doubt that he would have dis-
 covered the truth, if his researches on electricity, which do
 him so much honour, had allowed him time to prosecute
 the observation.

“ two on the point of separation, and exerting
“ themselves to attain it, they precipitate them-
“ selves between them as if to assist in break-
“ ing the connecting ligament. Nor can we
“ view this act as only fortuitous, since they are
“ generally careful to avoid one another, and
“ never strike together whatever the rapidity of
“ their course may be.

“ Another species, found in hempseed infu-
“ sions, with a beak or hook before, also multi-
“ ply by division, but in a more singular man-
“ ner. When going to divide, the animalcule
“ seeks a convenient place at the bottom of the
“ infusion, commonly that semi-transparent kind
“ of mucilage which forms in hemp infusions.
“ After searching and examining various places,
“ it at last fixes on one. The body, which is
“ naturally long, contracts, the curved beak is
“ retracted or concealed, and the animal as-
“ sumes a spherical form: it next insensibly be-
“ gins to revolve on itself, so that the centre of
“ motion is fixed, and the sphere never changes
“ its place. The motion is performed with the
“ most perfect regularity, but the direction of
“ rotation is constantly changing, so that the ro-
“ tation may be first from right to left, then
“ from before, and next from left to right. And
“ all these changes are imperceptibly performed,
“ without the animalcule or rotatory machine
“ changing

“ changing its place. At length the motion ac-
“ celerates; and at the point where the sphere
“ seemed motionless, two cross divisions begin to
“ be visible, exactly like the husk of a chestnut
“ ready to burst. In a little longer, the animal
“ appears agitated, and making great exertions,
“ and at last divides into four, the same as the
“ producing animalcule, but smaller. These
“ grow larger, and each divides into four, which,
“ in their turn, increase. I could see no end to
“ the subdivisions; the young always became
“ equal to their parents, if we may use the word
“ parent in this singular mode of generation.”

M. Bonnet adds the following words: ‘ In
‘ the last species of animalcula is another analogy
‘ with cluster polypi evident: We know that
‘ these create a little vortex in the water, which
‘ precipitates the food towards their mouth. Our
‘ animalcula perform a similar operation, and
‘ surely with the same intent.’

In this new course of experiments, I have had
the advantage of examining M. de Sauffure’s dis-
covery, to verify and extend it, and find, that
besides the species he observed, there are many
others which propagate by a natural division, but
often in the most singular and unaccountable
manner. We may begin with the simplest; and
first with the transverse division, being that
mentioned by the Genevese professor. It suc-
ceeds

ceeds both in spherical and elliptical animalcula, and in some other species without either beak or hook. For the purpose of correct observation, I isolate an animalcule in a watch-glass. If the weather is warm, traces of contraction are visible about the middle of the two sides; it insensibly advances; and the animalcule somewhat resembles a blown bladder tied tight across. It still swims about, darting its head among the particles of matter, if any are in the glass. The contraction continues increasing; and the animalcule is at last changed into two spherules touching in one point, Plate 1. Fig. 1, A B C. These connected spheres continue moving as the entire animal did, but they often stop. The posterior spherule seems to be carried on by the weight of the anterior, and appears to have no spontaneous motion of its own, but what is necessary for separation from its companion. This at length is done, and of one animalcula, two are formed. At first, they are apparently unable to move; however, each soon resumes the velocity of the original whole. The spherules in time acquire the size of the entire animal.

Though all the species dividing transversely separate into two equal halves, these parts are not uniformly spherical, but more or less elliptic when very near division: Nor are the new animalcula always torpid and inactive, for they of-

ten retain the former velocity of the composing whole. It particularly merits observation, that the size of the two animals, while actually dividing, is so much augmented, that each is almost equal to the original, of which I have had undoubted evidence, by comparing each portion with one entire of the same size and species as that divided. The animalcula from these divisions being also isolated, similar young are continually produced by divisions and subdivisions.

Among those dividing transversely are some generations, (like the elliptic kind, pointed before, sometimes originating in wheat infusions, and rather large) whose anterior part is provided with short fibrilli in constant motion. The vortex ascribed by M. De Saussure to the second species of his animalcula, is certainly produced by this motion (1); but acute vision and a powerful magnifier are necessary to discover the vortex and fibrilli (2). Neither the vibration nor

vortex

(1) Muller disputes the correctness of this observation. Vortex, quem animalculum, cujus meminit, claris. Saussure ex infusione cannabis, partitioni intentum ciet, non, uti autumat illustris Spallanzani, vibratione pilorum, cum iis careat *Kolpodeque* generis sit, sed totius corporis agitationi debetur, *Animal. Infus.* p 246.—T.

(2) There are few microscopic objects so difficult to discern accurately as the vibrating fibrilli of some animalcula. Their extreme minuteness, their continual motion and

and

vortex is interrupted, during the division of the animalcule; and both continue when it is finished. After separation, the posterior part acquires the filaments; and, in a short time, also produces a vortex.

I have counted fourteen species of animalcula multiplying in this manner: only two merit description. We see a kind of circular animalcula, above the middle size, in infusions of bearded wheat. From the circumference of the body arise a circle of minute protracted points similar to very slender cones, and in the quickest motion. This animalcule and its points are mentioned in my Dissertation; but for want of the necessary observations, I was uncertain of what use they might be (1). Now, I do not think myself deceived in supposing that they serve for swimming, as the fins and limbs of so many other aquatic animals. This is deduced from two reasons; first, because the points are at rest while the animal is tranquil, from their motion when it moves, and the accelerated vibration when at its greatest velocity. Secondly, if, by any accident, the number of points is diminished, the ani-

VOL. I.

I

mal

and removal from the focus of the microscope, render it a nice and delicate matter to bring them distinctly into view.—T.

(1) Capitol. 2.

mal no longer moves, or does so very slowly. Propagation is operated by a transverse division in two. The separation is slow, and attended with one singularity, that, before being fully accomplished, each portion is as large as the whole, and, in the place of division, has acquired points similar to those of the old animal, but shorter.

The other species, which must not be overlooked, is found in an infusion of marsh-lentil, and is sometimes so large as to be visible without the microscope. By filling a thin sided chrystal tube, and placing it in the sun, the animalcula are so conspicuous to the observer's eye, that the successive divisions may be easily seen. Other elliptic animalcula are observed with the contraction scarcely begun, some with it far advanced, and others with it almost completed. The multiplication is so abundant, that a single animalcule, at certain times at least, will, in a few days, people a whole infusion.

I have still to speak of longitudinal division, for that is also a way in which animalcula propagate. Those with the filament, already mentioned, divide longitudinally; but the easier to understand how it is effected, we must first describe the animalcule. On presenting a drop of infusion to the microscope, animalcula are seen among the vegetable fragments, some attached to particles of matter, and others wandering free-

ly about in the drop. The filament proceeds from the posterior part of the animal; and although its natural position is in a right line, it often contracts suddenly into a spiral whose volutes approach so near as to touch: in a moment they recede; the spiral unfolds, and resumes the straight line. While unfolding, or already stretched, if a gentle motion is given to the drop, the filament becomes a spiral. If its extremity is fixed, any contraction towards the spiral forces the animalcule rapidly to the fixed point; when free, it approaches the animalcule. This it frequently does, almost periodically. It is of a pearl colour; and of extreme slenderness, at least compared with the animalcule; the length equals it, and is sometimes more. The figure resembles an onion or bulb: to the extremity is attached the filament as the roots originate; thence it was named *the bulb-animalcule* (1). A circular row of filaments proceed from around a hollow. These extremely slender fibrilli are in a constant vibratory motion, which occasions a whirlpool in the fluid, absorbing the smallest adjacent particles, and sometimes very minute animalcula. As the bodies gradually approach, the motion becomes more rapid. Attending

I 2

carefully

(1) This is the *Vorticella Hians* of Muller. *Animalcula Infusoria*, p. 321.—T.

carefully to the fibrilli, it is not difficult to account for the operation. After the largest substances enter the hole or hollow of the animalcule, they are rejected, but the smallest remain; and there is every reason to believe they penetrate the body by some invisible channel. The intent of the operation is in all likelihood for the animals nutriment and preservation; the vibrating fibrilli cause a vortex; the vortex draws in the floating particles; and the animalcule selects either the most delicate or what suits it best for food.

Besides the periodical motions we have ascribed to the filaments, there are others peculiar to the animalcule. Whenever the filament contracts, the animalcule also contracts, suddenly concealing the hole and fibres within its body, and assumes the figure of a spherule, D. pl. 1. fig. 2: In a few seconds, the filament is extended, and the animalcule becomes like a pear, E; then its ordinary shape outlined F, and finished G: The fibrilli and hole re-appear; the vortices recommence when their motion begins, for there is an entire cessation while the animalcule remains contracted within itself.

I first saw these animalcula dividing in two in an infusion of white kidney beans boiled two hours. The anterior part of one seemed languid, which induced me to suspect it was going to divide. Two misshapen animalcula, attached
by

by many points, appeared : each had its appropriate fibrilli and consequent vortex. Besides the usual contraction and extension, the animalcula were full of agitations and contorsions, and always separating more from each other, changing their mutual position, until the two holes and vortices became diametrically opposite.—The separation advanced ; and in half an hour from the first observation, they were connected only by a point. The filament, which during the whole time of dividing periodically contracted and extended, was no longer common to both animalcula, but belonged to one whose only motion was vibrating the fibrilli, retracting them, and extending itself. On the contrary, the other animalcule was occupied with bending into different forms, in contorsions, and revolving on its own axis. At last it separated from its companion, began to swim in the liquid, and very soon left the field of the microscope.

This observation was a rule for experiment on many more of the same species ; and I uniformly obtained the same results by isolating them in watch-glasses. A little cleft was seen at the anterior part of the animalcule, dividing the hole asunder. The cleft increased ; the vortex became double ; and each portion acquired the rude figure of an animalcule. The separation advanced ; the shape grew more perfect ; and division

being almost completed, they were transmuted into two entire and well formed animalcula. One remained attached to the filament, and, in a short time, became as large as the whole, and, by new divisions, gave birth to new animals. The other had no filament; it rapidly traversed the fluid, contracted, extended, and an appendage soon budded from the posterior part, which was the rudiments of the filament. With this the animalcule fixed itself to some surrounding substances: the filament lengthened, and the animalcule began to divide again. In fig. 3. pl. 1. are the various degrees of division.

These animalcula sometimes perish when isolated in distilled water; and the like may be said of all that divide: however they often divide and subdivide, still their glasses are never populous; but the numbers encrease exceedingly, if portions of vegetable matter are mixed with the distilled water. Privation of food in the one case, and abundance in the other, is undoubtedly the cause of this difference.

Bulb animalcula not only inhabit boiled but also unboiled infusions of kidney beans, and many other legumes, as lentils, beans, and pease. Nothing more is required for the convenient observation of their propagation than to macerate a few particles of seeds. In two or three days, if the experiment is made in summer, some animal-
cula

cula are seen attached by the filament to minute fragments in the infusion; and they will divide before the observer. The number fixed by the filaments is proportioned to the number of divisions about to take place.

The same legumes produce another species of animalcula, also multiplying by longitudinal division, and presenting phenomena similar except in two facts: *first*, The fibrilli are not in the cavity, but on its lips; *secondly*, The figure resembles a monopetalous flower. The body divides exactly in two.

There is also a species considerably larger, which propagates by a little fragment detaching itself obliquely from the body. This animalcule is sometimes found in an infusion of beets. It is spherical, and has a filament which is not endowed with the singular motions of the other two species, nor is the body subject to those mutations of figure. The multiplication begins with a small portion insensibly detaching itself from the body, near to the origin of the filament, and it is in continual motion, Plate 1. fig. 4. H. When separated, it swims actively through the fluid; and although smaller than one-twelfth of the whole, it becomes equal to it in less than a day. Then it begins to propagate in the same manner.

As I have repeatedly spoke of isolating animalcula, or the method used of confining one in a watch-glass, on purpose to observe the successive degrees of division, the reader will naturally be earnest to learn the mode employed, much more so if he is accustomed to such matters, and knows the extreme difficulty of obtaining one alone in a drop of infusion, however small. Saussure himself states it as exceedingly difficult, and that by dint of patience he succeeded in confining one in a drop of water; and I must confess it was a great labour before I fell on a ready method. A drop of infusion is conveyed into a watch-glass with the point of a pen; it is of no consequence although abounding with animalcula: a drop of water is put two or three lines from the first, and they are made to communicate by a little channel formed by drawing out the circumference of the drops. The animalcula are not slow in traversing the channel, and arrive one after another in the drop of water. Observing this passage with a magnifier, whenever I see an animalcule enter the water, I cut off the communication with a hair pencil: thus imprisoning a single animalcule. If more than one are to be confined, it is easy to allow any number to enter the drop. The infusion being then taken away, only one remains in the watch-glass, or more if I choose it.

I shall here speak of an objection started by Mr Ellis, less because it merits refutation than because it should not be entirely overlooked. His opinion is, that the division of animalcula is not a natural mode of propagation, but the effect of accident, and that it is occasioned by accidental shocks, from striking against each other. This opinion he deduces from two reasons; first, from the proportion of animalcula dividing to those that do not, which is scarcely as one to fifty; and, secondly, from observing young in the body of adults, and within the young some still younger (1).

It was unfortunate that M. de Saussure's discovery had not been published when this learned naturalist composed his Memoir. Had he seen his observations, and what has since been observed by me, it is no arrogance to affirm, that he would have deeply penetrated into experimental research on infusion animalcula. He would also have perceived that the shocks and striking together are perfectly imaginary. In the end of my Dissertation, their anxiety to avoid one another, and different obstacles, are mentioned in express terms. The like is remarked by two excellent naturalists, Father Beccaria and M. de Saussure; and, in my new enquiries, I have had opportunities of seeing the fact confirmed a thousand times. Therefore,
it

(1) Philosophical Transactions.

it is false that the division of animalcula is the effect of mutual shocks: and if that species, which the Genevese naturalist mentions, seems to prove the reality of the shocks, it is not at the beginning, or when farther advanced, but when the division is almost at an end, and then only, that any shocks are given by the companion animalcula, and when the dividing ones are exerting themselves to separate. Besides, their instinct to assist in separating appears peculiar to this species. I have never witnessed any thing similar in the numerous kinds examined. But the *experimentum crucis* against Ellis's objection is, that animalcula, isolated in glasses, multiply by division as the rest, though they can experience no shocks from others.

Had my respectable colleague continued to study animalcula, he would have perceived the insufficiency of the proportions he has given from the immense numbers in actual division. Frequently among innumerable multitudes traversing an infusion, there has hardly been one that did not exhibit signs of division. But I can comprehend what has misled Ellis. By constant observation, I find that this mode of multiplication has determinate periods; at one time, it cannot be more general; at another, it is rarer; and now it is not to be seen at all. Apparently, his observations were made when the

propa-

propagation was about to end; thence was a proportion assumed which he supposes general. I cannot think myself deceived in conceiving this has misled the author, as he mentions having discovered the young and their descendants in the bodies of the old animalcula. Many of these animals appear to be transparent folliculi, with vesicles or grains internally strewed here and there, very often including others smaller. The first time of observing animalcula, we are easily persuaded that these vesicles or granuli are young. Many persons present at my observations were of this opinion; and I cannot deny that I was of the number. But in truth they are not animals, which I can affirm from the most certain and indubitable proofs. Several animalcula were isolated in a watch-glass; and that they might be all in the field of the microscope after the number had increased, a little water was always left in the glass. Thus some individuals might be selected and recognised. The granuli themselves aided me to this, because they are seldom or never in the same position in one animalcula as in another: so it was easy to observe whether they actually underwent any change. But the number never diminished; they remained invariably the same during the whole period of my examination; and at last had increased amazingly. Thus the granuli have no part in
the

the propagation; and we must admit that they are intended for some other use, though to us unknown. The whole substance of the arm polypi, which multiply by division, is also granulated; and M. Trembley has demonstrated, that these grains have no share in the multiplication.

In the extensive empire of animalcula, naturalists are acquainted with one species only, as far as I know, which multiplies in the manner Ellis describes. This is the celebrated *volvox*, apparently so named from revolving on itself in its progressive motion, first discovered by Leeuwenhoeck, and then found by other naturalists. From the great transparency, like most animalcula, the internal structure is clearly seen; and some observers have already discovered the young within even to the fifth generation. In my long observations on infusions, I have found two particularly abounding with the *volvox*, hempseed and tremella. There are often many in the putrid water of dunghills. These animals are originally very small, but grow so large as to be perceptible by the naked eye. They are of a greenish yellow colour, a globular shape, of a very transparent membranaceous substance, and strewed with the most minute globules within. Three *volvoxes* of different sizes are represented, Plate 1. fig. 5. Examined with a very powerful magnifier, these globules are discovered to be so many

many volvoxes infinitely more minute; and each provided with its diaphanous membrane. I have been able to discern the third generation, but never the other two, though I had recourse to magnifiers of the highest power. Perhaps it was not my fortune to recognize them, or they were not visible in the volvoxes examined, from a difference in the species and size between them and those observed by other naturalists (1). It is undoubted that globules within globules are so many generations included within each other; for when my volvoxes had attained a certain maturity, the smaller globuli began to move within the membrane, detached themselves from it, left the mother, and swam in the infusion, revolving on their axis, and in this manner passing along according to the mode peculiar to these animals. When all had come forth, the common membrane, or mother, burst, and dissolved; and having lost all motion, I lost sight of it also. In the meantime, the new volvoxes increased, as the included globules likewise did; these began to move, the common membrane burst, and they swam about in the infusion like the former. By
isolation

(1) Muller, who describes several species, has seen only the young and its offspring in the body of the mother, and that but in a single species which he calls *volvox globator*.

isolation in glasses, I came to have the thirteenth generation in succession.

Here I must be allowed to make a digression: One of the strongest objections to the theory of germs, is the great difficulty of conceiving the successive envelopment of animals in animals, and plants in plants. It has been attempted to obviate this objection, by stating, that it is more adapted to startle the imagination than to confound reason, which admits of the infinite divisibility of matter, and examples favourable to envelopment have been adduced to weaken it. One egg has oftener than once been found within another; and some osseous parts of one fœtus included in another fœtus (1). The butterfly is first included in the shell of the chrysalis, and the chrysalis in the skin of the caterpillar. In vegetable seeds are found the rudiments of the future plant; and the fourth generation has been seen in a hyacinth root (2). The volvox affords a new and beautiful instance of envelopment; the eye has been able to see the thirteenth generation: probably that is not the last. I cannot speak otherwise, since nothing but time was wanting to investigate whether further development would appear. But the naturalist is invited to extend this most important observation.

Baker,

(1) Histoire de L'Acad. Roy. 1742, 1746.

(2) Bonnet, Corps Organises, tom. 1.

Baker, in his Treatise *The Microscope made Easy*; speaking of the minute and innumerable creatures inhabiting waters, mentions a race of animalcula discovered by Leeuwenhoeck in the marsh lentil, remarkable for a long tail, with which it attaches itself to the roots of the plant, and a hollow like a bell in the anterior part of the body; it is also characterized by a spontaneous motion, contracting and extending the body and tail at pleasure.

These singularities, so analogous to those of my bulb animalcula, excited the desire of seeking for what was to me a new kind of animal, to learn whether its multiplication was by natural division. But as it often happens, the more one seeks a thing the less does he find it; and when least thinking of it he discovers it, or rather it seems to find him; so was it with Leeuwenhoeck's animalcula. When I gave myself much trouble and solicitude I never was able to discover them; and they at length appeared when I was occupied in matters entirely different. Intently considering some tadpoles about the roots of marsh lentils, which had been put into a vase of water to feed them, and the direct rays of the sun falling on the water, I saw the roots very distinctly, and distinguished one from the rest by a light spot of shining white, surrounding it about the middle of the length. This peculiarity did not make the smallest impression

pression on my mind at first, but it was soon evident that it disappeared in a few seconds, and in a little appeared again, which seemed to be periodical. While the tint was visible, I gently took away the radicle; it suddenly vanished; but, the shock having abated, unexpectedly re-appeared. The singularity of the phenomenon recalled to my memory the animalcula of the marsh lentil. Examining the spot more narrowly, I saw, with extreme pleasure, it was a group of more than fifty tails of the animalcula, the extremity of which was fixed to a lentil root. These animalcula resembled the bulb species, not only in extension and contraction of the body and tail, but in generating a vortex and directing the floating particles into the hollow or bell, by means of a circle of filaments or points, proceeding from the edge of the bell, Pl. 1. fig. 6. As this species is much larger than the bulb animalcula, so are the points and vortex proportionally larger. If the bell was wide open, which happened when the animal was extended, it seemed to terminate in the body by a little central hole, I. I transported this family of animalcula with the lentil root into a watch-glass, for more convenient examination. They remained several days without appearing to multiply. At length all perished; the animalcula were untwined; motion ceasing,

ing,

ing, the filaments ceased to move, and then the tails (1).

It may well be supposed, that similar groupes were eagerly sought on the same plants; but in vain. However in six days, I had the satisfaction to see a new spot formed on one of the roots, I say formed, for it certainly was not there before; as it was much larger, the animalcula were more numerous. They and their tails performed the wonted reciprocal extensions and contractions even when untouched, and the water at perfect rest; these motions diminished or augmented the spot. The whole could not be brought into the field of the microscope from their prodigious number, I therefore took away a considerable part, and, excluding a large half, reserved a portion for examination, adapted to the capacity of the instrument. New singularities occurred. The portion represented a tree in miniature; numberless branches, dividing into smaller ones, proceeded from the trunk; these into others successively less; and each of the smallest bore a bell animalcule at the extremity. No scene could be more uncommon or more agreeable. Every three or four seconds the trunk unexpectedly contracted towards the lentil root, and instantaneously

VOL. I. K drew

(1) Muller calls this the *Vorticella Convolvaria*. Animal. Infus. p. 315.—T.

drew in all the branches, twigs, and animalcula, but in a moment restored the tree complete, with all its animals, to the original state. The reader will easily comprehend, that a vegetable is not meant under the appellation *tree*, because it is evident from itself, that it is an *entire animal*, which cannot be better figured than by the representation of a tree. As each animalcule formed its own vortex, and there being above an hundred, the appearance of so many whirlpools at once presented a most singular and interesting spectacle, especially when highly magnified by the solar microscope.

I detached the shrub from the lentil root, by cutting through the trunk. The scene changed, but to one equally pleasing. The animals, branches, and twigs, no longer approached the stem, but the stem, twigs, and branches were suddenly carried away by the animals; and at this instant all the whirlpools disappeared. Amidst these alternatives, the animalcula, no longer fixed to the root by their trunk, swam slowly through the fluid, drawing along the plant and its branches; and, while this common motion continued, the various parts of the plant alternately approached and receded from the animalcula (1).

Having

(1) I cannot affirm that I perfectly comprehend the Author's description.—T.

Having left the plant thus in the glass, I examined it next day; all was in the same state, except that instead of one animalcule as before, proceeding from the extremity of each branch, there were two, Plate 1. fig. 7. K. And those yet single were marked with a very fine furrow, L. The novelty attracted my attention; and it was soon perceptible that the furrow indicated an incipient division; each in a short time became double. Then I began to understand how so many animalcula appeared double on one pedicle; it was a propagation from division. I cannot say whether the origin of the branches, to which they are attached, separate in the same manner; my observations on that subject have not been sufficient; but the animalcula were in pairs, and those at first almost in contact, in half a day, were far asunder, and had attained their complete size, K. L. fig. 7. plate 1. Further, I can affirm, that from each old branch two new ones budded; and the reproduced animals were implanted on their summit, K. These attained the necessary size, divided as the parent, and remained to terminate new branches or twigs; whence the multiplication of branches was in proportion to that of animalcula, and both continued multiplying many days (1).

K 2

During

(1) Muller seems to consider this a distinct species from the former, and names it *Vorticella Pyrarica*. The definition

During this the branches of the shrub had so much extended, and become enlarged, that the circumference was triple. But the supervening death of the animalcula occasioned that of the plant: They began to fall from the branches as fruit falls from the tree; and as they gradually separated, the motive faculty was destroyed. Spontaneous extension and contraction were no longer seen, the vibration of the fibrilli at the mouth of the bell, nor the consequent vortex. Every sign of animation was gone; each animalcule became misshapen, and was destroyed. The tree lived while it had animalcula; after that it neither lived nor vegetated; there was not the least indication of spontaneous motion. Such was the fate of half the spot which I had taken from the marsh lentil root and put in a watch-glass.

I could now see the generation of these animal shrubs. Although the animalcula often died where they were produced and vegetated, that is,
at

tion is, *Vorticella composita inversa conica pedunculo ramofo*. The other is defined; *Vorticella simplex campanulata pedunculo retortili*. It is not in my power to decide whether they are really different or not. The description of all these complicated animals will be much better understood by consulting the figures in Muller's work, Plate 44. 45 46.—T.

at the extremities of the branches, it was not uncommon to observe some swimming in the water, but always adhering to the limb or branch, since we thus term it. If the branch accidentally touch a lentil root, it immediately fastens, and gives existence to a tree bearing as many bell animalcula as there are branches to support them. The animal attached to the root soon divides in two, then into four, eight, sixteen, thirty-two: While these divisions or propagations are going on, the origin and multiplication of branches and twigs, bearing animalcula at the extremities, also advance; and all the branches and twigs are immediately or mediately connected with the stem fixed to the lentil root, already much thicker and longer; which stem, properly speaking, is precisely the trunk of the microscopic tree. Here I shall remark, in passing, that the animals, besides fixing and propagating on the marsh lentil, also breed on other substances, as fragments of wood, straws, leaves of grass, and even on the sides of the vessels, provided they always remain in water.

This species, whose mode of reproduction Leeuwenhoek could never divine, and was unknown to Baker, is a polypus much analogous to M. Trembley's *polype a masse*. The resemblance is evident from that eminent naturalist's description of the species which M. Bonnet calls *polypes a pennaches*,

pennaches, (polipi a fiocco). Besides, being clustered together like the fungi of rivulets, bellshaped, and producing a vortex, which draws particles to the mouth of the animalcule for food, and multiplying by a longitudinal division, they are also attached to little twigs; these to larger, and the larger to the common stem; and all the various branches, as well as the stem, animated by a most remarkable motion of contraction and extension. Still they are different from M. Trembley's, for his produce a vortex, not by points, of which they are destitute, but by moving the lips of the bell; and, before division, by losing the bell shape and assuming that of a roundish corpusculum: nor are they endowed with that contraction and consequent elongation: they divide into unequal parts, and the vortex ceases during division: finally, the contraction and extension of the branches is not natural and periodical, as in our animalcula, but the effect of constraint or accident, when the water is moved.

All the longitudinal divisions yet spoken of have commenced at the anterior part of the animalcule, that is the part before when it advances, and where the opening of a mouth may in many be perceived. But the division of other animalcula begins at the part exactly opposite, or behind. My observations here were too late, and
when

when I had no draughtsman to design them, therefore I must content myself with a simple description. One species represents an infinitely minute hedgehog, or rather sea hedgehog, being of a spherical figure, and the whole surface covered with long pointed prickles. The anterior part is distinguished by advancing first, and producing the usual vortex, by vibrating the spines: the rest are in constant agitation when the animal advances. Another species resembles the segment of a sphere or a hemisphere, and is entirely covered with spines: those on the convex part serve for fins: others, appropriated to form the vortex, are situated on the section or plane of the hemisphere, which is always the anterior part of the animal. All are disunited; and their separation seemed to smooth the animal's body, which can move any number of spines at a time: According to the number in motion, its activity, slowness, and even the vortex is greater. These two species which commonly inhabit the tremella, and are of a colossal size compared with many other infusion animalcula, divide longitudinally, but the division begins at the posterior part. A very faint cleft was seen there as usual, which extended more on the animal's body, and at length divided it into two portions exactly equal. They were not, as easily might be imagined, two halves only, but, before the division finished, two

complete animalcula equalling the size of the whole. The vortex never discontinues during division: minute spines proceed from the cleft as it gradually advances, which, encreasing in length and thickness, in some time are as large as the old. Two well formed hedgehogs are produced by division of the first species; and two hemispheres armed with spines by that of the second. A considerable period is required for completing the separation.

These being the most singular modes of longitudinal division, I have thought it of consequence to enter on some detail. Many similar propagations less worthy of recital are omitted; and I prepare to relate new methods of multiplication by division of the body into parts. A singularity is very frequently to be seen in an infusion of tremella. Two minute pellets, attached together by many continued points, traverse the fluid in an irregular course, Pl. 1. fig. 8. M. We cannot be mistaken if we suppose this an animal preparing to divide: in fact it is so; but one would be egregiously deceived if he formed an opinion of what was to happen here. Judging by other animalcula, we should imagine it had hardly begun, and that the cleft would encrease till the animalcula remained attached only by a point. It is otherwise; for in the twinkling of an eye, one pellet separates from the other in spite of the
apparent

apparent strong adhesion. Each having attained the full size, a faint contraction appears, which is the origin of two pellets similar to the first, that in their turn separate. Thus do the animals propagate (1).

Groupes of different round corpuscula are often seen in infusions of vegetable substances. Sometimes the group consists of four distinct corpuscles; sometimes of five or more: and the corpuscles are commonly different, according to the difference of the groupes, Fig. 8. N. pl. 1. It cannot be denied these groupes are real infusion animalcula: they possess every characteristic; but how are they reproduced? One corpuscle is detached after another from the cluster, which is at last divided into as many portions as there were composing animalcula; and these begin to traverse the infusion with much greater velocity than the respective groupes to which they belonged. It might be objected, that I am stating contradictions, and that the groupes are perhaps the casual or intentional clustering of animalcula, which separate in a given time, and thus occasion these apparent divisions. I had recourse to a decisive experiment, isolating some animalcula in a watch-glass the moment they separated from the cluster. When the solitary ones had acquired the size of their original groupes, fur-

rows

(1) *Monas uva.* Muller, *An. Inf.*—T.

rows were perceptible on various parts of the body, which by little and little was transmuted into a new cluster, perfectly similar to the old. The new group then decomposed into other corpuscles or animalcula, which in size and number were equal to the former. I had the same results from experiments on three different clusters: and we can make no conclusion, but that this is a new mode of a real and actual division.

But the most surprising and singular multiplication is that of certain animated globules, often rolling along like pellets at the bottom of marsh-malva lentil infusions, and visible by the naked eye. They are composed of external tumours, which are so many animalcula, situated above one another, and ready to escape, Pl. 1. fig. 8. N M. Let the reader figure a body almost spherical, formed of concentric strata, each of which is an aggregate of animalcula,—and he will have a sensible idea of these globules. The animalcula composing the exterior, or first stratum, separate from the body, and swim in the infusion: then is the second stratum, composed of similar animalcula, laid open. When all the first have departed, these separate from the body; and the third appears. This also vanishes by the departure of the animalcula that formed it. There are even a fourth and a fifth stratum, and others within to the last in the centre; so that the whole globe,

globe, from the circumference to the centre, is decomposed into a swarm of animalcula. The composing globe, I have observed, has no motion but rolling in the fluid; however, the animalcula, when detached, swim with the utmost rapidity. Their excessive abundance renders it impossible to number them; but, without exaggeration, each globe consists of a hundred (1).

It might be suspected that these globules are composed of many animalcula, at first separate, but afterwards collected together. I have had evident proof of the reverse. While the strata decomposed, I seized some detached animalcula, and immediately isolated them. Each (which did not equal one hundredth part of the globe in size) was as large as the whole in a few days. Their motion relaxed in proportion as they grew; so that when full grown, or complete globes, they had only a rolling progression after the manner of these animals. The exterior stratum was originally smooth: it afterwards became unequal, and covered with tumours. These were as many distinct animalcula, which, in future, separated from the globe to traverse the fluid. The animalcula

(1) Very much analogous to this, and the former, is the *Gonium Pectorale*. It consists of sixteen globular animalcula, invested by a common membrane.—The membrane bursts; and each animalcule becomes the parent of sixteen young.—T.

malcula of the second stratum did the same, as also those of the remaining strata, until the globe was entirely decomposed. This experiment was made on seven animalcula from different strata; and all seven afforded me as many globes.

These are the different generations of animalcula propagating by division, in the way hitherto explained; and which are in reality *polypi* that we will name *infusion*, or, more properly, *microscopic*, to use a general expression, as their kingdom is not bounded by the narrow confines of infusions. I have, at various times, examined the water of ditches, dunghills, stanks, and pools; fountain, snow, and rain water; thermal and medicinal water, both of mountains and plains; and I can affirm, that I have found all more or less abounding with minute polypi of infinite variety. If the multitude is such, that a drop of water contains hundreds, nay thousands, as experiment proves, every one may conceive the number inexpressibly immense, which should be contained in the recesses of all the waters so amply distributed over the surface of the globe (1).

It

(1) The number will rise above all belief, if to the polypi of fresh water we add those of the sea; for, by Muller's observations, the sea abounds in animalcula peculiar to itself.--A.

After the publication of these Tracts, the author seems

It must be remarked, that there are appointed times for these minute animals to originate, and be destroyed, as with other creatures that multiply to excess. Nature has with the wisest provision destined, that when one species begins to be excessively numerous, it is reduced, either from the greater part of the individuals perishing by disease, or a violent death by the voracity of other animalcula: for it is a perpetual and inviolable law with numberless animals, that one lives on another, and mutual destruction preserves each species. The same law is maintained in the originating and destruction of our animalcula. An infusion swarming to day will, in a few days,

to have extended his researches to marine *Animalcula Infusoria*. ‘The salt water, in which vegetable substances macerate and dissolve, contains numerous microscopic beings. Those places in particular, where it is stagnant and so shallow that subaquatic plants die and are decomposed, swarm with these minute animals. The same phenomenon happens in sea water kept in vessels, with vegetable substances dissolving. But what are the laws of nature regulating marine infusion animalcula? Are they the same with those to which the animalcula of fresh water are subject? Some of these propagate by the natural division of the body; others are viviparous, and some are oviparous. —Marine animalcula propagate exactly in this manner.’
Lettera Relativa a Diverse Produzioni Marine.—T.

days, have almost none; and, although thousands perish by a natural death, immense numbers are a prey to the larger animalcula. Sig. Abate Corti has before me observed some kinds carry on the most destructive war. The ingenious method which a cetaceous fish, called by the northern nations the great whale, uses to take herrings is well known: Having driven shoals of them into a bay or strait, a blow is given with its tail, so as to occasion a whirlpool of vast extent and great rapidity, which draws in the herrings; the sea monster then presenting its enormous mouth and tremendous jaws, the herrings are precipitated down the throat, and its stomach is soon filled. The carnivorous infusion animalcula, of which we treat, also create a vortex in the fluid by their vibrating fibrilli; but they are under no necessity of confining the animalcula in narrow limits. If abounding in infusions, they have only to keep their mouths open ready to ingulph them: if rare, they trace them out, and swallow them up. So voracious are they as to feed till they appear much larger: then the pursuit is no longer interesting: the animals become indolent and sluggish. On the contrary, if reduced to abstinence some time in distilled water, they are full of spirit, and eagerly devour the minute animalcula supplied. The transparency of their bodies allows

lows us to see the animalcula, whose motion continues after being swallowed (1).

All the divisions may be seen in every season, even the coldest and most rigorous. Heat as much promotes it as it is retarded by cold: and we may assert, that the time required for division is nearly in proportion to the heat of the atmosphere. In the middle of winter, it takes many hours: in spring and autumn, it is sooner performed: and finishes very soon in summer, especially if great heats prevail. Sometimes less than a quarter of an hour is then sufficient from the beginning to entire completion. This is one chief reason why summer infusions are much sooner peopled than winter ones.

Whoever wishes to employ himself with these curious observations, and the singular modes of multipli-

(1) It is singular, that Muller should deny that animalcula prey on each other. Some species he says prefer being among the particles of dust, animal and vegetable fragments, and seem to take pleasure in gnawing them; but he can easily suppose, that water alone may be their only nutriment, as he has seen the life of large animals, such as Hydrachnae or Entomostraca, supported by water, *Praefat.* p. 12, 13. However, he gives the figure of an animalcule containing one devoured, p. 165.—T.

multiplication by division, and is unwilling to fix the eye too long on the microscope, should prefer summer, if he does not chuse to have recourse to a stove, which my experiments prove operates equally well.

CHAP. VIII.

SEVERAL INFUSION ANIMALCULA ARE OVIPAROUS:
SOME VIVIPAROUS: AND ALL HERMAPHRODITES
IN THE STRICTEST SENSE.

IN my microscopic researches, I have observed, that many species of animalcula become extremely numerous in a very short time, without evincing any signs of division. How, then, do they propagate? Shall we say it is by instantaneous division, and on that account not easily perceptible: or that it is effected in any other manner? Experiment, the only method of dissipating doubt, has shown us that this propagation was not the consequence of division, but from eggs, and sometimes minute foetuses; for I have actually found many kinds of animalcula oviparous and some viviparous. Such an assertion is nothing unless supported by convincing and decisive evidence.

The

The reader ought so much the more to desire conviction, as this is positively denied by Messrs Needham and De Buffon, who exclude univocal generation from infusions entirely. Thus it becomes necessary to descend to circumstantiate details; at the same time preserving due attention to brevity.

One oviparous kind of the largest size among animalcula is found in rice infusions. It much resembles the figure of a kidney bean, except that one extremity is curved into a sharp beak, Plate 1. fig. 9. O. (1). Having seen the wonderful multiplication of this species, without being able to discover whence it arose, I thought of recurring to isolation, which on many occasions had been so useful an expedient. One was, therefore, put in the usual glasses with a little water, which, for security of containing no animalcula, had been a long time boiled. In seven hours, the animalcule was not alone, it had a companion. The new guest was so like the old one, it was impossible to distinguish them. I had no reason to suppose that it came from without, or was produced by the infusion. When the animalcule was isolated, equal portions of the same boiled infusions were

VOL. I.

L

put

(1) The *Kolpoda cucullus* of Muller: It has from 8 to 24 pellucid globules within, which he thinks are the offspring; in the young animals, none are to be seen. *Anim. Infus.* 103, 104.—T.

put into seven different glasses, for the purpose of comparing what might happen in glasses where there were originally no animalcula, and where there was one. But none either of one species or another ever appeared in the seven glasses: and I thought myself right in concluding, that the second animalcule derived its origin from the first. This might be in various ways; whether the first had produced the second alive, or laid an egg from which it came, or by dividing in two. More frequent examination of the glasses was required for discovering the truth. In half an hour, I found something new: two minute pellets at the bottom of the glass, P Q. Plate 1. fig. 9. One was oval; it moved from time to time; and in moving changed its place. Alternate motion and rest continued an hour and a third: then it was more frequent and entirely local, the pellet beginning to swim slowly through the fluid. After the lapse of some time, its motion was as considerable as that of the two animalcula. This, its equality in size to them, being pointed at the extremity, and apparently composed of the the same vascular substance, evinced it to be an animalcule of the same nature, expanding by degrees, and now become most active. While the elliptical pellet presented these phenomena, the round one O exhibited others. Within were included a lesser sphere difficult to be observed, and which

which I perhaps should not have noticed had it not been for a gentle revolving motion upon itself, while the including sphere was tranquil. After various revolutions, the shell burst, and the lesser sphere escaped: the envelope was reduced to a wrinkled irregular substance. The spherule extended, and grew small at one end to form the curved beak; and it began to swim: thus assuming all the characteristics of an animal which the other had. The origin of these animalcula is, therefore, from an egg, represented by the shell or involucre.

But the conjecture required further and more decisive proofs to become an established fact; and such I soon obtained. The glass being left in that state on the evening of 15 June, next morning there were more than forty-five animalcula, all exactly resembling the first which was isolated. At the bottom a number of pellets appeared, part round, part elliptical. With my eye intent on the round, I perceived they did not become elongated, as the pellet mentioned above: one after another burst, and as many inactive misshapen animalcula came out, afterwards growing into complete figures full of action. When the smaller became larger, they did the same. These substances were undoubtedly eggs; still it was to be elucidated whether they had proceeded from the animalcule, which was more than probable. For absolute

conviction, it was necessary to see them proceed from its body, which appeared difficult, not so much from the rapidity of its course, as because it left the field of the microscope every moment, from too great abundance of fluid. The fittest method was confining some in a very small quantity of water, that they might be constantly in view. I did so; and the success was sooner than I could have expected; since, in scarcely a quarter of an hour after confinement, one was delivered before me of a round corpuscle similar to the former: and it having opened, gave birth to one of the usual animalcula, first round, then oval, then diminishing into a curved beak, and commencing motion in the glass, as had happened to its other companions. More eggs were produced: I counted eleven that had proceeded from the posterior part of the isolated animalcule, producing an equal number of young. I might have counted more had not such very minute observations exhausted my patience. From the whole, it is clear that these animalcula are oviparous, and their mode of propagation by eggs.

This particular detail will render superfluous what I should have had to say on many other species also oviparous. I can only assure the reader, that by scrupulously practising such a plan, each species has laid eggs which produced animalcula similar to the mother. Some of these
animalcula,

animalcula, round or cylindrical, originate in infusions of radish and camomile seeds, beans, and buck-wheat.

Let us next treat of viviparous animalcula, of which I have found two species, both carnivorous. We distinctly see the animalcula absorbed by a great vortex, passing down the œsophagus into a little bag, and thence into a larger, apparently serving for a stomach. Each animalcule has a long tail forked at the extremity, by which it can attach itself to the adjacent substances. Two oval bodies project from each side of the tail, and above them two smaller, resembling narrow leaves, Pl. i. fig. 10. R. It is easy to suppose these four bodies integral parts of the animalcule; and the two leaves are actually so; but the other two are real animalcula. We not only perceive them move, but, examined by a powerful magnifier, they are evidently two living animals, resembling the large one, to which they are attached, but confined and contracted within themselves. If kept in view, they gradually expand, are emancipated from the mother, and begin to swim. The opacity of this kind prevented me from seeing the fœtus before it issued from the body. After an animalcule has attained maturity, two young ones are seen where the tail originates. I have never discovered more or less than two in all the animalcula I have examined. In other

animalcula three are to be seen, but them I judged of a different species, because the leaves were wanting, and the interior seemed somewhat different, Fig. 10. S. These two kinds of animalcula are commonly among the tremella of ditches.

Is copulation required for the propagation of their race by oviparous and viviparous animalcula? If I said that I had once beheld a real copulation, ever since I studied infusions, it would be advancing what is directly opposite to truth. But, adhering to the principles of strict logic, from which the naturalist should never deviate, no legitimate consequence can thence be deduced that they do not copulate. Like that of other animals, copulation might be instantaneous, and therefore escape observation. It was possible that the eggs of oviparous animalcula might be fecundated after exclusion from the body of the mother, the same as those of frogs and toads: therefore I had to attain the truth, by obviating every possibility of the contrary, which was accomplished in the following manner. Having put the egg of an animalcule in a watch-glass, I concluded, if the animalcule from this isolated egg produced a fertile egg, there would be no need for copulation: if a sterile one, that more than one individual was requisite for propagating the species, that is, copulation was essential. But the truth is, as many animalcula were produced as

eggs

eggs laid by the solitary animalcule, which succeeded with all the species I examined (1).

A similar method was pursued with viviparous animalcula, by taking several young, one by one, from the parent before being fully developed, and isolating them to prevent all suspicion of mutual intercourse. Each isolated animalcule, in due time, became parent of other two, that is, of two, speaking of the first species, and three, speaking of the second. And these young afterwards had descendants (2).

These two genera of oviparous and viviparous animalcula are, therefore, hermaphrodites in the

L. 4

strictest

(1) Some authors indeed deny the copulation of animalcula. Roffredi says he has been long acquainted with microscopic animalcula, and known the frivolity of their pretended copulations: immediately afterwards, however, he describes that of the eels of blighted corn. Several instances are related by Muller. The copulation of the *Paramecium Aurelia* has continued two hours, *Anim. Infus.* p. 58. The *Trichoda Aurantia*, *Prisma*, *Lyncæus*, copulate; as do the *Vorticella Hamata*, and *Crateriformis*, p. 185. 188. 226. 278. 279. 280. He has seen what he calls both a transverse and longitudinal copulation of the *Trichoda*, *Ignita*, and *Charon*, p. 186. 230.—T.

(2) The *Vorticella Nafuta* propagates both by producing living fetuses, and by the division of its own body into four parts, *Muller*, p. 269. In this it somewhat resembles other animals that produce both eggs and young.—T.

strictest sense. When we find infusion animalcula propagating by division to be such, since isolation does not prejudice their multiplication, it may readily be seen how far absolute hermaphroditism extends in the animated world, though formerly limited to few species.

This discovery tends greatly to elucidate a difficult question concerning the original inhabitants of infusions. Some time after an infusion is made, it will be swarming with animalcula, though the utmost precaution is used against any one being concealed; and for greater security it is boiled several hours. I ask, How do the original founders of the future most numerous inhabitants come there? I can conceive only two ways; they must either have pre-existed in the infusion mixed with it, or they must have come there by means of germs. The first opinion cannot be adopted; for had they pre-existed in the infusion, we are obliged to admit that they would never die when out of a fluid, or that they revive when restored to one, as the wheel animal and some other animals do. But experiments without number have demonstrated to me, that the inhabitants of infusions die irrecoverably on evaporation of the liquids (1). Thus there is a necessity for

(1) Muller, besides quoting Wrisberg's experiments, and mine, says he has observed the same. Decantatus infusorum.

for recurring to the second mode, namely, to some germ or ovulum passing from the air into the infusion, and becoming the origin and source of so numerous a race of creatures. Such an inference acquires

fufiorum vere demortuorum, Vibrionem anguillulam si excipias in vitam reditus mihi sese nullo experimento probavit, nec acutissimis observatoribus, Spallanzani et Wrisberg successit, neque quomodo eadem reviviscant perspicio cum corpora plerorumque post exhalatam aquam rumpi, et in moleculas efflari manifeste video.—A.

Here Muller evidently speaks of complete death. In the second edition of the work alluded to, the *Animalcula Infusoria*, some additional remarks are subjoined to these, which the author has not proceeded to quote.—“But a drop of water being supplied, before complete rupture of the parts, motion and life will return; though, from the violence the animal has suffered, a degree of languor will for some time, or always, remain. If the animalcule is defended from the injuries of the air, by means of any particles of dust or sand casually in the infusion, and the humidity not entirely exhausted, it will recover. Some are destroyed and totally dissolved by simple contact of the air. I have seen some decomposed on approaching the edge of a drop; and even others, amidst the rapidity of their course, I have seen dissolve in a moment.”

Perhaps all animals are subject to instantaneous death. It is frequently found in insects. But the apparent death of animalcula will often proceed from inability to move the members, except in water.—T.

acquires more force and persuasion when supported by facts. I allowed the fluid about animalcular eggs to fail, so that they remained quite dry ten days; then they were restored to their native liquid:—besides being revived, they were soon hatched. From this there is no difficulty in conceiving why animalcula originate in infusions where there are originally none; especially by reflecting on the immense abundance disseminated through the air and on terrestrial substances; and considering the innumerable animalcula inhabiting the waters of the globe.

Every fluid is not equally favourable to the expansion of animalcular eggs. Pure water alone is unfit for it: hence it is no longer a mystery, why in it, and much more in distilled water, we hardly ever see animalcula. On the other hand, they always originate in the water where vegetable seeds are macerated. I have found no fluids better adapted to the production of eggs than those where infused seeds began to corrupt. The appearance of animalcula shews, that incipient putrefaction creates qualities in the decomposing materials fit for development of the egg: for such is the tenor of nature, that eggs are not excluded wherever they happen to be, or in every case, but only in suitable situations, and by means of certain determinate conditions.

I have

I have particularly examined whether animalcula were specifically different, according to the difference of the feeds infused and whether each had its peculiar species. Here I have found no uniformity. Certain species only have been found in particular kinds of vegetables; but it often happens otherwise. Both at different times and different places is there a variety in the animalcula of the same infusion: and it is not uncommon in two infusions of feeds, taken from the same plant, made at the same time, and kept in the same situation; a fact which well coincides with the vast variety of animalcular eggs disseminated in the air, and falling every where without any law.

If we can affirm that all the species, multiplying without any apparent division, do so by means of some pre-organised principle, as is most credible, it must be allowed they form a most interesting part of our animalcula. The other class, propagating by division, and thence called microscopic polypi, present something still more interesting. What can we think of their origin in infusions? Doubtless they also proceed from some pre-organised principle: but is that a seed, an egg, or other analogous corpuscle? If facts are demanded, I acknowledge we have none; as these polypi die when deprived of the fluid, nor do they revive when it is restored, we cannot believe they fall from the air. I have no sensible evidence

evidence of their originating from a pre-organised principle, since it has never been discovered by me ; but, adhering to established facts, this opinion is to be embraced : for, if the polypi, first seen in infusions, are not produced by plastic or vegetative powers, which so many facts have proved chimerical, and cannot be the same that fall from the air into the infusion, it is most rational to infer, that they proceed from some germ, or pre-organised principle, whatever it may be called. It is of no importance whether the germ or seminal principle is invisible, or reproduction of the polypi effected by means of division ; because, with respect to the first, we know that we ought not always to conclude on the non-existence of a thing which we do not perceive ; and in the case before us, the germs may be either too transparent or too minute to fall under our senses ; and with respect to the second, this is not the only polypus which multiplies by germs or eggs, as some others do the same.

I have supposed that the germs whence animalcula originate come from the air ; and this appears most reasonable from the support of undoubted facts, which I shall briefly enumerate (1).

Sixteen

(1) Muller also thinks it probable that animalcula and their eggs come from the air. Praefat. p. 22, 297, 298.

Sixteen large equal sized glass vessels were selected and divided into four classes. Four were hermetically sealed; four stopped with wooden stoppers, well fitted; four with cotton; and the remaining four left open. By this means the external air had no communication with some; very little with others, with the third class more, and as free as possible with the rest. Every four contained infusions of hemp-seed, rice, lentils, and pease; and were boiled a full hour in the vases before being closed up. I began the experiments 11 May, and visited the vases 5 June. In each were two species of animalcula, large and small; but the four open infusions were so full and crowded, that they seemed to teem with life; with the cotton stoppers, they were about a third scarcer; and the animalcula still fewer in the vessels with wooden stoppers; in those hermetically sealed were fewest of all.

The essence of the experiment was the same on taking maize, wheat, and barley for infusion. Instead of using stoppers, I covered some of the infusions with nut or olive oil; and this new obstacle further diminished the number of animalcula.

The immediate consequence resulting from these facts is, that animalcula are more numerous in proportion to the communication of the infusions with the external air. From what we see, their origin is either from germs brought by
the

the external air to the vessels, or, being mixed with the infusions, it concurs to aid the expansion of them. That such germs may be partly mixed with infusions, and the air promote their evolution, I have no difficulty in believing. But the facts hitherto related, evidently demonstrate that the air serves as a vehicle to them ; and as it is impossible in this case to recur to those of the infusion, which should have been destroyed by boiling for an hour, we are under the necessity of referring to those of the air. This fluid entering more freely and copiously, should convey a much greater number of germs into the open vessels, and of consequence the population of the infusions should be greater. The reverse will happen, where little air enters and penetrates with more difficulty, as when the vessels are stopped with wood. The volume of air included in the vessels hermetically sealed, will produce the animalcula appearing there, but few in comparison to those in open vessels, on account of the rareness of the producing germs, which are proportioned to the small quantity of air that is never renewed.

CHAP. IX.

ANIMALCULA POSSESS THE REAL AND CHARACTER-
ISTIC MARKS OF ANIMALITY.

THE existence of an immaterial and sentient principle in animals, rests on the analogy between their organization and operations compared with the organization and operations of man. Many who have had recourse to this kind of analogy, though profound metaphysicians, have not been naturalists enough to examine it as it ought to be. Surely they have not taken the animal progression in its full extent, nor descended to a just and rigorous analysis, which would have demonstrated the inefficacy of analogical reasoning in many links of the animal chain. Without any intention of combating their laudable ideas, let us take a view of them ; and first of the animal organization. It cannot be denied, that the mechanical structure of numberless animals corresponds entirely or in the greater part with that of man. Not to name the oran-outang so similar to us, as differing only in the privation of reason, quadrupeds and birds in this respect could not approach nearer to the human species. The same organs for digestion, respiration, circulation, secretion ;

cretion; the same ramifications of nerves from the spinal marrow, the origin of this from the brain, and the similarity of its consistence; the same meandering of veins and arteries, producing innumerable rivers and rivulets through the whole body, conveying life and nutriment every where. No difference is perceptible in the action of the muscles, ligaments, teguments, cartilages, or tendons: the same variety in the nature, the motions, and offices of the bones. Some long, some bent, some curved into an arch. The hardness vies with that of stone in some: in others, the pliancy is equal to cartilages. Some are hollow and filled with marrow; others solid and massy throughout. Certain bones consist of a single piece, while various parts connected together form others. Lastly, all these animals have the same number of senses, and the organs of them situated in the same parts of the body, and constructed as ours. But it has pleased nature to diversify the figure of these animated machines: sometimes arming them with tusks, horns, nails, or claws: sometimes clothing them with scales, adorning them with feathers, or covering them with a hard hide; diminishing the anterior part of some into a pointed beak, a slender snout, or a long and monstrous trunk; or enlarging it to form a hideous head, frightful to behold, or exciting pleasure by its resemblance to
our

our own. This ingenious creatrix has formed the body of some so as to convey an idea of lightness and grace; while others display a slothful inactivity: one is contracted within itself, and apparently only of a single piece; another extended beyond all bounds; and a third most exactly proportioned. In a word, there are as many varieties among birds and quadrupeds as their forms are different from that of man; yet in every one is there the narrowest resemblance in the essential part of organization.

Analogical reasoning applied to these two races of animals cannot be stronger or more convincing; but how is it weakened by descending the animal scale to fishes, reptiles, insects, and at last is totally lost. Let us attend a moment to the structure of insects. Not only do the bones, blood, heart, and other viscera disappear, but we cannot discover either veins or arteries. A longitudinal vessel from one extremity to the other is seen, in which flows a liquid generally transparent. Although the nervous system is maintained entire, there is no brain, at least nothing properly so: and their respiratory organs much more resemble those of plants than those of the larger animals. Descending the animal scale still lower, every semblance of organs is lost, and the whole body of the animal is reduced to the most simple structure imaginable. Many polypi are

but an elongated faeculus covered with tubercles : Many aquatic animals are simply of a membranaceous or vascular texture. Many marine zoophytes are only a kind of jelly. The organization of these animals has not the smallest relation to that of man ; plants themselves may be said to resemble him more, because we find sap vessels, utricles, and tracheae in them (1).

The

(1) Every small animal was formerly called an insect, and is so still, by incorrect writers. The sub-divisions of animated nature must become more numerous, in proportion as science advances, and peculiar distinctive properties are discovered. A great family has been separated from proper Entomology, and called *crustacea* : but another, much more immense, has been removed farther under the name *Vermes* ; and additional changes are made by every new writer. But it will be long before they are universally observed, particularly in imperfect insects and worms.

It was generally believed, that none of the animals denominated insects had any brain, and very few ventured to dispute the fact ; and after they did so, the reverse was pertinaciously maintained. *Haller* lays it down as a general rule, that all animals, having a head and eyes, must also have a brain and spinal marrow : he thinks, neither eyes without a brain, nor a brain without eyes, exist in any animal ; likewise, that all those with a brain and spinal marrow must also have nerves, *Physiologia*, Tom. 4. p. 2. 155. *Fabricius* says, insects have only the rudiments of a
brain,

The degradation in the organic structure of animals is also visible in their operations. These, in many species, nearly approach to those of man. Such are the operations of quadrupeds in general; but more especially of the elephant, ape, and beaver. Those of birds, likewise, bear much analogy to ours: their ingenuity in constructing nests; the diversity of note to express the various affections of hatred, fear, pleasure and pain; the provident sagacity of many, in changing their climate according to the change of seasons; the facility of instructing birds of prey for the chase:

M 2

all

brain, *Entomologia Systematica*, Tom. 1. In one treatise, the great comparative anatomist Cuvier affirms, they have no brain properly so called, but only a spinal marrow, swelling into knots and tubercles at intervals, from which the nerves proceed, *Tableau de L'histoire Naturelle des Animaux*. However, in his late work on Comparative Anatomy, he describes the brain of many insects divided into two lobes, and sending forth nerves. The nervous system of the various genera of worms is much more obscure. According to Virey, Cuvier, and others, they have no brain, but ganglia on a nervous cord. The latter remarks, ‘Ganglia nearly equal being uniformly distributed
‘ on a cord, extending through the whole length of the
‘ body, seems designed to furnish each segment with a
‘ brain peculiar to itself.’ Neither brain nor nerves have yet been discovered in the actinæ, medusæ, polypi, and many more.—T.

all are qualities proving what I advance. But this analogy exists no more, when we come to fishes, reptiles, and insects. It is true, that among the last are many distinguished by their operations: whether considered by their anxiety for self-preservation, pursuing what is useful, and avoiding what is noxious; whether we consider their mutual anxiety for propagating the species, or singular sollicitude for their young, placing them in suitable situations, and providing them with food until they need maternal assistance no longer. We all know the ingenuity of bees, the sagacity of the leaf-moth (*tignuola delle foglie*), the industry of the ant-lion and spider, the ferocity of the hornet, or the ingenious cruelty of ichneumons. But the operations of numberless other animals are reduced simply to seizing and swallowing their prey, as the arm-polypus; or to open and shut their shells, as many testacea; or imbibing nutriment by an immense number of mouths on the surface of the body, as many marine animal plants.

By this hasty glance at the animal scale, we arrive in the degradation at a race of beings, which, to judge of their structure and operations compared with those of man, we should be more inclined to deprive of a sentient mind than to bestow one upon them. Behold how much analogical reasoning is enfeebled in the intermediate classes,

classes, and totally lost in the lowest, though appearing so evident and conclusive in the higher degrees! Can we thence assert that animals occupying the lowest rank bear the name of animals improperly, from being apparently deprived of an immaterial and sentient principle? This has already been suspected by Bonnet: he who, both as a profound metaphysician and a most able naturalist, has considered the gradual progression of beings so well. After supposing, in the *Corps Organises* and the *Contemplation*, that the polypus is a real animal; and, on this supposition, explaining the most embarrassing phenomena in his *Palingenese*, he does not hesitate to hazard a mechanical explanation, by considering the polypus as an animal simply vital, or endowed with irritability alone; and suspects there may be other animals similar from the simplicity of their structure or operations. Needham goes farther: All animals that repair their parts, lost either by amputation or by natural division, are, according to him, animals *simply vital*, in which he places the immense kingdom of infusion animalcula, since, by M. de Saussure's discovery, they propagate by division (1). But he is less inclined to

M 3

exclude

(1) There is such an immense variety of animalcula, that it is very difficult to say what class they belong to. Some late writers class them among worms, and some among

exclude them from the rank of animals from too great simplicity in structure or operations, than his inability to conceive how an organised being reproducing by division can have a soul.

That beings simply animated, or animals whose life consists only in irritability of the parts, are possible, I can easily believe; especially when speaking of those whose actions are few and little varied, and that by this hypothesis the gradations of organised beings is better united by connecting the animal and vegetable kingdoms by means of such simply vital or irritable beings, inferior to an animal, and superior to a plant. That it is possible infusion animalcula may be of the number, I offer nothing against: nor will any thing in the least disadvantageous to it be seen in what has yet been said in this Tract. Earnest, however, to reduce possibilities to facts, I am much more inclined to judge them real and actual animals than beings simply vital or irritable. There is foundation for my opinion, because an assemblage of qualities is recognised in them sufficient to constitute the qualities of absolute animality. I have had occasion to remark some of these qualities in my Dissertation, such as the exertions of animalcula

among zoophytes. If our microscopes could discover their internal structure, it is most probable that many would be removed far from both.—T.

cula to avoid each other and the obstacles to their course; suddenly changing their direction, taking an opposite one; and passing instantaneously from rest to motion, without any external impulse; eagerly darting to particles of the infused substances; incessantly revolving on themselves, without a change of place, their course against the current, and crowding into shallow parts of the fluid (1). Neither have other characteristics,

(1) M. Guettard, in a work which, from the prodigious multiplicity and variety of matter, might be called a treatise *de omnibus rebus et quibusdam aliis*, is convinced that infusion animalcula are only the farinaceous vesicles of seeds put in motion by external causes: and with this conviction does he judge it proper to discuss the qualities I mention; all which he esteems insufficient to prove the animation of animalcula. To adopt his mode of reasoning, it would be a matter of very great doubt whether horses or elephants were real animals, though possessing the same qualities. But the most wonderful circumstance is, that the author is perfectly innocent of all these matters; and evidently shows that he has never seen a single infusion animalcule in his life. It would be losing time to demonstrate the frivolity of his arguments, fit for the ignorant only. The reader may consult the author himself; and that he may not think me exaggerating, he is referred to Muller, who, without the least connection with me, either by friendship or literary intercourse, undertakes my defence.

characteristics, forcibly corroborating their animality, failed to occur in the composition of this work; partly deduced from various accidents to which they are subject, like other animals, when put in similar situations.

For the reader's convenience, I shall bring my different experiments briefly into view: from the recapitulation, he will be more enabled to understand the use of comparison, which, as he already knows, constitutes no small portion of the work.

Too great heat destroys animal life: 111° is fatal to the tadpoles of frogs, and to frogs themselves,

or rather the defence of truth. *Impresso huc usque libello in manus venit folium 30 novel. Lett. Gottingens. 1772, ubi clariss. Guettard animalcula infusoria meras vesciculas farinaceas arguere indicatur. Accersito libro (memoires sur differentes parties des Sciences et Arts, tom. 2. Paris 1770) avidissimeque, quae de his agunt perlectis, et quasi devoratis, vultu tamen continuo subridente non potui, non admirari doctissimi viri temeritatem, argumentis, quae solo ingenio debentur (vestigium enim observationis ullius infusorii ab ipso institutae nullum extat) tentandi refutationem eorum, quae meris observationibus inniuntur. Nec absque apparenti successu, licet enim meliora clariss. Spallanzani argumenta pro animalitate infusoriorum pugnantia in aream producat, cuilibet lectori, observationum aequae ignaro, ac ipse, fucum facit, quem tamen unaquaque infusoriorum contemplatio dispellet. In re enim naturali non ingenio, sed observatione vivitur.*

selves, the nymphs and larvae of muskitoes, and to water newts: 108° kills silk-worms and the larvae of the blue flesh fly: 106° kills leeches, rat-tailed worms, and water fleas: and animalcula die at about the same degree of heat, that is 106° , 108° , 111° .

All animalcula are not alike affected by cold. Some die at freezing, or a degree not much greater; others survive at 10° . Thus is it with insects. Winter destroys most of them, but many brave its rigour, and some retain the use of their members, as is seen in various species of infusion animalcula. During summer, I have often frozen water in a concave glass where different little insects swam. Freezing began at the circumference, and formed a wreath of ice: but the insects never remained to be imprisoned in it; they retreated to the interior where the water was yet fluid, and, as freezing advanced, collected in the centre of the glass, where they perished on complete induration of the fluid. Infusion animalcula exhibit precisely the same phenomena.

The odours and liquors that are a virulent poison to insects, are the same to animalcula. Such is the odour of camphor, the fumes of turpentine, sulphur, and tobacco. Oleaginous, spiritous, and saline liquors are equally destructive. The electric spark is a real thunderbolt to both. Agents slowly destructive of infusion animalcula
are

are likewise fatal to insects, as the vacuum of an air pump.

The motions of animalcula concur in proving their animality. They are not the same in all, but different, and produced by different means peculiar to each species. Many move in infusions only by undulating the body, as eels do in swimming. That undulation is not similar in every one; for some form a few slight curvatures, others deep and numerous. The figure is formed in a moment by some, by others slowly and gradually. The arms, points, and fibrils, proceeding from the extremity of the body, are instruments for many animalcula to swim: some are long, some short, some strike the water often, others seldom, and the rest with various degrees of velocity. There are animalcula whose motion is very languid, and there are some that move most rapidly. Some move at intervals; the motion of others is perpetual: they never seem to rest. I have seen one species whose posterior fibres, disengaged and separated far asunder, folding together in an instant, darted the animal to a considerable distance, like an arrow from a bow. The course of several species never deviates from a straight line; others continually pitch up and down like a vessel at sea. Some whirl like tops or balls on themselves, without moving from the spot; while others have a progression during this rotatory

rotatory motion. In short, there is no race whatever which, on diligent examination, does not exhibit motions peculiar to itself.

If to all this we join the artifice evinced in forming a vortiginous current to entrap their prey: their ferocious pursuit of the smaller animalcula, their indifference when the stomach is full, and greediness after them when hungry. If we consider all the qualities relative to their nature, motion, and properties, not single and disjointed, but collected and united in the same subject, it is impossible not to admit one of two things: either that an infinity of beings recognized by all the world as real animals are not actually so; or, if they are, such also must be the beings found in infusions.

If we resume the usual mode of analogy, which is the only support of accurate judgment, whether a sentient principle resides in animals, and compare the various operations of infusion animalcula with those of the largest animals and ourselves, we shall not find them so distant or different as not to correspond in several particulars. Besides the organization of many animalcula being so simple as to appear nothing but an aggregate of granuli invested with a skin, and completely included in it: in some we see an assemblage of parts for the most opposite uses, such are fibrilli for a vortex, fins for swimming, a mouth,

mouth, an oesophagus, a stomach, which seems to have a peristaltic motion, agitating the included aliments. I ought to add another organ I have discovered in this new course of observations, which I suspect is destined for respiration. It consists of two stars, with a very minute globe in the centre, and situated, as one may say, in the foci of elliptic animalcula of the largest or middle size, Plate 1. fig. 11. T. T. Whether the animalcule moves or not, the stars are always in alternate and regular motion. Every three or four seconds the minute central globules swell like a bladder to three or four times their natural size, and then fall: the inflation and efflation are performed very slowly. The same is done by the rays of the stars, except that inflation of the globes empties the rays, and inflation of the rays empties the globules. During this alternative, a long narrow ellipse is observed, in the largest animalcula, on the side between the two stars, in continual motion U. (1).

Under this conviction, that the animalcula of infusions are real animals, in addition to the full concurrence of past and present observers, except M. de Buffon, Mr Needham, and a few of their partisans, it gives me inexpressible pleasure to

(1) It is the opinion of several naturalists, that animalcula have no organs for respiration, and live without air.—T.

to see myself joined by a naturalist, whose authority, though standing single, I should not hesitate to oppose to that of all Europe. I speak of M. de Reaumur, that is of one who, in the study of the obscure kingdom of minute animals, indisputably holds the first rank among the naturalists of the age. In letters to M. Trembley and Bonnet, he thus expresses himself on the theories of Needham and de Buffon; and, with respect to the first, he says, ‘ my object was to
‘ verify observations that had given rise to such
‘ strange ideas of the generation of animals. Dif-
‘ ferent infusions have been my deepest study; and
‘ I not only find the imaginary organic molecules
‘ real animals, but that they are similar in gene-
‘ ration to others. That these animals, according
‘ to the new theory, always become smaller and
‘ smaller, I have found absolutely false; on the
‘ contrary, all here proceeds by the ordinary rules,
‘ those originally small at length becoming larg-
‘ er.’ (1).

This celebrated person expresses himself as decisively to M. Bonnet, signifying that he had repeated the experiments on the INSECTS of infusions; that he had examined them most attentively, and for whole hours; and had discovered what had imposed on those who supposed them simple globules in motion.

The

(1) Corps Organisés, tom. 1.

The first extract confirms what M. de Saussure and myself remarked of the erroneous idea which had induced the belief of the smaller infusion animalcula being generated by others larger, and these by some of still a larger size, according to M. Needham and de Buffon's sentiments, who have undoubtedly been misled by a fact very seductive in appearance. It often happens that the whole animalcula of an infusion are of the largest size. By an invariable law, the life of animalcula has a determinate period; therefore the largest perish in a certain time. Frequently, when they begin to diminish, a smaller species is generated, and these are succeeded by some still smaller; last of all comes a colony of less size than any of the whole. One accustomed to explore nature, and to have nothing but her operations in view, will soon perceive there is no relation of parent and offspring among the successive generations. But whoever disdains the trouble of analysing natural phenomena to the utmost, and fancies an hypothesis, that the smaller races proceed from the larger, will readily discover it in every successive colony of a different size.

If, from the reasons adduced, we are constrained to consider infusion animalcula real animals, what can we answer to M. Needham, who conceives himself obliged to suppose them machines simply vital,

vital, and from the singular cause, that they propagate by division? First, I say the author draws a general conclusion from particular facts, as he assumes a general proposition, that all animalcula propagate by division. But many others multiply without it. The objection therefore will affect only those of the first species; and far from not admitting a plausible answer, it had formerly been advanced by the partisans of *automatism*, when a discovery was made, that the sections of the polypus became complete animals, as may be seen in Bonnet's *Corps organisés*; which work, if Needham had taken the trouble to peruse, would have prevented him from publishing his objections; because if in abstruse and obscure matters one is contented with probability, as a wise and rational philosopher ought to be, there he would have found enough to his satisfaction. Therefore I adhere to M. Bonnet's principles, not only because ingenious but just; and by their means we can comprehend and explain how the divided parts of an animalcule are transformed into animated and sentient beings. The fact may be elucidated by an animal many million times larger than infusion animalcula, by the earth worm. Every segment becomes a new whole regenerating in itself the parts deficient, and among others the head and tail (1). The reproduction of these parts,

(1) Prodomo sopra le Reproduzioni Animali, In Modena, 1768,

parts, and the same may be said of the rest, is probably by means of two germs, one destined to develope into a tail, the other into a head. The soul of the worm when entire resided in the head, admitting in general that it resides there in animals. It will also reside in the same part of the regenerated worm, either because God has created a new mind, or, as appears more philosophic, because this mind pre-existed in the germ, and only required evolution to be called into existence. Behold how the sections of a worm are reproduced into new and sentient worms. This with the due proportions may be transferred to infusion animalcula, propagating by natural divisions. These, as far as yet known, may properly be reduced to three kinds, the *transverse*, *longitudinal*, and *anomalous*, or irregular. By the transverse, the animal separates into two parts, one the anterior, the other the posterior. As in the anterior the head remains entire, consequently the soul, that *self*, that personality by which a being may be called animated, will also remain entire. The question rests on the posterior part alone. The progress here is the encrease of this section, until it becomes equal to the whole animal; it assumes the figure peculiar to the animal's head, whether pointed, curved, obtuse, or bell-shaped, and if the animal is of the number that produce whirlpools, the points generating

a vortex

2

3

4

1

5

6

10

7

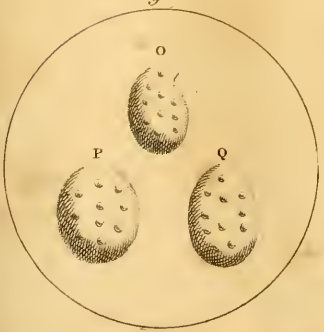

8

11

9

vortex begin to protrude. Therefore I have good reason to believe that a new head is developed, and consequently that this *whole* begins to be animated by a new sentient principle.

The theory easily applies to longitudinal division, since it is undoubted that the soul resides in one of the lateral portions, as it resides in the anterior part, where transverse division takes place, at the same time it is certain that the other lateral portion will be fully renewed, as the posterior part is in transverse divisions. Therefore, if this portion expands to form a real animated and sentient being, it is rational to suppose the same will happen to the other.

The like may be said of the anomalous or irregular division, by which I mean the division of an animal into more than two parts, without being referrible to either the longitudinal or transverse. Into whatever number of parts it divides, each, in acquiring the size and figure of the whole, will acquire that personality which constitutes it a real animal. One part only in these irregular divisions does not require the developement of a new soul, that is, what formed the original head, as is most evident.

TWO EPISTOLARY DISSERTATIONS ON INFUSION ANIMALCULA ADDRESSED TO THE AUTHOR BY THE CELEBRATED M. BONNET OF GENEVA.

ARGUMENT.

MANY of the results in these tracts had at different times been communicated to M. Bonnet, especially in two long letters of 20 December 1770, and 15 September 1771. The answer to the latter will be found in the Tract on Seminal Vermiculi, and that to the other is the first of the following. As these two letters particularly comprise the results on infusion animalcula, it has been judged proper to subjoin them to the tract. What the reader has previously perused will enable him to understand them properly.

According to M. Bonnet's desire, some annotations have been made by the author, where he felt himself necessitated to be of a different opinion. And he has been the more induced to it as he knew M. Bonnet was sincere. These letters, especially the second, would afford a striking instance of the facility with which this great philosopher abandons his opinions, when inconsistent with facts, or less probable than those of another, if his other works did not already demonstrate it.

LETTER.

LETTER I.

My Solitude, 17 January 1771.

THREE of your letters, my illustrious friend, are before me; the first dated 23 November, the second 20 December, and the third 6 January. I owe you a long answer, especially to the second, for it is an exuberant folio replete with new facts, on which it is impossible to bestow too much reflection. How much your interesting details have delighted me cannot be described, nor could I resolve to engross the whole to myself. Mess. Trembley and De Saussure have participated in the pleasure, and both have been equally satisfied; they desire many compliments, with most sincere wishes to you. Their applause was certain; and having traversed these unknown regions, they are the best judges of your discoveries. We all three coincide respecting your letter, and join in the just eulogiums which your ingenuity, accuracy, and correct reasoning merit so well. Some ideas, excited by that interesting epistle, were communicated to these intelligent observers, and appeared to give them satisfaction. I could have wished that theirs had been communicated in return, but M. Trembley delays until nature speaks in more intelligible language; and M. de Saussure till he has repeated the experiments. Therefore I shall alone run over the principal articles of your

curious dissertation, for such undoubtedly is the immense letter you have taken the trouble to write, and for which accept a thousand and a thousand acknowledgements. It has been perused with the pen in my hand, and a corrected extract made, that nothing essential might escape, and that I might be the better enabled to comply with your request. It is only discharging my heavy debt to your friendship.

I. Your distribution of infusions into classes, distinguished by the time of ebullition, has been most judicious. By excellent experiments, we are now assured that two hours boiling does not prevent the production of animalcula; we have even reason to admit that the population of infusions is generally proportioned to the duration of ebullition, and the longer it is continued, the more do animalcula encrease (1). Here then is enough to pulverise

(1) The meaning of my proposition is: although the least boiled infusions had originally few animalcula, compared with those that had boiled more, in time they had immense numbers. This greater abundance is naturally explicable by the increasing dissolution of the infused feeds, because dissolution is a condition most necessary for the population of infusions. M. Bonnet supposes that the additional animalcula may arise from more of them, or their germs, falling into the infusions. I have shewn that it is as little probable that animalcula fall from the air, as

pulverise all the sophisms of our obstinate Epigenesist. The infusions, at first rarely inhabited, became more populous in time, and you ascribe it to the gradual dissolution of the infused matter. As the vessels continued open, one might say the additional numbers depended on the seeds of animalcula, or on animalcula themselves precipitated from the air, perhaps being attracted by the penetrating odour of the infusion. I do not hesitate to make these suggestions: you wish it, and yourself discover many which are similar, in your investigations of nature.

N 3

II.

it is certain their germs do so. Whence I have no doubt that the animalcula, whose numbers increase with the lapse of time, partly originate from new germs precipitated into the vessels. However it cannot be thought, that the accession of these germs alone is equal to the additional population, otherwise an equal quantity having fallen into the infusions that had boiled much, as into those that had not, there is no reason why the animalcula of the first should be abundant in a few days, and those of the second only after an interval of many. A difference so sensible must depend on some secret condition, and I can see none other than decomposition of the infused substances which takes place as much sooner in the infusions boiled much, as later in those that have boiled little.

II. It was already important to see thousands of animalcula in every kind of infusion boiled two hours ; but substances were exposed to a trial still more severe, by roasting them in metallic cups, and then forming powders of which you composed infusions with boiled water. All swarmed with animalcula of every size and description. After this, how can we refuse our assent to the general conclusions which you deduce from such decisive experiments? How can we refuse to agree, that the *vegetative* or *productive* power of our friend the Epigenesist is a perfect chimera? He objects that too great heat in your first experiments might have destroyed the productive power of the matter infused ; yet, when exposed to much greater heat, it was still inhabited by numerous animated beings (1). If the obstinacy of our friend is not invincible, he will yield to such evidence.

III. It seems rigorously demonstrated by your experiments, that animalcula appear in substances included in vessels hermetically sealed, and exposed ten minutes to the influence of boiling water before inclusion. But the reason why as many animalcula are not exhibited in close as in open vessels, we may infer to be, because the excess in the latter arises from the seeds of animalcula and
ani-

(1) It is already seen how much heat was increased.

animalcula themselves precipitated from the external air. Perhaps the communication of the substances with the air may also facilitate their dissolution, and the generation of animalcula in consequence.

IV. By the clearest experiments, you have happily refuted an important objection, that the altered state of the air in the vessels had prejudiced the vegetative power of substances infused; but animalcula continued to appear in vessels hermetically sealed exposed to boiling heat, some from half a minute to two minutes, others from six minutes to twelve (1). The smallest animalcula only originate, and none of the largest or middle sized. Thus it seems sufficiently proved, that those of the higher class cannot originate or expand in substances subjected to similar experiments. A fact which may be the subject of the most profound meditation is demonstrated: the smaller the animalcula are, the less injurious is heat to their generation or developement. I shall soon return to this. If the higher classes are not seen in vessels hermetically sealed, and exposed half a minute to boiling heat, cannot we thence conclude, that all the animalcula you have seen so numerous in infusions boiled from half an

N 4

hour

(1) Ebullition above twelve minutes has not obstructed the production of the smallest animalcula.

hour to two hours, that these animalcula, I say, or part of them, may come from the external air, from that in the vessels or the seeds attached to their sides, or from all three? This conclusion seems the more probable concerning the higher classes. Indeed, if we suppose that they or their seeds lodged in the infused matter, there is no reason why they should not appear in vessels hermetically sealed, and exposed to the heat of boiling water, if that degree was not prejudicial to their appearance. You have proved that they are still seen in sealed vessels of infusions, which have not been exposed to heat. The higher class, therefore, did not pre-exist in the infused matter: But I do not thence mean to insinuate, that they or their germs could not pre-exist in it, for animal and vegetable substances are probably covered with them. I only mean, that these animalcula, or their germs, are probably destroyed by boiling the substances where they are lodged. Are you not surpris'd, my dear friend, that I do not say *certainly* destroyed? But I dare not make such a positive assertion concerning beings so little known. Is it not possible, that the heat of boiling water, or any other of equal or even greater degree, produces no effect but desiccation of animalcula or their germs, and thus reduces them to a state analogous to that of pennated polypi's eggs, which may be kept dry several months, as

I have observed, Article 317 of the *Corps Organisés*? After having boiled vessels hermetically sealed with various infused matter, I wish you would let it cool in the same vessels, and make observations to discover whether the animalcula gradually appear. This simple experiment may be very instructive (1).

V. By your letter, I perceive that the animalcula of what you term the *mediate and highest glass*, which are here more briefly designed of the
higher

(1) My answer to M. Bonnet is thus expressed: ‘The experiment which you, my illustrious friend, proposed, had already been made in part, although the sole object at the time was to examine whether vessels hermetically sealed, and exposed to the influence of heat, would afford more or fewer animalcula in proportion as I delayed to observe them. Therefore, on 26 September 1770, eleven vessels were boiled, and the seals broke 9 October: they contained only the most minute animalcula: five more were opened October 13: they had none but the same animalcula. Thus the prolongation of time had no influence on the production of the largest animalcula.’ Brevity prevents me from relating another experiment, where the effect was similar. We have already seen, that protraction of time did not favour the production of the largest animalcula, or highest class, in vessels hermetically sealed and exposed to heat. I think there is reason to conclude, that the heat of boiling water really destroys the germs of the higher classes.

higher orders, I perceive, I say, that these animalcula cannot expand at 174° , but want of time prevented the extension of your researches on this point. It would be very desirable to ascertain the degree, or to come near it, at which they may be developed(1); and it would be useful to ascertain how much cold they can sustain. All this would have some tendency to elucidate the singular constitution of these living beings, and afford us comparisons and inductions which might throw some light on so obscure a part of the animal kingdom. The evolution of animals is evidently proportioned to the heat necessary for putting their fluids in motion, and for extension of their vessels. The earliest plants are apparently those whose liquids are put in motion by the least degree of heat, and whose vessels afford but little resistance to gentle impressions of their fluids. The life of many insects may be abridged or prolonged by keeping them in cold or warm situations, *Corps Organisés*, Art. 167; and we know there are insects that can support the cold of 14 or 15° of Reaumur's thermometer, and remain alive though completely

(1) By experiments afterwards instituted, I was able to fix the precise degree.

ly frozen (1). To the celebrated Reaumur are we indebted for our knowledge of this part of the animal economy. In January 1767, I repeated the curious experiments with frozen insects. Chrysalids of the beautiful cabbage caterpillar were exposed to 12 or 13° (2); they seemed completely frozen; and, when dropt into a china vessel, sounded like a stone. But they were not dead; and, towards the middle of May, the butterfly appeared, nor was the transformation later than of others of the same species that had passed winter and part of spring on the stove of my apartment. Infusion animalcula might in this way present much more surprizing facts: we have only to invent experiments fit to discover them. The subject is too interesting not to excite the curiosity of a naturalist as intelligent as you (3).

VI.

(1) M. Bonnet means these degrees below freezing; because the scale of Reaumur's thermometer begins at the freezing point, or 32 of Fahrenheit's; therefore 14 will be nearly 0, and 15 about two below 0 of Fahrenheit's.—T.

(2) About 5 and 3 of Fahrenheit.—T.

(3) My answer to M. Bonnet informed him that I had anticipated the experiment he suggests; but that the communication was reserved until I had obtained enough of facts. These are detailed in the Tract,

VI. I now come to that article of your letter which has given me the most agreeable surprize, and affords most ample matter for reflection. You have completely proved that the smallest animalcula, or those I denominate the *lowest class*, originate and expand in infusions exposed from half a minute to twelve minutes to the effects of boiling water, in vessels hermetically sealed; while it is at the same time demonstrated that the animalcula themselves perished at 106 and 108°.

Here undoubtedly is a most important fact which philosophers would never have suspected without deep meditation on the nature of germs, and their analogy with the elements. This excellent discovery has given me much pleasure: it seems to corroborate my sentiments concerning germs; and the reflections which it has excited shall be submitted to your opinion.

You know, my dear friend, that the more diaphanous a body is, the less is it heated by the rays of the sun; and the greater the number of pores, the more open and direct, the less do the rays act on their sides. The celebrated Bouguer reasonably attributes the excessive cold felt on the highest mountains to the extreme rarity of the air admitting too free passage to the solar rays for them to make any sensible impression on this fluid. It is easy to conceive that some bodies may exist, so thin, homogeneous, and perfectly diaphanous,

nous, that light or heat may traverse them without impressiion. Even the densest and most opaque substances become transparent when divided into lamina extremely thin. Gold is a most remarkable instance (1). May not the germs of animalcula of the lowest class be among those substances so thin and transparent that heat may traverse them without alteration? Let this idea be prosecuted farther: it merits consideration.

The animal and vegetable kingdom first appear under the form of a whitish jelly more or less transparent. Such is the original form of the majestic oak and the powerful rhinoceros: in the beginning they are but a drop of jelly, and still less. Were we permitted to ascend higher in the animal and vegetable origin, we should find them much more transparent. We are acquainted with

(1) So far as I know, it can only be said that gold is not absolutely opaque; for brought to the greatest degree of thinness, $\frac{1}{180000}$ part of an inch, it appears of a green colour. Possibly other metals might transmit light if they were sufficiently malleable to bring their pores into a straight line; for it is hardly to be supposed that any substance is without pores, or does not consist of component parts, until we arrive at the atoms of matter, if there is such a thing. But it is a very different question whether the pores of some substances may not be smaller than the particles of light, however minute these are supposed to be.—T.

with insects which are so all their lives, and continue gelatinous during existence. Such are those belonging to the singular and numerous family of polypi: also the animalcula of infusions. How many insects should be transparent in their primitive state in the state of a germ! It is, indeed, a most remarkable fact, and on which sufficient attention is not bestowed, that all animals and vegetables are, in their original state, nearly of the same consistency, and those which, like the oak and rhinoceros, afterwards acquire the greatest solidity, have at first no more than the polypus. By what wonderful mechanism does nature bring them to the degree of consistence and opacity proper to the species? Here obscurity thickens more and more. Only the rudiments of the profound theory of increment are known. These rudiments I have attempted to trace in *Part II. Palingenesie Philosophique*, and shown the philosophic naturalist in what manner he may throw more light on this important subject. The principles, by which I many years ago attempted to give a reason for increment, are in some measure confirmed by Nature herself. M. Herissant has been her interpreter; and his excellent experiments on the growth of the bones and of marine bodies have greatly strengthened the probability of my ideas. He has communicated them to us; and I have had the satisfaction of doing justice to his

his

his labours. M. David of the Royal Academy of Sciences of Rouen, an excellent anatomist, and well known to the public by his various works, has just published a treatise on the increment of the foetus, where he inclines to adopt my principles, and establish them by new facts. On that subject, he has communicated information which gives me so much the greater pleasure, as it supports the opinion of M. Herissant, and as I had not indulged such hopes of approaching so near the great work of Nature. But this treatise I have not yet procured.

Increment supposes nutrition, and this the incorporation of numerous heterogeneous substances, terrene, oleaginous, saline, and others. All these are assimilated to the organic texture by its own interposition. It is the chief instrument of assimilation, consequently of the almost infinite partial secretions which are operated in all the organic points of this texture, and on which increment and solidity finally depend. At first the blood of a chicken is colourless; it next becomes white, then yellow, and lastly red. It colours and thickens only by the introduction of terrene aliments; therefore it should lose the primitive transparency in proportion as the animal grows. The gradual incorporation of foreign particles should obstruct the pores more, and shut the avenues to light.

What

What happens so much at large in the chicken probably passes in infinite miniature among our infusion animalcula. They feed; they expand by nutrition; and the more nutriment they take, the more is their transparency lessened, but it is never entirely destroyed. Their delicate vessels do not admit particles sufficiently gross or homogeneous to accomplish this. Those assimilated are proportioned to its extreme fineness (1).

While animalcula of the lower orders remain in their original state of germs, their transparency is probably so complete that light or heat traverses them without impression. It may be possible that the germs are so small as to admit only one or two rays of light. But when expansion commences, they begin to assimilate foreign particles with themselves. The association of these with the elements of the texture tends more or less to diminish the transparency, consequently to allow more influence to light or heat. It is nearly the same as with air, which, being condensed

(1) The parts of many animals are never expanded by nutrition. There is hardly an insect known that grows after its last metamorphosis; and if any do so, their increment is too sudden to arise from nutrition. A caterpillar feeds voraciously on leaves: Its size rapidly increases: it changes to a butterfly, which lives on the purest nectar of flowers; but increment is at an end.
—T.

condensed and loaded with foreign atoms; becomes susceptible of a greater degree of heat by the influence of light or fire.

In this way, my esteemed friend, do I conceive the germs of the lower animalcula can withstand the heat of ebullition, and how the animalcula themselves perish at 106° and 108° . Nutriment gradually changes the original constitution of animalcula, and incorporation of a quantity of foreign matter gives an efficacy to heat which it could not previously have. The nutritious atoms becoming constituent parts of the minute organic whole by incorporation, heat cannot but have such influence upon them as, to a certain degree, to affect the vital functions. Perhaps animalcula may exist in the atmosphere so perfectly diaphanous, and feed on substances so rare, that they may pass through the fire without perishing. These would be sylphs and gnomes a little less fabulous than those of poets: Your animalcula of the lowest class are gnomes yet more real.

All this has much analogy with what I have said, in the first five parts of the Palingenesie, on the little *ethereal* body which I have considered the real *abode of the soul*, and which, according to my ideas, has been rendered capable of triumphing over the effects of time and the elements to preserve the *personality* of the animal,

and one day restore it under another form. It is singular that direct experiment has already brought animalcula into view which resist the heat of ebullition. This is at least a small presumption in favour of my hypothesis on the future restitution of animals. It may remain to expose the germs of these animalcula, or rather the substances where they lodge, to fire. Let us despair of nothing; but let us investigate Nature farther. You understand how to interrogate her as she ought to be, and to you will she make her most favourable responses. You will not presume, apparently, that fire may be the natural element of a race of animalcula, much less will you think with M. Robinet that it is only an aggregate of animalcula. You limit yourself with inquiring, by judicious experiments, what degree of heat animalcula, in the state of germs, can support without destruction.

I greatly approve of your extending these experiments to the eggs of insects about which we know so little (1). Those of many butterflies, beetles, or flies, may afford ample scope for obtaining evidence fit to stimulate the scrutinizer of Nature. Reaumur's experiments, satisfactorily proving that one may prolong the duration of the embryo's life in the egg, are directly

(1) These have been detailed.

ly the inverse of those you propose on the eggs of insects. The life of the embryo in the egg evidently differs much from that of the animal developed. Therefore it is a law of the animal economy, that the germ of the embryo can support situations or accidents destructive of the animal evolved. Were we able to compare these two lives exactly, much light would be thrown on the experiments which we should make of this nature, and the effects that would ensue.

But how far is our physiological knowledge from extending to that ! We know the germ or embryo only by some of the most prominent, I should say the grossest features ; and we are ignorant of its principal connection with the various parts surrounding it in the egg. The little of the whole that we know only respects the chicken. How can we hope that the light of observation will one day penetrate the secret organization of an insect's egg infinitely minute when compared with that of a hen ? What a profound abyss to us is the egg of an insect ; but what subject in natural history, philosophy, or metaphysics, does not present similar abysses ? The sage will select the least profound, and consider them with modest and respectful reserve.

I have just re-perused the eighth and ninth chapters of your first Dissertation on Animalcula,

which appeared 1765. In page 117, you reason plausibly, without suspecting that experiment made by yourself would one day be adverse to it. You undertake to refute the author of *Lettres a un Americain*, who thinks, without any direct proof, that heat of great intensity is requisite for the production of certain animalcula, and expresses yourself thus. ‘It is enough that we view the fine and delicate texture composing the internal mechanism of the animal, which may be considered an assemblage of the slenderest silken filaments, and we shall easily be sensible what ravages and destruction an irregular intestine heat would cause among them: If we see this heat, in warming the fluid, kill adult and vigorous animalcula, so much the more will it affect them in their integuments while yet weak and tender.’ Nature itself evinces, that it is the germs or integuments of animals which support the heat of boiling water, whereas the animalcula themselves perish at 106° and 108° . This instance, like many others, proves how the most specious arguments may become deceitful in philosophy, and that we should distrust conclusions merely rational in subjects of natural history and philosophy. Thirty years ago, if one had asked the most acute philosopher, or the most expert anatomist, Whether he conceived that an animal could be multiplied by cutting it

in

in pieces, or even by mincing it down? Do you think, my worthy correspondent, that this philosopher, or anatomist, would not have advanced an hundred good reasons to prove the impossibility of the fact; and would any anatomist have been found attempting to combat his reasons? What would have happened had we asked that anatomist, If he thought an animal could exist which might be turned outside-in, like a glove, without ceasing to live, to grow, and to multiply? Nothing is fitter than such discoveries to inspire us with diffidence of our own opinions, and to create the most exalted ideas of the infinite variety of Nature's operations. This reflection, equally moral as logical, has often occupied a place in my writings. I have strongly endeavoured to inculcate it into the minds of my readers. While composing parts 12 and 13 of *La Palingenese*, it engrossed me much; and I attempted to point out the bounds and the natural imperfections of our knowledge. All that is said on this fertile subject is little in comparison to what a writer more enlightened and intelligent than me could have said. But I have mentioned enough for my principal object, and for the reflection of those readers who are capable of such meditations.

Perhaps you know, that the Abbé de Lignac was the author of these *Lettres a un Americain*,

whom you refute from a criticism on M. Needham. It appears that M. de Reaumur valued this work of his friend the Abbé; he sent me a copy with many requests to read it. His method does not please me: His criticism on M. Needham and de Buffon is loose and injudicious. Several points, however, are well founded; but he is neither philosopher nor observer enough to treat such matters skilfully. His theological sentiments often seem to spoil his philosophical. Some years afterwards, this same Abbé de Lignac undertook the refutation of some metaphysical works, and particularly the *Essai de Psychologie*, whose author you may one day enquire for of me. I can well assure you that the refuter has never understood this essay: all his objections are false; he censures the author every where; and what is still more strange, he puts a confession of faith in his mouth, the most absurd and opposite to the author's real sentiments. He prints it in Italic characters, as if the psychologist's own expressions. The title of this refutation, *Le temoignage du sens intime et de l'experience, oppose a la foi profane et ridicule des Fatalistes modernes*, 3 tom. 12. So he classes the psychologist among the modern fatalists, whose creed is profane and ridiculous. I have not understood that this absurd psychologist ever thought of answering his keen and inconsiderate adversary. Doubtless he has conceived that

that his time would have been misspent; and that his *Essai* would give no offence to those who could penetrate into the abstract points which serve as its basis. What could he have replied to a critic who forgot himself so much, as in some measure to become an accomplice of the detestable parricide Damiens? Those acquainted with the psychologist, knew that he has fully forgiven the monstrous errors of his critic. I also know it. How odious is it to attempt refuting an author by attacking consequences which may have any latitude according to the will of the critic! (1).

O 4

I

(1) Oftener than once I have felt myself inclined to reproach M. de Bonnet with some of his ablest metaphysical opinions being adopted from an *Essai de Psychologie*, by an anonymous author. His keen defence of the work, his very partial expressions in that defence, the *Psychologie* itself, altogether induce me to suppose him the author: Although I conceive the whole, I cannot explain myself further. But my readers may be assured, that the author of the *Psychologie* will not revenge the plagiaries with which some persons have reproached the Genevese naturalist, because, to my certain knowledge, he did not commit any; and if he had, he would have openly acknowledged them. I also know, that he is very far from adopting all the ideas in the *Essai de Psychologie*. He has even
impugned

I return to the original transparency of organized beings, concerning which your lower orders of animalcula have given me scope for reflection. In my *Considerations sur les Corps Organisés, Part 1. ch. 9.* you have seen the accurate discoveries of Haller, and the different consequences that seem to flow directly from them. These discoveries, which have gone far to perfect our knowledge of generation, form a series of facts, which I have ranged in a certain order, to present them with more precision and regularity to the mind. The second fact is thus expressed:—‘ The solid
 ‘ parts of the chicken are at first fluid: the fluid
 ‘ gradually inspissates and becomes a jelly: the
 ‘ bones themselves successively pass through the
 ‘ fluid and gelatinous state. On the seventh day
 ‘ of incubation, the cartilages are still gelatinous:
 ‘ on the eighth, the brain is but a transparent
 ‘ water, and is undoubtedly organized. Mean-
 ‘ time the foetus already moves its members.
 ‘ The vessels having become larger, admit gummy
 ‘ albuminous molecules, which are attracted to-
 ‘ wards them. The more the proximity of the
 ‘ element

impugned some, and laments his not having extended his criticism on the most important topics in the work.—A.

M. Bonnet was indeed the author of this anonymous work; he afterwards acknowledged it; and republished it in the collection of all his works in 9 vols. 4to.—T

‘element encreases, the greater force does the at-
‘tractive power acquire. The organized fluid is
‘thus conducted to mucosity by degrees: it be-
‘comes a membrane, a cartilage, a bone, by im-
‘perceptible shades, without the interposition of
‘any new part.’ There is still the third fact,
which so well establishes the primordial transpa-
rency of the solid parts of the germ. ‘It is only
‘on the sixth day that the lungs are visible; then
‘they are but ten hundredth parts of an inch in
‘length. If it was not for the transparency, they
‘would have been visible at four of these hun-
‘dred parts. The liver is larger still when it be-
‘gins to appear: it is on account of the trans-
‘parency alone that it is not visible sooner. From
‘mucous transparency to whiteness there is only
‘one degree, which simple evaporation suffices to
‘produce.—White is therefore the original colour
‘of the animal, and mucous transparency seems
‘to constitute its original state.’ You see what
I then said of the integuments, which are at first
so transparent that the external parts which they
invest appear perfectly naked. Therefore it seems
sufficiently evident, that fluidity and transparency
constitute the first state of an animal. In diffe-
rent passages, I have taken care to observe, that
this fluidity is but a simple appearance, and only
marks the extreme delicacy, or the wonderful
fineness of a texture already organized. Now,

if

if the solids of the chicken are originally so delicate and transparent, how much more ought they to be so in infusion animalcula, which, when fully developed, are but infinitely minute drops of transparent jelly? Thus, to guard organized beings against impressions of the elements, no more is necessary than increased minuteness and transparency. Those animalcula of the lower classes, so extremely minute, and which, according to you, are as *ants to whales*, are perhaps themselves as whales compared to many other animalcula. It may be so small that our best microscopes can never bring them into view. Probably we shall always be ignorant of the last terms into which organized matter can be divided. Somewhere I have said, the confines of the microscopic world alone are discovered.

VII. You were naturally induced, my worthy correspondent, to make the same researches on seeds exposed to heat as you had made on animalcula. I was very earnest that you should attempt similar comparisons between the two kingdoms, which I have before mentioned. Your letter presents interesting results, which shall occupy me a few minutes.

I am not surprised that buck-wheat and maize germinated in vessels hermetically sealed, or that their vegetation soon ceased. The little air included would serve for the first expansion of the germ,

germ, but would not be enough for its farther developement. So small an atmosphere must soon be furcharged with vapours and exhalations injurious to the young plants. Every thing that vegetates requires renewal of the circumambient air from time to time. The want of it is more sensibly felt by vegetables of the higher classes than by those of the lowest. These, I should conceive, would vegetate better in vessels hermetically sealed than legumes, and more especially ligneous plants. The higher a vegetable stands in the scale of organization, and the more complicated its life, it depends on a greater number of conditions, and conditions more diversified.

VIII. From your first experiments on seeds exposed to the action of boiling water in vessels hermetically sealed, it follows, that two minutes boiling does not prevent germination; but it is otherwise where they have been exposed two minutes and a half. It is very remarkable that the difference of half a minute should prevent germination: and this fact tends to prove how much the duration of an experiment affects the animal oeconomy.

In this respect, you have not observed any difference between seeds in open vessels and those hermetically sealed: Neither of them exhibited any sign of germination when boiling was protracted above two minutes; which should have happened after you had ascertained that seeds germinate in
vessels

vessels hermetically sealed. Here, then, the hermetic seal was a matter of indifference.

You remark, that the period of germination is proportioned to the duration of the experiment. The shorter it is, the more immediate the germination: a consequence which it was easy to foresee. As extreme heat is unfavourable to vegetation, it should naturally be retarded in the seeds longer exposed.

You also saw many more plants germinate of those in open vessels than in vessels hermetically sealed. Both were indeed exposed to the same heat; but the air in the open vessel could be renewed. The plants there should on that account have continued vegetating, while their vegetation soon ceased in the close vessels, which in fact you have seen.

IX. From all your experiments, a general and comparative result is deduced. 'It is not with seeds as with animalcula. The production of these is more immediate, in proportion as the heat is more intense: with the others it is precisely the reverse.' The vegetable organic system differs greatly from the animal. The laws of the one are not those of the other. The principle of the motion of the fluids is not the same in both: they are not nourished in the same manner; nor are their origin and development subject to the same restrictions. It is true, we discover

discover many analogies between the animal and the vegetable. This is a subject which has employed me, *p.* 10. *Contemplation de la Nature*. But, amidst all these resemblances, how many dissimilarities are there? The time is not yet arrived when we shall be able to extend experiment as far as it may go. Nor have experiments and observations hitherto been sufficiently numerous and diversified. They have been made but for a day; yet what an assemblage of unexpected facts have been obtained! Still are we ignorant of the character essentially distinguishing an animal from a vegetable (1). This interesting subject

(1) One of the most modern physiologists, distinguished by his philosophical researches, has made a long comparison between plants and animals, which I shall here abbreviate.

‘ The difference between the solid parts of vegetables
 ‘ and the bones of animals is immediately evident. The
 ‘ wood is formed by a layer of bark changing its place.
 ‘ The bone by the expansion of a net-work, all the parts
 ‘ of which at once expand; and it borrows nothing from
 ‘ the surrounding flesh as the wood does from the bark.
 ‘ Every year the wood acquires a new ring, and the full
 ‘ diameter is preserved until decrepitude; but the bones
 ‘ become thinner. Broken bones unite; wood never does.
 ‘ The bones are nourished by the surrounding parts; the
 ‘ wood is an assemblage of lymphatics providing sap to
 ‘ the

ject is discussed in the last chapter, part 10. of the *Contemplation*. ‘ Organised matter has received

‘ the plant. Marrow exists in the bones of an animal during all its life; the medullary substance of plants disappears in a few years. Bones are connected by muscles; plants have no moveable articulations.

‘ There is nothing in plants corresponding to the senses of animals. They have neither sensation nor nerves; and being destitute of this principle of motion, as they are without muscles, we are necessitated to ascribe the particular motions sometimes visible to mechanical causes.

‘ The course of the vegetable fluids is very different from the animal: there is no circulation, properly so called, in plants. The juices imbibed by the roots ascend and join those imbibed by the leaves: the rising fluids do not resemble the descending. There are no valves in the vessels of plants.

‘ Animals have a principle which is the origin of their motions: the heart is the spring of the machine, by impelling and preserving the impulse of their fluids. Plants have no organ similar, or which appears to supply its place. We cannot be certain that all their vessels are tubulous. Some, as the utricles, are involved in each other; and those which raise the sap do not resemble those that convey it back to the lower parts. Plants have several spiral vessels; animals have none similar: and if insects have tracheæ, certainly they are very different

ceived almost an infinite number of modifications, and all are as the shades of prismatic colours.

ferent from those of plants, since in the one they are air vessels, and in the other, vessels for the juices.

The traces of irritability only appear in certain parts of some plants, and in particular circumstances: We must explain their motions by a peculiar mechanism, regulated by the increase of the fibre, and especially of certain parts, as well as by the changes of the fluids in their vessels.

Vegetables do not respire air like animals: If the leaves were lungs, most plants would respire none during winter; and if the tracheæ were air vessels, they would not supply the place of the leaves, since none are in the bark. By the action of light on their leaves, plants decompose carbonic acid and give out oxygen gas, which is very different from the carbonic acid formed and discharged by animals, for the greatest part of that formed by plants in close vessels is a product from their alteration.

In animals, respiration is a source of heat: the decomposition of oxygen gas provides the blood with its caloric, and disengages the superfluous carbon, by combining with it to form carbonic acid. But in plants, the consequence is different: the carbonic acid which decomposes by light abandons its oxygen to the caloric, with which it forms the oxygen gas that escapes; thus depriving the plant of that source of heat which it might derive from light. Plants indeed form carbonic acid by

the

hours. We make points, we draw lines on the figure, and this we call a division into classes and

the combination of their carbon with the oxygen gas of the air; but the quantity is very small when the plant is in health, so that the caloric disengaged cannot be great, and it is disengaged at the exterior of the plant.

Most animals have a mouth for their aliments. Plants have as many as fibres and pores. There is no resemblance between the food. The ejecta of plants are generally gases, which must be collected and confined before becoming sensible. Animals feed only at stated periods; vegetables continually.

Most animals possess the faculty of emitting sounds; vegetables do not.

Can the nocturnal position of plants be called sleep? Is it repose or watching to have the leaves turned to one side more than to another, without any apparent relaxation? How can we suppose that the *tragopogon* watches three or four hours, when the flowers are open? It is evident, if the leaves changed their position their stalks would not be pendant; they are constantly close, and the leaves float no more than the flowers.

The phenomena of vegetable generation have no greater analogy to those of animals. Hermaphrodites are rare in the animal kingdom; most plants are strictly hermaphrodites. Very few want visible sexual parts; but the number of animals deprived of them is very great.

Animals

‘ and genera. We observe the predominant colours, while the delicate shades escape our notice.

‘ Animals reproduce only after attaining their perfect state: many plants multiply that are far from it, and are fecundated though they want leaves. In animals, the generative organs remain after fecundation, but they fall from plants, which have none the greatest part of their existence: then they are repaired, and in a different place from their original situation.

‘ Animals, that reproduce by the concurrence of sexes, propagate in no other manner, whereas plants multiply by shoots and buds, so that each part of a plant can furnish another complete individual. Finally, the generative organ of many becomes the fruit.

‘ The eggs of animals are full of a particular fluid; but feeds of a solid farinaceous substance.

‘ The number of germs is infinitely greater in the vegetable than in the animal kingdom; few animals reproduce by shoots.

‘ A tree, cut down during winter, will sometimes live till the following autumn, and be covered with leaves and branches.

‘ What animal may be ingrafted on another, as a peach tree on an almond? The graft of a polypus is different, for it is the same animal growing upon itself.

‘ Animals grow by a proportional expansion of all their parts, but leaves, flowers, and fruit, constantly remain the same after evolution.

‘ tice. Plants and animals, therefore, are only
 ‘ modifications of organized matter : all partici-
 ‘ pate

‘ Plants lose part of their organs during winter : still
 ‘ they live and are preparing to resume their original
 ‘ state in spring. This cannot be compared to the sleep
 ‘ of marmots, for in their organs, there is no apparent
 ‘ alteration.

‘ *Berthollet* has properly characterised animal and vege-
 ‘ table substances by shewing that the caustic alkali, which
 ‘ dissolves the former, does not act on the latter ; and that
 ‘ animal substances, with nitrous acid, gave out much
 ‘ azote, which, in distillation, produced ammoniac, by
 ‘ combining with the hydrogen of water : while vegetables
 ‘ afforded an acid by distillation, and an ardent spirit by
 ‘ fermentation, which has no resemblance to ammoniac.

‘ The singular work of *Girod Chantram* is known to me
 ‘ only by an extract. Like him, I had observed the glö-
 ‘ bules of certain confervæ of different spherical figures,
 ‘ but I found no animality. These researches were finished
 ‘ long ago. I communicated them to my friend *Spallan-*
 ‘ *zani*, and requested him to repeat some of my observa-
 ‘ tions. He did so ; but he could discover no kind of ani-
 ‘ mation in these plants. The chemical analysis by *Tingry*
 ‘ of the *Conferva Bullosa*, and my own of the green substance
 ‘ forming in vessels of water exposed to light, produced
 ‘ nothing more relative to animality than the analysis of
 ‘ other plants. Even admitting the animality of these
 ‘ Cryptogamia, I cannot see how it would prove that
 ‘ of other vegetables. *Senebier Physiologie Vegetale*, tom. 5. p.

‘pate of the same essence, but the distinctive attribute is unknown.’ The animal has derived its name from that soul which is considered the secret principle of its actions; and its existence is judged by the analogy seen between the soul of an animal and the soul of man. We should endeavour to discover the precise degree of organization when the capacity to be animated terminates; or, which is the same thing, at what degree a soul cannot be united, to compose that kind of identity which we denominate a mixed being. For, if in the quality of a physical being, the animal differs essentially from the vegetable, this ought to arise from that part of its organization which constitutes its physical animality. The nerves are the part which apparently render an animal animated. By their offices is the mind sentient and active: they are intermediate between the soul and the body. By means of them, the

P 2

mind

‘188.’ The reputation of M. Senebier is well known, and his opinion must have great influence on naturalists. His arguments against the animation of plants will be found more at large in the original work. Some of them however may be liable to objection, although the rest are well founded. Hooper’s *Oeconomy of Plants*, and Darwin’s *Phytologia*, contain many principles opposite to M. Senebier’s. Both works merit high consideration, as they descend minutely into vegetable properties. The precise term when animality terminates is yet uncertain, nor will general rules to find it be easily given.—T.

mind conceives the impressions of objects; by them does it act on the members; and, by the members, on every different thing. We cannot conceive that a soul should be united to a portion of organic matter through which no impression could be transmitted; and it can be easily imagined, that mind may reside in every portion of organized matter provided with nerves or any thing analogous. Real nerves have not hitherto been discovered in the vegetable; but it is no reason to suppose them absolutely destitute of either nerves or something analogous. You have read what is said, *Part 10. ch. 30. 31. Contemplation de la Nature*; and in *Part 4. de la Palingenese*; to which I have nothing to add (1).

X. If

(1) These reflections, on the distinctions between the animal and vegetable, cannot be more profound or logical. By means of the difference, the author apparently means to insinuate, that we ought not to be surpris'd that heat has such opposite or various effects upon animals and vegetables. But this difference may be satisfactorily explained, without recurring to the dissimilarity between the two kingdoms, which I told M. Bonnet in the following paragraph of a letter: ‘When I observed, that *the same results did not proceed from my experiments on seeds as on animalcula*; that *the longer the action of heat is continued on the latter, their origin is the more immediate, and the number greater*; and that *the reverse happened to the former in the*

‘*same*

X. If the conjectures I have already hazarded have any probability, it ought to appear more surprizing, that feeds support the heat of sand at 185 and 212°, without losing the germinating power, than that the germs of animalcula may

P 3

expand

‘ *same situation*, I only related a fact, which may be ac-
 ‘ counted for without recurring to the difference between
 ‘ animals and vegetables. The continued action of heat
 ‘ obstructs the expansion of vegetable feeds and infusion
 ‘ animalcula. This my experiments have proved. But
 ‘ if it shall happen, that after a certain period the infusions
 ‘ are full of animalcula, it is evident they do not owe
 ‘ their existence to germs, which have been exposed to
 ‘ heat, but to some precipitated into the infusion after it
 ‘ has cooled. Therefore animalcula are produced by new
 ‘ germs: but feeds not having the same advantage, it is
 ‘ no wonder that those which have suffered the action of
 ‘ heat do not germinate. Were they suspended in the air,
 ‘ as animalcular germs probably are, plants would un-
 ‘ doubtedly be produced as well as animalcula.’

M. Bonnet is now of my opinion. “ I subscribe,” he replies, “ to your reflections on the difference between
 “ vegetable feeds and animalcula which have been exposed
 “ to boiling heat. You have truly good reason to say,
 “ the higher class of animalcula, which are produced af-
 “ ter boiling the infusions, do not come from germs
 “ which have endured such violent heat, but from those
 “ that have fallen from the air after the infusion has
 “ cooled.”

expand after enduring the heat of ebullition. As these germs seem incomparably more delicate than those included by seeds, our surprise must augment in proportion to the increasing delicacy of the organic wholes, on which these experiments are made; yet, in my opinion, this excessive delicacy of texture is the very thing that will protect them from the action of heat. The germ of a bean is large in comparison to the germ of an animalcula; thus it should suffer much more from heat; and, as more extensive portions are presented to this element, its action should be more powerful. However, we are not sufficiently acquainted with what constitutes life in the germ of an animalcula, or the embryo of a plant, to be enabled to judge correctly of the matter. By your experiments, and those of M. Duhamel, we learn that seeds do not lose the germinating faculty at 212° , and even 234° , of Fahrenheit's thermometer. Senegal is not without vegetables: there the thermometer often stands at 122° , or 133° , in the shade; which will make the direct heat of the sun 212° or 232° , according to the experiments of President Bon of the Montpellier Society (1). Thus, there are vegetables
produced

(1) These experiments were fallacious, because they were made without the necessary precautions. In summer,

getation, it is very certain, that its last effect is to extend the plant in every way, and to increase the size. This secret I attempted to penetrate, *Part 7. ch. 7. de la Contemplation de la Nature*; and my sentiments, on a subject so obscure, have been a little extended, *Palingenesie, part II.*

‘The extension of the fibre infers that its parts can change their relative position; that they may recede from each other, but within limits, and these limits are the bounds of increment.’ If we suppose that the elements of the vegetable fibre are united by a sort of gluten, which allows them to slide more freely on each other, and thus to admit of their separating to a certain degree, we may conceive how the heat of 212° , or 232° , should tend to inspissate or coagulate the glutinous matter, and to diminish, or even destroy, its motion. ‘The animal or vegetable gluten,’ I continue in the *Palingenesie*, ‘is the natural connection of all the parts whether original or acquired. It merits the greatest attention. Doubtless it is the principal basis of the assimilating or nutritious substance of plants and animals.’ Must it not be wonderfully fine in the lower orders of animalcula? In proportion as the plantula receives new juices, it discharges those superfluous, by sensible or insensible transpiration, which operates by means of the most minute secretory vessels, whose ac-

tion

tion regulates the secretion. For this, a certain heat is required; if too powerful, the quantity evacuated is no longer proportioned to the quantity imbibed, which must be prepared in the viscera. Excess of transpiration debilitates the plant, it inspissates the fluids, dries and contracts the vessels, and at length prevents circulation.

The vegetables which perspire little should undoubtedly suffer most in experiments such as your's on seeds: such, for example, are evergreens. You know the celebrated Hailes has proved that these trees perspire much more than others. Their sap seems more viscous, therefore has greater tendency to thicken and coagulate by heat.

In *Article 168, des Corps Organisés*, I observed that we are yet ignorant of the power secretly governing the motions of the sap. It does not reside in the leaves alone; the bleeding of the vine affords cogent evidence of it. Branches which had been intentionally dried, and no longer would raise coloured liquors as other branches; yet green, and without leaves, raised it perfectly: These branches, I say, sufficiently prove, that the course of the sap depends on some secret motion of the vessels, which is destroyed when they are dried. But 212° or 232° apparently are not enough to effect complete desiccation of all vegetables; some expand in a certain measure even at this heat. These curious experiments certainly merit

merit repetition, extension, and variation, much more than they have hitherto received ; and here you have done well.

Excess of heat tends to destroy the essential qualities in the nutritive juices of the plant ; and the alterations thence consequent are a natural cause of its death. Ancient philosophers would have said, extreme heat took away the radical humidity of the plant ; and although the expression is not used by the moderns, it is good sense.

XI. Your experiments on mould have excited my attention very much. When the vegetation of these minute plants ceases, in vessels hermetically sealed and exposed to the action of heat, it is more than probable that the numbers, which appeared on vegetable substances that had boiled from half an hour to two hours, came from the ambient air. The seeds must be of such extreme minuteness that we cannot wonder if they penetrate wherever air has access. These vegetables, so very small, are, in the vegetable kingdom, what animalcula are in the animal. Once, my dear friend, I wrote to you how earnest I was that some one should perfect the botanical microscope. How many interesting singularities would it not present ? and how incomplete is it still ? We are acquainted with the large and the middle sized vegetables. The most able botanists have carefully described the chief external parts.

The

The Anatomy of Plants, by Malpighi and Grew, and Duhamel's *Physique des Arbres*, have in a manner traced the history of herbs and trees. They have communicated much information on the structure and use of flowers, seeds, and fruits; and they have brought the principal viscera of the plant into view. The *Vegetable Statics* of Hales teach us the power of leaves, or their principal province in the mechanism of vegetation. *Les Recherches sur l'usage de Feuilles* have added some facts to the number already known. But the botanical microscope has not made the same progress, because it has not been so much cultivated; and because it requires eyes made on purpose. What we owe on this subject to Hook and Micheli, though precious, is very little in comparison to what we might expect from the assiduous researches of our best observers. Here are the *terreæ australes* of the vegetable world, as animalcula are those of the animal. How much may the figure, the nature of life, the manner of nutrition, increment and propagation of microscopic plants, stimulate the curiosity of a naturalist who can observe and reflect! How much does the economy of this part of the vegetable kingdom, so considerable and so little known, differ from the other parts of it! How great is the hazard of error by taking analogy for our guide! Let us judge them by the real and improbable facts

facts which the different classes of polypi have taught us, and which have created such a reform in our ideas of animality. Perhaps microscopic plants would occasion a similar reform in our ideas of vegetation. I wish a society of botanists would engage in the study of these plants alone. What do I say, 'mould' only would demand their whole attention. Nothing is better adapted to make us forcibly feel the narrow limits of our corporal and mental abilities than applying to researches on the most minute productions of nature. All the finest faculties seem to vanish at the root of a stalk of mould.

If mould appears sooner, and more abundant, on substances that have boiled long, perhaps it is because boiling prepares them in a manner similar to what we prepare the earth by our labour. Ebullition separates them more, multiplies the surface, opens new pores, forms new channels for admission of the air and the like. Internal changes may also be occasioned in the substances favourable to the generation and expansion of mould. Finally, a certain degree of heat, which boiled substances preserve for a time, may tend to accelerate the germination of mould, and to increase its multiplication (1).

I

(1) When M. Bonnet made these excellent reflections on the botanical microscope, I had not communicated any thing

I cannot leave mouldiness without a reflection which I made only a moment before ; that one could not make use of analogy here. More than once have I had an opportunity of applying the same reflection to the polypus. The naturalists, who study microscopic plants, should therefore be very reserved in their opinions of the various singularities they present to view. If real logicians, they will not insist on transferring the ideas applicable to vegetables of the higher classes to those of the lower. Nature has not been restricted to work always on the same models. These have been infinitely varied by the Divine Author. Observation alone can discover the direction which HIS WISDOM has prescribed to Nature, relative to the different classes of organised beings. The bounds to view and review are here ; and individuals must only be compared with the nearest species. Who knows that all mouldiness actually belongs to the class of vegetables ? Who knows but there may be something whose formation approaches nearer to chrySTALLIZATION than evolution ? The same may be said of many other analogous productions, whose properties have not yet been investigated. It is not impossible that
several

thing on the subject ; because only one or two results on the plants had been obtained. But I had occasion afterwards to penetrate the matter deeper, as will appear by my observations and experiments on the origin of the plantulæ of mould.

several of the productions which botanists class among plants, may approach nearer to the mineral than the vegetable; at least they may be the shades between the two. Among these plants probably are modes of multiplication and increment that have not the most distant connection with those of vegetables the best known to us.

XII. I am delighted, my dear Malpighi, that you have confirmed M. de Saussure's singular discovery concerning the mode in which many infusion animalcula propagate, and which I have published in the second edition of *La Palingenesie*, p. 426, 427. Though the figures that accompany your letters are only simple sketches, they are sufficient to show that those animalcula, whose propagation you have attended to, are of the class of polypi (1). This article has given M. Trembley much pleasure, and brought to his remembrance the cluster polypi, which he first discovered, and described so well in his works, and of which I have said much in my three last treatises. Wrisberg has also seen these very minute polypi in infusions, and given good figures of them; but he has not observed their mode of multiplication. When one considers the different figures we have of femi-
minal

(1) My observations on the propagation of animalcula were only in their infancy at the time I communicated them to M. Bonnet.

minat vermiculi, he will be induced to believe they approach these minute polypi, if they are not actually polypi. I should have earnestly wished that a laudable scruple had not prevented you from examining the feminal vermiculi of different animals. Your descriptions would have been more exact than any hitherto given, and you would have discovered many peculiarities which escape eyes less practised and less philosophic than your's (1). I can recollect that Mr Needham bestows some reproach that you did not investigate the animalcula on which he dwells with such complaisance. The strange ideas that possessed him during his observations are not very fit to satisfy us of the truth of his observations. I would recommend a more profound and impartial enquiry.

Among the animals that occupy the lower scales of animality, none so numerous or diversified as the polypus are known. The liberal hand of Nature has dispersed them every where. The carpet, thus to speak, the bottom of pools, rivers, lakes, and seas, and they are even found in infusions. No one could have suspected this; nor would we have suspected all the accessory facts which these minute animals have exhibited
in

(1) I have endeavoured, as far as in my power, to satisfy the curiosity of my illustrious friend, in the tract on the feminal vermiculi of man and other animals.

in latter times. Did not your illustrious countryman, Marfigli, imagine that the history of corals, corallines, and lithophytes, besides many other productions, taken from real plants, would one day be the history of a very minute animal? This is a most instructive fact to the philosopher: it presents the progress of the human mind, in the secret of Nature's truths. I remarked, *page 393, Tom. 1. de la Palingenesie*; 'One discovery begets another. The intellectual world, as well as the physical world, has its generations, and neither are more real generations than the others. By attention, the mind discovers pre-existing ideas, to use the expression, in other ideas. By reflection, the possibility of a fact is deduced from another fact actually existing; and by experiment, the possibility is realised. Thus when an acute person obtains a fact, he obtains the first link of a chain on which other links, also facts, depend.' This is the generation of ideas, which Encyclopedical Dictionarists ought to place before us, but never do. It would require much more art to explain such intellectual generations than what is employed in composing these huge compilations. A good history of the human mind would be that of the generation of its ideas of every kind; and it would be the basis of that *Histoire de l'Attention* which I formerly presented,

ed, and is mentioned, § 279, *de l'Essai de Analytique sur l'Amè*, and Art. 20, *de l'Analyse Abregée*, tom 1., *Palinogenesie*. ‘We want a book,’ I there observed, ‘and that book would be the most useful that human genius could invent; it would be a *Histoire de l'Attention*. If well composed, and maturely studied, it would overturn all logic; that is, it would be logic restored to action.’

In my three last writings, I have insisted much on the important lesson afforded by polypi, concerning the imaginary general rules of analogy. In *chap. 16. part 8. de la Contemplation*, I said, ‘This is not the time to form general rules, to arrange nature. . . . to raise a structure which future ages, more learned and more philosophical, will even hesitate to project. When we scarcely knew the animal, we undertook to define it: now, when a little better acquainted with it, shall we presume to suppose we know it completely? . . . How many animals still more extraordinary than the polypus may exist, and may confound all our reasoning if we should happen to discover them! We shall then have to invent a new language to describe our observations. Polypi are the extremities of a new universe which one day will have its Columbus and Vespucius. Is it to be conceived that the interior of a country has been penetrated with

‘ only a distant view of its confines? More sublime ideas of nature will be formed by considering her as an immense whole, and being convinced that our discoveries are but of the most minute portion of what she includes. Our astonishment will increase, but we shall observe; we shall amass new facts, connect them if possible, and attend correctly to every thing.’

It seemed proper to recur to these logical reflections, *part 10, de la Palingenesie*. There I attempted to retrace and unfold my principles further on organic preformations. Four kinds were established; and that my reader might not suppose that I considered these genera universal, I added, ‘ One ought not to infer from this, that all small animals are at first enveloped in one or more integuments, or in eggs. It would be deducing too general a consequence from specific facts. The Author of nature has spread such a vast variety throughout, that we cannot define general conclusions too well. How many new and unforeseen facts have destroyed conclusions which a strict logician would not acknowledge!—The cluster polypus is another exception much more singular; and is an additional conviction of the uncertainty, not to say the falsity, of our general conclusions. Infusion animalcula will be other exceptions; and very probably, what was taken for eggs in them

‘ is

is not so.—The ideas of animality, applicable to the higher classes, are too confidently transferred to the lower.—How absurd would it be to confine nature in the limited circle of our feeble conceptions! I avow then, that all I have said on the different kinds of organic preformations, chiefly regards the species best known to us, or on which we have been able to make exact and connected observations. I confess myself ignorant of the laws which regulate the evolutions of those numerous microscopic beings, whose existence, and nothing more, is discovered by our most powerful magnifiers, and which belong to another world, that may be called the world of *invisibles*.’

These passages are transcribed, my dear friend, because we cannot fortify ourselves, and our fellow naturalists, too well against the seductions of analogical conclusions. If it is sufficiently evident, that we cannot refer the propagation of polypi by natural division to any known kind of organic preformation, surely we ought to renounce the prospect of explaining their generation by the generations exhibited by other animals. If we are unable to divine this new mode of multiplication, we ought thence to conclude that many others may exist in the animal kingdom, of which we can form no idea.

Q 2

Therefore

Therefore it appears, that abiding by the facts best known, and aided by sound philosophy, we have reason to affirm, that *organised wholes* are not daily formed by a sort of secret mechanism, or that they are not presently generated. This we may admit, at least it is very probable, that they have been preformed from the first: but we should beware of presuming that we know every mode in which the AUTHOR of nature has originally preformed the multitudes of organised beings peopling our planet. The propagation of the cluster polypus, and other polypi similar, is far remote from the generations most familiar to us; nevertheless, strange as it appears, it has a constant regularity and uniformity, which is not fallacious, and must convince us that it is subjected to fixed laws, as every other mode of propagation, which new researches will demonstrate more and more. If all the productions of nature are connected by a continued chain, it necessarily follows, that the generation of polypi is attached to those of other animals by certain links which we are not yet wise enough to discover. The whole of these generations should possess some common or very general character, which is as a centre to which all converge. This centre probably conceals a general preformation. If it existed in animals forming mechanically, they would not converge to this
common

common centre; they would be distinguished from all the rest by a specific character, or one which would affect the essence of animality.

I have remarked, if man, and the animals which we esteem the most perfect, propagated after the manner of polypi and puçerons; in a word, if we had never seen animals in copulation, could we have suspected that generation was effected by the concurrence of the sexes? Could we have imagined that, for the production of an individual, the concurrence of two individuals of the same species was necessary? But from the propagation of all the large animals by copulation, it had been precipitately concluded, that it was a general law for the propagation of every species. Because it had been observed, that all known animals grew, after issuing from the womb of the mother, with the same precipitation, it was concluded that it must be so with the whole animal kingdom. The *spider-fly* has proved it false (1). These striking examples, and others which I have elsewhere cited, are well adapted to perfect the logic of the naturalist, and to make him reserved in his opinion on the ways of Nature. I am so much satisfied with the principles of this logic, that it would not surprize me if, in our seas, there was one day discovered a species of whales or

Q 3

marine

(1) Contemplation de la Nature, part 9. ch. 3. 7.
Corps Organisés, Art. 323. 324.

marine monsters, propagating in a manner altogether different from that hitherto seen in the same class of large animals. The sea probably contains prodigies of this kind, which would no less astonish naturalists than polypi have done. I repeat, that natural history, treated by a skilful philosopher, will always prove the most convincing reasoning.

All our physical knowledge chiefly rests on analogy; where this is wanting, or too imperfect, we should distrust explications or hypotheses founded upon it. How many different classes of polypi have little analogy with other animals? I cannot but applaud the prudent reserve of my illustrious friend M. Trembley, who was unwilling to hazard an explanation of the polypus, though he discovered it, and has so ably described the figure, habits, regeneration, and propagation. His excellent memoirs are a real logical phenomenon of this description; for how is it possible continually to describe wonders without yielding to the temptation of accounting for them? I should have to reproach myself with not following his example, had I not taken the greatest precautions to prevent my readers from confounding my trivial hypothesis with facts. I have not even hazarded an explanation of the arm polypus, excepting in those things that seem to approximate them to vegetables. An error re-
marked

marked by M. Trembley in one of my explanations must be pointed out. It forms part of a long letter which I wrote you, 1 November 1766, on animal reproductions, which at my desire you have communicated to the public in one of your notes on *la Contemplation de la Nature*; but you bestow too much praise on my sincere avowal of the error; for in one as fallible as me, there is little merit in publicly acknowledging he has been deceived. I said so at the end of the Preface to *Considerations sur les Corps Organisés*. One 'I have erred' is worth more than an hundred ingenious replies. You have also seen that I guarded against an attempt to explain the cluster polypus. On these in particular, and on polypi in general, I have published *Philosophical Considerations*, where materials are collected for logic to be employed by naturalists. These occupy the three last chapters, Part 6. of the *Contemplation*. The intelligent reader, who takes the trouble to read and meditate on them, will find good preservatives against precipitate judgments. 'What analogy can apply in the examination of the bulb-polypus? Can we even define the bulbs, or does this name express more than their mere appearance? How can analogy elucidate the nature of these minute bodies, the manner in which they engender or are engendered, while nothing is presented either by the animal

‘ or vegetable kingdom bearing the smallest re-
 ‘ lation to productions so different from all those
 ‘ hitherto known? I say the same of the natural
 ‘ division of the bell, and the sections of the arm
 ‘ polypus. Here is an order of things entirely
 ‘ new, with particular laws, which we might dis-
 ‘ cover if we had any method of penetrating in-
 ‘ to the mechanism of these minute beings. We
 ‘ should then see the relations connecting them
 ‘ to the other parts of the organic system. . . . But
 ‘ I would not banish analogical method from
 ‘ philosophy; it conducts itself to observation by
 ‘ the ideas which it associates on every subject.
 ‘ I only mean, that this method, otherwise of
 ‘ great general utility, cannot be applied to phi-
 ‘ losophy with too much circumspection. . . . Have
 ‘ we ever had a good treatise on analogy, though
 ‘ the want has been sensibly felt? We shall be
 ‘ indebted to some philosophic naturalist for it.
 ‘ Analogy is connected with the doctrine of hy-
 ‘ potheses and probabilities; in proportion as our
 ‘ knowledge extends and is perfected, all proba-
 ‘ bilities will approach to certainty. Could the
 ‘ totality of beings on our globe be comprehend-
 ‘ ed, analogical reasoning would be demonstra-
 ‘ tion.’

M. Trembley has greatly approved these *Phi-*
losophical Considerations on Polypi; and his ap-
 probation flatters me the more as it is not indis-
 criminate.

criminatedly bestowed. He writes to me, 'The system of Epigenesis is absurd; he would not wish to be obliged to explain any fact;' and adds, 'that he would rather collect a certain number, and then make some reflections, which would justify his reserve.' I earnestly wish this excellent observer would realize his sentiments, and give us the reflections which various polypi have excited: but notwithstanding the interval of many years since I solicited him to resume the pen, I have not yet been able to obtain a single page. Domestic occupations of much greater importance prevent him from again beginning his works on natural history: he has resigned this department to me, and I endeavour to acquit myself as well as possible.

I have paid particular attention to that paragraph of your letter, my esteemed correspondent, where it is said you have seen the propagation of infusion animalcula by division into parts. Does this mode of propagation differ from that of the other animalcula which you have observed dividing through the middle of the body? I have likewise to ask, whether it is instantaneous or gradual? If the latter, it will return to the division and subdivision of bell-polypi; if the former, it will be a new and most wonderful manner of propagation. Nevertheless, it is referrible to that which M. de Saussure describes in his letter, published

lished page 428 of the *Palingenēsie*. ‘ All the
 ‘ changes are made by imperceptible degrees, and
 ‘ without the animalcule or revolving machine
 ‘ changing its place. At last the motion is ac-
 ‘ celerated; and where the sphere appeared even,
 ‘ you begin to see two cross divisions, as on the
 ‘ husk of chestnuts ready to open; a little after-
 ‘ wards the animal is agitated, and then divides
 ‘ into four animalcula, perfectly similar, but small-
 ‘ er.’

An important remark is made in this letter, which you will not fail to notice in your new dissertation. M. de Sauffure supplies Mr Needham’s defective information on his discovery. ‘ Doubtless, in four years which have passed
 ‘ since I communicated this observation to Mr
 ‘ Needham, he must have forgot that I constant-
 ‘ ly observed the parts of the divided animalcule
 ‘ become as large as the whole which they had
 ‘ composed; so that the same constancy and uni-
 ‘ formity are preserved in these generations as in
 ‘ the rest of nature.’ How much have I myself insisted on the constant uniformity of this new order of propagation. We may almost suppose, Mr Needham has taken that part only of the discovery which he mentions, and seemed favourable to his theory.

XIII. You terminate the abstract of your observations, my dear correspondent, with a general
 ral

ral reflection, which, if there was any necessity, would prove that you know when to suspend your judgment on what is presented to view in the extensive field of Nature. ‘The results of my observations,’ you tell me, ‘do not appear so decisive, in favour of the theory of germs, as I at first conceived. That class of germs which does not perish at boiling heat, while the animalcula produced by them die at 106° and 108° ; these germs, I say, embarrass me a little. Yet when the reasons on both sides are balanced, it would seem that my experiments are more in favour of germs than of the imaginary vegetative power which, according to Needham, produces animalcula. For, according to the principles of this Epigenesist, that power should tend to become weaker in proportion as the action of heat is augmented. But we see the reverse from the first results of my experiments on animalcula, and in those on mouldiness. All these results would rather insinuate, that the productive principles of these organized beings are suspended in the air (1).’

It

(1) When this was written, I had not the complete evidence of the origin of animalcula which was afterwards obtained. However, I knew the different kinds of seed that supported boiling heat without losing the germinating faculty. To them I now add the minute seeds of mould which germinate after exposure to the heat of the fire in a chafing dish.

It is the germs, then, that resist the heat of ebullition, and their animalcula perishing at 106° and 108° , which embarrasses you, and appear to weaken what you call the *theory of germs*. Perhaps you may find the conjectures on this obscure subject, which I have hazarded, Article 6. of this letter, assist you in accounting for the fact, at least in conceiving how it happens. If you have any thing more probable to suggest, I will not hesitate to give it the preference to my slender conjectures. I have not pretended to divine nature; nor have I a better opinion of diviners in natural history than of those in politics: but you will not be displeas'd at my communicating the various reflections which your observations have excited. Consider them only as dreams, if you think fit: yet I must flatter myself that you will judge them more philosophical than those of our friend the English Epigenesist.

You speak of the theory of germs. It is most important to understand the exact general meaning conveyed by the word *germ*. It is frequently recurred to in my two last works. I have been very sensible how much the precise meaning may affect all our reasonings on the material origin of organized bodies. The polypus first induced me to seek for a proper definition of the word *germ*.
 ‘ By this word is commonly understood a most
 ‘ minute organized body; so that, if it could be
 ‘ found

‘ found in this state, we should discover the same
 ‘ essential parts as organized bodies exhibit after
 ‘ their evolution. It is necessary to give the
 ‘ word a more comprehensive signification, as is
 ‘ manifested by my principles themselves. Thus,
 ‘ it will not only design a most minute organized
 ‘ body, but also every kind of original preforma-
 ‘ tion from which an organized whole may pro-
 ‘ ceed as from its immediate principle.’ In a
 note, I have added, ‘ Remark, that I say immedi-
 ‘ ate, to distinguish the preformed part or parts,
 ‘ in miniature, from the great whole where they
 ‘ are to grow or be developed; for that cannot
 ‘ here be viewed as the *immediate* principle of re-
 ‘ production; it is only the *mediate* cause’ (1).
 This is afterwards more directly applied to the
 polypus (2); and what is said of it may extend
 to all analogous animals.

Before me, much has been said on germs.
 They are discussed in all the good treatises on na-
 tural history or physiology which appeared at the
 end of the last century and in this. Yet I do
 not observe that the authors, who have recurred
 to the philosophical hypothesis of germs, have en-
 tered deeply into the subject, or viewed it from
 every side, as I have endeavoured to do in the

Corps

(1) Tom. 1. page 362. first edition.

(2) P. 369.

Corps Organisés, and *Palingenesie*, part 11. 12. As these authors, valuable in other respects, have not analysed a sufficient number of facts, and facts very various; and as they have not been induced to give themselves up to the same reflections as I have, it is not surprising that they did not penetrate the theory of germs further. Therefore, when you wish to review the consequence of my principles on this beautiful part of the animal œconomy, you have only to revise part 10. of *la Palingenesie*. My latest reflections on the origin of organized beings are there. You, of all persons, are the naturalist from whom I expect most instruction in this fertile field; and your learned researches will confirm, regulate, or destroy, my trivial hypotheses. - You will not listen to the language of friendship, when Nature decides against me, and I shall be the first to submit to her sentence.

The insects which like the bell, funnel, and tubulated polypus, as the animalcula of infusions, propagating by natural division and sub-division, undoubtedly follow very different laws from those which govern the propagation of arm polypi, earth worms, fresh water worms, and other animals that are multiplied by being cut in pieces (1). The solution of continuity, which
art

(1) It is most singular, that the same animal can propagate its species by natural division, as by an artificial division

art or accident effects in the one, and nature herself in the other, and the method by which it is performed, we are ignorant of. Our best microscopes give us no access to the interior of these animated

division with an edged instrument. When M. Bonnet wrote to me, he was ignorant of this. Every one knows his beautiful discoveries on fresh water worms, which reproduce themselves when cut in pieces, *Traité d'Insectologie, part 2.* Muller has now observed that they multiply by natural division, which M. Bonnet informed me last year, in these words: 'Muller last year sent me a splendid work in quarto, illustrated with figures, on insects which are reproduced by section or division both natural and artificial. This work is unfortunately in German; and I could only learn his discoveries by the translation of some passages which a friend made *viva voce.* The estimable author has particularly repeated my observations, published 1744, part 2. of the *Traité d'Insectologie.* He confirms most of them, and adds much of his own enquiries. Among other things, he has seen the apodal worms of fresh water multiply before his eyes by natural division. He minutely describes this propagation, which is very different from that of the cluster polypus and infusion animalcula. Behold, how these singular generations extend more and more! I had myself observed the same in worms of the same kind, but from ignorance ascribed it to accidental causes. The fact is related in my *Insectologie, 'Anguilles de l'eau douce.'*—The cluster polypus was then unknown to me.'

animated corpuscula : but we can easily conceive that the propagation of an animal, naturally dividing into two or four pieces, cannot be performed by a preformation similar to that which gives existence to the buds of a tree, or the shoots of an arm polypus. Nothing is discovered in the natural division with the least resemblance to the known animal or vegetable generations. However, it is most evident that there must be an original preformation, which determines what precedes, accompanies, and follows the natural division of the animal. Changes or alterations, more or less considerable, should take place within ;—a kind of contraction preparatory to the solution of the unity : this should occasion the diversion of the nutritious juices towards certain particles on fibrilli, by means of which these fibrilli expand, and assume new positions with respect to each other. Thus is the enormous world consolidated : the exterior and interior of the animal is renewed or recomposed ; and each half, or each quarter, becomes a perfect animal.

It would seem that this singular regeneration has some slight resemblance to the first kind of organic preformation, described part 10 of *La Palingenesie* : but here our glimmerings are too faint to guide us through the profound obscurity. It is most probable, that an animal destined to multiply thus, has received a structure of little intricacy,

intricacy; or of great simplicity, from Nature. The parts will be dispersed through the body, and the animal will consist of such only. It may be all brain, or all stomach, if in this case we can speak of either. I would rather allude to nothing but my organic points, *Palingenesie*, part 10. p. 363, 364; and it may be much better to be silent altogether concerning such mysterious propagation.

XIV. It is certainly most proper for you, my dear philosopher, to examine Mr Needham's *Vitality*. This idea is not one that I would banish to the region of chimeras: it has a philosophic appearance which merits our attention, and belongs to that beautiful gradation of natural beings which I have attempted to gloss over. In part 15 of *La Palingenesie*, you have the *Essai d'Application* that I have endeavoured to make of irritability to the polypus, and other animals of the neighbouring classes. I had not then perused our Epigenesist's reflections on vitality. Perhaps my own thoughts on irritability, which is the foundation of vitality itself, will not be useless to you in your intended examination of our friend's opinion; and I shall view the results, to which this examination leads you, with pleasure. No new reflections on the subject are offered to you. In the part cited of my last work, is said what seemed the most reasonable or philosophic.

I have indeed a faint conjecture on the secret cause of this irritability, but it is not sufficiently mature to lay before the public.

XV. The examination of Mr Needham's hypothesis on generation will require a severe criticism from you; but you will make it in polite, moderate, and friendly terms. You are acquainted with the character of this learned naturalist, and cherish the same esteem for him as I do myself. I have written to him on his opinions with the greatest freedom; and it should be observed in his praise, that he was never offended with it. It is true, he has not abandoned them: on the contrary, he seems to support them more and more.—His last work, which you are called upon to refute, is too good evidence. Perhaps it is reserved for you to convert him, which will be no small addition to your literary glory. Probably you will not forget to say a word of the Reggio Professor, to whose observations Mr Needham referred me with such confidence, but who, notwithstanding, was less an Epigenesist than any one in the world. *Corps Organisés, Art. 331. Palingenesie, T. 1. p. 425, 426 (1).*

In

(1) Fourteen years ago, when I was professor of philosophy in the University and College of Reggio, and beginning to make experiments on infusion animalcula, I began a correspondence with Mr Needham, who was then making

In several parts of my *Corps Organifés*, this author is commended, particularly *Ch. 6. Tom. 2.*

R 2

I

making the tour of Italy, and for some time communicated my observations on them. I cannot precisely say what were the results, because I have neither copies of the letters, nor the journals, where my discoveries were noted down. I only remember of agreeing in two facts with Mr Needham, which I communicated to him, namely, that although infusions had boiled, they produced animalcula; and that they generally appeared when the substances began to decompose. These two facts pleased Mr Needham; he thought he saw a confirmation of his favourite hypothesis in them. M. Bonnet was just going to publish his *Corps Organifés*, where there is a complete refutation of it; and enquired whether Mr Needham still persisted in his opinion. It was natural to suppose he had abandoned ideas so extraordinary; but he said, that far from having changed his sentiments they were fully confirmed by a Reggian Professor, as would appear from a work he was about to publish.

I had said to Needham indeed that I did intend to publish a little treatise on animalcula; but it is far from true that I was ever an Epigenesist, for there was no foundation for me being so: and although some of my results did correspond with Needham's, it did not follow that I should decide for Epigenesis, especially as these results could easily explain the opposite theory of germs. I had then no inclination to take any side. I found myself necessitated

I did it with impartiality and friendship. The work appeared 1762: I hastened to send it to him;

hesitated to interrogate nature further, in hopes of discovering some decisive fact. But my future observations favoured the pre-existence of germs as much as they contradicted the Epigenesis. This I have attempted to demonstrate in the Dissertation published some time ago, (*Saggio di Osservazioni Microscopiche.*)

Needham's too great anxiety to predict the result of my observations has rendered him a false prophet. But I cannot be silent on another prediction by Bonnet, though very different from his, as it has been fulfilled. After quoting Needham's letter in the *Corps Organisés*, he does not hesitate to affirm that the observations of the Reggio Professor will not demonstrate that animalcula have so extraordinary an origin as he would ascribe to them. It should be remarked, that I was then unacquainted with M. Bonnet, nor had I even read his *Corps Organisés*.

The English philosopher, though a pseudo prophet, has given my observations a very gracious reception: he has approved of them; and does not conceal that they have induced him to change his opinion. I shall mention what he wrote to M. Bonnet and myself on the subject, to shew that although he was remote from real philosophy for a time, he afterwards approached it, and did not always remain in error.

'The singular agreement of your observations with my remarks,' M. Bonnet writes, 'gives me the greatest
' pleasure,

him ; but he had not the same desire to read, far less to study it. Much time elapsed ; and he had

R 3

not

‘ pleasure, as they have been the decision of Nature herself
 ‘ to our valuable friend. With philosophic candour, he
 ‘ informs me, that he will adopt our sentiments, and ex-
 ‘ amine the interesting subject anew ; adding what does
 ‘ honour to his sincerity : *I begin to think my ideas have*
 ‘ *been extended too far in giving power to matter, which is un-*
 ‘ *necessary to explain the phenomena of the microscopic world.*

‘ He also says, he is much inclined to admit my con-
 ‘ jecture on the generation of animalcula, p. 217 of the *Corps*
 ‘ *Organisés*. If you will take the trouble to revise it, you
 ‘ will see that I insinuate, animalcula may multiply by di-
 ‘ vision as the cluster polypus. This appears to our friend
 ‘ a happy conjecture. He adds, *You have justly observed*
 ‘ *that the generation of these beings may be by division ; but it*
 ‘ *would require a course of observations, such as I find in Sig.*
 ‘ *Spallanzani, to convince me of it : besides, I still have doubts*
 ‘ *which will probably be solved by reflecting maturely on the*
 ‘ *subject.*

‘ It is thus, Sir, that you have succeeded in removing
 ‘ the veil which covered the eyes of our learned corres-
 ‘ pondent. What I suggested, you have finished—What
 ‘ I predicted, you have seen.

Needham’s letter to me coincided with what he had
 written to M. Bonnet. ‘ Besides recollecting all that I
 ‘ have at other times observed, comparing it with your
 ‘ observations, and the new discoveries in a course of ob-
 ‘ servations

not then perused the work. Yet he has quoted me, p. 219 of his *New Researches*: He there wishes to give an abstract of what is said of the formation of the chicken, after the beautiful discovery of my illustrious friend Haller. On reading the passage, it is easy to see that he has not had the account before him when he abridged it. He evidently cites it from memory: unfortunately

‘servations by a young professor here (M. de Saussure),
 ‘I am determined to limit my ideas of generation. This
 ‘limitation will render the *pre-existence of a being, specifically*
 ‘*similar*, absolutely necessary to the generation of any or-
 ‘ganised being, without restricting Nature to make it vi-
 ‘viparous or oviparous, to produce it by the concurrence
 ‘of two sexes, or without it to effect reproduction by shoots
 ‘or divisions. By this means we shall comprehend all
 ‘phenomena, and have germs or prolific parts, which
 ‘from their subtilty may insinuate themselves through all.
 ‘Therefore I shall abandon, in those classes of infusion
 ‘animalcula, and in all other organised bodies however
 ‘simple they may be, I shall abandon, I say, the vegeta-
 ‘tive power of matter which I formerly believed necessary
 ‘to explain these phenomena. Only a few difficulties re-
 ‘main, which may be easily solved by the indefinite divi-
 ‘sion of the microscopic beings from the universality of
 ‘their germs or prolific parts, their extreme minuteness,
 ‘and their instantaneous evolution, which uniformly suc-
 ‘ceeds when the germs or prolific parts are in a suitable
 ‘situation.’

tunately his memory has been very treacherous ; and he has lamed my chicken. I told him so : he said it was true ; and his custom, whether good or bad, was to follow the train of his ideas. I wrote to him again : ‘ You have not paid the least attention to the consequences immediately flowing from the facts I mention. You have overlooked them : but they require to be analysed. It is not in this manner that one should treat facts.’ I am no less sensible of the obliging and truly friendly things with which the citation of which we speak is attended.

This avowed partizan of Epigenesis incessantly refers us to what he calls the *chain of his reasonings*. He seems not to suppose that it is a spider’s web to catch flies. He almost uniformly draws certain conclusions from uncertain premises. The two sophisms into which he most frequently falls, are the *petitio principii* and *imperfect enumeration*. Because the decomposition of vegetable substances produce particular filaments, whence animalcula seem to proceed, he conceives it demonstrated, that the animalcula, which he calls zoophytes, are produced by the filaments. Then, to account for this strange production, he imagines a vegetative power, which he charges with the office of organizing or animalizing. He endeavours to give us an idea of the action of this force, by a comparison with the

combined action of the projectile force and gravity in fire-works. Thus does our Epigenesist undertake to penetrate the mystery of the reproduction of animated beings, by substituting occult qualities in the place of sound philosophy. He seems to treat natural history as alchemists do chemistry. He speaks of the doctrine of germs as a monstrous hypothesis: he thinks he is supported by the great Leibnitz: but no one is ignorant that this illustrious metaphysician was a most zealous favourer of the theory of germs. You have seen what I say after him, *Palingenesie, part 7.* how pointed it is. There is also another passage of the same profound philosopher still more applicable, in his *Considerations on the Principles of Life and Plastic Nature.* ‘ With Mr
‘ Cudworth, I think the laws of mechanism alone cannot form an animal, where there is yet
‘ nothing organized; and I find that he justly
‘ opposes what some of the ancients have said on
‘ this subject, and even M. Descartes in his
‘ *Man*, whose formation costs him so little, but
‘ he approaches as little to a real man. And I
‘ confirm Cudworth’s sentiments, which consider
‘ that matter, arranged by a Divine Wisdom, must
‘ be essentially organized throughout; that there
‘ is thus a machine to infinity in the parts
‘ of the natural machine; and so many en-
‘ velopes and organic bodies involved in each
‘ other,

‘other, that an organic body entirely new, and
‘without any preformation; can never be produc-
‘ed, and that we cannot entirely destroy an ani-
‘mal not yet existing.’ From this circumstanti-
ate passage, we perceive that Leibnitz not only
rejects the mechanical formation of the animal,
but that he admits germs or preorganization, and
also the infinite involution of organic machines.
Can we believe this is actual infinity? Must not
every series have an ultimate term? Is the infi-
nity of geometricians *real infinity*? However,
this passage, and many others of the same author,
strictly demonstrates that Mr Needham has not
been aware of the real sentiments of the German
Plato on the origin of organized beings.

Thus, it will be important for you to show
your readers that our friend’s method is unphilo-
sophical. I do not despair, however, that your
new experiments, and the logical deductions
which you know how to draw from them, will tri-
umph over his attachment to Epigenesis. It
should also be expected from his love of truth.

XVI. The plan of your Dissertation pleases me
much, my dear correspondent; and I offer up
sincere vows for its execution. No naturalist
will have equally perfected this part of natural
history, fit in itself to complete the logic of
the observer, and to exercise his genius.

In answering the little volume of facts which you addressed to me 20th of last December; I have made one of reflections, which have employed me some weeks to write. You send me gold, but you will receive only brass in exchange. Should this letter seem worthy of appearing at the end of the work which you are preparing on animalcula, you are at full liberty to publish it. I have attempted to collect my latest reflections on a subject which has engaged my attention for many years. Perhaps you will make some notes on the letter, where I have not correctly comprehended your meaning, and always where your own opinion is different. This is the real method to render it most useful to the public; and you will afford me much pleasure by doing so.

I cannot terminate this long epistle, my worthy correspondent, without renewing the testimony of the great esteem, and sincere attachment, which have ever been borne towards you by the

24 February 1771.

PALINGENISIST.

LETTER II.

My Solitude, 20 April 1771.

I REJOICE, my dear Redi, that you are satisfied with my long letter on animalcula, and that my reflections

reflections do not seem useless towards perfecting the interesting subject. With the greatest eagerness I shall read the brief commentary which you propose on the letter, when it is published at the end of your new *Dissertation*. This commentary will undoubtedly contain a number of facts; and many reflections on them will be necessary to enhance the value of the text, too destitute of the former, and too much loaded with the latter.

Before considering several articles in your obliging answer, I hasten to acknowledge a misconception, or error, which the learned and estimable M. de Saussure has pointed out. As he knows me well, he is aware that my regard for truth is sincere; and that I am always grateful to those who discover my errors. In the hypothesis, where I attempted to account for the phenomena of animalcula, in their germ state, supporting the heat of ebullition, and perishing at 106° and 108° , when developed; and supposed, as you have seen, that the extreme transparency of the germs protected them from the action of heat; I corroborated my supposition, by considering that the solar rays do not sensibly warm the atmosphere on high mountains, because it is too rare or diaphanous. I then quoted observations, proving organized bodies to be more and more transparent as we ascend towards their origin. Finally, I insisted much on the extreme
rarity,

rarity, and on the great simplicity or homogeneity of the organic texture of our animalcula, considered in their primitive state. I transcribe what M. de Sauffure wrote to me on the sixth of this month, on a hypothesis which I had favoured too much.

‘ You have more regard for truth, Sir, than to
‘ allow me to conceal that the indestructibility of
‘ the germs or eggs of our animalcula seems to
‘ me to depend on the nature of the mixture or
‘ aggregation of the parts rather than on their
‘ transparency. Without recurring to the re-
‘ mote example of crucibles, you see jpanning
‘ support the heat of boiling water, and even
‘ a greater degree; not because this heat is
‘ not acquired, but because the intimate con-
‘ nection and equal dilation of the parts pre-
‘ serve them from destruction. May it not be
‘ possible that the animalcular germs, or eggs
‘ of which we treat, are provided with some
‘ varnish which is soluble in the seminal fluid
‘ only, or in a liquid fit for the developement
‘ and nutrition of the included animal?

‘ In general, if the soluble and volatile parts
‘ of a body, insoluble in a given fluid, are so con-
‘ nected with the fixed and refractory parts, and
‘ these, serving as a connection, prevent them
‘ from dissolving or dissipating; and if the total
‘ aggregate has such ductility, that the fire may
‘ expand

‘ expand it without attacking its substances, I believe I may affirm that this body, immersed in the fluid, will resist the action of the fire.

‘ I know well, that for eggs or germs to preserve their fecundity, it is essential not only that the external integument remains entire, but that the interior retains the same proportions and the same pliancy. Therefore we must add to the preceding conditions, that no fluid is to be contained which heat can coagulate, and that the whole vessels and fibres may be sufficiently pliant to dilate without rupture, and, in contracting, to resume their original situations.

‘ Collecting and generalizing these ideas, I find that all the determinations are reduced, *first*, To reciprocal indissolubility as well of the contiguous parts of the exterior and interior parts of the germ, as of the medium in which it exists: *Secondly*, To the fixed and refractory nature of the germ: *Thirdly*, To the proportionate capacity of contraction and dilation of its whole parts. Germs continue fertile so long as the heat does not exceed the conditions within which these determinations may subsist; and they may do so at heat far surpassing that of boiling water. It is easy to see how the germ may lose them during its expansion.

‘ Explanations of this kind, I acknowledge, I would prefer to those deduced from transparen-

‘ cy,

‘cy, however ingenious they may be. For, ex-
 ‘cepting the case of the solar rays, it has not
 ‘been observed that transparent substances are
 ‘more easily heated than opaque; that clear
 ‘water is more difficult to boil than ink, allow-
 ‘ance being made for their different density. It
 ‘is true, there are no experiments made *ex pro-*
 ‘*fesso* on this subject; but, if the difference was
 ‘very remarkable, it would have been observed
 ‘as with the rays of the sun.’

M. de Sauffure’s letter is terminated in the most modest manner, and, at the same time, in terms the most polite to the author whose hypothesis he was examining. You will judge from my answer, my dear correspondent, what I have thought of our judicious observer’s remarks, who is also an able chemist, as his letter shows.

‘*My Solitude, 8 April 1771.*

‘YOUR crucible could not confine my little
 ‘hypothesis, my dear Becker; it has been vola-
 ‘tilized or reduced to smoke; but the residue
 ‘consists of two facts, which are most precious
 ‘to me: the one, that you love me well enough
 ‘not to conceal my errors; the other, that I can-
 ‘not distrust my own opinions too much. Your
 ‘remarks have great weight in my estimation.
 ‘I shall not fail, in a second letter, to correct
 ‘this article of my first, nor shall the valuable
 ‘philosopher

‘ philosopher be forgot to whom I am indebted
 ‘ for the correction. I had paid too great atten-
 ‘ tion to the solar rays, which seem to have daz-
 ‘ zled me. However it is to be wished, that this
 ‘ may give an opening to direct experiments; it
 ‘ would be worth while to make them. I shall
 ‘ meditate anew on the subject, as if I had never
 ‘ attended to it before. In addition, I made other
 ‘ two conditions intervene, the extreme rareness
 ‘ of the texture, and its simplicity or homoge-
 ‘ neity: pliancy and ductility were produced by
 ‘ the first; the second occasioned a certain de-
 ‘ gree of resistance to a certain degree of heat.
 ‘ The connection of the elements of the texture
 ‘ passed unnoticed. But I repeat, that all this is
 ‘ an old spoil, of which I divest myself. My
 ‘ heart shall never be refractory to truth.’

Thus you perceive, my dear Malpighi, that I
 intend to reflect anew on this interesting subject.
 I invite you to reflection on your part; and I am
 convinced your meditations will not be fruitless:
 surely they will suggest new experiments, which
 must be more instructive, therefore more satisfac-
 tory, than our meditations.

Since you are determined to print my long
 letter at the end of the Dissertation which you
 are now composing, will you be good enough
 to add what I say concerning my hypothesis on
 the indestructibility of infusion animalcula? I
 doubt

doubt that my reveries may lead those readers into error who have too great an opinion of my feeble meditations, and my trivial writings in general. From your answer of 24 March, I perceive you had the same doubt as M. de Saussure. ‘The facts you collect,’ you observe, ‘prove, without reply, the extreme transparency of these germs. The heating of bodies by the rays of the sun, which is always reciprocally in proportion to their transparency, persuades us that the heat freely passes through the germs without altering their structure. But this persuasion would become much stronger, if we could prove directly that it is the same with our fire as with the solar rays.’ What you add immediately afterwards excites my admiration. ‘It seems that a course of experiments on this point would be of the first importance, and your excellent conjecture might be exposed to other trials: to examine whether certain insects which are very transparent would support the action of heat better than those which are very opaque. Among the animalcula of infusions are some whose transparency is almost infinitely greater than those of others. Perhaps there might be foundation for supposing, according to your principle, that heat has less influence on the former than the latter. It is true, I have said in my letter, that animalcula

‘in

‘ in general perish at 106° or 108° ; but as
 ‘ transparency did not then occur to me, I am
 ‘ ignorant whether any very transparent were of
 ‘ the number. I only touch on the subject;’
 and it cannot be too often repeated, that I view
 all that I wrote you before but as simple conjec-
 tures, or rather doubts (1).

(1) In the course of the letter, from which M. Bon-
 net has given two extracts, I had sketched an explana-
 tion similar to that of M. de Saussure, though unacquaint-
 ed at the time with the sentiments of that celebrated Ge-
 nevese Professor, as appears from the date of the letter.
 ‘ If the decision of Nature should not favour your con-
 ‘ jecture, Why may we not explain the *indestructibility*
 ‘ of germs from the indestructibility of their component
 ‘ parts? Without recurring to asbestos or amianthus,
 ‘ there are substances known to us whose structure sup-
 ‘ ports the influence of heat infinitely surpassing that of
 ‘ boiling water. These are earthen vessels in which glass,
 ‘ melted by the heat of furnaces, remains many weeks,
 ‘ yet they do not suffer. Therefore a germ, composed
 ‘ of matter analogous, would easily resist the heat of
 ‘ boiling water, and be destroyed by it when beginning
 ‘ to expand; for, being replete with foreign matter,
 ‘ the primordial molecules, forming its original state,
 ‘ would be removed farther from each other; their reci-
 ‘ procal attraction would be diminished, consequently
 ‘ their former cohesion. Therefore the heat dissipating the
 Vol. I. S ‘ foreign

‘ foreign matter, would destroy the mutual relation of
 ‘ the primitive molecules, and the germ would be de-
 ‘ composed though these molecules remained untouched.
 ‘ Here I only outline an hypothesis which shall be extend-
 ‘ ed when I have leisure.’

It was really my intention to do so, when I wrote thus to M. Bonnet; but the intervention of other successive operations has not allowed me time. The same has happened to M. Bonnet, who promised me new reflections on the subject, and has undoubtedly been prevented by similar causes. The explanation of his illustrious nephew seems to me sufficient, especially if we admit, that not only several inorganic bodies, as asbestos or amianthus, some earths, and several other mineral substances, support the action of fire without suffering by it; but there are also particular bodies, bearing great analogy to animals, and organized like them, that enjoy the same advantages. There are certain roots which may be ignited without being consumed: an incombustible flax is made of others. Such, in the former case, is the *Andropogon* of Dioscorides; and, in the latter, the Indian tree *Sodda*. *Waller Mineralog.*

It should not be concealed from the reader, that, on putting M. Bonnet’s conjecture to the test, I did not find it agree with facts; and so I informed him. ‘ The colossal size of the animalcula in these infusions has been
 ‘ mentioned, my celebrated colleague, in my other letters. As they are nearly opaque, and as others very
 ‘ minute and transparent appear along with them, if your
 ‘ hypothesis is true, it follows, that the animalcula of the
 ‘ second

‘second species should support heat much longer than those of the first. But just the reverse has happened. The smallest animalcula perished at 106° ; and those of colossal size, only when the thermometer rose to 140° and 142° . We must remark that animalcula supporting heat so great are very rare.

‘If animalcula are compared with frogs, it is at once evident, that these are composed of matter infinitely more dense and heterogeneous. Notwithstanding so disproportionate a difference, however, frogs support a degree of heat far greater than what is fatal to animalcula.’

These facts appeared to satisfy M. Bonnet; and he replied with that candour and indifference for his opinions, which are almost peculiar to him, and so desirable in most of the literary world.

OBSERVATIONS AND EXPERIMENTS

ON THE

SEMINAL VERMICULI OF MAN AND OTHER ANIMALS;
 WITH AN EXAMINATION OF THE CELEBRATED
 THEORY OF ORGANIC MOLECULES.

INTRODUCTION.

THE subject of which I am about to treat was intended for a chapter of the preceding treatise on Infusion Animacula, from the great analogy between these beings and spermatic vermiculi: but the obliging suggestions of M. Bonnet have changed my determination. I had sent him the result of my experiments on Animalcula, Vermiculi, and Mould; he honoured them with his approbation, and advised me to separate the subjects, to treat of each in a different dissertation. In this form he thought they would more readily fix the attention and attract the curiosity of

readers. I have found his counfels falutory, and profited by them: they have enabled me to extend the matter, and enlarge my researches on spermatic vermiculi.

The reality of the existence of these animals, and a knowledge of their peculiar nature, are as fit to engage the enquiries of a philosopher as they seem to retreat from his penetrating examination. I may say that, like the Proteus of fables, their figure and appearance change with the naturalists who attempt to study them.

The feminal fluid of man and of certain animals, microscopically examined by Leeuwenhoeck, appeared full of animalcula, which he named *vermes*, from their similarity in figure and motion. But they were soon considered by some philosophers as a phantom of the imagination, an illusion of the senses, or some imperfection in the microscope; they supposed there was nothing real in what he had described. Others judged the Dutch naturalist with less severity; they admitted there was a number of corpuscula in the feminal fluid, but, denying they were animals, conceived them inorganic particles, which, from subtilty, were raised and evaporated sooner than the rest; thus forming a fermentation and motion in the fluid that created the idea of animation.

Nearly

Nearly this opinion is adopted by the celebrated Linnæus. He thinks the vermiculi are only inert molecules swimming like oil in the seminal fluid, moving and darting in various directions, as they are affected or heated by the temperature of the semen.

Mess. Needham and de Buffon, as is well known, have published their sentiments concerning these disputed microscopic beings; and appear to have beheld them as suited their respective theories best. The former thinks they originate from the vegetative power acting on the seminal fluid after it comes from the body of the animal, by which it is necessitated to vegetate, expand, put itself in motion, and change into beings not yet animated but *simply vital*. M. de Buffon, ever prejudiced for his favourite *organic molecules*, supposes he finds them in the vermiculi, and, from a long detail of experiments and observations, endeavours to establish his own theory on the ruins of Leeuwenhoeck's.

Who could imagine that so many disputes, and such opposition of sentiment, would arise on a matter of fact? I confess it has singularly surprised me: and I have often thought that the diversity of opinion originated less from essential difficulties than the fault of observers; who had not the proper methods of examination; who were prejudiced in favour of some theory, and

made their senses the cause of error; or who wanted sufficient practice in the difficult art of accurate observation. As I investigated a subject analogous to the history of spermatic vermiculi, I wished to study them: and applying with all the attention, care, and reflection in my power, to discover the truth if possible, for the greater certainty, endeavoured first to forget all that had been written, and act as if I had been the original author of the enquiry. In controverted facts, I have uniformly found this the safest method, to avoid confounding the opinion of the philosopher with the responses of Nature: only, after reaping a fruitful harvest of facts, I begin to consider what has been seen by others; I compare their results with my own, and, with respectful deference, allow myself to give an opinion. My sincerity will be believed when it is known that I had taken no side of the question, and that it absolutely was indifferent to me whether my discoveries corroborated or refuted those of others.

The feminal fluids examined were that of man and different quadrupeds; neither did I neglect the smallest animals. The human semen was used as recent as it could be obtained, by taking it from dead bodies while yet warm: that of animals the moment they were killed; I have frequently examined the feminal fluid of animals
alive,

alive, and often used what was ejected during copulation. The importance of these facts, in the illustration of this research, will be evident to the reader of the following chapters.

LETTER FROM M. BONNET.

In the Country, 16 October 1771.

I ACCEDE to your request, my esteemed correspondent, and hasten to inform you that I have received the excellent letter, which is owing to your friendship for the *Palingenesist*.—Excellent book I should say; it is almost such in size, and shall be added to those of the same kind with which you have already enriched my library. I could not engross to myself a work almost every line of which has excited the deepest attention, but determined to revise it along with an observer worthy to understand and to imitate you, and who can equally well appreciate your interesting researches and fortunate discoveries. I mean my worthy friend, the illustrious discoverer of polypi. Yesterday we perused it together: I am unable to describe how much your experiments delighted us; at some other opportunity, when you give me more leisure, I shall speak of them. But M. Trembley and myself are most desirous, that your observations and experiments on Infusions, Vermiculi, the *Plantulæ* of Mould, and the other subjects you have treated with so
much

much learning and success, should be published separately. They are too important not to merit and require a separate impression. In detached treatises they would make an admirable appearance, and thus more firmly fix the attention of amateurs. Send them to me whenever they come from the press: M. Trembley and I will cause them immediately be translated into French, under our own inspection. Surely you will comply with our request. This new Treatise on infusions will form an appendix to the former.—We may even reprint the French translation of the last, and place it at the beginning of the new work. Think of all this, and inform me. It has been mentioned to M. Trembley.

Your tracts on infusions, and other subjects, will, in my opinion, be excellent logic for the use of naturalists; which, believe me, in my view, is not the least merit of your learned researches.

You may well conceive we would have associated M. de Sauffure in our philosophic amusements, but he has been absent fifteen days on a journey to Lyons; however, we shall regale him with your productions at his return.

Still a word on infusions.—Behold the poor Epigenesist reduced to an impalpable powder; and you have no less pulverised his friend De Buffon. I have read nothing on seminal vermiculi

culi with so much satisfaction, and congratulate myself for having induced you to study them. The observations are invaluable: they are both new and accurate. Would that I could reanimate the worthy Leeuwenhoeck! What pleasure would it afford him to see M. de Buffon's attack so well repelled! I hope he will now be philosopher enough to acknowledge that his microscopes have not done him justice, and yield to your evidence.

Your mould is almost as new as your vermiculi.—But I forget that I am beginning to answer your interesting letter in detail: if it is continued, you will not so soon know that I have received it. I therefore end, with renewing the assurance of my inviolable regard,

BONNET.

CHAP. I.

DESCRIPTION OF THE SEMINAL VERMICULI OF MAN,
AND VARIOUS OTHER ANIMALS.

THE seminal fluid, taken from a dead human body, December 21, resembled coagulated milk in colour and consistence (1). Examined with a magnifier,

(1) Thermometer 48°.

magnifier, nothing could be discovered on account of its opacity. It began to dissolve; and, losing the whiteness, acquired the colour of soapy water. It was again examined with a magnifier of small power; the irregular parts seemed to be in an indistinct slow fermentation. With the assistance of a much more powerful glass, I observed that these parts were moved by corpuscula, infinitely more minute, of a globular figure. Each had a sort of filament or short appendage, Pl. 2. fig. 1. A. The grosser part of the fluid was evidently put in motion by them, for there was none when they were at rest. The corpuscula themselves had two motions; one oscillating from right to left and from left to right, curving the appendage from one side to another; the other was progressive, advancing by means of oscillation. During this, one would suppose them blind; they strike against every obstacle; and, when amidst a number, make agitations and contortions, at last, taking that way where there is least resistance. They are restless and continually moving.

In twenty-three minutes the oscillation and progression had diminished; and it had lessened so much in an hour and a half, that very few corpuscula preserved any appearance of motion. The progressive motion generally ceases before the oscillatory, so that the corpuscle at last merely bends from right to left, and reciprocally. They
continue

continue fixed to the same spot until the oscillation insensibly dies away: then they remain entire in the fluid, and are better seen when it is diluted with water. We discover that each corpuscle is not globular, but elliptic; and the appendage is not only much longer than it appeared, but the thickness not uniform through the whole length, and encreasing as it approaches the body, fig. 1. B. I was unable to discern where it terminated, being so much immersed in the fluid. When motion entirely ceases, the filament remains extended in a straight line, or with very little deviation.

If the seminal fluid has been kept a day, or indeed less, in a watch-glass, it becomes transparent, though preserving its original viscosity. A sediment of whitish matter is deposited, which, by the microscope, resembles a parcel of slender rags.

In another observation, January 11, the fluid dissolving later than that of the preceding observation, some particles were put in rain water (1). The elliptic corpuscula, swimming with progression and oscillation, became motionless when the water touched them. Other waters, as dunghill, river, snow, ice, and even distilled water, mixed with the seminal fluid, produced the same effect.

I have

(1) Thermometer 36°.

I have found nothing but saliva preserve their motion; and it may be used indifferently, either from the mouth, or when cold; therefore I have often taken advantage of it for continuing my observations. These ovular corpuscula, and the phenomena exhibited, were exactly the same as in the former observation.

When the drop dries up, all, without exception, become motionless; and as it dries first at the circumference, that is, where thinner, and advances to the centre, those first becoming motionless are at the edge, then those of the interior, and, lastly, those in the centre. The corpuscula do not recover on putting a drop of saliva, or seminal fluid, on that which is dried, though humidity continues long. In this observation, they became motionless sooner. In fourteen minutes they were languid; in three quarters of an hour, there was complete repose. While a remnant of oscillation continued, progression had ended; and when both motions had ceased, most of the appendages remained extended in a straight line.

Semen taken from a dead human body was chiefly coagulated, 18 February (1). It was inhabited by the usual corpuscula. In one of the preceding observations, it appeared to me that there were some larger among the rest. I apprehended

(1) Thermometer 49°.

hended I might be deceived, and that any difference of size might arise from portions of semen attached to them; but I was now convinced it could not be the case; because when the feminal fluid was completely dissolved, they retained the same size, though transmitted through another fluid. Fig. 2. pl. 2. Motion ceased two hours after taking the semen from the body.

The feminal fluid of a man was like milk ready to coagulate, March 8 (1). A small portion taken for examination, presented a singular phenomenon. Four corpuscles were attached, by the filaments, to a dissolving clot. They seemed to make every effort to disengage themselves from this incumbrance, by many motions and contortions; ascending, descending, now turning to either side, now remaining motionless; the filament sometimes describing a curve, and sometimes extending in a straight line. Amidst the struggles one disengaged itself, and began to swim like the rest, with an oscillatory and progressive motion. The other three corpuscula, one after another, did the same, and the clot gradually dissolved.

The novelty of the phenomenon made me desirous to examine whether other ovular corpuscula could be found in similar situations in
molecules

molecules of semen incompletely dissolved. In some they were free, and swam in the place of the clot dissolved; others were attached by the appendage to what part of it was entire, and endeavouring by great exertions to disengage themselves. When altogether detached from the spermatic molecules, they swam about in the fluid. I found something more. A clot was partly in filaments; many ovular corpuscula appeared about them, which, notwithstanding their exertions, were unable to accomplish their liberation. In this semen they lived about two hours and a half.

When I took the feminal fluid from a dead human body, most part seemed dissolved (1). Many corpuscula surpassed the common size. Here my object was to search with all possible care for what had been seen in the course of the preceding observation; and I saw the whole, except the phenomenon of corpuscles, attached to clots, which could not happen as the semen was entirely dissolved. Some corpuscula continued to move for three hours.

In the examination of this feminal fluid (2), which was at first a little thick, I accidentally discovered a method of observing the corpuscula
and.

(1) March 27. The Thermometer 54°.

(2) April 15. The Thermometer 60°.

and their appendages with much greater convenience and precision. As the thickness of a clot on a talc slider prevented me from seeing it distinctly, I swept it with a hair-pencil; but the talc was not so clean that some little portion of spermatic matter did not remain which dried in a moment. I cannot say what induced me to examine the talc again with the microscope, but I there found what could never have been supposed. Scores of corpuscula were visible, and the whole motionless because they were dry; they were very distinct and free from any mixture with the spermatic matter. The appendage of some was curved; of others straight, and nearly of the same length in all, that is, about six times the length of the body; not much pointed at the extremity, and thicker as it approached the body; and it was evidently perceptible, that the corpuscule or body made one whole with the appendage, which, in the thickest part, was thrice as small as the body, and even more. Each corpuscule was somewhat like the red globules of blood, but smaller. Both the appendage and the corpuscule seemed to be composed of an homogeneous substance.

After this fortunate event, I frequently wiped the talc bearing drops of semen, and constantly saw the corpuscule with equal precision. They remained dry on the talc several days without any change of figure.

I wished to proceed rigorously with my researches, as it appeared that the results hitherto obtained were insufficient to bestow the character of real animals on the corpuscula. We have not had that assemblage of characteristic marks to decide their animality. Doubtless however we may name them self-moving corpuscula, or possessing a spontaneous motion; for the testimony of our senses will not permit us to believe this double motion of oscillation and progression the effect of any external cause. The sequel of the Tract will make us more intimately acquainted with their nature.

These observations likewise demonstrate another fact, that the duration of motion, after the corpuscula come from the body of the animal, depends in a certain degree on the temperature of the atmosphere. At 36° , all motion was gone in three quarters of an hour; at 48° , in an hour and a half; at 49° , in two hours; at 51° , in two hours and a half; at 54° , in three hours; and at 60° , only after three hours and three quarters.

Thus I remarked that motion continued longer as the temperature of the atmosphere increased; and examining human semen, in the warmer months, to learn whether the phenomena already witnessed might be then observed, I had the satisfaction of seeing them again. The duration of motion constantly increased as the heat

was greater ; so that when the thermometer rose to 81° , in the middle of summer, our corpuscula moved seven and three quarters, even eight hours. While this heat continued, the experiments were varied.—A portion of feminal fluid, taken from a man, was exposed to the air of an apartment where the thermometer stood at 82° ; and another portion put in a cave, where the heat was 66° ; a third in an ice-house, where the thermometer stood at 42° . Here the corpuscula moved an hour ; in the cave, four hours ; and in the apartment, eight.

Each of the fluids hitherto examined was full of moving corpuscula. The smallest drop included an innumerable multitude.

After the feminal fluid of man, that of the horse was examined. No method of observing it could be more proper, as it was always obtained at the moment of copulation. I used the semen of different horses.—The first was without clots, very fluid, and of a light cinder colour (1). The corpuscula were not so numerous as those of human semen : there was no difference that I could discover, except that those of the horse were a little larger. The appendage is more visible, probably from being thicker ; it is distinctly and completely seen, though immersed in the feminal lymph, fig. 3. Their oscillatory motion is not

T 2

so

(1) 11 March, the thermometer, from a cold north wind, only at 43° .

fo great as that of the human corpuscula, which may be the reason why they advance further in the same time: their progressive motion is quicker, and sometimes saltatory. The size of all is not the same, nor do the whole die in the same time. A few have continued moving more than an hour; the greater part died in three quarters; and sometimes, but seldom, they did not live above half an hour. When motion ceases, they remain entire, with the appendage extended in a straight line, or a little curved.

The semen of the horse is very glutinous and filamentous (1). There we see the corpuscula attached by the body, and particularly by the filament, to various irregular substances mixed with the fluid; and, unable to disengage themselves, the substances are sensibly agitated by their motion. Thus it is that in several places corpuscula are seen attached together, which might induce us to think them larger than the rest: but, with attention, the two separate appendages are soon perceived, each oscillating by itself; and if the observation is prolonged, it is not uncommon to see the bodies divide and form two distinct corpuscula. I am well assured it is not an optical illusion, regarding the corpuscula of a different size, but a positive fact. Some were a third larger than the rest; which diversity

was

(1) 22 March, the thermometer 57°.

was remarked in a former observation, 11 March. I particularly attended to the diminution of their motion, in proportion to the time that the fluid had been exposed to the air. Scarcely has it come from the animal when the corpuscula are seen in great agitation, darting through it with vast rapidity, and oscillating to both sides. This activity insensibly decreases; so that if they at first describe a certain given space in a second,—in a quarter of an hour, they do not traverse a third of it in the same time. The arcs of oscillation become successively smaller; and at last, the motion of the corpuscula is reduced to a languid vibration of the body and appendage, without any change of position. The vibration disappears, and the appendage remains extended in a straight line, after the manner of these beings.

Many aquatic animals of the apodal class transport themselves by contorsions of their members vibrating and oscillating from side to side: and indeed one can positively affirm, that the anterior part of the body is pushed forward, and moves progressively by the contorsions and oscillations of the posterior part. I paid the strictest attention to discover whether the anterior part of the corpuscle was pushed forward by oscillations of the appendage. When in very rapid motion, the quickness of the mutual vibrations of the body and appendage render it impossible to be distinctly

tingly observed; but, beginning to relax, we easily see their mode of advancing, and that it is the same with that of the aquatic animals just mentioned. When the appendage ceases to oscillate, progression also stops, but begins again when the oscillations recommence. I made this important observation, not only on the corpuscula in the seminal fluid of the horse, but on those of the human semen, and of all the animals I shall afterwards name. The motion here did not continue above an hour and a half.

The corpuscula of the two portions already spoken of were very numerous; in a third portion they were rare, but perfectly similar both in figure and properties. Their motion continued eight hours (1).

I examined the semen of other six horses. The corpuscula, except in being more or less numerous, were exactly like the preceding, therefore it is needless to describe them. When the seminal fluid is mixed with water, or even with saliva, all instantly become motionless.

The seminal fluid of the bull contained moving corpuscula in numbers surpassing those in the human semen (2). The appendage is longer than that of the human seminal corpuscula, and the body also seems a little larger, fig. 4. Pl. 2.

The

(1) May 2, the thermometer 64°.

(2) March 30, the thermometer 57°.

The whole length, to the extremity of the appendage, is distinctly seen, though deeply immersed in the feminal matter, which is perfectly fluid and of a whitish colour. Here likewise is progression while the appendage oscillates. This motion is different from that of the human corpuscula: it is much more rapid, and suspended for short intervals, which is not to be seen in the others. The small quantity of the semen of the bull which I had on this occasion prevented me from extending my researches farther.

At another time, having abundance, I was more able to satisfy my curiosity (1). Besides the phenomena before described, I remarked, 1. That the corpuscula both swam horizontally, and rose and sunk in the semen, as fishes do in water; 2. When the fluid dried, their motion was irrecoverably gone; 3. In times of equal heat, they moved quicker than those of man or the horse; 4. The mixture of every kind of water, even of saliva, was fatal to them. Similar phenomena were observed in the feminal fluid of other three bulls. I had the semen from all these at the moment of copulation.

The testicles of a dog, alive and in perfect health, being opened, the epididymis was full of semen, a little viscous, very thick, and of a dark ash colour (2). The thickness prevented me

T 4

from

(1) May 30, the thermometer 68°.

(2) February 14, the thermometer at 48°.

from seeing the corpuscula accurately. Only a confused agitation of the substance was perceived, which ceased on mixing the semen with water: the corpuscula now become motionless were distinctly seen. I then suspected they had been the cause of the agitation, which mixture with water had destroyed: my suspicions were confirmed on mixing saliva with the semen, for the tumultuous motion continued.—I saw it was produced by prodigious numbers of corpuscula. The reader will not be surpris'd if nothing is said of their figure, size, and motions, as it would be repeating all that I have said of the human corpuscula; for these of the dog most exactly resemble those in the seminal fluid of man. In three quarters of an hour, they became motionless.

The semen of a dog, which I procur'd at the moment of copulation, was a little viscous, and like turbid water (1). The moving corpuscula were not so much immerse'd as in that taken from the epididymis: and it was unnecessary to mix it with any other fluid to see them. Every part was sufficiently visible, and their motion very rapid, but the velocity insensibly diminished; and two hours after the fluid came from the animal's body, all motion was at an end: the corpuscula
for

(1) April 27, The thermometer 61°.

for the most part remained with their appendages extended in a straight line.

These experiments were repeated on other five dogs, and the results found perfectly alike.

If between the human and canine corpuscula no difference has been discovered, neither has any been seen in the rabbit, except that the body and appendage are a little less. Though I obtained the fluid in summer by spontaneous emission, their motion did not continue half an hour: and, repeating the observation in winter, they ceased to live in ten minutes.

Nine hours after a ram was killed, I opened the testicles, and expressed the fluid into a watch glass (1). All the corpuscula were motionless: they were larger, therefore more easily seen than those of the dog or man.

In the seminal fluid of a living ram, all the corpuscula were in motion (2). The oval part or body of each corpuscle sometimes immersed itself in the fluid and escaped the eye, and sometimes came to the surface. Their properties resembled those of others, if we add a certain gentle vibration and a little more activity. When the corpuscle contracted itself, the appendage was less curved. The duration of motion was
much

(1) May 10, The thermometer 66°.

(2) June 18, The thermometer 66°.

much less than in many others: though the heat of the atmosphere raised the thermometer to 66° , all ceased to move in half an hour.

The epididymis of another living ram was examined (3). The quantity of seminal fluid was so great as to fill two-thirds of a watch-glass. Viewed with the naked eye, it seemed in continual agitation, notwithstanding the glass was situated on an immovable plane. A drop was examined with a magnifier of small power: the whole seemed in motion: and the microscope proved that this was produced by the agitation of the corpuscula alone. They hardly moved an hour.

After examining the seminal fluid of so many warm blooded animals, I determined to examine the semen of some whose blood is cold. I began with fishes; and for this purpose the experiment was delayed until they spawned. The milt of a living carp being taken, and the fluid expressed into a vessel, it appeared tenacious, thickish, and of a dull white. Many moving corpuscula were seen, but I could not obtain distinct vision until the density was diminished by water. Here was a new scene: the corpuscula were no longer composed of two parts, a body and an appendage, but a united whole resembling minute spheres, and apparently solid,

(1) July 15, The thermometer 77° .

solid, Pl. 2. fig. 5. These spherules, of a darkish colour to the eye, swam through the liquid in every direction, advanced, retreated, mutually avoided each other, immersed themselves deep in the fluid, and ceased to move in a moment. In a word, they had many motions and properties peculiar to infusion animalcula. Their number was infinite; their course continued a quarter of an hour, then they stopped and moved no more. I repeated the experiment five times, expressing the fluid of the milt anew, and the consequences were the same. If any fresh liquid was mixed with the semen, I was sure of putting the spherical corpuscula in motion, or rather of increasing their motion; but, if the liquid was ardent or corrosive, instead of being increased, it was destroyed.

Having at that time water newts, I cut the testicles of a male in pieces, and expressed the fluid which was thick and glutinous. Applied to the microscope, the appearance changed: there was an immense number of long slender corpuscula. Some were extended in a straight line, others curved, some solitary, others entangled like a skein of thread. I examined those that were single as the most easily distinguished. Each corpuscle was composed of a body and a very long appendage, fig. 6. They moved with difficulty, the greater part of the body being immersed in the
viscous

viscous substance. Being diluted with common water, they all began to traverse the liquid. As it was at perfect rest, and no external cause appearing to act upon the corpuscula, I was inclined to think this motion spontaneous and peculiar to them. My opinion was afterwards confirmed by discovering the efficient cause of motion. With steadfast attention, two rows of minute points on the sides of the appendage were observed moving like most minute oars, fig. 7. and then it was that the situation of the corpuscle changed; but when their motion ceased, it also ceased to move.

When the mixture of semen and water dried up, the motion of the corpuscula was irrecoverably lost, though again wet with fresh fluid.

Similar experiments were repeated on semen taken from the testicles of other newts, and with the same results; but, on diluting it, the corpuscula often collected in numbers, placed themselves parallel to each other, and bent into a circle. When all collected, they bent themselves so much that the point of each appendage almost touched the opposite extremity of the body. In this position, they began to revolve round a common center like a reel, and continued for some time.

I found corpuscula not only in the testicles of newts, but also in the vasa deferentia. These vessels resemble two very white little pipes, running along
the

the middle of the spine. One end is fixed near the head of the animal; the aperture of the other is evidently in the cloaca, through which the excrement passes. The vessels are always full of semen, particularly while the males fecundate the eggs of the females. The semen is very white, like milk, and the number of corpuscula it contains is so great that the fluid part is small compared with the mass they form. They are perfectly similar to those in the seminal fluid of the testicles; with this difference, however, that neither water nor any other liquid is required to increase their motion. In the semen, they naturally move with the quickness of the corpuscula in fluid from the testicles diluted with water. The corpuscula of the vasa deferentia retain motion much longer than those of the testicles; yet it is far from equal to that of the human corpuscula, those of the horse and other animals. I have always found them in male newts in every season of the year.

By expressing the seminal fluid from the testicles of frogs, it is visibly full of corpuscula. They are infinitely shorter than those of the newts. They have progression, and in advancing make gentle vibrations. They are of a long elliptical shape, and very soon cease to move, fig. 8. Plate

CHAP. II.

THE PRECEDING OBSERVATIONS COMPARED WITH
THOSE OF LEEUWENHOECK.—CONFUTATION OF
SOME OPINIONS CONCERNING THE NATURE OF
SEMINAL VERMICULI.

AFTER this course of observations on the seminal fluid of man and different animals, I determined to read and consider what Leeuwenhoeck and Buffon had written, two authors who, more than all others, had made this subject their particular study. Several years had elapsed since I read their discoveries on seminal vermiculi, so that only a general idea of their opinion remained. I even wished to proscribe that remembrance, and in these researches to have my mind as a pure tablet, the more fit to receive the real impressions of what my eyes might behold without any prepossession for the observations of others.

I shall begin with Leeuwenhoeck; and that the reader may have before him the real sentiments of this naturalist, and that he may compare

pare his observations with mine, it is necessary to transcribe some of the chief passages where he speaks of spermatic vermiculi. M. de Buffon has, before me, employed part of the passages to compare his own observations with those of this eminent observer,—and here I have the pleasure of following his example.

The excellent Dutch microscopist sent a communication of his discoveries on the human semen to Lord Brounker, President of the London Royal Society, 1677. “ Postquam excellentissimus dominus Professor Cranen me visitatione sua saepius honorabat, literis rogavit domino Ham. Cognato suo, quasdam observationum mearum videndas darem. Hic dominus Ham me secundo invisens secum in lagenula vitrea semen viri gonorrhœa laborantis, sponte distillatum attulit, dicens se post paucissimas temporis minutias (cum materia illa jam in tantum esset resoluta, ut in fistulae vitreae immitti posset) animalcula viva in eo observasse, quæ caudata, et ultra 24 horas non viventia judicabat. Idem referebat se animalculam observasse mortua post sumptam ab aegroto terebinthinam. Materiam praedicatam fistulae vitreae immissam, praesente Domino Ham observavi, quasdam in ea creaturas viventes; at post decursum 2, aut 3 horarum eandem solum materiam observans, mortuas vidi.

Eandem

Eandem materiam (semen virile) non ægroti alicujus, non diuturna conservatione corruptam, vel post aliquot momenta fluidiorem factam, sed sani viri statim post ejectionem ne interlabentibus quidem sex arteriæ pulsibus, sæpiuscule observavi, tantamque in ea viventium animalculorum multitudinem vidi, ut interdum plura quam 1000 in magnitudine arenæ sese moverent ; non in toto semine, sed in materia fluida crassiori adhaerente ingentem illam animalculorum multitudinem observavi ; in crassiori vero seminis materia quasi sine motu jacebant, quod inde provenire mihi imaginabar, quod materia illa crassa ex tam variis inhæreat partibus, ut animalcula in ea sese movere nequirent ; minora globulis sanguini ruborem adferentibus hæc animalcula erant, ut judicem millena millia arenam grandiolem magnitudine non æquatúra(1). Corpora eorum rotunda, anteriora obtusa, posteriora ferme in aculeum desinentia habebant ; cauda tenui, longitudine corporis quinquies, sexiesve excedentē, et pellucida, crassitiem vero ad 25 partem corporis habente prædita erant, adeo ut ea quoad figuram cum cydaminis minoribus longam caudam habentibus optime comparare queam : motu caudæ serpentino, aut ut anguillæ in aqua natantis progrediebantur ; in materia vero aliquantulum crassiori caudam octies, deciesque quidem evibrabant antequam latitudinem capilli

(1) Læwenhoeck's calculations of the minuteness of animalcula are generally received : but in my opinion they are very liable to objection.—T.

capilli procederent. Interdum mihi imaginabar me internoscere posse adhuc varias in corpore horum animalculorum partes, quia vero continuo eas videre nequibam, de iis tacebo (1)".

These observations were accompanied by others, written by Leeuwenhoek to the Secretary of the Royal Society, 1678. He composed them because some person had suggested to him to examine the feminal fluid of animals. "Si quando canes coeunt," Leeuwenhoek answers the Secretary, "marem a femina statim seponas, materia quaedam tenuis, et aquosa (lymphæ scilicet spermatica) e pene solet paulatim extillare; hanc materiam numerosissimis animalculis repletam aliquoties vidi, eorum magnitudine, quæ in femine virili conspiciuntur, quibus particulæ globulares aliquot quinquagies majores permiscebantur.

"A cuniculorum coitu lymphæ spermaticæ guttulam unam, et alteram e femella extillantem examini subjeci, ubi animalia prædictorum similia, sed longe pauciora comparuere."

In the same year, 1678, Leeuwenhoek also communicated to the Royal Society the animalcula he had found in the semen of the dog,---
 "Semini canini tantillum microscopio applicatum iterum contemplatus sum, in eoque antea descripta animalia numerosissima conspexi. Aqua
 VOL. I. U pluvialis

(1) Philosophical Transactions, No. 141, p. 1041.

pluvialis pari quantitate adjecta, iisdem confestim mortem accersit. Eiusdem feminis canini portiuncula in vitreo tubulo unciae partem duodecimalem crasso servata, sex, et triginta horarum spatio, contenta animalia vita destituta pleraque, reliqua moribunda videbantur."

He confirmed his discoveries during the following years, and made additions to them. In a letter to Mr Wren, 1683, he thus expresses himself respecting the seminal vermiculi of frogs: "Hic animalculorum numerus erat tantus, ut credere subiret ad quodvis fœmellæ ovulum a masculino emitti forte 10000 talium animalculorum, quæ in femine ejus continentur." And in the year 1699, writing to the Royal Society on his theory of seminal vermiculi, some of which he believed male and some female, he proceeds: "Si porro his addamus, quod me antehac in observationibus meis animadvertere censei inter animalcula ex femine virili quædam apparuisse, quæ aliquantulum ex se mutuo differre videbantur, unde concludere non verebar, alterum genus mares, alterum vero fœmellas repræsentare, atque si cogitemus idem in omnibus feminibus masculinis locum habere, nullus video, &c." There is another passage coinciding with this: "Sed jam ubi etiam in feminibus masculinis animalium, avium, piscium, imo etiam insectorum reperi animalcula, multo certius esse statuo, quam antea, hominem

hominem non ex ovo, sed ex animalculo in femine virili oriri; ac praesertim cum reminiscor, me in femine masculino hominis, et etiam canis vidisse duorum generum animalcula. Hoc videns mihi imaginabar, alterum genus esse masculinum, alterum fœmininum.”

In 1701, Leeuwenhoeck wrote to the Royal Society in these words: “Die Julii 27, circa horam nonam vespertinam accepi testiculos juvenis arietis. Cum vero lanus hisce testieulis primam detraxisset cutim, seu membranam, ego vicissim quoque eos altera privavi membrana, ut hac ratione vasa feminifera nuda visui exposita jacerent. Primo ergo aperui vasa feminalia in testiculi parte exteriori sita, iisque exemi semen masculinum (quod nudo observatum oculo album repræsentabat colorem) illudque microscopio apposui, atque hoc pacto oculo admovi, quando mihi animalcula feminalia tam stupendo apparuere numero, ut vix fidem apud quemquam, nisi testem oculatum, inventurus sit. Haec animalcula nubium in morem integris agminibus inter se vagabantur, natitabantque, quorum multa eodem tendere natatu videbantur, ut mox aliquot millena sese ab uno agmine separantia alteri sese agmini adjungebant, illudque sequi videbantur.”

A little lower he adds, “Haec vero animalcula nuper a me observata caudas habent juxta corpus crassiores, atque sensim fiunt tenuiores,

adeo ut earum extremitates ubi materia, cui animalcula infunt, atque innatant, paulo densior est, visum plane effugiant; atque sic horum animalculorum caudae fabrica plane convenit cum omnium piscium caudis.”

Respecting the nature and properties of spermatic vermiculi, these are the words of Leeuwenhoeck: “Quotiescumque animalcula in femine masculo animalium fuerim contemplatus, at tamen illa se unquam ad quietem contulisse, me nunquam vidisse mihi dicendum est, si modo sat fluidae superesset materię, in qua sese commode movere poterant; at eadem in continuo manent motu, et tempore, quo ipsis moriendum, appropinquante, motus magis, magisque deficit, usque dum nullus prorsus motus in illis agnoscendus sit (1).”

From these quotations, it may be easily seen, that Leeuwenhoeck and myself have remarked the same facts in the animals of human semen. This observer calling them animalcula or spermatic vermiculi. We both agree, 1. on assigning the same figure to the corpuscula in the seminal fluid of man, the ram, the dog, and rabbit. In my description of them, I have said they seemed composed of two parts, a body and an appendage. Leeuwenhoeck also acknowledges the existence of these parts,

(1) Leeuwenhoeck Opera, vol. 1.

parts. 2. That we agree concerning the size of the body, the length, the figure, and proportions of the appendage, will farther appear from the designs he has given of the spermatic vermiculi of man and other animals. 3. We have each discovered a prodigious number of beings in the semen: We have remarked the size of some different from that of the rest: We have also allowed them the same properties, and said their motion in swimming was serpentine like that of eels, and uninterrupted unless towards the termination of life: that the progress of the vermiculi in the grosser parts of the fluid met with great opposition. But I have observed all this in the preceding chapter. We have both remarked one singularity, that rain water deprived the canine vermiculi of motion. I have likewise found the same effect on those of the ram and man even from other kinds of water, as dunghill, ice, snow, and river water. I have constantly remarked, that when motion ceases, the appendage never encircles the body, but always remains extended in a straight line, or in one very little curved; a fact observed by Leeuwenhoeck, as appears from his engravings of the vermiculi of the dog and the rabbit. When he means to represent them dead, he exhibits the appendage extended; if he means to represent them alive, it is with the appendage curved.

Therefore the moving corpuscula found by me

in the semen of man, the horse, the bull, the dog, the rabbit, the ram, newts, and frogs, are precisely the beings which Leeuwenhoeck terms worms or spermatic animals. The last appellation shall also be used, not only to speak in the language of this naturalist, but because I esteem the facts related sufficient authority to bestow the name of animals on them. Spontaneous motion and contorsions of the body, by means of which they move from one place to another, are characteristics sufficiently decisive of animality. Of this we shall have more conclusive evidence in the sequel.

What has been said is enough to show how erroneous the opinion of Sir Charles Linnæus must be, when he maintains that the vermiculi are only particles of inert matter suspended in the fluid, and put in motion by heat. As the celebrity of the Swedish naturalist might induce us to suppose that he does not advance this without foundation, the reasons which made him determine to adopt his sentiments should be mentioned; and that none of their force may be lost, I shall give them, such as they have been written by the author himself in a Latin Thesis, while he was President 1759, entitled *Generatio Ambigena*. “*Vermiculos feminales Leeuwenhoeckii vivos esse vermes, in omni genitura prolifica maris praesentes, ad nostra tempora firmiter fatis credit*”

quidem verbis. ‘Vermiculi isti Leeuwenhoecki-
ani minime sunt animalcula proprio, et voluntario
motu gaudentia, sed corpuscula inertia, quæ ca-

lidæ genituræ innatant, non fecus ac particulae oleosæ, quod selecta Lieberkunii microscopia nobis manifeste ostenderunt.' Hoc postea etiam vidit, et confirmavit summus Physiologus illustris D. V. Hallerus, ut adeo auctoritas vermium seminalium jam prorsus fere in defuetudinem venerit."

This singular opinion of Linnaeus was unknown to me until communicated in a letter from M. Bonnet, who transcribed his words. He, undoubtedly from politeness, or perhaps with a design to encourage me to prosecute my researches on spermatic vermiculi, added the following paragraph: ' You perceive there is here cited ' the eminent testimony of a Gronovius, a Van. ' Swieten, a Lieberkuhn, &c. and even that of ' Haller. At some future period, I shall write to ' him about it; nevertheless, all these authorities. ' could not weigh with me, nor, in my view, ba- ' lance your opinion, because I know you to be ' a much better judge of such things than the il- ' lustrious authors Linnaeus names in his thesis. ' You have paid much more attention to the ' vermiculi in question, and long studied the ' animalcula analogous to them; you have thus ' obtained a kind of touchstone, which experi- ' ment more and more improves, and which can ' never prove deceitful.'

Before.

Previous to deep consideration of what was advanced by Linnaeus, I could not dissemble my extreme surprize to see Haller cited as one of those who denied the existence of spermatic vermiculi, whereas he had always been one of their most strenuous supporters. His annotations on the Lectures of Boerhaave, his Elements of Physiology, his Physiology at large, in a word, all his works bear the most manifest evidence of it. In the sequel of this tract, I shall have occasion to use the authority of so great a physiologist.

We see how easily the opinion of the celebrated Upsal botanist is established; scarcely has he viewed Leeuwenhoeck's animalcula when he decidedly pronounces they are not animals. I leave it to the judgment of the learned and impartial reader, Whether a hasty glance of the vermiculi, and of only one species, is sufficient for positively deciding their nature, and deciding it better than Leeuwenhoeck, who had, during a number of years, examined so many species with so practised and attentive an eye. We know well the time and labour that naturalists have bestowed in ascertaining the nature of certain organised bodies doubted whether to belong to the class of animals or plants. Yet these bodies were not; like seminal vermiculi, microscopic animals; their size admitted of them being completely manipulated, and easily seen with the eye. Linnæus
should

should have been better convinced, he who, with reiterated examinations and infinite patience, has characterised such a number of bodies in the three kingdoms of Nature. If his laborious and useful occupations had left him sufficient leisure to penetrate the world of *invisibles*, where, as the illustrious Muller observes, one may well be a stranger without a crime (1); and had he applied to this subject with that diligence and acuteness which he has displayed in his discoveries in the visible world, we cannot doubt that he would have omitted in his thesis the quotations we have just made; for, with an attentive view of the seminal vermiculi, he would easily have seen that they do not swim in the liquid like oleaginous particles; but at some depth, I have had eminent proofs of this. Penetrating the first stratum of the dog's semen with the microscope, I pressed it downwards so as to reach the lower parts; in each an equal number of vermiculi were visible. The same method was adopted with

(1) *In Mundo Invisibili, de quo Dissertationem dedit, hospes.*

In fact, as far as is known, this very learned naturalist never employed himself in contemplating invisible animals, and his doubt whether infusion animalcula were living beings, or rather *oleaginous* or *saline* particles, (a proposition disgraceful to our days,) forcibly convinces one of it.

with a considerable quantity in a watch-glass. Wherever the microscope penetrated, the motion of vermiculi was seen. A third experiment has demonstrated their presence at a great depth. A thin-sided chrystal tube, half a line in calibre, and five inches in length, was filled with semen. I held it perpendicular; and, in this position, applied a magnifier to the sides, the great transparency of which permitted me to see the included semen clearly, when the tube was interposed between the sun and my eye. Wherever the lens was applied, whether to the top, bottom, or middle of the tube, I always saw vermiculi. The experiment was repeated with a tube of much greater capacity; it was a third of an inch in diameter within, and at least four inches long, but the opacity of the fluid prevented me from seeing the vermiculi it contained. However, the bottom, being insecurely stopped, allowed some drops to exude; all were equally full of vermiculi as the liquid in the higher part of the tube. The consequences were the same on repeating the experiment with the semen of the dog and other animals.

In the second place, had the Swedish naturalist bestowed on seminal vermiculi the attention they deserve, he must have perceived they are not inert corpuscles, but possessing a spontaneous motion well characterised; that it is regulat-
ed

ed by the mode in which they advance; that they swim in the spermatic lymph, contorting and vibrating their parts like many other aquatic animals; he would not have ascribed their motion to the heat of the semen, since, when this is gone, and the heat of the atmosphere only remains, which happens a little after the semen comes from the animal, the vermiculi do not cease to move; but their motion continues for a limited time; sometimes several days when they are included in small tubes.

In short, the spermatic vermiculi of frogs, fishes, and newts, completely refute the opinion of Linnaeus. Their seminal fluid being destitute of every sensible principle of internal heat, as it constitutes part of cold blooded animals, heat cannot here be the cause of the motion of vermiculi, on the contrary, they should absolutely be motionless.

All this evinces how much two modern naturalists, Valmont de Bomare, and Ernest Asch, are deceived in thinking seminal vermiculi do not exist in nature, or that they are only the most active parts of the semen; and this they maintain, from their never being able to discover them, notwithstanding repeated observation. A similar objection had been started, after Leeuwenhoeck's discoveries, who was content with remitting its authors to their studies. 'Dominos
' illos

‘ illos nondum eo usque profecisse, ut res recte
‘ observare valeant.’ I must be pardoned if
I make the same answer to these new oppo-
nents; for we must say their observations have
been very unfortunate, their vision very bad,
their microscopes good for nothing, or their
inaccuracy and inexperience very great in the
art of observation. It is true M. de Bomare as-
serts that his eyes are very good, and his micro-
scopes excellent, and does not hesitate to say,
‘ We have repeated all the experiments of ani-
‘ malculists on semen; and although our eyes are
‘ very good, and our microscopes excellent, we
‘ have been able to discover nothing (1).’ I was
almost prompted to exclaim, May heaven pre-
serve us from such good eyes and such excellent
microscopes; for, with them, we should be in
great hazard of regarding as illusions, the most
beautiful microscopical discoveries which philoso-
phers have hitherto made; and we should have
to dread that we and our posterity would be forc-
ed to relinquish the prospect of making new
ones! With this acuteness of vision, and this
perfection of microscopes, we should have to re-
visit the ignorance of our ancestors in the world
of invisibles. But I would rather believe M. de
Bomare’s

(1) Bomare Dictionnaire. Art. Semence. T. 10. p. 420.
Edit, d’Yverdon.

Bomare's sight is truly very acute, and that his microscopes are the most perfect. What reason can we then assign for the unsuccess of his attempts to see any thing in semen with all this assistance? The conclusion is simple. When I presume to affirm his experience is not infinite in the observation of such objects, I do not wish to lessen the esteem due to his merit. He has acquired the name of a laborious and indefatigable compiler. His Mineralogy, and his Dictionary, which are an assemblage of fragments copied here and there, will do him that justice. But no one knows that he has been, or that he may be, a microscopical observer. To make microscopical observations with accuracy, many natural and acquired qualities are requisite, and many more are necessary to guard against being deceived in the subtle researches after beings of infinite minuteness.

I have frequently, *viva voce*, confirmed the difference of sentiment that books afford concerning the nature of spermatic vermiculi, by means of persons whom I made observe the semen of man and different animals. Some, though all had distinguished merit in other pursuits, were certain they saw nothing, notwithstanding they looked long at a time through the microscope, and even returned often to observation; and the number of these was the greatest. Others, after
very

very long and painful examination, seemed to perceive an indistinct obscure fermentation in the fluids. A few could see the body or corpusculum of the vermiculi, but were unable to distinguish the appendage: and very few could perceive their form and all their motions. These last, indeed, were well accustomed to study microscopical objects, and might reasonably be called professional observers. Let those who deny the existence of spermatic vermiculi endeavour to enter this class, and practise on minute objects, and I assure them, if they repeat their experiments on the seminal fluid, they will see vermiculi as I and Leeuwenhoeck, with many other naturalists, have seen long before. Then, if they chuse to communicate their observations, they will enjoy one advantage: if their previous publications excite the compassion of the learned, their future works may perhaps merit an eulogium.

CHAP. III.

A BRIEF ACCOUNT OF M. DE BUFFON'S OBSERVATIONS
ON SEMINAL VERMICULI.—CRITICAL REFLECTIONS
ON THESE OBSERVATIONS.

WE descend from the observations of Leeuwenhoeck to those of Buffon, which, although very numerous, comprehensive, and specific, we shall but abridge. With the compound microscope he observed the fluid from the seminal vessels of a dead human body (1). It was full of filaments, moving about and branching into many parts. The filaments swelling burst, and many ovular corpuscula escaped, which still remained attached to the filaments by a thread; then they oscillated like a pendulum, and during the oscillations the thread extended. The corpuscula, at length detached, traversed the most fluid part of the semen along with their filament, the extreme length of which impeded their motion, and they seemed to him to endeavour to free themselves of it. Having diluted the semen with rain water, the microscopic view was better defined. It clearly appeared that each ovular corpusculum had

2

(1) *Histoire Naturelle*, tom. 3. edit. 12.

a double motion, oscillation, and progression. In two or three hours the seminal matter acquired greater fluidity: the filaments disappeared; the number of corpuscula increased; the threads contracted; oscillation relaxed; and progressive motion increased. In five or six hours, the corpuscula, having lost the threads, resembled animals more than ever; not only because their quickness in swimming increased, but because their course was directed to every quarter. The size and figure of several seemed to change. In twelve hours, the activity of the corpuscula was great, and some revolved upon their axis; others changed from an ovular to a globular figure, under the observer's eye. Several divided asunder, so that one formed two. After one day, the number diminished; and on the third, none were to be seen.

In other semen, which appeared entirely filamentous, the ovular corpuscula did not proceed from the filaments, but these dividing were metamorphosed into corpuscula. They were embarrassed by a thread: the longer it was, the more it impeded their motion; but it gradually shortened, and was at last completely destroyed.---- Their figure then resembled that of infusion animalcula: they swam with a progressive motion, though the thread at first confined them to simple oscillation.

Buffon having examined a new drop of semen, ten or twelve hours after coming from the animal, he saw the whole corpuscula proceed in crowds from the same side where there was a net of filaments which continually produced them. The size of the net gradually diminished, and at length appeared less by one half.

In his first observation, the author thought the corpuscula gradually became smaller, at the same time he was not certain; however, another observation convinced him of it.

He then observed the feminal fluid of a dog. It was clear, and without filaments. The ovular corpuscula almost resembled those in the human semen completely, only he found them more active and less numerous. On the fourth day, very few had threads.

In another portion of the feminal fluid of the same dog, beside this, he saw corpuscula proceeding from a mucilaginous substance in the semen, that seemed internally animated by an inflating motion, which induced him to think the mucous swelled in some parts forming little tumours. All these corpuscles were without a thread. The figure of some changed: they extended, contracted, and were inflated; and, amidst these wonderful operations, divided asunder, each giving existence to two corpuscula, whose figure and properties

properties were similar to those of the generating corpuscles.

The French naturalist extended his experiments to rabbits. From the seminal vessels of one, he took the fluid, and, mixing it with water, observed the following phenomena: In three hours, the globular corpuscula became smaller, and thus constantly diminished until the eighth day, when they were scarcely visible; but, as their size diminished, their number and activity increased; their figure also varied, becoming ovular, spherical, and elliptical.

He repeated the experiment on the semen of another rabbit ejected at the moment of copulation. Ovular corpuscula were found, some with a filament, others without it: the former greatly resembled those of the dog and of man, except in being less, more entire, and the thread shorter. He could not be certain whether he saw real filaments, or only faint furrows formed in the liquid by the course of the corpuscula.

The semen of the ram presented elliptical corpuscula, without filaments, and equal in size, moving in every direction.

M. De Buffon also examined the seminal fluid of some fishes: of the carp, the pike, and barbel, procuring it while the animals were alive. There, he found many corpuscula in motion, of a very dark colour, almost black, and extremely small.

Such is an abbreviation of the observations made on the semen of animals by the illustrious author of *Natural History*; whence he draws a general conclusion, that the corpuscula examined and described by Leeuwenhoeck a century ago cannot, with the Dutch observer, by any means be termed spermatic vermiculi, because they possess no characteristics of animality. The labour experienced in drawing along their tails, in divesting themselves of them, in changing their figure so often to form anew, before the observer's eyes, their division into parts, and diminution of size, seem to him peculiarities incompatible with animality. On the other hand, not being able to say they were bodies perfectly inert, because he had really seen signs of animation, he inclines to constitute them into a particular class under the name of *organic molecules*, which are particles disseminated throughout matter, original, incorruptible, animated, and always active. Nor does he hesitate to confide the formation of the winged universe to these molecules.

Here I enter not into a discussion on organic molecules, but occupied solely with the facts which M. de Buffon relates, I sincerely regret that the essential difference between his account, and what I have myself seen, has made a deep impression on my mind. It is not that I wish to flatter myself

self my observations are of more value than his, from exactness of execution or assiduity in continuance. If it may be allowed, I shall even say they may be preferred from being more numerous. At the same time, M. de Buffon's perfect conviction of the truth of his observations: his great confidence that the readers who repeat them will find them scrupulously exact: the natural and decided manner in which he opposes them to those of Leeuwenhoeck; and the errors he reproaches him with: all made me judge it possible that the Dutch microscopist and myself might be deceived. And this was aided by a consideration which, though foreign to the subject, is plausible; I mean the great reputation and celebrity the French naturalist deservedly enjoys. I long hesitated whether to prosecute my observations, and subject them to as rigorous an examination as might be possible, or whether it might be more proper to abandon them lest they should not be credited from the formidable trial they had to undergo. I would actually have done so; had not my illustrious friend M. Bonnet, who is well skilled in such matters, diverted my intention. He strenuously advised me to study the seminal vermiculi of various animals. I replied, it had already been partially done, but my labours had been suspended on finding my observations so very different from those of M. de Buffon, whose

authority I respected. He had the goodness to answer, ‘ You judge well, my valued correspondent, that I am not much surpris’d to find you in opposition to M. de Buffon with regard to spermatic vermiculi; nor do I forget, what he has in some measure told us, and which I have repeated after him, that his theory preceded his observations. Now you know as well as I do, that a favoured theory is a mirror which changes the appearance of objects.

‘ Fear not that M. de Buffon’s authority will in the least invalidate the truth of your discoveries on seminal vermiculi. You have proved yourself an excellent observer, and acquired the right of being believed. You have cherish’d no theory, but are satisfied with interrogating nature, and giving the public a faithful account of her responses. Philosophers will always listen to you; and they will esteem your observations so much the more certain that you prove yourself to possess the art of observation.’

These obliging invitations encouraged me to draw my observations from the obscurity in which I had left them, and to continue increasing them as much as my humble talents would admit. Without interruption, this was my chief employment for the greater part of three years. But the various facts gradually discovered, and of which an abbreviated narrative shall be given, little correspond

respond with those of M. de Buffon: at the same time, it appeared to me that I had, during this long research, discovered several reasons which might have induced him to think as he does.

One of the principal phenomena which the French author considers as the chief basis of his hypothesis, is the formation of the spermatic vermiculi, being derived from the mucilaginous parts of the semen and its filaments, which are transmuted into these animated beings under the observer's eye, as he has found in the semen of man and the dog. Mr Needham readily embraces this opinion: he supposes the vermiculi do not exist in the semen while in the body of the animal, but are formed some minutes after coming from it, and when beginning to decompose and change by the influence of the air (1).

In my experiments on semen, related in the first chapter, this formation is not mentioned, because I had not seen the smallest indication of it. Whether the vermiculi were observed at first, or not till the semen settled, I never perceived the gross or filamentous parts give existence to them. It is true, in the first course of experiments, I did not think of examining this part of the subject profoundly; my attention was not fixed upon it,

X 4

as

(1) *New Microscopical Discoveries,*

as it has since been in my other experiments. I have therefore directed the utmost observation to what happened in the solid or filamentous part of the semen as it dissolved, but I never could see the present production of vermiculi, and have even incontestible evidence of the reverse. In the mean time, the origin of the French naturalist's error has been discovered, which will be demonstrated by some facts that I must be permitted to detail.

From human semen, as yet but partially dissolved, I took two little clots forming a net of filaments, and began to consider them with the utmost attention. The vermiculi included in the filaments occasioned a motion; the filaments dissolved before me, and the two clots in a few seconds became two drops of semen. It was with singular surprise I saw the few vermiculi in these drops compared with the numbers observed in others much smaller, and not formed as they were by dissolution of coagulated semen, but of a portion found fluid in the seminal vessels.

The experiment was repeated on a clot less dissolved than the former, and still fewer vermiculi found. Then it began to occur that they perhaps did not inhabit the grosser parts of semen, but the more fluid. The suspicion was strengthened on seeing all the corpuscula perish when the fluid evaporated. But that the fact
might

might be verified or confuted, I examined many clots from each spermatic fluid, which at first was very difficult to accomplish; for the solid and consistent parts of the human semen are commonly immersed in the fluid parts, even while in the feminal vessels. These trivial obstacles were at length overcome. With the extremity of a pair of small pincers, I took a portion of human semen, similar to coagulated milk, from the feminal vessels: as it was moist, I drew it along a dry piece of glass that it might deposit its humidity, and then put it into a watch-glass, attending its dissolution in order to apply the microscope. It was not without vermiculi. Compared with another portion of the fluid part, taken from the vessels, there was no proportion; the number in the solid was so much smaller than in the fluid parts.

These results did not satisfy me: the few vermiculi in the solid semen might be owing to some little portion of fluid remaining along with it; and, instead of finding few, I could have wished to find none, or almost none. Having taken another clot of human semen from the vessels, I endeavoured, as far as possible, to disengage it from the fluid that might remain in and about it. Here we should observe, *en passant*, that this operation of drawing along the solid part, to take away the fluid, should be performed with
great

great adroitness and celerity, otherwise the solid part gets time to dissolve during exposure to the air; and by drawing it long or slowly over the glass, instead of drying, it always becomes more humid. I succeeded in freeing a clot of semen from all sensible moisture. I put it in a watch-glass; and, when dissolved, examined it with the microscope. The truth is, that here were found no vermiculi, nor were any discovered in other clots treated after the same manner, although they were numerous in the fluid parts of the semen in the seminal vessels of the animal which had afforded me the clots. Repetition of so important an observation was not delayed. In my journal of experiments, I find this has been done fourteen times; in thirteen, the dissolved clots exhibited no vermiculi, and only once a small number in the coagulated clot.

The seminal fluid of the rabbit is always partially coagulated; therefore, whenever taken from the vessels, it afforded the means of repeating my experiments. But I have never discovered vermiculi when the spermatic lymph could be completely taken away. These united facts convince me that the natural habitation of the vermiculi is in the fluid part of semen. The same facts ascertain the degree of credibility we should bestow on what M. de Buffon says of their formation. It is evident, that far from being generated by
the

the solid or filamentous part of the semen dissolving, they even do not attach themselves to it, as has been demonstrated. When they are found there, it is on account of the fluid part, which is their natural abode, mixing with the solid. This is doubtless the cause of M. de Buffon's error. He saw the thick and filamentous parts in motion, and, amidst the agitation, vermiculi proceeded from it: he even observed the number increase, in proportion as the gross and solid parts decreased; and remarked that the number was greatest when the filaments had entirely disappeared. Allowing himself to be deceived by these appearances, it was easy to believe the decomposition of the filaments was the productive cause. But, in truth, the vermiculi pre-existed in the filaments; they were concealed and enveloped in the parts immersed in the seminal fluid, and only when disengaged did they become visible to the observer, nearly in the same manner as if one had steeped a piece of ice in an infusion full of animalcula, and taking it out, carried it to the fire, as the ice melted, it would exhibit the animalcula that had insinuated themselves into the crevices.

M. de Buffon, by a very simple experiment, might have satisfied himself, that the vermiculi existed before dissolution of the semen. He should first have examined the fluid part, which,

on opening the seminal vessels, we find mixed with the solid. There he would have found a abundance of vermiculi, though at that time they could not be produced by the solid semen dissolving, since this solid part only begins to dissolve after it proceeds from the animal, and experiences the influence of the air.

What has already been said, and what I shall continue to say, proves the falsity of Needham's opinion, who assures us the vermiculi are produced some minutes after the semen comes from the animal, that is, after it begins to be altered and decomposed by the air. Respecting the human semen, it is necessary to consider whether the portion is solid or fluid. If the former, when completely deprived of the spermatic fluid, no vermiculi are seen, although it remains during some time exposed to the air, and though it changes and is decomposed. If the latter, vermiculi appear in it before the time required for this alteration. It has often happened, that the time consumed in taking the fluid matter from the vessels, still warm, did not exceed a second, yet I found the same number of vermiculi as afterwards, even when the fluid had been long enough exposed to the air to effect its decomposition.

My observations, on the semen of other animals, further convinces me of the falsity of such
an

an opinion. I prepared a ram, alive and vigorous, so that a friend cut the epididymis, which is usually full of semen, and while he cut it, one might take a drop of semen, and immediately present it to the microscope where my eye was kept ready fixed. It may well be seen that the time in performing the operation could not be shorter. I saw numbers of vermiculi, and all very vivacious. This experiment was repeated on the semen of a newt, and I saw the same. In spring, when the vasa deferentia are full of semen, it was unnecessary to open the animal to obtain it for observation; on gently pressing the belly, it escaped by the anus where the two vessels terminate.

This animal has afforded me proof still more decisive: I let the males suffer hunger so long that they became much emaciated; the vasa deferentia then contained a very small quantity of semen, and from the transparency of the tunics of the vessels, now rendered very thin, it might easily be observed with a magnifier. Opening the abdomen, and applying the microscope to the vessels, without affecting or deranging their situation, we saw vermiculi swimming in the fluid, and they were visible to those least skilled in the art of observation, because, as it has been remarked in the first chapter, they were infinitely longer than others.

We may, therefore, conclude, that the sper-
matic vermiculi of man and animals exist in the
femen previous to any alteration or decomposi-
tion by the influence of the air, and that they are
active in the fluid, even while it is included in
the organs of generation.

END OF THE FIRST VOLUME.
