The Unity of Science and Religion.

THE Cardiff meeting of the British Association will be marked with a red stone in the road of progress because of two noteworthy events. One was the suggestion of the president, Prof. W. A. Herdman, eagerly taken up by members of the Association, that the time had come for a new *Challenger* expedition for the exploration of the oceans, and another was the enlightened sermon, which we print in full elsewhere, delivered by Canon E. W. Barnes, a distinguished mathematician who is both a fellow of the Royal Society and a Canon of Westminster. We do not hesitate to say that not for a long time has such a conciliatory attitude been presented to men of science by a leader in the Church as is represented by Canon Barnes's address. The position taken up in it is one upon which the two standards of science and religion can be placed side by side to display to the world their unity of purpose. For Science and Religion are twin sisters, each studying her own sacred book of God and building a structure which remains sure only when established upon the foundation of truth.

The day of bitter controversy between dogmatic theology and often no less dogmatic science is, we hope and believe, past and gone, and no one would wish to recall it. We certainly have no intention of opening a discussion in our columns upon Biblical interpretation or the bearing of scientific discovery upon it. The complete story of the struggle through which the present position has been gained is told by Dr. A. W. White in his "History of the Warfare of Science with Theology in Christendom," published last year. It is difficult now to realise what was done to pour contempt upon Darwin's works and discredit him and his followers by theologians of all types; but towards the end of the conflict it became clear that leaders in all Churches were beginning to understand that men could be Christians and at the same time Darwinians, and in latter days they have not only relinquished the struggle against science, but have also frankly shown their willingness to make an alliance with it.

Canon J. M. Wilson, another distinguished mathematician who has also the highest credentials to represent the views of thoughtful Churchmen, referred to this change of attitude in an article contributed to our Jubilee issue in November last. He then wrote: "Insensibly a change has occurred which is not easy to define. Perhaps it may be described broadly as the discovery by the scientific world that the sphere of religion is not inherently anti-rational; that faith, like knowledge, rests ultimately on experience; that science has its sphere in the world of matter leading up to forces of unknown origin and nature; and that faith has its sphere in a world of personality leading up to a similarly unknown goal of personality: that their methods are not inconsistent; and that their goals may be identical."

Religion cannot, in fact, afford to ignore what is true, and can have no real interest in believing what is not true. We have passed the dangerous stage when apologists strained analogies to prove that science and orthodox Christianity, so far from being in conflict, are really in perfectly amicable agreement, and have reached a point at which it is understood that science and religion both contain systems of truth which must ultimately prove to be congruent. Theological beliefs no longer rest solely upon the ancient foundation of authority, but are built upon a basis of reason. Just as every event in Nature is a manifestation of natural law or principle, known or unknown, so religion is natural and not supernatural, and the conceptions to which it leads may be submitted to similar inquiry. It is not a simple phenomenon, but a complex of thought and emotion, and the components of this complex have yet to be resolved.

The insufficiency of human life itself as an end is dealt with philosophically by Prof. Boutroux in his "Science and Religion in Contemporary Philosophy," in which it is urged that the ideal of duty summons us beyond the specifically human to a noble struggle and a great hope, an ideal which implies faith and love, and demands divinity and a Being with Whom we can be in communion. It is in the "living reason" interpreted in the light of duty that science, without which we cannot live, and religion, without which we do not wish to live, find their reconciliation.

The scientific view of religion, now accepted by men of science and Churchmen alike, is that religion is the spiritual life of the individual, and subject to development. Progress is possible here as elsewhere, and in fact the history of the forms of religion shows a gradual purification and emancipation advancing with the gradual refinement of experience. The goal, as a reviewer has said in these columns, is a union of God and humanity, and the end must be the concrete realisation of unity in life and purpose for which, as for the unity of the world as object of the sciences, the reality of the Divine immanence is the only sure ground.

The origin of religion itself is still obscure. Whether it arose from belief in spiritual beings, in the worship of the soul, in ancestor worship, in ghost propitiation, or in any other of the various views which have been put forward, has yet to be decided. The system of social morality early developed when primitive communities were formed by man has little to do with religious perceptions. It is easy to pass, however, from the stage of veneration for great heroes or benefactors during life to that of ancestor worship after death, and later to soul worship. There would be sainted dead to worship, as well as malevolent dead and spirits of disease to propitiate. Eventually might arise the philosophic conception that continuation of life lies, not in the immortality of the soul, but in the perpetual remembrance of the righteous by mankind. All these matters are legitimate subjects of inquiry, and men of science may join with theologians in elucidating them. The problems are difficult, but not beyond solution, and they are approached to-day in a less dogmatic spirit than they were a few years ago by advocates on both sides. As regards the true relations between soul and body, we are in much the same position as that of the Persian poet who wrote long ago:—

> There was a Door to which I found no Key;
> There was a Veil past which I could not see.

Whatever the end may be, we are urged to the quest by that something within ourselves which has produced from a primitive ancestry the noblest types of intellectual man, and regards evolution, not as a finite, but as an infinite, process of development of spiritual as well as of physical life.

The Drying Up of South Africa—and the Remedy.

The Kalahari or Thirstland Redemption. By Prof. E. H. L. Schwarz. Pp. vi+163+xiv plates. (Cape Town: T. Maskew Miller; Oxford: B. H. Blackwell, n.d.) Price 8*s*. 6*d*. net.

WHILST Man of all races and skin-colours is once more involved in fratricidal quarrels—*how* Superior Intelligences in more advanced spheres must grin as they watch our wars against one another through super-telescopes or by æthereal telegraphy!—Nature is making one more effort to get rid of man. This time through Drought. She has seemingly hated everything that rose above the mediocre on this planet, whether it was in fish shape, or in the fish-saurian, the dinosaur, the struthious bird, the ungulate mammal, or the brain-worker, Man. She tried to nip us in the bud by reviving the Ice ages which she had used for other destructive purposes in the pre-Cambrian, Devonian, Permian, and Jurassic periods. But this succession of cold spells only braced Northern Man to greater efforts and greater triumphs, and sent Southern Man to grapple with the tropics, and to digest and partly overcome their germ diseases. Now the tropics, and above all the sub-tropical regions, are being threatened by drought. The desert is spreading in sub-tropical North America, in tropical South America, in temperate and sub-tropical Asia and eastern Europe, in northern and north-central Africa, and in that prolongation of the African continent which lies beyond the Zambezi and Kunene Rivers.

Prof. Schwarz theorises on the earlier theories of others—British, South African, French, and German—and propounds explanations and suggests remedies derived from his own geographical and geological investigations in South and South-west Africa; and the result is an exceedingly interesting little book, well illustrated and well worth the modest price asked for it—though insufficiently served by its maps. He points out that the main cause of the creation—the recent creation—of the Sahara, Libyan, and Kalahari deserts in Africa has been the diversion of river courses, most of which ran (more or less) from south to north and north to south, but now reach the sea by shorter courses almost at right angles to their former direction.

At no great distance in time it is highly probable that the Kunene River of southern Angola had made no breach in the western rock rampart of the Ovambo plain; it flowed instead by several dried-up water-courses into the Etosha lake, and thence along the Ovambo River to the Omatako and the Kalahari plain. Joined further by the waters of the Kwito, Okavango, and Kwando, this accumulated drainage of the lofty plateau of eastern Angola emptied itself, not—as now—into the Atlantic or the Zambezi, but into a huge expanse of water of which Lake Ngami and the Makarikari "depression" and salt pans are the shrunken remnants. Finally, in all probability this great lake of South-west Africa found an outlet through the Molopo River of western Bechuanaland into the Orange, and so at last reached the sea. But its moisture, through the soil and the atmosphere, rendered the western half of South Africa a fertile land endowed with exuberant vegetation and animal life, and able to support a large human population.

The author shows in this book how by engineering operations less difficult, probably, than those which have tripled the value of the Nile waters, the Kunene and Okavango and their tributaries might once more be diverted into the old channels and restore to human use and benefit an area of more than a million square miles. His schemes and plans will, of course, be riddled by the same "expert" criticism which declared the Suez Canal an impossibility, or be side-tracked through some political jealousy. But, all the same, if something more or less in the nature of his proposals is not soon put in hand, the habitable area of trans-Zambezian Africa will shrink considerably.

Man must give up internecine warfare and unite all his forces to defeat his arch-enemy, Nature. He must melt the ice at the North and South Poles, and put a stop to the spread of desert conditions in Asia, Africa, Australia, and the Americas. H. H. JOHNSTON.

Cement Manufacture and Testing.

Cement. By Bertram Blount. Assisted by William H. Woodcock and Henry J. Gillett. (Monographs on Industrial Chemistry.) Pp. xii+284. (London: Longmans, Green, and Co., 1920.) Price 18*s*. net.

THE need for a handy text-book on cement, which should include the modern processes of manufacture and also a review of the chemical aspects of the subject, has been felt for some time, and this work of Mr. Blount should go far towards meeting the requirements. The author has an extensive practical experience of cement manufacture and testing, and is accustomed to present accounts of the industrial processes in a readable form. With the exception of a few passages, the work is devoted to Portland cement, and the processes of manufacture selected for description are almost exclusively those which are adopted in England. Rather fuller references to Continental and American methods would have been welcome, since those methods, almost similar in principle, present great differences of practical detail.

The use of blast-furnace slag as a raw material for the manufacture of Portland cement receives only the briefest mention, but this is now extensively practised, and the product is likely to play an important part in building and engineering operations in such regions as the North of England and Scotland, where suitable clays or marls are rare, whilst slag is a waste by-product of the iron industry. The further use of finely ground slag as a pozzolanic material is not noticed, and, indeed, the whole subject of pozzolanas deserves more attention. It is not sufficiently recognised that the lime set free during the setting of Portland cement, like the slaked lime of an ordinary mortar, is capable of combining with silica when presented to it in a sufficiently active form, and that even a good cement may be considerably improved by the addition of a suitable pozzolanic substance. White Portland cement made from raw materials exceptionally free from iron is not mentioned, but its manufacture is of some interest, and has been conducted with success on a technical scale.

The account of the consumption of energy in grinding is not quite correct. It is not true of most minerals that the energy required to separate crystals along their cleavages is very small, and clinker, although it may be in a state of internal strain, nevertheless possesses a degree of hardness which requires great energy to disintegrate it, as may be shown by applying direct pressure to single granules of clinker in a testing machine. There are several suggestive notes regarding possible improvements in the manufacturing processes. The author has long argued that the logical goal of improved manufacture should be the production of such a high temperature as will yield a fused product, in which case a higher percentage of lime could be used and a homogeneous cement obtained. Certain improvements in regard to fuel economy and to the recovery of potash are also suggested.

On the subjects of chemical analysis and mechanical testing the author speaks with authority, and the chapters dealing with these sections may safely be used as a laboratory guide, whilst their usefulness is enhanced by the inclusion of a number of the more important official specifications for Portland cement in force in various countries. The fact is mentioned that "a cement which will pass the British standard specification is at least as good as that acceptable under any of the foreign specifications."

The vexed question of the chemistry of Portland cement is well treated, but a good deal of space is occupied by an account of researches and speculations which have no more than an historical interest. It is not so widely known as it should be that the whole chemistry of silicates has been revolutionised by the brilliant work emanating from the Geophysical Laboratory at Washington, which has replaced guesswork by an accurate physico-chemical survey of the systems concerned. The triangular equilibrium diagram of the lime-silica-alumina system is now known with sufficient accuracy to serve as a practical guide in the cement laboratory. The study of setting, on the other hand, has not advanced very greatly beyond the stage reached by Le Chatelier. The author, in referring to the work of Stern, has overlooked the fact that the examination of clinker and cement by reflected light after etching has been used successfully by several workers, and that excellent photographs of the fine eutectic structures have been published, some of them in Japan.

These points might well receive attention in a future edition, and would still further increase the value of a very useful book.

C. H. DESCH.

Psychology, Normal and Subnormal.

(1) *Psychology of the Normal and the Subnormal.* By Dr. H. H. Goddard. Pp. xxiv + 349. (London: Kegan Paul, Trench, Trubner, and Co., Ltd., 1919.) Price 25s. net.

(2) *Psychology and the Day's Work: A Study in the Application of Psychology to Daily Life.* By Prof. E. J. Swift. Pp. ix + 388. (London: George Allen and Unwin, Ltd., 1918.) Price 10s. 6d. net.

(3) *The Child's Unconscious Mind: The Relations of Psychoanalysis to Education: A Book for Teachers and Parents.* By Dr. Wilfrid Lay. Pp. vii + 329. (London: Kegan Paul, Trench, Trubner, and Co., Ltd., 1919.) Price 10s. net.

UNTIL the last half-century psychology was based almost exclusively upon the observation of a highly intelligent and highly civilised type of mind—usually the mind of the psychologist himself. Modern psychology owes its remarkable progress chiefly to two factors: first, to the addition of the method of experiment to the method of observation; and secondly—a factor the importance of which is less generally recognised—to the extension of these two methods to the study of simpler types of minds—of the minds of animals, of children, of savages, and of abnormal adults. The recent increase in the number of institutions for feeble-minded children has now provided psychology with the simplest human material available for investigation. Just as the ultra-rapid camera slows down the kinematographic picture of the swift movements of leaping and running, so Nature, by an arrest of the brain, retards the normal development of the child so that it can be observed and tested at leisure.

(1) The laboratory attached to the Vineland School for Feeble-minded Children—a laboratory unique of its kind, not only in America, but also in the world—has been utilised for such studies since 1906. Dr. Goddard's book provides a popular *résumé* of the conclusions progressively accumulated by the investigators in that laboratory. It is not a psychology merely of the mentally defective child. It is a psychology of the normal human mind as illuminated and illustrated by the observations upon the mentally defective. The volume, however, is by no means confined to observations carried out at Vineland. Indeed,

these are all too modestly alluded to. The exposition incorporates, in a clear and for the most part non-technical form, much of the most recent work done elsewhere upon the obscurer functions of the nervous system and of the mind.

The first two chapters give a simple but up-to-date account of the nervous system, admirably illustrated by nearly forty diagrams and photographs. Due emphasis is laid upon the importance attached by recent studies to the part played in the formation of mind and temperament by the activities of the "sympathetic" portion of the nervous system. Mental deficiency is then treated; it is described as an arrest in the development of intelligence, due to an arrest in the development of the nervous system at or before twelve years of age—that is, at some period before the onset of puberty. Memory, attention, and association are discussed in turn, and considered primarily as properties inherent in the nervous mechanism. The higher mental processes—action voluntary and involuntary, language, and (to adopt the author's spelling) "thot"—are then discussed as the complex results of the interaction of the fundamental properties of the nervous system. The affective side of experience—the emotions, simple and complex, and that elusive quality called temperament—receive full attention; and a lucid exposition is given of the views more particularly of Mosso, Cannon, and McDougall. To the results of psycho-analysis no reference whatever is made.

The first half of the book is thus an exposition of psychology from a physiological point of view. The second part proceeds to apply the views so expounded to certain theoretical and practical problems. A brief account is given of the distribution of intelligence, of its diagnosis by means of mental tests, of its relations to will, and to emotion. The book concludes with two chapters embodying applications of the results achieved to questions of scholastic and moral training.

(2) Prof. Swift's book consists of a series of popular essays upon the psychology of daily life. It is not a systematic survey of the whole field of mental hygiene. Rather the choice of subjects has been determined, as the preface acknowledges, by the author's personal interests. It includes, however, several important topics upon which recent investigation has thrown great light—topics which are closely related to everyday problems, although the relation has not always been recognised: for example, the psychical aspect of matters commonly considered to be primarily physiological, such as digestion, fatigue, and biological adaptation. There are also chapters upon matters the psychological and practical aspects of which are alike better recognised—testimony and rumour, memory-training, habit-formation, and learning generally. Illustrative material is drawn not only from the latest researches, but also from a wide reading of fiction, biography, and general literature. A couple of papers are inserted upon problems connected with unconscious processes of the mind, such as multiple personality and the curiosities of recollection. But here the point of view and the data are not always quite up-to-date.

(3) In the two foregoing books Dr. Goddard and Prof. Swift scrupulously avoid all mention of psycho-analytical doctrines. Dr. Lay's book barely refers to any others. His chapters attempt an interesting and even urgent task. The recent work of the psycho-analytic school has emphasised the important part played by unconscious tendencies in the formation of human personality. The simpler of these tendencies appear to be inherited, much as instincts are inherited by lower animals, and first emerge during the immature period we term childhood. The more complex are acquired through experience after birth; but even these are largely built up during the first few years of life. It follows that parents and teachers who view their task as comprising not merely the education of the intellect, but also the training of the character, should be instructed in the nature and properties of these unconscious tendencies, since, just because they are unconscious, they are so easily overlooked and so subtly persistent. The application, therefore, to educational problems of the better-established facts and principles embodied in the doctrines of psycho-analysis constitutes a fruitful field of discussion.

In his book Dr. Lay has set himself to attack this field. Twenty years of teaching in a secondary school, he tells us, has convinced him that "the modes of thinking on the part of children are irremediably (without the teacher's knowing of the effects of the unconscious) twisted, and that they are so by virtue of their numerous complexes." Unfortunately, Dr. Lay's own mode of thinking is apt at times to become, like his sentences, itself a little involved; and one may venture to doubt whether the teacher or the parent whose first introduction to psycho-analysis is obtained from the present volume will reach a very clear conception of the nature or the value of the new doctrines. He is required to think in very technical terms—of "*libido*," its "displacement," its "transference," and its "sublimation," of "identification" and its two forms of "projection" and "introjection," of "censorship" and "resistances" and "ambivalences" and "compensations." And for all these concepts very little empirical evidence is adduced.

Dr. Lay's method of demonstration inclines, too, almost exclusively to an *a priori* form: "*It is inconceivable* that all the sights, sounds, and other impressions we have had should not have an effect upon each other and so upon our present constitution . . ."; "*It seems in every way more rational to suppose* that conscious and unconscious thought and action are causally connected in both directions. . . ." This is scarcely the soundest type of scientific reasoning. Apart from a casual reference to William James (who incurs Dr. Lay's censure because he devoted to the sex-instinct only one page out of a thousand), pre-Freudian psychology is almost entirely ignored. That Ward and Stout and McDougall had constantly emphasised the importance of unconscious dispositions; that James, McDougall, and Shand had elaborated a widely accepted theory of instincts and emotions as the true basis of character; that the part played by conflict and repression in the formation of character had been succinctly stated by Stout; that the formation of a sentiment of maternal love has been described by Shand and McDougall in terms almost the same as Freud and Jung have used to describe the formation of parental complexes; that the nature and development of the sex-instinct had been closely studied by Stanley Hall and Havelock Ellis—of this the lay parent and the lay teacher learn nothing. Nor would they gather that for knowledge of the nature of the child's unconscious processes, of his complexes, his repressions, and his fantasies, the psycho-analyst is still almost entirely dependent upon the results gained by analysing the minds of abnormal adults, and can scarcely quote more than tiny fragments of first-hand observation made upon young and normal children. The psycho-analyst will perhaps contend that the earlier writers did not grasp the profound and all-pervading significance of the facts they partly formulated. But it is scarcely fair to suggest that upon such problems, before the new era of Freud had dawned, "no really scientific observations had been made." This is not the attitude or the method of Freud himself.

Yet, despite his shortcomings as a man of science and as a psychologist, Dr. Lay, as a practical teacher, has interspersed his somewhat diffuse and theoretical disquisitions with many shrewd observations upon child life, with many suggestive deductions from his master's principles, and with many opportune recommendations for home-training and for class-room procedure.

Three Philosophers.

(1) *Aristotle.* By Dr. A. E. Taylor. Revised edition. (The People's Books.) Pp. 126. (London and Edinburgh: T. C. and E. C. Jack, Ltd.; T. Nelson and Sons, Ltd., 1919.) Price 1*s.* 3*d.* net.

(2) *Auguste Comte.* By F. J. Gould. (Life-stories of Famous Men.) Pp. v+122. (London: Watts and Co., 1920.) Price 3*s.* 6*d.* net.

(3) *Thomas Henry Huxley: A Character Sketch.* By Dr. Leonard Huxley. (Life-stories of Famous Men.) Pp. vii+120. (London: Watts and Co., 1920.) Price 3*s.* 6*d.* net.

AT a time when constitutions are in process of adoption for so many unfamiliar areas on the map, it seems singularly appropriate that some attention should be diverted from such modern problems as relativity and Bolshevism to the older struggles and the ideas to which they gave rise. An excellent opportunity is provided by the three books under notice.

(1) Dr. Taylor's "Aristotle" is not quite in the same class as the others, for Aristotle's life occupies but little space. The author directs attention to the debt we owe to "the Stagyrite" for many of the commonest ideas in our language, and his avowed object is "to help the English reader to a better understanding of such familiar language and a fuller understanding of much that he will find in Dante, Shakespeare, Bacon, and Milton." It is a pity that he has not managed to avoid the frequent use of "logical" terms, probably unintelligible to those whose education has been merely commercial. It is possible that this usage has been deliberate, in order to support Aristotle's contention that a curriculum which includes only "useful" subjects does not constitute education at all—a doctrine that has not yet lost all its supporters. The book gives a fairly comprehensive sketch of Aristotle's progression, from "first philosophy" to physics, and on to practical philosophy—*i.e.* ethics and politics. It is interesting to recall that Aristotle objected equally to democracy and to oligarchy as understood by the Greeks, so that his ideal State would scarcely find favour with many of our present-day politicians. Dr. Taylor is impartial in dealing with points of difference between Aristotle and his quondam teacher Plato, but he does little to help to account for the ascendancy of Aristotle for so many centuries.

(2) It is a far cry from Aristotle to the nineteenth century, though we may regard many of the old Greeks, in spite of their mythology, as rationalists in much the same sense as Comte, though perhaps

not in the same degree. Comte's biography is the work of a professed disciple, but he seems unable to make the apostle of "Humanity" a sympathetic figure. There is a feeling of something lacking in the book in this respect. There is no evidence that it is intended only for the elect, and the ordinary reader may easily be repelled, even if he belongs to the class, so generally miscalled the proletariat, to whom Comte expected his social philosophy to appeal most powerfully. His Positivism certainly made a great impression on those of the working class who attended his free lectures on astronomy, the first science to become "positive" in Comte's view. The Positivist calendar, given as an appendix, is interesting, though to the general reader many of the names are quite unknown.

(3) This book is a really fascinating character-sketch of Huxley by his son, and the great "agnostic" stands out a vivid, rugged, but very sympathetic figure, an honest seeker after truth, a resolute opponent of "dogma." We meet also the outstanding personalities of his contemporaries, Darwin, with Hooker, Tyndall, and other members of the famous X Club. Had the question arisen forty or fifty years earlier, what would we not have given to be present at a symposium debating Einstein's theory of relativity? Huxley's indictment of "the Church" is as thorough as his championship of Darwin, and might be unanswerable could we altogether ignore the limitations of the human intellect. His logical conclusion that his views precluded the hope of future rewards as well as the fear of future punishments enforced on him the duty of living the most upright of lives, and Sir S. Walpole could not have been by any means the only one to endorse the verdict of the little girl who emphatically declared: "I think Prof. Huxley is the best man I have ever known."

W. W. B.

Our Bookshelf.

The Dyeing Industry. Being a third edition of *Dyeing in Germany and America.* By S. H. Higgins. Pp. viii+189. (Manchester: At the University Press; London: Longmans, Green, and Co., 1919.) Price 8*s.* 6*d.* net.

In the first edition of Mr. Higgins's book (NATURE, November 7, 1907, p. 4) the subject-matter presented was mainly novel in character, giving, as it did, the author's impression of the state of development of the dyeing industry in Germany, Austria, and the United States. A second edition was issued during the war period (NATURE, June 4, 1917, p. 303), and the present notice refers to a third edition.

It is gratifying to find such a steady demand for technical literature, which presumably arises from new readers, but the revised title of the book, "The Dyeing Industry," may lead such to look for a systematic treatment of the various aspects of the industry. This is not attempted in the book, the only new features of which are the inclusion of some of the author's recent valuable contributions to current literature and an extension of the section dealing with the manufacture of dyestuffs—which, by the way, is a quite distinct industry.

It is to be hoped that the author will find an opportunity of producing a book dealing with the dyeing industry of the present day, since information gathered so long ago as 1907 is unlikely now to represent the position with regard to such a rapidly developing scientific industry as dyeing.

W. M. G.

A Handbook of British Mosquitoes. By Dr. William Dickson Lang. Pp. vii+125+5 plates. (London: British Museum (Natural History), 1920.) Price 20*s.*

DR. LANG'S work makes it possible to determine with comparative ease most, if not all, British mosquitoes, including, so far as they are known, the larvæ in their various instars. The book consists mainly of three sections—(1) Introductory; (2) Identification; and (3) Systematic Account. In the introductory section are given the characters by which mosquitoes may be distinguished from gnat-like flies, a general account of the life-history, and such discussion of the morphology of the adults and larvæ as is necessary for purposes of identification. The second section is treated in an eminently practical manner, and the interpretation of the directions, lucid themselves, is rendered simple by the numerous excellent illustrations. In the third section the taxonomic aspect is considered, and our knowledge of each species summarised.

Dr. Lang's work will prove of great value to all interested in mosquitoes, and particularly to those who find the existing monographs on these insects too technical or involved. It gives a clear insight into the characters used in distinguishing these insects and their larvæ, but it must be remembered that the value of some of the points used, although great in separating the British species, is really exaggerated, and, therefore, neither they nor the sequence of instructions can be rigidly applied to foreign mosquitoes.

Volumetric Analysis. By J. B. Coppock. Second edition, revised and enlarged. Pp. 100. (London: Sir Isaac Pitman and Sons, Ltd., n.d.) Price 3*s.* 6*d.* net.

THOUGH this volume has no special features to distinguish it from others of a similar type, it should prove useful to elementary students of chemistry preparing for examinations of Intermediate B.Sc. standard.

C

Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Colour of the Night Sky.

So far as I have been able to learn, little or nothing is known about the colour of the night sky. The light is too faint for ordinary visual discrimination of colour, which disappears with diminishing intensity of illumination much before the light itself ceases to be perceptible.

I have obtained evidence, both visual and photographic, that the clear sky at night is much yellower or less blue than the clear, or even the cloudy, sky at twilight.

The visual observations were made in the following way:—Two gelatine films were prepared, one dyed yellow with flavazine and the other with methylene-blue, the relative intensities being adjusted by trial to give the effects that will presently be described. The films were mounted edge to edge at the end of a pasteboard tube, which was pointed at the sky. During the daytime the yellow film was confidently pronounced by all observers to be the brightest, the difference being too marked to be embarrassed by colour difference. As twilight advanced the Purkinje phenomenon came into evidence, and the blue film became much the brighter. This remained the case when the light had waned so far that the colour sensation had disappeared. As the stars came out the predominance of the blue became less marked, and before the Milky Way was distinguished there was equality. Finally, when the Milky Way was conspicuous the yellow film was notably the brighter, whether the tube was pointed to the Milky Way or to other parts of the sky.

The changes described were very marked. Their general course was the same whether the sky was clear or cloudy at any particular stage. The first change, when blue becomes predominant, is due solely to physiological causes. But the second change, which makes the yellow predominant again, occurs below the "threshold" of colour-vision, and, according to received views, there should be no marked complication from physiological causes within this range. Accordingly we may conclude that the observation affords definite evidence that the night sky is yellower or less blue than the day sky.

This conclusion has been confirmed photographically. A yellow and a dense blue filter were selected, and an Ilford panchromatic plate was exposed to the sky under these. It was seen at a glance that the density under the blue filter was the greater for the twilight sky, while for the night sky this relation was reversed.

The results point to the conclusion that the light of the night sky, whatever the cause of it may be, is not due to the scattering of sunlight by rarefied gas situated beyond the earth's shadow. The comparative absence of polarisation, formerly found, points to the same conclusion. RAYLEIGH.

University Grants.

THE article and letters in NATURE upon the subject of university finance are very timely. It is essential that the country should be alive to the perilous condition of the universities from a financial point of view.

The raising of fees that has just taken place can be only a partial remedy. Fee revenue before the war provided at the various universities at the most for 40 per cent. of the necessary expenditure, the average being about 33 per cent. The recent increase in fees will barely re-establish the pre-war percentage.

I agree with the Principal of Birmingham University that the stipends of the non-professorial staffs must be increased; the urgency is not less great for the salaries of the professorial staffs. In London the utmost that has been done for the professorial staff is to increase the minimum full-time salary from 600*l.* to 800*l.*

Now the majority of the London professors receive the minimum. Considering the responsibilities of a university professor, what is 800*l.* a year for a man in that position under present conditions? Such a prospect will not induce young men of the right calibre to make university teaching their profession.

It is true that the Government has made non-recurring grants to pay off war losses, and for the time being doubled the grants. Having regard to the condition of the National Exchequer, the Government has perhaps done as much as could be expected for the current year. The all-important question for the universities is: What is the Government going to do next year?

It must be remembered that the maintenance grants are made for periods of five years, and are then revised. Revision was due in 1915, but was impossible during the war. The period 1910–15 had been one of unusual activity and development in all the universities. It was the general expectation in 1914 that the grant for the quinquennium 1910–15 would be doubled for the period 1915–20. By doubling the 1910–15 grant now the Government has done no more than redress the disadvantage due to the depreciation in the value of money.

Having that in mind, the deputation of Vice-Chancellors and Principals in 1919 impressed on the President of the Board of Education and the Chancellor of the Exchequer that the smallest grant that would meet the needs of the moment would be the 1910–15 grant quadrupled. That will do no more than enable the universities to carry on; it will not provide the capital necessary for new buildings, new plant, and equipment, nor will it enable justice to be done to the older men who bore the heat and burden of the day of pioneer work before the time of the establishment of superannuation funds.

There are many such men due to retire in the next few years; they are entitled to treatment at least as generous as that given to schoolmasters by the Fisher Act. GREGORY FOSTER.

University of London, University College, August 23.

THE only elements of our society which seem to benefit from the great increase in the wealth of the world through science are those which it will be one of the hardest problems of reconstruction to divert into more productive and honourable means of livelihood. Those who sow the seed and reap the harvest alike, year by year, by their labours seem to be able only to increase their dependence upon private charity and public doles. Universities sow the seed, and their claims, like the claims of the farmer for seed for his future harvest, ought to be absolutely the first charge upon the yearly revenue. It is as idle to say the country cannot afford it as it would be for a farmer to grudge the seed for his next year's crop. It affords a plethora of most expensive evils and unnecessary luxuries. In the spirit of one of the early Methodist preachers, I feel, whenever I see a specially sumptuous motor-car, "There, but for the grace of Parliament, goes a professor of chemistry"; and even a humble two-seater might in happier circumstances have become a demonstrator!

Under the scheme of a professor of literature with fifteen years' experience of fostering scientific research with the Carnegie Trust, a million of the taxpayers' money is now well on its way to provide more sumptuous motor-cars rather than professors of chemistry, and another two millions or so to foster dye-making as it is understood in the City by directors more innocent of the art than our early woad-besmeared ancestors. To such ill-informed and costly efforts the complete indifference with which science was regarded in official circles before the war is surely preferable. It may be difficult to break with the habit of a hundred years in patiently expecting a miraculous change of attitude on the part of the Government towards the debt- and wealth-producing elements of the community respectively. A more practical and practically attainable objective would, it seems to me, be for the universities to ally themselves with Labour to provide saner government. Incidentally, some long overdue reforms of the universities might then be effected, and the paralysing and deliberate stranglehold of the old vested interests upon science broken, once for all.

I may merely be more outspoken than my colleagues, but I believe I am more scientific in diagnosing the trouble before seeking a remedy. The failure of a century's efforts on the part of scientific men is not due to ignorance, apathy, or any other negative cause. But for the clever, tireless, and all-embracing activities of all those to whom science spells *finis*, the existing absurdities would not survive a year, and against this combination Labour is the only real force. The unpopularity of the proposed remedy with all those who have proved themselves such good friends of science in the past is, to my mind, an unsolicited testimonial to its efficiency from a quarter eminently in a position to judge.

FREDERICK SODDY.

The Separation of the Isotopes of Chlorine.

IN my letter to NATURE of June 17 I showed that inappreciable separability of the isotopes of chlorine by a special class of chemical change would be difficult to reconcile with Nernst's heat theorem, and in a later issue of NATURE (July 15), at the request of Prof. Soddy, the argument was more fully given. Mr. Core (NATURE, July 29) has endeavoured to remove the difficulty to which attention was directed by me. With most of his deductions I agree, but I am not satisfied that he has reconciled Nernst's theory with the inappreciable separability of the isotopes by the specified chemical method. Mr. Core contends that the solid compound ClCl′ which would actually be formed in the chemical change represented by the equation

$$Cl_2 + Cl'_2 = 2ClCl'$$

is a solid solution—since in the crystal the molecules would be indifferently oriented as ClCl′ or Cl′Cl—and Nernst's theorem cannot be applied to solutions.

Now Nernst states his theorem as follows:

"I have been led to the conclusion that not only do A and U become equal at the absolute zero of temperature, but that their *curves touch asymptotically at this point*. That is to say,

$$\lim \frac{dA}{dT} = \lim \frac{dU}{dT} \text{ (for } T = 0).$$

It is to be remembered that this equation is only strictly applicable to pure solid or liquid substances" (H. T. Tizard's translation of Nernst's "Theoretical Chemistry," 1916 edition, p. 746).

Again, Nernst (*loc. cit.*, p. 748) identifies liquid with amorphous substances

Further, Planck limits the application of his more general enunciation of Nernst's theorem to chemically homogeneous substances, which he defines as substances made up of nothing but molecules of the same kind (Max Planck, "Thermodynamik," § 67).

Neither of these definitions appears to me to exclude the crystalline modifications of ClCl′, which are stable at finite temperatures. But even if it be conceded that the intention was to exclude such solid compounds, the difficulty I find in reconciling Nernst's heat theorem with the inappreciable separability of the isotopes by the specified chemical method has not been removed, for the solid substances taken in performing the thermodynamic cycles can (without modifying the reasoning) be the liquid (amorphous) forms.

The Scratch-Reflex in the Cat.

I HAD lately the opportunity of examining in a young cat eight weeks old the conditions of the scratch-reflex, and the results would seem to be worth noting. The animal had been through an unusually heavy day of play on a hot day, and in the evening was lying asleep on the lap of one of her friends in a profound sleep. I thought this a good occasion for finding out what reactions she would show to gentle mechanical stimuli. A very light touch with a wooden match on the conchal surface of the pinna, or one extending to the meatus, produced immediate response as follows:—First, the facial muscles on the same side twitched irregularly; this ceased, and then the fore foot was moved irregularly towards, but not so far as, the ear; when this had ceased there occurred at once a *rhythmical* movement of the hind limb, with a rate closely similar to that of the scratch-reflex of the dog, the hind foot, as in the fore foot, being brought *towards*, but not up to, the ear.

This unusual sleep lasted for a quarter of an hour, during which repeated light mechanical stimuli of various kinds failed to wake the animal, and the above series of reactions was frequently evoked, but none of the later attempts produced results so strongly marked as the first. I was unfortunate then in not having read more than an abstract of the paper in the *Journal of Physiology* of December, 1917, by Prof. Sherrington on "The Pinna Reflexes in the Cat." He has now very kindly sent me a copy of the paper, and I see how much better I might have marked out the receptive field of this reflex if I had known the accurate observations he has made on it.

I examined in this animal then and since the various regions of the back and flanks, and have found there no receptive field like that of the dog, which seems to be in accordance with the experience of others. Since the first occasion I have found the foregoing reactions present many times, but the sleep has always been lighter and the results less orderly and striking.

Portraits Wanted.

I SHOULD greatly appreciate any information readers of NATURE may be able to give me which would lead to the discovery of portraits of any of the following early myriapodologists:—Shaw (who published a paper in 1789, Trans. Linn. Soc., vol. ii., p. 7), W. E. Leach, George Newport, John Edward Gray, and John Curtis. The last four all published papers during the first half of the nineteenth century.

The Christian Revelation and Modern Science.[1]

By the Rev. E. W. Barnes, M.A., Sc.D., F.R.S., Canon of Westminster.

"I am the Light of the world."—St. John viii. 12.

I HAVE been asked to preach here to-day in connection with the meeting of the British Association which has been held in this city during the past week. My subject is Christ, the Light of the world, and I ask you to think of the Christian revelation and scientific progress. For more than a hundred years there has been strife—sometimes veiled, but more often open—between "religion and science." I use the popular phraseology. More accurately, opinions as to the origins of the earth and of man which were held as a result of Christian tradition have been directly challenged by a succession of novel theories put forward by men of science. At the beginning of last century the foundations of geology were being laid, largely in this country. Gradually it became clear, from a study of our rocks and their fossil remains, that the earth had an almost unimaginable antiquity. The coal which we dig is all that is left of vast tropical forests that once flourished here for tens of thousands of years. In successive ages of vast duration the most diverse forms of animal life have existed in these lands. The East of England has repeatedly for long periods been submerged beneath the sea. The climate has varied from tropical heat to arctic severity.

Such knowledge is now a commonplace. But when it was being established by patient discovery during the early part of last century Christian theologians showed violent hostility to the new ideas. The curious may examine the expression of this hostility in Bampton Lectures of the period, which are now happily forgotten. On second-hand bookstalls it is not uncommon to find pathetic attempts to reconcile geology and Genesis such as were continually made even to our own time. But truth triumphed. Just as two centuries earlier the Roman Church had failed to prevent men from receiving the then new knowledge that the earth was not the fixed centre of the universe, so the new geological ideas won their way despite religious prejudice. Galileo triumphed; it is agreed that the earth moves round the sun; heliocentric books were removed from the Roman Index in 1835. The early nineteenth-century geologists triumphed; it is agreed that life has existed on this earth for something like a hundred million years. Though in each case the new views are directly opposed to those which Christianity took over from Judaism, we accept them with confidence and surely without harm to our faith in Christ.

But sixty years ago a far more vital controversy began when the Biblical account of man's origin was disputed. A series of discoveries in caves and river-beds in England and in France made it clear that primitive men had lived here when the mammoth, the cave lion, and the rhinoceros flourished in Western Europe. Evidence quickly accumulated which showed that even in this corner of the world human beings existed more than a hundred thousand years ago. Scarcely had these novel conclusions been reached when a scientific theory was put forward which to the great majority of the religious people of the time seemed destructive of essentials in our faith. It was in the year 1859 that Darwin, in his book "The Origin of Species," urged the truth of the doctrine of evolution. At the ensuing Oxford meeting of the British Association, Bishop Wilberforce denounced the idea that man shared a common ancestry with the higher apes. His speech showed deplorable prejudice; it contained a grave error in taste, and Huxley's dignified rebuke of the Bishop is still remembered. For forty years after that famous encounter evolution was a *casus belli* between religion and science. Christian opinion refused to accept the new doctrine, and religious teachers traversed it by arguments good and bad. It is not fair to regard them with the scorn which the younger people of to-day, trained in modern science, not seldom feel.

Evolution was, and still is, not an observed fact, but a very probable theory. Our forefathers saw that acceptance of it meant the abandonment of the story of Adam; it meant giving up belief in the Fall, and in all the theology built upon it by theologians from St. Paul onwards. Half a century ago, the evolutionary view of man's origin meant that what then appeared to be the strongest reasons for the belief that man has an immortal soul had to be set aside. But truth has triumphed. In our own time the leaders of Christian thought have, with substantial unanimity, accepted the conclusion that biological evolution is a fact; man is descended from the lower animals. It is even becoming common to say that there is no quarrel between science and religion. But let us be honest. There has as regards the origin of man been a sharp conflict between science and traditional religious belief, and the battle has been won by science. Furthermore, let us not when driven from one position take up another that may have to be abandoned. It is dangerous to assert that, although God may not have specially created man, nevertheless He did specially create life. Probably the beginning of terrestrial life was but a stage in the great scheme of natural evolution. We may even expect that some day in the laboratory the man of science will produce living from non-living matter.

The time has come when we must not try to evade any implications of the theory of natural evolution. We must, not silently, but explicitly, abandon religious dogmas which it overthrows. We must, moreover, avoid the temptation to allegorise beliefs which it is no longer possible

[1] Sermon preached in St. John's Church, Cardiff, on Sunday, August 29, to members of the British Association.

to hold. Allegory has its value, but it is misused when we employ it to obscure the revolutionary consequences of new knowledge. Religion is too important for us to base it upon, or to join it to, any theories of the nature of the universe that are doubtful or untrue. If Christ is the Light of the world, all intellectual discovery must be a part of His revelation. If He rightly explained the nature and purpose of God, then the more accurately we discover how God planned and guided the universe so that men have come to exist upon earth, the more natural will it be to accept Christ's teaching. If, on the contrary, the progress of knowledge really discredits the Christian faith, in so far as that faith comes from Jesus Christ, we must sadly admit that Christ cannot have been the Light of mankind. Whatever the consequences, we must accept truth by whomsoever it may have been discovered. A religion not based on truth is vain. A faith that fears the progress of knowledge anticipates its own dissolution.

Now, the Christian faith is belief in Christ, in His Person, and in His teaching. If Jesus was Divine, His spiritual revelation was without error, His example perfect. In so far as He was man we expect His secular knowledge to have been that of the Galilean carpenter's son. But we can no longer call ourselves Christians if we find that we are forced to admit that He was morally imperfect or mistaken in His view of God or of man's relation to God. I contend that the progress of science has not forced us to make any such admission. It has not destroyed the spiritual infallibility of our Lord, or done anything to upset His teaching as to the nature of God, or as to man's nature and destiny. It has rather, as I hold, confirmed His insight and made His spiritual wisdom more profoundly impressive.

Traditional Christian belief was built up of other things besides Christ's teaching. The early Christian Church took over the old Jewish Scriptures because it deemed them inspired by God. It placed among its sacred books writings of St. Paul and other earlier followers of the Lord because it found that they reflected the Mind of the Master. But there never was a time when thoughtful Christians could thoughtfully have maintained that the Jewish Scriptures were free from moral and historical error. The cursing Psalms are obviously un-Christian. Books like Kings and Chronicles are rival histories which disagree in spirit and in detail. As a matter of fact, the Church has never formally defined inspiration. We may say truly that inspired books are of peculiar spiritual value; but we may find such value in St. Paul's teaching, though we freely admit that his arguments were sometimes unsound. If we discover that old Christian beliefs which did not come from Christ are erroneous let us not be troubled. For Christianity the perfection of Christ's religious teaching and His revelation of His own supreme excellence are alone of decisive importance. Views of ancient Jews or of early Apostles we can abandon when we discover that they were wrong. Christianity is belief in Christ as Way, Truth, and Life; belief that He was the Light of the world, the Guide of the spiritual evolution of humanity. It is not belief in the scientific value of Genesis or even in the infallibility of St. Paul. Grasp this fact firmly and you will understand that last century's tragic quarrel between religion and science had its origin in a natural, but none the less deplorable, mistake. The mistake was natural, for there is so much of supreme value in the books of the Bible that men will always venerate them profoundly. In the recent past veneration led to exaggeration, to the claim of infallibility. Let us thank God that men of science have forced us to get a fuller, if more difficult, type of understanding of the value of the Bible.

But some of you may say, Has not the new knowledge made it impossible to accept the teaching of Jesus with regard to God and human immortality? Can we accept evolution and yet believe that God, a loving Father, made the world? Can we accept the idea that man and the gorilla have sprung from a common stock and yet hold that man has an immortal soul? I answer emphatically that we can. I remain sure that God, Who is Love, made and rules the world, certain that man was created that he might enjoy eternal life in communion with God in the world to come. Do you doubt? Reflect for a few moments. Surely the universe had a beginning, and therefore a Creator. It cannot be a meaningless dance of atoms or a whirl of electrons that has gone on for an infinite time. Surely, too, evolution describes a wonderful development, an upward progress, which implies a design in the mind of God. Surely man is on earth the present end of this process, and his spiritual qualities, his love of beauty, goodness, and truth, are its crown. Surely, moreover, the God Who by a design extending over hundreds of millions of years has called these spiritual qualities into existence is Himself a spiritual Being Who made spiritual man for communion with Himself. And, last of all, surely the finest products of evolution have not been made for nothing. And yet, in the distant future, when all life vanishes from the earth, as it certainly must, heroes and saints will in vain have gained knowledge of God, in vain have spent their strength, unless they continue to live eternally in the spiritual world.

Evolution seemed disastrous to faith two generations ago because men fixed their attention narrowly on but one part of the process. Now a wider vista seems to be coming into view as theories are tested by experiment and unified by the speculative reason. From some fundamental stuff in the universe the electrons arose. From them came matter. From matter life emerged. From life came mind. From mind spiritual consciousness developed. At every stage, in this vast process and progress, something new has come, we know not how, into existence. There was a time when matter, life, mind, the soul of man were not; but now they are. Each has arisen as part of a vast scheme planned by God. And the soul of man is the glory of the whole design. Because of the soul within him man, as Jesus taught, is meant to be the child of God. As our souls grow through the quickening power of the Spirit of Christ we can on earth know and serve the Father of us all and begin to enjoy that Divine communion which is eternal life. The Christ Spirit within us, the "quality of deity," as it has been called, separates us from the animals whence we have sprung just as life separates them from the matter of which they are made. And through the Spirit of Christ we put on immortality, for the things that are of God are eternally with God.

Science describes the process by which man has come into being. Religion takes man as he is and offers him guidance towards his spiritual destiny. Between the religious revelation of Jesus and modern science there is no opposition. The two dovetail into one another with singular exactness. Evolution describes facts; the ultimate meaning of those facts Christ's teaching discloses. We need faith to accept the Lord's message; we cannot prove its truth by the methods of scientific inquiry, for the spiritual world is a type of reality which the organs of sense will not reveal. But by living the Christian life, by prayer and communion with God, we can continuously strengthen the faith which is not sight, and become ever more confident that the Lord was in very truth the Light of the world.

The British Association at Cardiff.

THE Cardiff meeting of the British Association came to an end on Sunday morning, when the Lord Mayor of Cardiff (Councillor G. F. Forsdike) and the Corporation, with the general officers of the Association and some of the members, attended the service at St. John's Church. The Association sermon was preached by Canon E. W. Barnes, F.R.S., and we are glad to be able to reproduce it this week. The scientific work of the Association concluded on Friday evening, August 27, when Sir Daniel Hall delivered a stimulating discourse under the title of "A Grain of Wheat from the Field to the Table." A comprehensive vote of thanks to the Lord Mayor, Corporation, and citizens of Cardiff was carried with acclamation, and was responded to by the Lord Mayor and by Dr. W. Evans Hoyle, whose valuable work as local secretary was much appreciated by all.

There were 1378 members present during the week, but the meeting, though relatively small, has been particularly interesting from the scientific point of view. Among the new features was a conference on "Science applied to Public Services," held on August 26, when Mr. F. E. Smith, director of scientific research at the Admiralty, described the admirable scheme of research which has recently been introduced (see NATURE, April 22, p. 245). Prof. C. F. Jenkin, Mr. J. Barcroft, Sir Francis Ogilvie, and Dr. J. W. Evans referred to similar research work in other Government Departments. It was felt that a similar conference, with perhaps some description of results obtained, so far as they can be made public, and opportunity for free and adequate discussion, could usefully be held at each meeting.

As we stated last week, a message was sent from the inaugural meeting to the King in Scotland, where the Association is to meet next year. The message was as follows:—"The members of the British Association for the Advancement of Science desire to express their loyal devotion to your Majesty, and at their meeting in the Principality of Wales hope that they may be permitted to congratulate your Majesty on the splendid work done by the Prince of Wales, which has drawn towards him the thoughts and the hearts of the whole Empire."

The King, in thanking the Association through Sir Charles Parsons, the retiring president, for this loyal greeting, added:—"I feel greatly touched at the kind references to my son, which are the more appreciated coming as these do from members of this distinguished society assembled in the Principality of Wales. I shall follow your deliberations with close interest, and I gratefully recognise all that is being done for the advancement of civilisation by the men of science."

There is probably no more remarkable example of the scientific spirit which animates the British Association than that displayed in the allocation of its annual grants for research purposes. Each section of the Association nominates research committees, and most of them apply for small grants to carry out the work and defray the clerical and other incidental expenses involved. A total of about 1000*l*. a year is voted by the Committee of Recommendations to these committees and approved by the General Committee, and every pound of this comes out of the subscriptions of the members. This year the amount voted in grants for research was about 1100*l*., part of which will be required for expenses of publication. It is hoped some external support will be forthcoming for this branch of the Association's work, and that Government Departments interested in particular subjects will assist in the publication of some of the reports prepared by research committees.

Among the corresponding members and other foreign representatives present at the meeting were:—M. Brieux (Directeur de la Station Agronomique de Rouen, France); M. Bruno (Insp. Gén. des Stations Agronomiques, Paris); Prof. C. J. Chamberlain (Chicago); Prof. R. Chodat (Geneva); Dr. S. I. Franz (George Washington

University, representing the American Association); Prof. A. Gilson (Louvain, Belgium); Prof. R. W. Hegner (Dept. Medical Zoology, Johns Hopkins University); Prof. F. Jaeger (Groningen); Prof. C. A. Kofoid (University of California); Prof. Graham Lusk (Cornell University Medical College); Dr. Naser (representing the International Students' Union, University of Copenhagen); Don G. J. de Osma (Madrid); and Yoshimaro Tanaka (Japan). The General Committee has resolved that national associations for the advancement of science shall in future be invited to send representatives to meetings of the British Association.

The new members of the Council are:—Mr. Joseph Barcroft, Prof. J. Stanley Gardiner, Sir Daniel Hall, Dr. Chalmers Mitchell, and Sir W. J. Pope.

Next year's meeting at Edinburgh, under the presidency of Sir Edward Thorpe, will be from Wednesday, September 7, to Wednesday, September 14. In the following year the meeting will be held at Hull, an invitation tendered by the Lord Mayor and the Town Clerk of that city having been unanimously accepted by the General Committee. No further meetings were actually arranged at Cardiff, but there is a possibility that the meeting in 1923 will be in another northern city, and invitations have been received to meet in Canada in 1924.

Dr. R. V. Stanford, secretary of the Press and Publicity Sub-Committee at Cardiff, who acted as our local correspondent for the meeting, has sent us the following statement, which merits the attention of the Council of the Association and of local committees organising the annual meetings. We are sure that, in making these comments, Dr. Stanford is as desirous of increasing public interest in the work of the Association as we are in publishing it.

"It is difficult to resist taking this opportunity to make one or two observations, though in proposing to offer any criticisms of such a great and venerable institution as the British Association one has rather the feelings of a curate meditating a mild attack on his bishop. There are many members of the Association who are of the opinion that some changes in its policy are not only desirable, but are also rapidly becoming inevitable. Now is the time to take stock of the position, for the recent meeting at Cardiff was really the first normal post-war meeting. The Bournemouth meeting could scarcely be called so, because of its situation and of the very general curiosity regarding war secrets. It is, therefore, rather disappointing to find the membership no greater. What is more disappointing still is that the principal reason for this is the apathy of local people of the educated classes to the presence of the Association. The plain fact remains that it is the exception to find anyone who has even heard of the Association. Is this regrettable state of affairs due to something lacking in these individuals themselves, or is the blame to be laid at the door of the Association? It certainly is not peculiar to Cardiff.

"Everyone will agree that the Association serves three main purposes, namely, to furnish opportunity for scientific workers themselves to get in touch with men working on allied subjects, to try to encourage research, and (what some of us think most important of all) to make scientific knowledge accessible to the general public. It may very well be maintained that the first two of these purposes are being very much better served than the third. Some lay organ of the Press referred to this Cardiff meeting as a 'jamboree of science.' So it was—for the scientific men. But if we were the scouts, where were the delighted parents, who should be such a feature of the entertainment? The point of this analogy is that while the scientific men themselves had four whole days in twelve sections to meet each other and discuss matters in a way of little intelligibility to anyone but themselves, the educated man in the street could only expect a couple of evening discourses to interest him, with a possibility of three more if there was room. The local Press reported the meetings astonishingly well, but such reports, however widely they may be read, do not take the place of a full lecture.

"The importance of scientific work will never be recognised adequately by the general public until they are better instructed as to the practical results which are to be expected from it, and this end can be reached only by the leaders of scientific thought and discovery going out of their way to show the ordinary man that he has a personal interest in the matter. It cannot be pretended that this result is properly secured by five lectures during the whole meeting. We should like to have seen fifty of them, and to have seen them delivered, not to the scientific, but to the non-scientific, public. What is being suggested is not a return to what might be called the lecture habit of the Victorian period, often a perfectly useless type of scientific conjuring entertainment. It is also not necessarily implied that they shall be delivered in the largest hall in the district: sectional meeting rooms would do in many cases.

"Some change in this direction has been referred to above as desirable, and also as inevitable. The inevitability arises from the need which is bound to be felt by the Association of increasing its membership, and consequently its financial resources, rather than the reverse. There are certainly some points that might be thought of, which would result, for example, in a considerable reduction of expenditure for the meeting, and that is a matter which cannot be neglected in these days of high wages and long prices, either by the Association or by its hosts from year to year. A great saving of time and trouble would be effected by the adoption of some method of getting an idea before the meeting as to how many people were coming. This might be done by adding a surcharge to the price of any tickets sold after a certain date. The same consideration applies to excursions: it is easy to lose considerable sums in the way of guarantees for motor transport and meals."

The Internal Constitution of the Stars.*

By PROF. A. S. EDDINGTON, M.A., M.Sc., F.R.S.

LAST year at Bournemouth we listened to a proposal from the President of the Association to bore a hole in the crust of the earth and discover the conditions deep down below the surface. This proposal may remind us that the most secret places of Nature are, perhaps, not 10 to the *n*th miles above our heads, but 10 miles below our feet. In the last five years the outward march of astronomical discovery has been rapid, and the most remote worlds are now scarcely safe from its inquisition. By the work of H. Shapley the globular clusters, which are found to be at distances scarcely dreamt of hitherto, have been explored, and our knowledge of them is in some respects more complete than that of the local aggregation of stars which includes the sun. Distance lends not enchantment, but precision, to the view. Moreover, theoretical researches of Einstein and Weyl make it probable that the space which remains beyond is not illimitable; not merely the material universe, but also space itself, is perhaps finite; and the explorer must one day stay his conquering march for lack of fresh realms to invade. But to-day let us turn our thoughts inwards to that other region of mystery—a region cut off by more substantial barriers, for, contrary to many anticipations, even the discovery of the fourth dimension has not enabled us to get at the inside of a body. Science has material and non-material appliances to bore into the interior, and I have chosen to devote this address to what may be described as analytical boring devices —*absit omen!*

The analytical appliance is delicate at present, and, I fear, would make little headway against the solid crust of the earth. Instead of letting it blunt itself against the rocks, let us look round for something easier to penetrate. The sun? Well, perhaps. Many have struggled to penetrate the mystery of the interior of the sun; but the difficulties are great, for its substance is denser than water. It may not be quite so bad as Biron makes out in "Love's Labour's Lost":

> The heaven s glorious sun
> That will not be deep-search'd with saucy looks:
> Small have continual plodders ever won
> Save base authority from others' books.

But it is far better if we can deal with matter in that state known as a perfect gas, which charms away difficulties as by magic.* Where shall it be found?

A few years ago we should have been puzzled to say where, except perhaps in certain nebulæ; but now it is known that abundant material of this kind awaits investigation. Stars in a truly gaseous state exist in great numbers, although at first sight they are scarcely to be discriminated from dense stars like our sun. Not only so, but the gaseous stars are the most powerful light-givers, so that they force themselves on our attention. Many of the familiar stars are of this kind —Aldebaran, Canopus, Arcturus, Antares; and it would be safe to say that three-quarters of the naked-eye stars are in this diffuse state. This remarkable condition has been made known through the researches of H. N. Russell (NATURE, vol. xciii., pp. 227, 252, 281) and E. Hertzsprung; the way in which their conclusions, which ran counter to the prevailing thought of the time, have been substantiated on all sides by overwhelming evidence is the outstanding feature of recent progress in stellar astronomy.

The diffuse gaseous stars are called *giants*, and the dense stars *dwarfs*. During the life of a star there is presumably a gradual increase of density through contraction, so that these terms distinguish the earlier and later stages of stellar history. It appears that a star begins its effective life as a giant of comparatively low temperature—a red or M-type star. As this diffuse mass of gas contracts its temperature must rise, a conclusion long ago pointed out by Homer Lane. The rise continues until the star becomes too dense, and ceases to behave as a perfect gas. A maximum temperature is attained, depending on the mass, after which the star, which has now become a dwarf, cools and further contracts. Thus each temperature-level is passed through twice, once in an ascending and once in a descending stage—once as a giant, once as a dwarf. Temperature plays so predominant a part in the usual spectral classification that the ascending and descending stars were not originally discriminated, and the customary classification led to some perplexities. The separation of the two series was discovered through their great difference in luminosity, particularly striking in the case of the red and yellow stars, where the two stages fall widely apart in the star's history. The bloated giant has a far larger surface than the compact dwarf, and gives correspondingly greater light. The distinction was also revealed by direct determinations of stellar densities, which are possible in the case of eclipsing variables like Algol. Finally, Adams and Kohlschütter have set the seal on this discussion by showing that there are actual spectral differences between the ascending and descending stars at the same temperature-level, which are conspicuous enough when they are looked for.

Perhaps we should not too hastily assume that the direction of evolution is necessarily in the order of increasing density, in view of our ignorance of the origin of a star's heat, to which I must allude later. But, at any rate, it is a great advance to have disentangled what is the true order of continuous increase of density, which was hidden by superficial resemblances.

The giant stars, representing the first half of a star's life, are taken as material for our first boring experiment. Probably, measured in time, this stage corresponds to much less than half the life, for here it is the ascent which is easy and the way down is long and slow. Let us try to picture the conditions inside a giant star. We need not dwell on the vast dimensions—a mass like that of the sun, but swollen to much greater volume on account of the low density, often below that of our own atmosphere. It is the star as a storehouse of heat which especially engages our attention. In the hot bodies familiar to us the heat consists in the energy of motion of the ultimate particles, flying at great speeds hither and thither. So, too, in the stars a great store of heat exists in this form; but a new feature arises. A large proportion, sometimes more than half the total heat, consists of imprisoned radiant energy—æther-waves travelling in all directions trying to break through the material which encages them. The star is like a sieve, which can retain them only temporarily; they are turned aside, scattered, absorbed for a moment, and flung out again in a new direction. An element of energy may thread the maze for hundreds of years before it attains the freedom of outer space. Nevertheless, the sieve leaks, and a steady stream permeates outwards, supplying the light and heat which the star radiates all round.

That some æthereal heat as well as material heat exists in any hot body would naturally be admitted; but the point on which we have here to lay stress is

*Opening address of the president of Section A (Mathematical and Physical Science) delivered at the Cardiff meeting of the British Association on August 24.

that in the stars, particularly in the giant stars, the æthereal portion rises to an importance which quite transcends our ordinary experience, so that we are confronted with a new type of problem. In a red-hot mass of iron the æthereal energy constitutes less than a billionth part of the whole; but in the tussle between matter and æther the æther gains a larger and larger proportion of the energy as the temperature rises. This change in proportion is rapid, the æthereal energy increasing rigorously as the fourth power of the temperature, and the material energy roughly as the first power. But even at the temperature of some millions of degrees attained inside the stars there would still remain a great disproportion; and it is the low density of material, and accordingly the reduced material energy per unit volume in the giant stars, which wipes out the last few powers of 10. In all the giant stars known to us, widely as they differ from one another, the conditions are just reached at which these two varieties of heat-energy have attained a rough equality; at any rate, one cannot be neglected compared with the other. Theoretically there could be conditions in which the disproportion was reversed and the æthereal far outweighed the material energy; but we do not find them in the stars. It is as though the stars had been measured out—that their sizes had been determined—with a view to this balance of power; and one cannot refrain from attributing to this condition a deep significance in the evolution of the cosmos into separate stars.

To recapitulate. We are acquainted with heat in two forms—the energy of motion of material atoms and the energy of æther waves. In familiar hot bodies the second form exists only in insignificant quantities. In the giant stars the two forms are present in more or less equal proportions. That is the new feature of the problem.

On account of this new aspect of the problem the first attempts to penetrate the interior of a star are now seen to need correction. In saying this we do not depreciate the great importance of the early researches of Lane, Ritter, Emden, and others, which not only pointed the way for us to follow, but also achieved conclusions of permanent value. One of the first questions they had to consider was by what means the heat radiated into space was brought up to the surface from the low level where it was stored. They imagined a bodily transfer of the hot material to the surface by currents of convection, as in our own atmosphere. But actually the problem is, not how the heat can be brought to the surface, but how the heat in the interior can be held back sufficiently—how it can be barred in and the leakage reduced to the comparatively small radiation emitted by the stars. Smaller bodies have to manufacture the radiant heat which they emit, living from hand to mouth; the giant stars merely leak radiant heat from their store. I have put that much too crudely; but perhaps it suggests the general idea.

The recognition of æthereal energy necessitates a twofold modification in the calculations. In the first place, it abolishes the supposed convection currents; and the type of equilibrium is that known as radiative instead of convective. This change was first suggested by R. A. Sampson so long ago as 1894. The detailed theory of radiative equilibrium is particularly associated with K. Schwarzschild, who applied it to the sun's atmosphere. It is perhaps still uncertain whether it holds strictly for the atmospheric layers, but the arguments for its validity in the interior of a star are far more cogent. Secondly, the outflowing stream of æthereal energy is powerful enough to exert a *direct mechanical effect* on the equilibrium of a star. It is as though a strong wind were rushing outwards. In fact, we may fairly say that the stream of radiant energy *is* a wind; for though æther waves are not usually classed as material, they have the chief mechanical properties of matter, viz. mass and momentum. This wind distends the star and relieves the pressure on the inner parts. The pressure on the gas in the interior is not the full weight of the superincumbent columns, because that weight is partially borne by the force of the escaping æther waves beating their way out. This force of radiation-pressure, as it is called, makes an important difference in the formulation of the conditions for equilibrium of a star.

Having revised the theoretical investigations in accordance with these considerations (*Astrophysical Journal*, vol. xlviii., p. 205), we are in a position to deduce some definite numerical results. On the observational side we have fairly satisfactory knowledge of the masses and densities of the stars and of the total radiation emitted by them; this knowledge is partly individual and partly statistical. The theoretical analysis connects these observational data on the one hand with the physical properties of the material inside the star on the other. We can thus find certain information as to the inner material, as though we had actually bored a hole. So far as can be judged, there are only two physical properties of the material which can concern us—always provided that it is sufficiently rarefied to behave as a perfect gas—viz. the average molecular weight and the transparency or permeability to radiant energy. In connecting these two unknowns with the quantities given directly by astronomical observation we depend entirely on the well-tried principles of conservation of momentum and the second law of thermodynamics. If any element of speculation remains in this method of investigation, I think it is no more than is inseparable from every kind of theoretical advance.

We have, then, on one side the mass, density, and output of heat, quantities as to which we have observational knowledge; on the other side, molecular weight and transparency, quantities which we want to discover.

To find the transparency of stellar material to the radiation traversing it is of particular interest, because it links on this astronomical inquiry to physical investigations now being carried on in the laboratory, and to some extent it extends those investigations to conditions unattainable on the earth. At high temperatures the æther waves are mainly of very short wave-length, and in the stars we are dealing mainly with radiation of wave-length 3 to 30 Ångström units, which might be described as very soft X-rays. It is interesting, therefore, to compare the results with the absorption of the harder X-rays dealt with by physicists. To obtain an exact measure of this absorption in the stars we have to assume a value of the molecular weight; but fortunately the extreme range possible for the molecular weight gives fairly narrow limits for the absorption. The average weight of the ultimate independent particles in a star is probably rather low, because in the conditions prevailing there the atoms would be strongly ionised; that is to say, many of the outer electrons of the system of the atom would be broken off; and as each of these free electrons counts as an independent molecule for present purposes, this brings down the average weight. In the extreme case (probably not reached in a star) when the whole of the electrons outside the nucleus are detached the average weight comes down to about 2, *whatever the material*, because the number of electrons is about half the atomic weight for all the elements (except hydrogen). We may, then, safely take 2 as the extreme lower limit. For an upper limit we might perhaps take

200; but to avoid controversy we shall be generous and merely assume that the molecular weight is not greater than—infinity. Here is the result:—

For molecular weight 2, mass-coefficient of absorption = 10 C.G.S. units.

For molecular weight ∞, mass-coefficient of absorption = 130 C.G.S. units.

The true value, then, must be between 10 and 130. Partly from thermodynamical considerations, and partly from further comparisons of astronomical observation with theory, the most likely value seems to be about 35 C.G.S. units, corresponding to molecular weight 3·5.

Now this is of the same order of magnitude as the absorption of X-rays measured in the laboratory. I think the result is in itself of some interest, that in such widely different investigations we should approach the same kind of value of the opacity of matter to radiation. The penetrating power of the radiation in the star is much like that of X-rays; more than half is absorbed in a path of 20 cm. at atmospheric density. Incidentally, this very high opacity explains why a star is so nearly heat-tight, and can store vast supplies of heat with comparatively little leakage.

So far this agrees with what might have been anticipated; but there is another conclusion which physicists would probably not have foreseen. The giant series comprises stars differing widely in their densities and temperatures, those at one end of the series being on the average about ten times hotter throughout than those at the other end. By the present investigation we can compare directly the opacity of the hottest stars with that of the coolest. The rather surprising result emerges that the opacity is the same for all; at any rate, there is no difference large enough for us to detect. There seems no room for doubt that at these high temperatures the absorption-coefficient is approaching a limiting value, so that over a wide range it remains practically constant. With regard to this constancy, it is to be noted that the temperature is concerned twice over: it determines the character and wave-length of the radiation to be absorbed, as well as the physical condition of the material which is absorbing. From the experimental knowledge of X-rays we should have expected the absorption to vary very rapidly with the wave-length, and therefore with the temperature. It is surprising, therefore, to find a nearly constant value

The result becomes a little less mysterious when we consider more closely the nature of absorption. Absorption is not a continuous process, and after an atom has absorbed its quantum it is put out of action for a time until it can recover its original state. We know very little of what determines the rate of recovery of the atom, but it seems clear that there is a limit to the amount of absorption that can be performed by an atom in a given time. When that limit is reached no increase in the intensity of the incident radiation will lead to any more absorption. There is, in fact, a saturation effect. In the laboratory experiments the radiation used is extremely weak; the atom is practically never caught unprepared, and the absorption is proportional to the incident radiation. But in the stars the radiation is very intense and the saturation effect comes in.

Even granting that the problem of absorption in the stars involves this saturation effect, which does not affect laboratory experiments, it is not very easy to understand theoretically how the various conditions combine to give a constant absorption-coefficient independent of temperature and wave-length. But the astronomical results seem conclusive. Perhaps the most hopeful suggestion is one made to me a few years ago by C. G. Barkla. He suggested that the opacity of the stars may depend mainly on *scattering* rather than on true atomic absorption. In that case the constancy has a simple explanation, for it is known that the coefficient of scattering (unlike true absorption) approaches a definite constant value for radiation of short wave-length. The value, moreover, is independent of the material. Further, scattering is a continuous process, and there is no likelihood of any saturation effect; thus for very intense streams of radiation its value is maintained, whilst the true absorption may sink to comparative insignificance. The difficulty in this suggestion is a numerical discrepancy between the known theoretical scattering and the values already given as deduced from the stars. The theoretical coefficient is only 0·2 compared with the observed value 10 to 130. Barkla further pointed out that the waves here concerned are not short enough to give the ideal coefficient; they would be scattered more powerfully, because under their influence the electrons in any atom would all vibrate in the same phase instead of in haphazard phases. This might help to bridge the gap, but not sufficiently. It must be remembered that many of the electrons have broken loose from the atom and do not contribute to the increase.[1] Making all allowances for uncertainties in the data, it seems clear that the astronomical opacity is definitely higher than the theoretical scattering. Very recently, however, a new possibility has opened up which may possibly effect a reconciliation. Later in the address I shall refer to it again.

Astronomers must watch with deep interest the investigations of these short waves, which are being pursued in the laboratory, as well as the study of the conditions of ionisation by both experimental and theoretical physics, and I am glad of this opportunity of bringing before those who deal with these problems the astronomical bearing of their work.

I can allude only very briefly to the purely astronomical results which follow from this investigation (Monthly Notices, vol. lxxvii., pp. 16, 596; vol. lxxix., p. 2); it is here that the best opportunity occurs for checking the theory by comparison with observation, and for finding out in what respects it may be deficient. Unfortunately, the observational data are generally not very precise, and the test is not so stringent as we could wish. It turns out that (the opacity being constant) the total radiation of a giant star should be a function of its mass only, independent of its temperature or state of diffuseness. The total radiation (which is measured roughly by the luminosity) of any one star thus remains constant during the whole giant stage of its history. This agrees with the fundamental feature, pointed out by Russell in introducing the giant and dwarf hypothesis, that giant stars of every spectral type have nearly the same luminosity. From the range of luminosity of these stars it is now possible to find their range of mass. The masses are remarkably alike—a fact already suggested by work on double stars. Limits of mass in the ratio 3:1 would cover the great majority of the giant stars. Somewhat tentatively we are able to extend the investigation to dwarf stars, taking account of the deviations of dense gas from the ideal laws and using our own sun to supply a determination of the unknown constant involved. We can calculate the maximum temperature reached by different masses; for example, a star must have at least ¼ the mass of the sun in order to reach the lowest spectral type, M; and in order to reach the hottest type, B, it must be at least 2½ times as massive as the sun. Happily for the

[1] *E.g.* for iron non-ionised the theoretical scattering is 5·2, against an astronomical value 120. If 16 electrons (2 rings) are broken off, the theoretical coefficient is 0·9, against an astronomical value 35. For different assumptions as to ionisation the values chase one another, but cannot be brought within reasonable range.

theory, no star has yet been found with a mass less than 1/[illegible] of the sun's; and it is a well-known fact, discovered from the study of spectroscopic binaries, that the masses of the B stars are large compared with those of other types. Again, it is possible to calculate the difference of brightness of the giant and dwarf stars of type M, *i.e.* at the beginning and end of their career; the result agrees closely with the observed difference. In the case of a class of variable stars in which the light changes seem to depend on a mechanical pulsation of the star, the knowledge we have obtained of the internal conditions enables us to predict the period of pulsation within narrow limits. For example, for δ Cephei, the best-known star of this kind, the theoretical period is between four and ten days, and the actual period is $5\frac{1}{3}$ days. Corresponding agreement is found in all the other cases tested.

Our observational knowledge of the things here discussed is chiefly of a rather vague kind, and we can scarcely claim more than a general agreement of theory and observation. What we have been able to do in the way of tests is to offer the theory a considerable number of opportunities to "make a fool of itself," and so far it has not fallen into our traps. When the theory tells us that a star having the mass of the sun will at one stage in its career reach a maximum effective temperature of 9000° (the sun's effective temperature being 6000°) we cannot do much in the way of checking it; but an erroneous theory might well have said that the maximum temperature was 20,000° (hotter than any known star), in which case we should have detected its error. If we cannot feel confident that the answers of the theory are true, it must be admitted that it has shown some discretion in lying without being found out.

It would not be surprising if individual stars occasionally depart considerably from the calculated results, because at present no serious attempt has been made to take into account rotation, which may modify the conditions when sufficiently rapid. That appears to be the next step needed for a more exact study of the question.

Probably the greatest need of stellar astronomy at the present day, in order to make sure that our theoretical deductions are starting on the right lines, is some means of measuring the apparent angular diameters of stars. At present we can calculate them approximately from theory, but there is no observational check. We believe we know with fair accuracy the apparent surface brightness corresponding to each spectral type; then all that is necessary is to divide the total apparent brightness by this surface brightness, and the result is the angular area subtended by the star. The unknown distance is not involved, because surface brightness is independent of distance. Thus the estimation of the angular diameter of any star seems to be a very simple matter. For instance, the star with the greatest apparent diameter is almost certainly Betelgeuse, diameter 0·051″. Next to it comes Antares, 0·043″. Other examples are Aldebaran 0·022″, Arcturus 0·020″, Pollux 0·013″. Sirius comes rather low down with diameter 0·007″. The following table may be of interest as showing the angular diameters expected for stars of various types and visual magnitudes:—

Probable Angular Diameters of Stars.

Vis. Mag.	A	F	G	K	M
m	″	″	″	″	″
0·0	0·0034	0·0054	0·0098	0·0219	0·0859
2·0	0·0014	0·0022	0·0039	0·0087	0·0342
4·0	0·0005	0·0009	0·0016	0·0035	0·0136

However confidently we may believe in these values, it would be an immense advantage to have this first step in our deductions placed beyond doubt. If the direct measurement of these diameters could be made with any accuracy it would make a wonderfully rapid advance in our knowledge. The prospects of accomplishing some part of this task are now quite hopeful. We have learnt with great interest this year that work is being carried out by interferometer methods with the 100-in. reflector at Mount Wilson, and the results are most promising. At present the method has been applied only to measuring the separation of close double stars, but there seems to be no doubt that an angular diameter of 0·05″ is well within reach. Although the great mirror is used for convenience, the interferometer method does not in principle require great apertures, but rather two small apertures widely separated, as in a range-finder. Prof. Hale has stated, moreover, that successful results were obtained on nights of poor seeing. Perhaps it would be unsafe to assume that "poor seeing" at Mount Wilson means quite the same thing as it does for us, and I anticipate that atmospheric disturbance will ultimately set the limit to what can be accomplished. But even if we have to send special expeditions to the top of one of the highest mountains in the world, the attack on this far-reaching problem must not be allowed to languish.

I spoke earlier of the radiation-pressure exerted by the outflowing heat, which has an important effect on the equilibrium of a star. It is quite easy to calculate what proportion of the weight of the material is supported in this way; it depends on neither the density nor the opacity, but solely on the star's total mass and on the molecular weight. No astronomical data are needed; the calculation involves only fundamental physical constants found by laboratory researches. Here are the figures, first for average molecular weight 3·0:—

> For mass $\frac{1}{3}$ × sun, fraction of weight supported by radiation-pressure = 0·044.
>
> For mass 5 × sun, fraction of weight supported by radiation-pressure = 0·457.

For molecular weight 5·0 the corresponding fractions are 0·182 and 0·645.

The molecular weight can scarcely go beyond this range,[2] and for the conclusions I am about to draw it does not much matter which limit we take. Probably 90 per cent. of the giant stars have masses between $\frac{1}{3}$ and 5 times the sun's, and we see that this is just the range in which radiation-pressure rises from unimportance to importance. It seems clear that a globe of gas of larger mass, in which radiation-pressure and gravitation are nearly balancing, would be likely to be unstable. The condition may not be strictly unstable in itself, but a small rotation or perturbation would make it so. It may therefore be conjectured that, if nebulous material began to concentrate into a mass much greater than five times the sun's, it would probably break up, and continue to redivide until more stable masses resulted. Above the upper limit the chances of survival are small; when the lower limit is approached the danger has practically disappeared, and there is little likelihood of any further breaking-up. Thus the final masses are left distributed almost entirely between the limits given. To put the matter slightly differently, we are able to predict from general principles that the material of the stellar universe will aggregate primarily into masses chiefly lying between 10^{33} and 10^{34} grams; and this is just the

[2] As an illustration of these limits, iron has 26 outer electrons; if 10 break away the average molecular weight is 5; if 18 break away the molecular weight is 3. Eggert (*Phys. Zeits.*, 1019, p. 570) has suggested by thermodynamical reasoning that in most cases the two outer rings (16 electrons) would break away in the stars. The comparison of theory and observation for the dwarf stars also points to a molecular weight a little greater than 3.

magnitude of the masses of the stars according to astronomical observation.[3]

This study of the radiation and internal conditions of a star brings forward very pressingly a problem often debated in this Section: What is the source of the heat which the sun and stars are continually squandering? The answer given is almost unanimous —that it is obtained from the gravitational energy converted as the star steadily contracts. But almost as unanimously this answer is ignored in its practical consequences. Lord Kelvin showed that this hypothesis, due to Helmholtz, necessarily dates the birth of the sun about 20,000,000 years ago; and he made strenuous efforts to induce geologists and biologists to accommodate their demands to this time-scale. I do not think they proved altogether tractable. But it is among his own colleagues, physicists and astronomers, that the most outrageous violations of this limit have prevailed. I need only refer to Sir George Darwin's theory of the earth-moon system, to the present Lord Rayleigh's determination of the age of terrestrial rocks from occluded helium, and to all modern discussions of the statistical equilibrium of the stellar system. No one seems to have any hesitation, if it suits him, in carrying back the history of the earth long before the supposed date of formation of the solar system; and, in some cases at least, this appears to be justified by experimental evidence which it is difficult to dispute. Lord Kelvin's date of the creation of the sun is treated with no more respect than Archbishop Ussher's.

The serious consequences of this contraction hypothesis are particularly prominent in the case of giant stars, for the giants are prodigal with their heat and radiate at least a hundred times as fast as the sun. The supply of energy which suffices to maintain the sun for 10,000,000 years would be squandered by a giant star in less than 100,000 years. The whole evolution in the giant stage would have to be very rapid. In 18,000 years at the most a typical star must pass from the initial M stage to type G. In 80,000 years it has reached type A, near the top of the scale, and is about to start on the downward path. Even these figures are probably very much over-estimated.[4] Most of the naked-eye stars are still in the giant stage. Dare we believe that they were all formed within the last 80,000 years? The telescope reveals to us objects remote not only in distance, but also in time. We can turn it on a globular cluster and behold what was passing 20,000, 50,000, even 200,000 years ago unfortunately not all in the same cluster, but in different clusters representing different epochs of the past. As Shapley has pointed out, the verdict appears to be "no change." This is perhaps not conclusive, because it does not follow that individual stars have suffered no change in the interval; but it is difficult to resist the impression that the evolution of the stellar universe proceeds at a slow, majestic pace, with respect to which these periods of time are insignificant.

There is another line of astronomical evidence which appears to show more definitely that the evolution of the stars proceeds far more slowly than the contraction hypothesis allows; and perhaps it may ultimately enable us to measure the true rate of progress. There are certain stars, known as Cepheid variables, which undergo a regular fluctuation of light of a characteristic kind, generally with a period of a few days. This light change is *not* due to eclipse. Moreover, the colour quality of the light changes between maximum and minimum, evidently pointing to a periodic change in the physical condition of the star. Although these objects were formerly thought to be double stars, it now seems clear that this was a misinterpretation of the spectroscopic evidence. There is, in fact, no room for the hypothetical companion star; the orbit is so small that we should have to place it inside the principal star. Everything points to the period of the light pulsation being something intrinsic in the star; and the hypothesis advocated by Shapley, that it represents a mechanical pulsation of the star, seems to be the most plausible. I have already mentioned that the observed period does, in fact, agree with the calculated period of mechanical pulsation, so that the pulsation explanation survives one fairly stringent test. But whatever the cause of the variability, whether pulsation or rotation, provided only that it is intrinsic in the star, and not forced from outside, the density must be the leading factor in determining the period. If the star is contracting so that its density changes appreciably, the period cannot remain constant. Now, on the contraction hypothesis the change of density must amount to at least 1 per cent. in forty years. (I give the figures for δ Cephei, the best-known variable of this class.) The corresponding change of period should be very easily detectable. For δ Cephei the period ought to decrease 40 seconds annually.

Now δ Cephei has been under careful observation since 1785, and it is known that the change of period, if any, must be very small. S. Chandler found a decrease of period of $\frac{1}{20}$ second per annum, and in a recent investigation E. Hertzsprung has found a decrease of $\frac{1}{10}$ second per annum. The evidence that there is any decrease at all rests almost entirely on the earliest observations made before 1800, so that it is not very certain; but in any case the evolution is proceeding at not more than $\frac{1}{400}$ of the rate required by the contraction hypothesis. There must at this stage of the evolution of the star be some other source of energy which prolongs the life of the star 400-fold. The time-scale so enlarged would suffice for practically all reasonable demands.

I hope the dilemma is plain. Either we must admit that whilst the density changes 1 per cent. a certain period intrinsic in the star can change no more than $\frac{1}{400}$ of 1 per cent., or we must give up the contraction hypothesis.

If the contraction theory were proposed to-day as a novel hypothesis I do not think it would stand the smallest chance of acceptance. From all sides—biology, geology, physics, astronomy—it would be objected that the suggested source of energy was hopelessly inadequate to provide the heat spent during the necessary time of evolution; and, so far as it is possible to interpret observational evidence confidently, the theory would be held to be negatived definitely. Only the inertia of tradition keeps the contraction hypothesis alive—or, rather, not alive, but an unburied corpse. But if we decide to inter the corpse, let us frankly recognise the position in which we are left. A star is drawing on some vast reservoir of energy by means unknown to us. This reservoir can scarcely be other than the sub-atomic energy which, it is known, exists abundantly in all matter; we sometimes dream that man will one day learn how to release it and use it for his service. The store is well-nigh inexhaustible, if only it could be tapped. There is sufficient in the sun to maintain its output of heat for 15 billion years.

Certain physical investigations in the past year, which I hope we may hear about at this meeting, make it probable to my mind that some portion of this

[3] By admitting plausible assumptions closer limits could be drawn. Taking the molecular weight as 3·5, and assuming that the most critical condition is when $\frac{1}{4}$ of gravitation is counterbalanced (by analogy with the case of rotating spheroids, in which centrifugal force opposes gravitation and creates instability), we find that the critical mass is just twice that of the sun, and stellar masses may be expected to cluster closely round this value.

[4] I have taken the ratio of specific heats at the extreme possible value, $\frac{5}{3}$; that is to say, no allowance has been made for the energy needed for ionisation and internal vibrations of the atoms, which makes a further call on the scanty supply available.

sub-atomic energy is actually being set free in the stars. F. W. Aston's experiments seem to leave no room for doubt that all the elements are constituted out of hydrogen atoms bound together with negative electrons. The nucleus of the helium atom, for example, consists of four hydrogen atoms bound with two electrons. But Aston has further shown conclusively that the mass of the helium atom is less than the sum of the masses of the four hydrogen atoms which enter into it; and in this, at any rate, the chemists agree with him. There is a loss of mass in the synthesis amounting to about 1 part in 120, the atomic weight of hydrogen being 1·008 and that of helium just 4. I will not dwell on his beautiful proof of this, as you will, no doubt, be able to hear it from himself. Now mass cannot be annihilated, and the deficit can only represent the mass of the electrical energy set free in the transmutation. We can therefore at once calculate the quantity of energy liberated when helium is made out of hydrogen. If 5 per cent. of a star's mass consists initially of hydrogen atoms, which are gradually being combined to form more complex elements, the total heat liberated will more than suffice for our demands, and we need look no further for the source of a star's energy.

But is it possible to admit that such a transmutation is occurring? It is difficult to assert, but perhaps more difficult to deny, that this is going on. Sir Ernest Rutherford has recently been breaking down the atoms of oxygen and nitrogen, driving out an isotope of helium from them; and what is possible in the Cavendish Laboratory may not be too difficult in the sun. I think that the suspicion has been generally entertained that the stars are the crucibles in which the lighter atoms which abound in the nebulæ are compounded into more complex elements. In the stars matter has its preliminary brewing to prepare the greater variety of elements which are needed for a world of life. The radio-active elements must have been formed at no very distant date; and their synthesis, unlike the generation of helium from hydrogen, is endothermic. If combinations requiring the addition of energy can occur in the stars, combinations which liberate energy ought not to be impossible.

We need not bind ourselves to the formation of helium from hydrogen as the sole reaction which supplies the energy, although it would seem that the further stages in building up the elements involve much less liberation, and sometimes even absorption, of energy. It is a question of accurate measurement of the deviations of atomic weights from integers, and up to the present hydrogen is the only element for which Dr. Aston has been able to detect the deviation. No doubt we shall learn more about the possibilities in due time. The position may be summarised in these terms: the atoms of all elements are built of hydrogen atoms bound together, and presumably have at one time been formed from hydrogen; the interior of a star seems as likely a place as any for the evolution to have occurred; whenever it did occur a great amount of energy must have been set free; in a star a vast quantity of energy is being set free which is hitherto unaccounted for. You may draw a conclusion if you like.

If, indeed, the sub-atomic energy in the stars is being freely used to maintain their great furnaces, it seems to bring a little nearer to fulfilment our dream of controlling this latent power for the well-being of the human race—or for its suicide.

So far as the immediate needs of astronomy are concerned, it is not of any great consequence whether in this suggestion we have actually laid a finger on the true source of the heat. It is sufficient if the discussion opens our eyes to the wider possibilities. We can get rid of the obsession that there is no other conceivable supply besides contraction, but we need not again cramp ourselves by adopting prematurely what is perhaps a still wilder guess. Rather we should admit that the source is not certainly known, and seek for any possible astronomical evidence which may help to define its necessary character. One piece of evidence of this kind may be worth mentioning. It seems clear that it must be the high temperature inside the stars which determines the liberation of energy, as H. N. Russell has pointed out (Pubns. Ast. Soc. Pacific, August, 1919). If so, the supply may come mainly from the hottest region at the centre. I have already stated that the general uniformity of the opacity of the stars is much more easily intelligible if it depends on scattering rather than on true absorption; but it did not seem possible to reconcile the deduced stellar opacity with the theoretical scattering coefficient. Within reasonable limits it makes no great difference in our calculations at what parts of the star the heat energy is supplied, and it was assumed that it comes more or less evenly from all parts, as would be the case on the contraction theory. The possibility was scarcely contemplated that the energy is supplied entirely in a restricted region round the centre. Now, the more concentrated the supply, the lower is the opacity requisite to account for the observed radiation. I have not made any detailed calculations, but it seems possible that for a sufficiently concentrated source the deduced and the theoretical coefficients could be made to agree, and there does not seem to be any other way of accomplishing this. Conversely, we might perhaps argue that the present discrepancy of the coefficients shows that the energy supply is not spread out in the way required by the contraction hypothesis, but belongs to some new source available only at the hottest, central part of the star.

I should not be surprised if it is whispered that this address has at times verged on being a little bit speculative; perhaps some outspoken friend may bluntly say that it has been highly speculative from beginning to end. I wonder what is the touchstone by which we may test the legitimate development of scientific theory and reject the idly speculative. We all know of theories which the scientific mind instinctively rejects as fruitless guesses; but it is difficult to specify their exact defect or to supply a rule which will show us when we ourselves do err. It is often supposed that to speculate and to make hypotheses are the same thing; but more often they are opposed. It is when we let our thoughts stray outside venerable, but sometimes insecure, hypotheses that we are said to speculate. Hypothesis limits speculation. Moreover, distrust of speculation often serves as a cover for loose thinking; wild ideas take anchorage in our minds and influence our outlook; whilst it is considered too speculative to subject them to the scientific scrutiny which would exorcise them.

If we are not content with the dull accumulation of experimental facts, if we make any deductions or generalisations, if we seek for any theory to guide us, some degree of speculation cannot be avoided. Some will prefer to take the interpretation which seems to be indicated most immediately and at once adopt that as an hypothesis; others will rather seek to explore and classify the widest possibilities which are not definitely inconsistent with the facts. Either choice has it dangers: the first may be too narrow a view and lead progress into a cul-de-sac; the second may be so broad that it is useless as a guide, and diverges indefinitely from experimental knowledge. When this last case happens, it must be concluded that the knowledge is not yet ripe for theoretical treatment and that speculation is premature. The time when speculative theory and observational research may profitably go hand in hand is when the possibilities, or at any rate the probabilities, can be narrowed down by experiment, and the theory can indicate the tests by which the remaining wrong paths may be blocked up one by one.

The mathematical physicist is in a position of peculiar difficulty. He may work out the behaviour of an ideal model of material with specifically defined properties, obeying mathematically exact laws, and so far his work is unimpeachable. It is no more speculative than the binomial theorem. But when he claims a serious interest for his toy, when he suggests that his model is like something going on in Nature, he inevitably begins to speculate. Is the actual body really like the ideal model? May not other unknown conditions intervene? He cannot be sure, but he cannot suppress the comparison; for it is by looking continually to Nature that he is guided in his choice of a subject. A common fault, to which he must often plead guilty, is to use for the comparison data over which the more experienced observer shakes his head; they are too insecure to build extensively upon. Yet even in this, theory may help observation by showing the kind of data which it is especially important to improve.

I think that the more idle kinds of speculation will be avoided if the investigation is conducted from the right point of view. When the properties of an ideal model have been worked out by rigorous mathematics, all the underlying assumptions being clearly understood, then it becomes possible to say that such-and-such properties and laws lead precisely to such-and-such effects. If any other disregarded factors are present, they should now betray themselves when a comparison is made with Nature. There is no need for disappointment at the failure of the model to give perfect agreement with observation; it has served its purpose, for it has distinguished what are the features of the actual phenomena which require new conditions for their explanation. A general preliminary agreement with observation is necessary, otherwise the model is hopeless; not that it is necessarily wrong so far as it goes, but it has evidently put the less essential properties foremost. We have been pulling at the wrong end of the tangle, which has to be unravelled by a different approach. But after a general agreement with observation is established, and the tangle begins to loosen, we should always make ready for the next knot. I suppose that the applied mathematician whose theory has just passed one still more stringent test by observation ought not to feel satisfaction, but rather disappointment—"Foiled again! This time I *had* hoped to find a discordance which would throw light on the points where my model could be improved." Perhaps that is a counsel of perfection; I own that I have never felt very keenly a disappointment of this kind.

Our model of Nature should not be like a building—a handsome structure for the populace to admire, until in the course of time someone takes away a corner-stone and the edifice comes toppling down. It should be like an engine with movable parts. We need not fix the position of any one lever; that is to be adjusted from time to time as the latest observations indicate. The aim of the theorist is to know the train of wheels which the lever sets in motion—that binding of the parts which is the soul of the engine.

In ancient days two aviators procured to themselves wings. Dædalus flew safely through the middle air across the sea, and was duly honoured on his landing. Young Icarus soared upwards towards the sun until the wax which bound his wings melted, and his flight ended in fiasco. In weighing their achievements perhaps there is something to be said for Icarus. The classic authorities tell us that he was only "doing a stunt," but I prefer to think of him as the man who certainly brought to light a constructional defect in the flying-machines of his day. So, too, in science. Cautious Dædalus will apply his theories where he feels most confident they will safely go; but by his excess of caution their hidden weaknesses cannot be brought to light. Icarus will strain his theories to the breaking-point until the weak joints gape. For a spectacular stunt? Perhaps partly; he is often very human. But if he is not yet destined to reach the sun and solve for all time the riddle of its constitution, yet he may hope to learn from his journey some hints to build a better machine.

Memorial Tributes to Sir Norman Lockyer.

IN Sir Norman Lockyer the country loses one of the most ardent supporters of science in his time. As one who enjoyed his intimate friendship for more than half a century, I would fain add my personal contribution to the many expressions of regret and appreciation which the loss is sure to call forth.

There never was a man more thoroughly imbued than he with a sense of the importance of the cultivation of science, not only for its own sake, but also for the multitude of ways in which it may be made to minister to the welfare of mankind. Though he had made choice of astronomy as his own field of work, he was no mere specialist, but kept his sympathy in touch with the progress of science as a whole, and worked, harder than most of his contemporaries knew, to further that progress. Sir Norman's younger years as a clerk in the War Office, while affording him an insight into the methods of a Government Department, furnished also a training in business habits which served him in good stead through later life. The secretaryship of the Duke of Devonshire's Commission on scientific instruction, to which as a young man he was appointed, undoubtedly gave the impetus that made him so strenuous an advocate of a wider recognition of the claims of science for a place in our educational and industrial organisation. This appointment, by bringing him into personal acquaintance with the leading men of science of the day, strengthened and widened his sympathies. One of the first results of the experience thus gained was to convince him of the need for better teaching of the rudiments of science in our schools. He saw that one of the first requirements was the production of simple elementary treatises on the different departments of natural knowledge, written not by mere book-makers, but by the best living authorities on the several subjects. He confided to me the scheme which he drew up, and asked me to co-operate with him. It so happened that a similar proposal was about the same time laid before Mr. Alexander Macmillan, head of the publishing firm, by Profs. Huxley, Balfour Stewart, and Roscoe. It was finally arranged that the scheme of these eminent professors should be adopted, and that Lockyer and I should contribute to it. In this way arose the series of elementary text-books or Primers, of which millions of copies have been sold, some of them having been translated into most of the languages of Europe and into some of those of Asia.

Sir Norman's energy also led him to project a weekly journal entirely devoted to science. He convinced the same enterprising publisher that such a journal would be of much value in chronicling for the general public the progress of scientific opinion and discovery. Thus the present publication came into existence. Lockyer was, of course, its editor, and he continued to fill the editorial chair with amazing industry and success for fifty years. It would be difficult to appraise the value of this service to the cause of science. But the historian of the future, when he comes to describe the various influences which have fostered that cause in this country since 1870, will not forget to include Sir Norman and NATURE.

My old friend's enthusiasm spurred him to take part in a long succession of solar eclipse expeditions, which took him into remote parts of the world, and sometimes involved no little risk. These foreign journeys he continued to undertake until he was not far from seventy years of age.

Sir Norman Lockyer's many communications to the Royal Society and other learned bodies, and also the array of his separately published volumes, form the best monument of his life-work. Those who knew him best often wondered how, with only one serviceable eye, he could get through the amount of telescopic and spectroscopic work which he accomplished. His personal charm was great. The kindly nature, ready helpfulness, and infectious enthusiasm that were so characteristic of him endeared him to those who had the privilege of his friendship, and who feel that he leaves a vacant place among the men of science in this country which it will be hard to fill as he filled it.

ARCH. GEIKIE.

WITH the death, at an advanced age, of Joseph Norman Lockyer, a remarkable and in some respects unique personality passes away from the English scientific world. It would be unnecessary for me, even if I were competent, to describe the progress and achievements of his work in science; that has been done already in these pages; nor need I dwell on merely biographical detail. I have been invited to write an appreciation of Lockyer. I can only respond by giving my impression of the man drawn from tolerably close intimacy in an acquaintanceship extending over half a century. Some biographical detail is a necessary framework.

Lockyer's education, though doubtless sufficient, seems to have been unsystematic; part was obtained on the Continent, where he attended lectures at the Sorbonne. He did not receive the training either of a public school or of a university; he started in life unhampered by any educational shibboleths or the acquirement of academic status. This was amply made up to him in after-life, for it is more than doubtful if any contemporary man of science had more honorary degrees showered upon him. Lockyer's father was a man of scientific occupation and probably of some attainment; the son evidently received from him an impulse towards science which no schooling in the early half of the last century could have supplied.

At the age of twenty-one Lockyer was appointed to a clerkship in the War Office; there he remained for thirteen years. Hundreds of young men in such a position have merely matured or withered towards a pension. From that fate he was preserved by the tumultuous energy which characterised him all through life. In the face of opposition he carried out internal administrative reforms in the Office, and had his reward in 1865 in being appointed by Lord de Grey editor of the Army Regulations. I remember his telling me that their codification cost him two years' work, and that the strain of having to carry in his head for the purpose a vast mass of detail almost broke him down. It seems almost incredible that, apart from his official life, he was able to carry on successful astronomical research. He was elected to the Royal Astronomical Society in 1860, and in 1866 devised a method of observing the solar prominences without an eclipse; this was afterwards applied by Janssen and himself, and commemorated in a medal by the French Government. In 1868 he discovered in the sun helium, then unknown as a terrestrial element. In 1869, while still in the War Office, he was elected into the Royal Society.

With such a record of administrative and scientific ability it is not surprising to find Lockyer in the following year appointed secretary of the Royal Commission on Scientific Instruction. At its conclusion Disraeli transferred him to the Science and Art Department, for which he organised the extremely successful Loan Exhibition of Scientific Apparatus opened by Queen Victoria in 1876. In 1881 he became professor of astronomical physics in the Royal College of Science. Research into solar phenomena now became the dominant purpose of his life; it led him into fertile speculations in various directions. They engaged him to the last, and but a year ago he contributed a paper to this journal. The earliest was the correlation between climate and solar activity. I well remember the cold douche he administered when he pointed out to me that its effect, far from being direct, might be the reverse. The importance of this principle, which at the time seemed paradoxical, has now become fundamental in meteorological research; regions are now known to be affected oppositely by changes in the sun's heat supply. Lockyer was chief of eight Government eclipse expeditions in which a brief examination of the isolated chromosphere became possible. In these he had the assistance of the Navy, and their success was due not only to his capacity for leadership and organisation, but also to his ability to inspire interest and enthusiasm in the work in both officers and bluejackets. The installation of a temporary observatory in some remote and uninhabited spot was not seldom difficult.

In 1869 Lockyer and Alexander Macmillan founded NATURE; English science in other respects owes much to the latter and his successors. Henry Woodward, who is still with us, was present at a dinner at the Garrick Club to celebrate its birth. It needed a good send-off, for Sir H. Trueman Wood thought that at the time it "can scarcely have been regarded as a very promising speculation." Probably it was not, but both founders—and Lockyer the most—had a different aim. It may be permitted to quote from the present Vice-Chancellor of the University of Leeds a record of how it has been attained:—"The exacting care with which it has been edited, the impartiality and precision of its judgments, the wide range of its information, the accuracy of its reports, have given NATURE in its own sphere unique distinction and authority."

As to the first, I remember hearing from a distinguished man of science that at a dinner party at which both he and Lockyer were guests, the latter received an urgent printer's proof in the middle of dinner and corrected it then and there.

Lockyer's service with the Commission on Scientific Instruction gave him a thorough insight into the resources, or rather lack of them, throughout the country. It is certainly true, as the present Vice-Principal of Birmingham University tells us, that through the columns of NATURE "there has appeared an informed and helpful criticism that has furthered university growth and development." The criticism was sometimes pretty vigorous. Henry Smith, at Oxford, himself a mathematician of European fame, thought that the editor rather trespassed on the creative function of the Author of Nature.

At Oxford Henry Acland had devoted the best years of his life to getting biology and chemistry admitted to the medical curriculum. Tireless energy with "*aeterna mansuetudine*" succeeded not merely in this, but also in the erection of the New Museum, which was opened in 1861. This, with its Venetian gothic and Skidmore ironwork, is a shrine rather than a laboratory. It was, in fact, an outcome of the Oxford æsthetic renaissance, which in turn owed its filiation to the "Oxford movement." So far science was in the best of company with Dr. Pusey in its support. But Acland really only wanted biology and chemistry for his medical school; accordingly we find in the New Museum Rolleston overtaxing his strength in the attempt to cover the whole biological field; Brodie, emancipated from the cellar of the Ashmolean, treating inorganic chemistry with originality and freshness; and Vernon Harcourt working at chemical change in a reproduction of the Glastonbury kitchen. This was excellent, but unfortunately it was all. As to the rest of the science faculty, some never lectured, some were physically incapacitated, some were frankly non-resident. Much has changed since; new professorships have been founded and entrusted to men of assured accomplishment; new laboratories have been built; and the present Vice-Chancellor finds it convenient occasionally to borrow a number of NATURE to verify an appointment.

At Cambridge we have the testimony of Dr. Glaisher as to "the almost complete lack of interest in natural science that existed in the university when NATURE was founded"; even in mathematics "there was no encouragement—quite the reverse—to research of any kind." To the "great expansion of thought, study, and learning" that has taken place since, "NATURE has largely and worthily contributed."

These testimonials, borrowed from the record on the occasion of last year's jubilee, acquire a true significance when we read in them LOCKYER for NATURE. He never ceased to insist on the necessity of combining university teaching with research. He displeased the somnolent, and still more when he supported a better distribution of available funds in which the untimely death of Dr. Appleton deprived him of support from the side of the "humanities." He was in no way deterred by the sarcasm of Henry Smith and Sir John Evans—who ought to have known better—that the endowment of research only camouflaged—to use the phrase of the day—the research for endowment.

We may congratulate ourselves with Sir Donald MacAlister that NATURE "still informs, chastens, and stimulates the scientific worker and the scientific teacher." Chastening is now seldom called for, but in the early days it was vigorously applied. Teaching and text-books were largely obsolete, and received criticism that was often ruthless. Controversies in its pages were sometimes fierce; they cleared things up, and Lockyer kept the ring with complete impartiality. He would himself submit to a little chastening without ill-will. On one occasion a series of articles was commenced with a general approval from Huxley. But it immediately became apparent that the fundamental assumption was unsound. I sent him a short statement of the fact; he admitted that it was unanswerable, published it, and stopped the series.

If the early days were in some measure marked by storm and stress, Lockyer's transparent sincerity and enthusiasm carried him through. When NATURE had completed its twenty-fifth year the publishers assembled for a dinner at the Savoy Hotel in Lockyer's honour some fifty of the most active and representative of our scientific men then available. Huxley emerged from retirement to be present. With sly humour he hinted at the chastening, and recalled a story of an aggrieved wife who had received some discipline from her husband, but who explained to the magistrate that she "didn't look upon him as a 'usband so much as a friend."

Here I must stop. Otherwise I might touch on Lockyer's kind-heartedness, his capacity for making friends, his courage in family sorrow, his literary labours, and other aspects of a full and many-sided life. I conclude by once more drawing on the jubilee record for the testimony of the Royal Engineers Institute, Chatham, that the Editor of Nature "never failed to enforce the great lesson that the search for knowledge, pursued for its own ends and with no immediate thoughts of material gain, should be one of the most potent driving forces in the life of a nation."

W. T. Thiselton-Dyer.

My acquaintance—and I may add my friendship—with the late Sir Norman Lockyer dates back from almost exactly half a century ago. It began in the autumn of 1870, when the details of the arrangements in connection with the projected Government expedition to observe the total solar eclipse of December 22 of that year were under consideration. Lockyer was then in the full tide of his intellectual vigour. Two years previously he had leaped into fame, and established a commanding position as one of the pioneers of the newly developed domain of solar physics, by his memorable discovery, made simultaneously with, but independently of, Janssen, of a spectroscopic method of observing, delineating, and analysing the chromosphere at any time the sun is unobscured. In conjunction with Frankland he had detected the existence of a new element in the solar atmosphere named by the discoverers "helium," which Ramsay and others, twenty-seven years later, proved to be present in many terrestrial rocks and minerals, and to occur among the gases evolved from springs. Helium, in fact, has been shown to be a widely distributed element, and to be capable of useful application. But with its singular properties, its origin and mode of genesis, and its relations to other "elements," we are not now concerned. The immediate point is that these two cardinal discoveries, with which Lockyer's name will be associated for all time, rendered it a matter of national honour and obligation that every effort should be made, and no opportunity lost, to follow up the line of inquiry he had initiated.

Even although half a century has elapsed, much of the physical history of the sun can be traced only by the observation and study of the phenomena of a total solar eclipse. In 1870 the present methods of attack were, comparatively speaking, in their infancy. Warren de la Rue first used his photo-heliograph during the eclipse of July 18, 1860. In the same year Bunsen constructed the first spectroscope, which was quickly applied to the examination of celestial objects. Tennant had directed it to the corona of the Indian eclipse of 1868, and Young to that of the eclipse of 1869. But the results were contradictory. Tennant found that the spectrum was the ordinary solar spectrum; Young detected the existence of bright lines, but was uncertain as to whether they might not be due to the outlying and nebulous portion of the chromosphere. To the world of science the question was of the greatest interest. Hence the importance of the eclipse of 1870, which, it was hoped, would settle the matter. Mr. Robert Lowe at that period was Chancellor of the Exchequer, but, even if he were so minded, the Government was unable to resist the appeal of the Royal and Royal Astronomical Societies that properly equipped expeditions should be sent to suitable places along the central line of totality. Lockyer was by common consent designated as a leader of one of the parties. With characteristic zeal and ardour he threw himself heartily into the work of organisation. Arrangements were made to observe at various stations along the eastern coast of Sicily. He elaborated a comprehensive plan of observation, mainly directed to the elucidation of the structure and physical nature of the corona, and secured the co-operation of competent physicists and trained observers. Unfortunately, all his forethought, labour, and anxiety came to nothing. The Admiralty dispatch-boat *Psyche*, conveying the party from Naples to Catania, struck a submerged rock near Aci Reale. All on board were safely put on shore, and so, ultimately, were the instruments, but the poor dispatch-boat became a total loss. It was characteristic of Lockyer, whose whole thought was concentrated on the work he had undertaken, that he should have telegraphed home as soon as he reached Catania:—"*Psyche* totally wrecked. Instruments saved." Anxious relatives might infer the rest as they pleased.

Misfortune, however, still followed us. We managed to get everything in readiness for the eventful day, but as the total phase approached, the rapid fall of temperature occasioned the formation of cloud; the corona was wholly obscured, and no spectroscopic or other observations during totality were possible, and photographic exposures were useless. The work entrusted to me consisted in determining the photometric intensity of the solar light during the progress of the eclipse, and was independent of the total phase. Fortunately, I was able to obtain a complete set of measurements, which afterwards found their way into one of the publications of the Royal Society. But our philosophy was sorely exercised on learning that a perfect view of the unclouded corona was obtained from the deck of the wrecked *Psyche* some few miles away. The greatest sympathy was felt by everybody for Lockyer, and his disappointment was naturally very keen. But he bore it stoically; if he had not secured success, he had at least deserved it. Of the band of observers associated with him—among them Sir Henry Roscoe, Sir George Darwin, W. K. Clifford, W. G. Adams, Ranyard, John Brett, the artist, Sir Alexander Pedler, Brothers, Bowen, and Seabroke—I believe I am now the sole survivor.

I was a member of another expedition of which Lockyer was the leader—viz. that sent to the island of Granada, in the West Indies, to observe the total solar eclipse of August 29, 1886, when we were generally more fortunate, good observations being made by the late Father Perry, S.J., at Carriacou, Prof. Turner, Savilian professor at Oxford, Sir Arthur Schuster, and Major Darwin. Lockyer was not in good health at the time, and appeared to suffer from the heat and humidity of the climate.

On my translation to the Normal School of Science, South Kensington, as successor to Sir Edward Frankland, I became closely associated with Lockyer as a member of the teaching staff. He lectured on solar physics, and directed the observatory then standing near the western side of Exhibition Road. His laboratory and private room were in the main building close to the chemical laboratories, and I naturally saw much of him at this period. He was an indefatigable experimenter, and I was not infrequently called upon to see his results. He was always ready to discuss his work with anybody who showed an interest in it, and never made the slightest secret of what he was doing and why he was doing it. He was fertile in ideas and prolific in working hypotheses, which were discarded as readily as they were formed if found barren of results. No man ever made a greater scientific use of the imagination, and at times, in the course of conversation, he seemed to give the loosest possible rein to his fancy. Much of his routine observatory work was, of course, done by assistants, by whom he was well served. But he took a very active part in the work of the laboratory, and generally made the crucial observations himself, or assured himself of their validity by repetition. He was an excellent teacher, with a remarkable gift of exposition. He spoke fluently, with a ready command of apt expression and telling phrase, and he had no difficulty in retaining the attention of any audience he addressed. At one period of his career he was in great request as a popular lecturer, and undoubtedly did much to arouse interest and disseminate information concerning celestial phenomena, especially in connection with solar chemistry and physics. He had little opportunity of creating a "school." The primary duty of the Normal School of Science, or, as it was afterwards called, the Royal College of Science, was to train science-teachers, and the subjects of his chair offered little promise of a lucrative career.

He was a loyal colleague, and, under Huxley's wise direction as Dean, took his fair share in discussion and advice. Of his many social gifts others will no doubt be able to testify. He was fond of the society of his fellows, a genial host, entertaining and hospitable, an excellent conversationalist, with a nimble wit, and an unfailing power of ready repartee. There must be very many who have the pleasantest recollections of the delightful dinner parties in his town house in Penywern Road, and of the conversaziones which usually followed them.

Lockyer early enlisted me into the service of NATURE, and I became a frequent contributor to the journal which, under his judicious and enlightened direction, has done so much to foster and advance the interests of science in this country. My relations with him as the Editor were of the most cordial character, and I collaborated with him occasionally in the production of a leading article. Such work when done in common with him in his sanctum, frequently late at night, necessarily took up much time when protracted, as was usual, by his too ready flow of ideas, which needed a certain power of compression to get them into literary form; and at times it was only in the small hours of the morning that I was able to wend my way home—a not infrequent experience, however, of leader-writers.

It cannot, of course, be maintained that all that Lockyer has published has withstood the test of time. Some of his experimental evidence, and certain of his deductions and generalisations, were hotly challenged at about the time he made them known. But when all is said that can be said in the way of criticism and detraction, it may be confidently asserted that he has left an indelible impress on the scientific history of his epoch. His memory will be cherished by all who have come under his influence, or have learned to appreciate his many excellent qualities of head and heart, and have knowledge of his untiring efforts to serve the highest interests of science.

T. E. THORPE.

I FIRST made the acquaintance of Lockyer in Clifton, where I met him at dinner at the house of the late William Lant Carpenter in or about 1874. Lockyer had come to give a popular lecture in Bristol on his own and other recent discoveries in celestial spectroscopy, and he was full of his new ideas about the origin and nature of the elements. I remember his asking me whether I considered calcium to be an element, and, having been brought up in the then prevalent view of the permanence of the chemical elements, I replied that I should certainly so regard it. The periodic scheme of Mendeléeff was comparatively new, and Mendeléeff himself did not encourage the notion that it involved the question of the origin of the elements. Lockyer was the first to pursue the subject systematically, and much of his astrophysical research was directed towards establishing his ideas as to the dissociation of the terrestrial elements in the hottest of the stars.

I also remember coming into contact with Lockyer at the time when he was secretary of the Duke of Devonshire's Commission on Scientific Instruction, in the operations of which I was, of course, deeply interested, owing to the position I held as senior science master in Clifton College. I never at that time could have expected to be thrown into daily communication with him, as I was twenty years later, owing to an arrangement with Frankland, then professor of chemistry in the Royal College of Science at South Kensington. Frankland and Lockyer had in 1869 been engaged in joint researches on the "Physical Constitution of the Sun," and when in 1881 Lockyer became professor of astrophysics at the Royal

College of Science he secured the use of a room in the new building to which access was obtainable only through the two intermediate rooms occupied by Frankland and his successors as the research laboratory for chemistry. The consequence was that the professor of astrophysics and his satellites were compelled to pass many times in the day through the chemical rooms. It cannot be said that this was an advantage to the chemical work, for, owing to draughts and general disturbance, some chemical operations were absolutely prohibited; but the arrangement had one compensation in the opportunities afforded of frequent talk with the professor, and of hearing from him what was going on. Lockyer was always very helpful to other less experienced workers with the spectroscope, and after the discovery by Ramsay of terrestrial helium it can be readily imagined what a bustle arose in the room occupied by the professor of astrophysics, to whom the original observation of the same element in the sun was due. This naturally gave rise to many conferences with the professor of chemistry on the subject of the minerals from which the gas was obtained.

Lockyer was also a genial and jovial member of the circle which assembled daily round the luncheon table in the museum, which included in later years some of the professors from the City and Guilds Central College. Nearly all are now gone, and only memories remain to the few survivors. Those recollections include the conviction that Lockyer was a strong man who always knew his own mind, and hence accomplished much both by practice and example where lesser men, though with the same aspirations, only met with failure and disappointment. William A. Tilden.

The privilege of taking part in the memorial tributes to Sir Norman Lockyer is perhaps something more than I deserve, for, although it is true we were on terms of cordial friendship, we were never associated in official or scientific occupations, unless his invitation to join in the founding of the British Science Guild, and his many courtesies as Editor of Nature, may be so described. To speak of Lockyer's researches as contributions to science seems inadequate. Incapable as I was of following his scientific work in detail, I felt it to be more than contributory; we admired him rather as a builder, and a builder on big and original lines. There was something large in his undertakings and in his vision, and happily to sustain them he had also within him a fountain of energy which seemed perennial. His prescience and his vigour together were enormous, and carried him into many spheres of activity. If sometimes I was tempted to grudge his spending in the clouds what was needed by mankind, this was ungrateful, for Lockyer put his driving power freely into many sublunary affairs.

That Lockyer was disposed to be combative he was the first to admit, but always on liberal and generous lines; and in personal differences he was always kindly and good-humoured. His was the combativeness that keeps societies from stagnation. On two important affairs he and I differed decisively, but always in good temper, and I gladly admit that in the main he was right on both issues. From the time of his departure from London most of us had to lament the loss, not, happily, at the time, of an original worker in science, but of a most ingenious and stimulating companion. At length we have lost a colleague not only a master of minute and diligent observation, but also endowed with that wide and abstract imagination which, if other than the individual imagination of the artist, is no less prophetic in the sphere of science. Clifford Allbutt.

I cannot call myself an intimate friend of the late Sir Norman Lockyer, though we frequently met and talked, but two characteristics in him always impressed me. One was his energy. He seemed always to be at work, always to be full of interests, and whatever he took up he did well. The other was the many-sidedness of his mind, and his power of combining business ability and scientific acuteness. Quite early in his career he made important contributions to solar physics, discovering (with Janssen) how to examine the solar prominences apart from an eclipse, investigated meteors, and was one of the three simultaneously to explain the wonderful glows which followed the Krakatoa eruption. Besides this he wrote valuable and suggestive papers on Stonehenge and other British stone circles. With all this he was a very efficient public servant, both in the War Office and in the Science and Art Department, secretary to the Duke of Devonshire's Commission on Scientific Instruction in 1870, and Editor of Nature for fifty years from its commencement. We shall not readily meet again with his like. T. G. Bonney.

Mr. Arthur Savage writes:—Like many other people, I have been reading the life-story of Sir Norman Lockyer, the great man of science who was able to add so liberal a contribution to the accumulation of human knowledge. I was interested to learn from the obituary notice which appeared in the *Times* of August 17 that Sir Norman was the founder of Nature, and I have thought the opportunity a fitting one to express a young man's humble word of appreciation of your excellent journal.

Although I have not received a university education, and my daily duties are outside the domain of scientific study, you may be glad to know that I follow your columns regularly in order to keep myself "up to date" in matters relating to those branches of knowledge in which I am interested. Should you consider this note worthy of publication I have no doubt that it would represent the feelings of numerous other "ordinary" individuals like myself.

Notes.

WE have received from a correspondent in India a letter which states that the present director of the Indian Institute of Science at Bangalore, Sir Alfred Bourne, is to be succeeded by an administrator with no scientific experience. Such an appointment would be greatly deprecated by scientific workers, and we trust it is not too late to prevent it. In our view the head of such an institution should be a man who combines scientific experience with administrative ability; and if this principle is deliberately ignored in the case of the directorship of the leading scientific institution in India, the strongest protest should be made to the authorities responsible for the appointment.

WHEN Mr. B. B. Woodward retired from the British Museum (Natural History) last June he was still occupied with the proofs of the supplement to his well-known catalogue of the natural history library. Naturalists will be glad to learn that his services have now been temporarily retained for the completion of this valuable work.

WE learn from the *British Medical Journal* for August 28 that the fifth Congress of Physical Therapy, instituted by the Belgian societies of physical therapy and radiology and the Antwerp Association for Physical Therapy, will be held at Antwerp on September 11 and 12; also that the nineteenth Flemish Congress of Medicine and Natural Science will be held at Ghent on September 18 and 19.

THE thirty-first annual general meeting of the Institution of Mining Engineers will be held at Manchester on September 15–17, under the presidency of Col. W. C. Blackett. The institution medal for the year 1919–20 will be presented to Dr. John Bell Simpson, and the following papers will be presented: The Normal Occurrence of Carbon Monoxide in Coal-mines, J. Ivon Graham; The Better Utilisation of Coking Slack, A. E. Beet and A. E. Findley; Richard Trevithick: His Life and Inventions, J. Harvey Trevithick; The Froth Flotation Processes as Applied to the Treatment of Coal, Ernest Bury; and An Improved Method of Determining the Relative Directions of Two Reference Lines or Bases for Mining Surveys, T. Lindsay Galloway.

EARLY last year a Speleological Society was founded in the University of Bristol, and a record of its activities has now been published in the first part of its Proceedings. The society is fortunate in being within easy reach of the Mendip Hills, where so many important caves have already been explored, and it has been able to obtain special facilities for field-work. It has also been favoured with a course of lectures by several leading authorities on prehistoric archæology. In his presidential address Prof. E. Fawcett describes some human skulls found by the society in a cave, associated with Late Palæolithic flint implements and remains of red deer, wild cat, and brown bear. The skulls are both dolichocephalic and brachycephalic, and Prof. Fawcett compares the discovery with one made at Ofnet, near Munich. Mr. L. S. Palmer gives an account of the exploration of another cave, in which numerous Late Celtic objects were found. There are also brief reports of the lectures at the meetings. The society is to be congratulated on its first year's work, and will have the best wishes of all who are interested in the study of early man, but its publication could be improved by more careful editing and by a judicious selection of illustrations produced in better style.

WE have just received from Dr. Hornaday, the director of the New York Zoological Park, a very interesting and important summary of the results of the five-year close season which was deemed necessary in 1912 for the replenishing of the herds of the fur seal of the Pribilof Islands. The results have been everything that the close-season advocates foretold. This conclusion is supported by figures. In 1912 there were 215,738 seals of all ages; in 1917 they had increased to 468,692, and by 1919 these numbers had risen to 530,237. This protection was devised for purely commercial ends, and the result is most emphatically satisfactory. This much is shown by the fact that at the St. Louis fur auction held on February 2, 1920, there were sold for the United States Government 9100 skins of fur seals which averaged 140.98 dollars per skin. Skins of the same quality in 1918 averaged no more than 46.34 dollars, but in 1919 the price had risen to 78.38 dollars. Thus the cost of this fur has risen by leaps and bounds, and it is anticipated that it will rise yet higher. "In the future," Dr. Hornaday remarks, "when all other bearers of good fur have been utterly exterminated—*as they soon will be*—the protected fur seal herds will produce . . . a really vast quantity of the finest fur in the world. It needs no stretch of prophecy to foretell the annual increment to the three nations (the United States, England, and Japan) who are now so sensibly preserving the fur seals of Alaska from killing at sea."

THE Forestry Commission has made considerable and satisfactory progress both in the acquisition of land and in planting. Landowners have shown considerable sympathy with the objects of the Commission, and in several cases free gifts of land or long leases on specially favourable terms have been obtained. The area of land acquired in the United Kingdom is as follows:—England, 9177 acres; Wales, 6329; Scotland, 23,472; and Ireland, 4716. This excludes lands acquired by the Department of Agriculture for Ireland, administered by the Commission. In addition, without taking into account estates which are merely under consideration, negotiations are proceeding in respect of the following areas:—England, 24,973 acres; Wales, 7900; Scotland, 6956; and Ireland, 7000. During the season 1919–20 the area of land planted, most of which is showing satisfactory progress, was 850 acres in England, 535 in Scotland, and 200 in Ireland. To meet the heavy cost of transport and the shortage of plants, new nurseries are being set up in the more important planting areas. Every effort is being made to increase the supply of seed and of seedlings. In conjunction with the

Ministry of Labour, the Commission has established at Brockenhurst, New Forest, a school for the forestry training of disabled ex-Service men, to be opened this month. A similar school is open at Birnam, near Dunkeld, and a new school for forest apprentices has recently started at Beauly, Inverness-shire. Offers of land may be addressed to the offices of the Assistant Commissioners at 22 Grosvenor Gardens, London; 25 Drumsheugh Gardens, Edinburgh; or 6 Hume Street, Dublin. All inquiries should be addressed to the headquarters of the Commission at 22 Grosvenor Gardens, London.

THE passages in classical literature which have been quoted in support of the assertion that mother-right existed in ancient Italy are discussed in the June issue of *Folk-lore* by Mr. H. J. Rose. One of the most daring attempts to support this position is a review of the succession of the members of the great Iulio-Claudian house (Journal of the Royal Anthropological Institute, vol. xlv., 1915, pp. 317 *sqq.*). A number of these counted their descent from women, but of matrilinear descent proper we have not a trace. In Italy, as Mr. Rose remarks, "we cannot, whatever we may do in Greece, weave sociological fantasies from the relationships of the gods, for the excellent reason that the Italian *numina* have no families. If any better arguments remain I shall await their production with interest, but, frankly, I have small expectation of anything of the sort."

IN a discourse delivered on March 12 last before the Royal Institution Mr. W. W. Rouse Ball, of Trinity College, Cambridge, gave an instructive illustrated account of the art of weaving string figures, usually made by weaving on the fingers a loop of string about 6½–7 ft. long so as to produce a pleasing design, often supposed to suggest a familiar object either at rest or in motion. Mr. Ball remarks that "friends who have learned the rules tell me that in convalescence and during long journeys the amusement has helped to while away many a tedious hour; moreover, the figures are easy to weave, they have a history, and they are capable of many varieties. Thus even in England the game may prove well worth the time spent in learning to play it; and admittedly to the very few who travel among aborigines it may sometimes be of real service."

MR. A. L. ARMSTRONG describes, in the *Naturalist* for July, with an illustration, an interesting series of six bone implements picked up by Mr. W. F. Jackson on a ploughed field at Rocher Head, Bradfield, near Sheffield, in 1888. They were associated with a number of well-worked implements of flint, consisting of round and horseshoe scrapers, a "spoon" scraper, and several trimmed flakes and knives. The collection has recently been examined by Mr. Reginald Smith, of the British Museum, and Sir W. Boyd Dawkins, who agree in regarding them as belonging to the Late Neolithic or Early Bronze age. The bones are those of an unidentified mammalian long bone, small metatarsal bones of a horse, and one of a bird. The largest specimen seems to have been rubbed down to form a blade on one long edge for about half its length, and it may have been used in dressing skins. They may be the grave furniture of a tumulus now demolished, or may represent a hoard.

DR. WM. MCDOUGALL deals, in *Mind* (N.S., No. 115, July, 1920), with the problem of motives in the light of recent discussion. He reviews briefly his own point of view as expressed in "Social Psychology," the view, namely, that the instincts are the mainsprings or motives of all man's activity. He then considers, first, the criticism and suggested alterations of Prof. Woodworth, who in "Dynamic Psychology" maintains that, in addition to the instincts, other mechanisms, *e.g.* native capacities and acquired habits, have also driving force; and, secondly, those of Mr. Graham Wallas, who seeks to establish thought as an independent native capacity containing its own "drive." Dr. McDougall considers the various arguments brought forward by these critics, but fails to find them convincing, and himself brings further evidence in support of his original contention. The article is interesting and suggestive to all who, whether from the theoretical point of view of abstract thought or from that of the practical necessities of life, find themselves confronted with the difficult problems concerned with human motives.

IT is well known that the large European ground-beetle, *Calosoma sycophanta*, has been introduced into the eastern United States in order that it may prey upon caterpillars destructive to deciduous trees. Messrs. C. W. Collins and Clifford E. Hood have shown (*Journ. Agric. Research*, vol. xviii., No. 9, 1920) that an American tachinid fly, *Eubiomyia calosomae*, has formed the habit of laying eggs on the introduced beetle, within which the maggots feed.

WE have received No. 15 of the Journal of the East Africa and Uganda Natural History Society (November, 1919), which contains, among other interesting papers, a lecture on "The Geological History of the Rift Valley," delivered at Nairobi by Prof. J. W. Gregory, who narrates how on his journey of 1893 he had encamped on the unoccupied site of that now busy and important town. Dr. G. D. Hale Carpenter, in "Discursive Notes on the Fossorial Hymenoptera," summarises the results of his studies on the habits of tropical African Sphegidæ and Pompilidæ. This well-produced journal is, we notice, printed in England; so are the Annals of the Transvaal Museum, of which vol. vii., part 3 (June, 1920), comprises an important systematic entomological paper, "On the South African Notodontidæ," by Mr. A. J. T. Janse.

WHEN the surface of a lava-stream hardens, the lava below may continue to flow, forming a tube beneath the frozen crust. In some volcanic areas lava-tubes of small size are abundant, but those of great length are rare. In the Monthly Bulletin of the Hawaian Volcanic Observatory for March, 1920, Mr. S. Power describes and illustrates a tube near Kilauea of unusual size, known as Thurston's tube, 1494 ft. in length, with a maximum height and width of 20 ft. and 22 ft. respectively. It opens into the Kaluaiki pit crater, and is one of the channels by which the crater was drained shortly before the final disappearance of the lava-lake.

In the last issue of the *Bollettino* of the Italian Seismological Society (vol. xxii., 1919, pp. 129–42) Dr. Agamennone describes a series of slight earthquakes at Frascati on November 6–7, 1909, of the same nature as true volcanic earthquakes, and yet originating on the flank of the extinct volcano of the Alban Hills. Small as is the area covered by these hills, Dr. Baratta distinguishes within it nine seismic zones, and the interest of the shocks described lies in the evidence which they offer of the continual migration of activity from one of these zones to another. The same number of the *Bollettino* contains Dr. G. Martinelli's catalogue of 568 earthquakes felt in Italy in 1917 (pp. 164–87). This takes the place of the very full pre-war reports which formerly occupied several hundred pages every year. While the completeness of the record does not seem to have suffered under war conditions, the catalogue in its restricted form has lost none of its usefulness for statistical purposes.

In the latest part of the Transactions of the Nova Scotian Institute of Science (vol. xiv., part 4) Prof. John Cameron describes two remarkable human skulls from South Malekula, in the New Hebrides. They seem to have been elongated by distortion through bandaging in infancy, and they exhibit the enormous development of the frontal air sinuses which are such a marked feature of the Melanesian skull. These sinuses not only produce very prominent superciliary ridges, but also, with the large maxillary sinuses, cause a flattening of the upper and lower margins of the orbit, imparting to it a quadrangular shape. The various features are compared with those of the known fossil human skulls from Europe.

During the war the Geological Survey of Egypt had the opportunity of obtaining some of the interesting fossil vertebrates from the Lower Miocene estuarine deposits at Moghara, and it has just published a description of the collection in a "Contribution à l'Etude des Vertébrés Miocènes de l'Egypte," by M. R. Fourtau. The fish-remains, on which there are notes by M. F. Priem, are unimportant, but among the reptilian remains there are fine skulls of new species of Crocodilus and Tomistoma and of a new genus of gavials named Euthecodon. The primitive artiodactyl mammals of the family Anthracotheriidæ are represented as usual by many valuable fragments, and there are several teeth of Mastodon. Dinotherium is curiously absent, and M. Fourtau finds it difficult to explain why this genus should be found with Mastodon further south in Africa. One tooth of a hyæna is the sole fragment of a carnivore, but there are two portions of mandibles of anthropoid apes which are of great interest. The figures of these two fossils are very unsatisfactory, but according to the description one seems to represent a new genus related to Hylobates, while the other may belong to a species of Dryopithecus.

Two lecture-demonstrations to teachers of science in secondary schools on "The Study of Crystals in Schools," given by Mr. T. V. Barker at the University Museum, Oxford, on August 10–11, are published in a small pamphlet by the Holywell Press, Oxford. In the first lecture some of the salient facts of crystallography were experimentally demonstrated on growing crystals by means of the lantern-microscope, in order to illustrate the lecturer's view that some instruction about crystals should be given in all chemical lectures and laboratories. It was pointed out that almost every answer to an examination question on atomic-weight determinations will include a dissertation on Mitscherlich's discovery of isomorphism learnt from a text-book, yet probably neither the candidate nor even the writer of the text-book had ever seen isomorphous crystals, and still less proved them to be so by simple measurement. In the second lecture some simple crystal measurements were made of microscopic crystals on the screen and of larger crystals with a contact goniometer, and the properties of cleavage, hardness, and density were also demonstrated on a variety of crystallised substances. The object aimed at, of showing the possibility of introducing simple experiments on crystals into secondary-school natural science teaching as part of the physics and chemistry courses, and of demonstrating how interesting to young people such experiments could be made, appears to have been fully attained, and doubtless many of the teachers who attended will make some effort to respond in their own schools, and thus to give our possible future chemists an early idea of the great value of crystallography to the chemist.

A valuable contribution to South African botany is a paper on new and interesting South African mosses by Mr. H. N. Dixon (Trans. Roy. Soc. South Africa, vol. viii., part 3, 1920), in which the results are given of the work on collections received from various districts during recent years. A considerable number of novelties are described, new records established for South Africa, and many of the genera or species critically examined.

In the *Kew Bulletin* (No. 5, 1920) Dr. A. W. Hill gives some account of the Tresco Abbey Gardens, Scilly Isles, emphasising their claim to be regarded as an Imperial asset of great importance to the botanists of this country whose work concerns the botanical resources of the British Empire, and pointing out the desirability of arranging that systematic botanists should be given facilities for studying in the Gardens in the living condition the plants with which they have become familiar in the herbarium. In this favoured spot may be studied not only the principal features of the temperate regions of New Zealand and outlying islands, of Australia, and of South America, but also many of the characteristic features of the sub-tropical vegetation of South Africa. A great number of plants were introduced from Australia, New Zealand, and South Africa about the middle of last century by Mr. Augustus Smith, whose botanical enterprise and interest in gardening were continued by his nephew and heir, Thomas Algernon Dorrien-Smith, who succeeded to the lordship of the islands in 1872, and, since the death of Mr. Dorrien-Smith in 1918, by Major A. A. Dorrien-Smith. A feature of the collection is a large series of drawings of many of the interesting plants which have flowered in the Gardens. Dr. Hill refers to the possibility of growing New Zealand flax as a crop for the production of fibre in the Scilly Isles in co-operation with growers in Cornwall.

PROF. AUGUSTINE HENRY and Miss Margaret Flood contribute to the Proceedings of the Royal Irish Academy (vol. xxxv., B5, May, 1920) a botanical and sylvicultural account of the species of Douglas fir comprising the genus Pseudotsuga. The Douglas fir of North America is one of the great timber trees of the world, and includes two species, one the Pacific Coast, Oregon, or green Douglas fir (*Pseudotsuga Douglasii*), and the other the Rocky Mountains, Colorado, or blue Douglas fir (*P. glauca*). The Oregon species forms forests of immense trees on the Pacific Coast, and is now much cultivated in the British Isles, where its rapid growth and enormous yields of timber in a short term of years render it very valuable. The Colorado species throughout its home in the Rocky Mountains is much inferior in size and vigour, and is of little or no value in commercial afforestation in this country. The paper is mainly concerned with a comparative study of these two species, but is extended to include an account of the whole genus. In all, seven species have been distinguished; besides the two already mentioned, a third American species with very large cones occurs in Southern California, another in Japan, and there are also three very closely allied species, two native in Yunnan and one in Formosa. The microscopic structure of the leaves has been found to be a distinct and constant character in each species, evidently correlated with the special climate in which the tree is native. The oil obtained by distillation of the leaves of the Colorado and Oregon species respectively proves to be very distinct in chemical composition.

THE Meteorological Service of the Philippines has recently issued part iii. of the Report of the Weather Bureau for 1917. The report is entirely statistical, and contains the observations made at the secondary stations during the year. All the results are carefully collated and examined at the Central Observatory under the supervision of the director, the Rev. José Algué, S.J., and the tables fill 360 pages, closely printed. The stations extend from latitude 6°–20° N. and longitude 118°–144° E. Observations at first- and second-class stations are for each four hours, six daily, for most elements, and annual summaries are given for these stations at the end of the volume. Observations at third-class and rain stations are made twice daily. In all cases the results are separated into months, and the means and totals given. The stations in all number fifty-four. For world-meteorology, and especially for aviation, the Meteorological Service of the Philippines is doing work of a very high order. Data are given for atmospheric pressure, air temperature, relative humidity, rain, wind direction and movement, and cloud form and direction. A rough examination of the wind directions and the movement of the clouds is of considerable interest. The movement of wind is greater, and calms are far less numerous, during the day than at night. Easterly and north-easterly winds prevail generally during the winter, and southerly and westerly winds during the summer. There is a distinct range of wind in the twenty-four hours. Upper and lower cloud observations are given twice daily; the direction of upper clouds is less regularly entered than that of lower, and the latter show commonly a veering of four points or more in comparison with the surface wind at the corresponding time.

ONE of the Meteorological Office publications, a section of the *Geophysical Journal*, gives daily values of certain elements at the Meteorological Office observatories. The data, which are not all observed every day, include air pressure, temperature and humidity, wind direction and velocity, sunshine and rain, cloud amount and weather, solar radiation and grass minimum, magnetic elements, earth temperature, atmospheric electricity, earthquakes and aurora, nephoscope observations, and pilot-balloon soundings. The normals are not of equal value, as we find at Kew Observatory 45, 35, 30, and 12 years for different elements, and at St. Louis (Jersey) 26, 25, 23, 22, and 16 years; while of the four wind observatories three give the daily maximum gust, while the fourth can give only the velocity during the windiest hour. There are other points of considerable dissimilarity between the different observatories. Eskdalemuir is, of course, of recent foundation, but it does not seem necessary to quote five-year normals in the ninth year, and it would be better to adopt fresh normals every year until at least the tenth in the case of a new observatory. The South Kensington normals are for a seven-year period, so that the quinquennium is obviously not insisted upon. The information about the height of the anemometer head above the cups at Holyhead appears to be conflicting, figures of 4·2 m., 6·1 m., and 4·0 m. being all derivable from the headings.

THE benefits accruing from a considered system of engineering standardisation have met with but a tardy recognition in Australia. It was not until the necessities of war pressed the subject to the foreground that any tangible steps were taken towards introducing a systematic scheme for engineering standardisation in the Commonwealth. The Institute of Science and Industry has given considerable attention to the matter, and after informing itself fully as to what has been done in other countries, and consulting various experts in Australia, it has put forward the outline of a scheme for the creation of an Australian Engineering Standards Association. This scheme has now been agreed to by the engineering societies, and a recommendation made to the Commonwealth Government for the establishment of a Standards Association. In the meantime, the Institute of Science and Industry has taken a further step and issued an Australian Standard Specification for Structural Steel, with appendices as to the forms of standard tensile test-pieces and data as to standard sections, sizes, weights, and sectional areas.

Our Astronomical Column.

LIVERPOOL UNIVERSITY TIDAL INSTITUTE.—The first annual report of this institute, established in 1919 with funds provided by Sir Alfred and Mr. Charles Booth, gives a brief and interesting account of the work so far taken up under the auspices of Prof. J. Proudman, the honorary director, and Dr. A. T. Doodson, the secretary. Besides theoretical work on the seiches in Lake Geneva and on the dynamical equations of the tides, the study of tide-prediction has been vigorously prosecuted. The official British and American predictions of the tides in the Mersey, calculated by machines of Lord Kelvin's type on the basis of analyses made many years ago by a committee of the British Association, often differ by a foot in height between themselves, and from the actual observed heights by amounts up to 3 ft. Dr. Doodson finds that the predicting machines are susceptible to error, though further examination is necessary to determine whether to an extent which unfits them for use in research. Meanwhile, the institute has embarked on an intensive study of the tides at Newlyn, near Land's End, from the continuous record taken by the Ordnance Survey. This work has also been assisted financially and otherwise by a British Association committee. Analysis has been made by computations on a novel plan; the five most important constituents in the tides were first removed, using approximate values inferred from the results of analyses for neighbouring stations. This reduced the range from 18·5 ft. to 2·5 ft., and disclosed the presence of quarter-diurnal constituents, which also were removed by a method suggested by theoretical considerations. This revealed constituents of higher orders and the presence of some unremoved semi-diurnal constituents, as was to be anticipated. By this method the real constituents are discovered, and these alone removed.

LONGITUDE BY AEROPLANE.—The *Comptes rendus* of the Paris Academy of Sciences for August 2 contains a paper by M. Paul Ditisheim describing a new determination of the Paris-Greenwich longitude by the repeated transfer of a series of chronometer watches between the two observatories by an aeroplane. Twelve watches were used which had previously been tested at Teddington with most satisfactory results. They were packed in wooden cases surrounded by layers of wool, and remained in a horizontal position during transit. They were compared with the standard clocks at Greenwich and Paris by Mr. Bowyer and M. Lancelin respectively. The average time of transit was 2¾ hours; on one occasion the double journey was completed on the same day.

The resulting longitude difference is 9m. 20·947s., with a probable error of 0·027s. It is only 0·005s. less than the mean of the British and French results in the 1902 determination. It is needless to say that the new value does not claim anything like so much weight as that of 1902, in which the observers were exchanged and personal equation was eliminated. It is, however, an interesting confirmation of it, and it illustrates the fact, already known, that the use of the travelling wire in observing transits greatly diminishes personal differences. This fact gives ground for hope that the method of wireless signals, without interchange of observers, will give close approximations to the longitudes of all the participating observatories.

OBSERVATIONS WITH THE PHOTO-ELECTRIC CELL.—Prof. Joel Stebbins's valuable pioneer work with the selenium cell (with which he discovered the secondary minimum of Algol) is now being continued with still greater refinement with the photo-electric cell. The *Astrophysical Journal* for May contains two of his researches. The first is on the Algol-variable λ Tauri. The light-curve much resembles that of Algol, a secondary minimum being shown here also. Elements are deduced from Prof. Stebbins's results combined with the spectroscopic ones. The masses of the two stars are 2·5 and 1·0 times that of the sun; the radii are 4·8 and 3·6 times the sun's; and a third body is suspected with mass 0·4. The side of the secondary that is turned towards the primary is much brighter than the other, which is ascribed to the intense radiation of the primary.

The other star examined is π^5 Orionis. The variability was detected before Prof. Stebbins noted that it had already been classified by Lee as a spectroscopic binary (with only one visible spectrum). The total range of light is only 0·06 magnitude, yet the observations suffice to give a consistent curve. As this proves to be a sine-curve with two periods in the time of revolution, it is concluded that the light-variation does not arise from eclipse, but from the spheroidal figure of the bright component. The ratio of axes is 0·95, which is quite a reasonable figure.

Prof. Stebbins states that he has at last succeeded in obtaining a potassium cell, with walls of fused quartz, that gives complete satisfaction. It was only after ninety-eight trials that this result was reached.

The Scientific Investigation of the Ocean.

NEED FOR A NEW "CHALLENGER" EXPEDITION.

THE outstanding feature of the proceedings of Section D (Zoology) at the meeting of the British Association at Cardiff was the discussion on August 26 on the need for the scientific investigation of the ocean.

In opening the discussion, Prof. W. A. Herdman, president of the Association, pointed out that this need may be considered under two heads—the scientific need and the industrial. Simply as a matter of advancing knowledge, the need for much further investigation of the ocean is very great indeed, and biologists realise that the industries connected with those marine animals—fishes and others—which are of economic importance are all of them badly in need of scientific investigation. There is not a single marine animal in regard to which it can be said that we know anything like all there is to be known and fully understand its mode of life. Even our commonest fishes, such as the herring and the cod, are in some respects unknown and mysterious to us. Prof. Herdman then proceeded to give a few examples of the need for further investigation.

The first report of the Tidal Institute of the University of Liverpool, issued a few weeks ago, shows that the two independent published predictions of the Liverpool tides—one issued by the Admiralty and the other by the United States Coast and Geodetic Survey—"seldom agree; they often differ by a foot in height; also, both of them sometimes differ from the actual tide by as much as 3 ft. in height." It is evident from this report that the present state of affairs urgently calls for more scientific research both in regard to the theory of the tides and to the accuracy of observations.

The work of the bio-chemist and of the physical chemist in connection with hydrography seems likely to be of fundamental importance, *e.g.* the possibility of determining the point of entrance to known currents of water by means of indicators showing the hydrogen-ion concentration may be of practical utility to navigators. Then again, Otto Pettersson's submarine waves in the Gullmar Fjord and elsewhere, and their possible influence on the winter herring fisheries, is a subject worthy of further investigation. Enough is known as to the influence of variations in the great oceanic currents upon the movements and abundance of migratory fishes to indicate the need for further and more complete investigation of the subject.

Prof. Herdman pointed out that, though we may suspect that the periodic changes in the physico-chemical characters of the sea may be correlated with the distribution at different seasons of the microscopic organisms that are an important source of food to larger animals, the matter has still to be proved and worked out in detail. The plankton curve has to be traced and the succession of organisms explained in terms of environmental conditions, including the ion-concentrations in the water and the amount and quality of solar radiation, and that not only in temperate seas, but also in the tropics and in all the oceans, and at various depths. It is known that many marine animals are profoundly affected in their distribution by the hydrographic conditions. For example, it has been shown that the herring of our summer fisheries is influenced in its movements by the temperature of the water, the catches being heavier in seasons when the water is colder, so long as it is not below 54·5° F., when the shoals break up and disperse.

Bionomics is the basis from which all oceanographic work on the biological side started, and there is still much to be done in tracing and explaining the life-histories and distribution and relations of marine plants and animals. In this connection, Prof. Herdman referred to the recent investigations of Dr. Joh. Schmidt, who has devoted the present summer to an oceanographic expedition in the Atlantic, the work of which included a search for the spawning eel.

The whole of the large question of the evaluation of the sea—a natural extension of the old-fashioned faunistic work—is a great field for research lying before the oceanographer of the future. Dr. Petersen in Denmark has done notable work in the Kattegat and the Limfjord, but it is probable that the "animal communities" which he has defined differ in other seas, and will have to be worked out independently in each marine area. Prof. Herdman cited the excellent marine surveys made by Sumner at Wood's Hole and by the Royal Irish Academy at Clare Island as work on the right lines as a preparation for the evaluation of large areas.

Similarly, systematic plankton work, studied intensively and treated statistically, and correlated with the food of migratory fishes and of the post-larval and other young stages of all food fishes, is a promising subject requiring much further investigation. Dr. Hjort's suggestion that the future year-classes of commercial fishes may depend not only upon favourable spawning seasons, but also upon an exact coincidence between the appearance of the phyto-plankton in sufficient quantity in spring and the time of hatching of the larval fishes, provides a subject of careful and difficult investigation and of far-reaching practical importance. A cognate subject bearing upon the same practical results—viz. future commercial fisheries—is Dr. Johnstone's demonstration of a natural periodicity in the abundance of certain fish. The extent and causes of this periodicity clearly call for further investigation; and in any discussion of, say, pre-war and post-war fishery statistics, the possibility of this periodicity affecting the question must be kept in mind.

Prof. Herdman emphasised the point that it is impossible to keep purely scientific research and investigations with a practical end in view completely separate. They are inter-related, and the one may become the other at any point. It was in the purely scientific investigation of the bionomics of the "warm" and "cold" areas of the Faroe Channel, in the *Triton* in 1882, that Tizard and Murray incidentally discovered the famous Dubh-Artach fishing-grounds which have been so extensively exploited since by British trawlers. It was a French man of science, Prof. Coste, who made the investigations and recommendations that started the flourishing oyster industries at Arcachon and in Brittany. It was his purely scientific studies of the deep-sea deposits that enabled Sir John Murray to discover the valuable phosphatic deposits of Christmas Island.

Metabolism, the cycle of changes taking place in the sea, the income and expenditure and the resulting balance available, is perhaps the department of oceanography which deals with the most fundamental problems and is most in need of immediate investigation.

The question of the abundance of tropical plankton as compared with that of temperate and polar seas, the distribution and action of denitrifying bacteria, the variations of the plankton in relation to environmental conditions, the determination of what constitutes uniformity of conditions over a large sea-area from the point of view of plankton distribution, the questions of the ultimate food of the ocean, the supply of the necessary minimal substances such as nitrogen, silica, and phosphorus to the living organisms, and the determination of the rate of production and rate of destruction of all organic substances in the sea—these are some of the fundamental problems of the metabolism of the ocean, and all of them require investigation. Most of these, moreover, are cases where the biologist or the oceanographer requires to appeal for assistance to the bio-chemist. In fact, in many oceanographic investigations team-work, in which the specialists of two or more sciences unite in tackling the problem, leads to the best results.

To the question, then: Is there need for further investigation of the ocean? Prof. Herdman answered emphatically in the affirmative, and referred, in conclusion, to the two suggestions made in his presidential address: (1) that there should be established at Cardiff a department of oceanographic and fisheries research, and (2) that there should be a great national oceanographical expedition—that is, another *Challenger* expedition, fitted out by the British Admiralty, and embracing all departments of the science of the sea investigated by modern methods under the best expert advice and control. Such an expedition would require long and careful preparation, so even though the present time may seem to some inopportune to press such an undertaking, if this suggestion is received with favour by oceanographers, it might be wise to form a preliminary committee to collect information and prepare a scheme.

Prof. J. Stanley Gardiner urged that to obtain results in economic work on fisheries there must be advance in wider scientific research. He endorsed the suggestion of the president for the establishment of oceanographical investigation in Cardiff, and said that, in his opinion, if this country is to keep in the forefront of oceanographical research, a new *Challenger* expedition has become necessary.

Dr. E. J. Allen supported the proposals for a new deep-sea expedition, and illustrated the need for further researches on marine organisms by reference to his recent experiments at Plymouth on the culture of plankton diatoms in artificial sea-water. He found that in solutions of pure chemicals, having as nearly as possible the composition of sea-water, to which nutrient salts such as nitrates and phosphates were added, diatom cultures did not develop, but when to such artificial sea-waters traces (say 1 per cent.) of natural sea-water were added, very good growth occurred. Experiments indicated that probably an organic substance in the natural sea-water stimulated growth, but its composition was still quite unknown. The culture method had also been used to obtain a minimum figure for the number of organisms living in a given volume of natural sea-water, and had shown that, whereas the number obtained in the usual way with the centrifuge was 14,000 per litre for a particular sample, there must actually have been at least 460,000 per litre.

Dr. E. C. Jee directed attention to the necessity for elucidating the movements of the current of dense water which pours out of the Mediterranean and forms an intermediate layer in the deeper waters of the near Atlantic Ocean. It seemed to him likely that the current moves northward, and in certain circumstances comes to the surface within the region of the pelagic fisheries of the British south-western area. It is important to ascertain the influence of this current on the northward migration of planktonic organisms and on the migrations of plankton-feeding fishes, and the investigation of its boundaries would throw light on the salinity variations observed in the surface waters of the English Channel, which are known to exhibit varying degrees of periodicity.

Mr. C. Tate Regan remarked that the study of the ocean was important in many other ways than in relation to fisheries, *e.g.* it was found, during the war, that a knowledge of salinity and currents was of great value in regard to submarine operations and the course of drifting mines. He suggested that work oversea should include the investigation of the seas on the coasts of our colonies; the fauna of the great area within the 100-fathom line that surrounds the Falkland Islands and extends northward to Montevideo is known only from two hauls made by the *Challenger* and five or six by the *Albatross*. In view of the pre-eminence of our Navy, mercantile marine, and fisheries, this country should lead the world in oceanographical research.

Prof. C. A. Kofoid pointed out that the magnitude of oceanographical problems and their diversity necessitate a definite but flexible programme and the co-operation of many investigators, for without such co-operation results must be fragmentary. Standardisation of methods, elimination of unnecessary duplication, and international co-operation are indispensable. He remarked upon the need for a monthly bulletin which should contain a bibliography of the subjects in this field of work together with synopses of the contents of these papers—a work which might well be undertaken by the International Commission for the Investigation of the Sea. He referred briefly to the project for the renewed exploration of the Pacific which is under consideration by a committee of the National Research Council of the United States.

Prof. J. E. Duerden urged that in the organisation of any extensive scheme of research in oceanography, or of a new *Challenger* expedition, the possibility of assistance from, and co-operation with, the various Dominions should be kept in mind. He had no doubt that, upon proper representation being made, the Union of South Africa would take its part, both financially and in *personnel*.

Mr. F. E. Smith, director of scientific research at the Admiralty, stated that his department had considered the question of a new *Challenger* expedition, and was of opinion that such an expedition was required, and he felt sure that the Admiralty would take its share in the organisation thereof.

At the close of the discussion a resolution was unanimously agreed to pointing out the importance of urging the initiation of a national expedition for the exploration of the ocean, and requesting that the council of the British Association should take the necessary steps to impress this need upon his Majesty's Government and the nation. On the following day, at the Committee of Recommendations, this resolution also received vigorous support from other sections, *e.g.* those dealing with chemistry, physics, geology, and geography, in all of which, as well as in zoology, investigations are required which could be undertaken by such an expedition. The General Committee of the Association recommended the Council to appoint an expert committee to prepare a programme of work and to consider the *personnel* and apparatus required. It is the hope of all those who have heard the cogent reasons for the expedition that it may be possible for the Government, in the not distant future, to undertake this great enterprise.

The New Star in Cygnus.

FROM the occasional observations which I have been able to make of the nova in Cygnus, I have formed the impression that the star has followed the normal course for such objects, except that the rise to maximum may have been more prolonged, and the subsequent decline in brightness more rapid, than usual. On August 22, two days after discovery, bright lines were not discernible with a small spectroscope attached to a 3-in. refractor, thus suggesting that the maximum had not then been reached. The star was seen for a short time on August 23, when it had risen to nearly second magnitude, but there was no opportunity of making spectroscopic observations. On August 26 observations were made by Sir Frank Dyson and myself with the 12-in. reflector of the Penylan Observatory, Cardiff, from 10h. to 11h. G.M.T. The star was then very slightly brighter than δ Cygni, but not so bright as γ Cygni, so that its magnitude would be about 2·8. Bright lines were then well developed, Hα being conspicuous, and also the group of four lines in the green assumed to be Hβ, 4924, 5018, and 5169. On August 28, so far as could be observed with a 3-in. telescope (in London), the spectrum showed no marked change, though the star had then fallen to nearly fourth magnitude.

A. FOWLER.

The announcement of the discovery of the new star in Cygnus was received at the Hill Observatory, Sidmouth, on the afternoon of August 21, but the cloudy state of the sky prevented any observation being made on that night. The sky was, however, clear on the night of August 22, and several photographs of its spectrum were secured. The following table sums up the observations taken since that date, and shows the fluctuations in magnitude recorded and the number of photographs of the spectra taken:—

Day.	State of Sky.	Estimated Magnitude.	No. of Spectra obtained.
21	Cloudy	—	—
22	Clear	2·8	4
23	Cloudy	—	—
24	Clear	2·2	3
25	Clear	2·2	5
26	Clear	2·8	4
27	Cloudy	—	—
28	Clear	3·6	3
29	Clear	3·8	4

On the night of August 22 the spectra were all very closely similar to that of α Cygni, the type of star which presents the most prominent enhanced-line stage. The nova spectra indicate dark hydrogen absorption lines only a little broader than those in α Cygni, and the dark enhanced lines are sharp and well defined, and correspond line for line with those in α Cygni. The only conspicuous bright lines are those at $H\gamma$ and at $H\beta$ and to the red side of $H\beta$. The nova had increased in magnitude by August 24, and all the lines in the spectrum became more diffuse and broader, the bright lines increasing in number towards the violet.

On August 25 the star was estimated to have retained the same magnitude as on August 24. All lines appeared a little more diffuse and the bright lines more conspicuous.

Dimming down to magnitude 2·8 on the night of August 26, the main spectral changes indicated an increase in intensity and width of the bright lines, so much so that the dark hydrogen lines became less broad, owing to the overlapping of the bright components. By August 28 the magnitude of the nova had reduced considerably, but the spectrum exhibited no great changes except that the bright hydrogen components showed signs of splitting up into two parts. On the night of August 29 the fall in magnitude had decreased somewhat, the star being about 3·8. The splitting up of the bright hydrogen components was more pronounced. All photographs exhibit extensive movement in the line of sight.

The foregoing general features illustrate only the most conspicuous changes in the spectrum up to date. The nova seems now to be following the ordinary course of the sequence of phenomena of previous new stars.

WILLIAM J. S. LOCKYER.

This object continued to brighten until the night of August 23, when it attained the second magnitude; since that date the decline of lustre has been considerable, and on August 29 I estimated the magnitude as 3·9.

It is probable that in a week's time the star's light will be reduced to the sixth magnitude, in which case it will only be just visible to the naked eye on a clear, dark night.

The astronomical world has been fortunate during the last twenty years in being able to study the phenomena of three bright temporary stars, viz. Anderson's Nova Persei of 1901, Nova Aquilæ of 1918, and the one now visible.

W. F. DENNING.

British Agriculture during Great War Periods.

A VERY interesting article by Lord Ernle appears in the June issue of the *Journal of the Ministry of Agriculture*. The subject is "Agriculture during Two Great Wars," and the state of agriculture in Great Britain during the Napoleonic wars is compared and contrasted with that prevailing during the recent struggle.

Shortage of corn was the great fear of our ancestors, and if the home harvests were deficient the deficiency had to be met by supplies from Northern Europe. But, since the climatic conditions of the two regions are practically the same, scarcity at home generally meant scarcity abroad. The weather was of the utmost importance, and everyone watched the skies with great anxiety. Provision for such a deficiency was, therefore, one of the main features of the Corn Laws down to 1815. If home harvests were abundant, then exports were encouraged by a bounty and imports of foreign corn were limited. Foreign corn, with its additional costs of freight and insurance, could rarely have lowered the price of English corn, while during scarcity home consumers benefited from the large corn acreage which was maintained by the export bounty. Between 1801 and 1816 the yearly average of foreign wheat imported was under 600,000 quarters, while in 1821 the imports were only 450,000 quarters. Yet between 1801 and 1821 the number of people supplied with home-grown breadstuffs had risen from 14,000,000 to 20,500,000.

Weather conditions were adverse for the greater part of the Napoleonic wars, yet food was not rationed, neither were prices controlled. The Government probably relied on the high prices to prevent extravagance in the use of a scanty supply. The condition of some of the poor people was improved by increases in wages and by the distribution of privately raised funds. To give relief the Poor Law was invoked, and this was a fatal blunder, the full consequences of which appeared only after the peace. Various other measures were adopted at different times: bread could not be sold until it was twenty-four hours old; the manufacture of spirits and starch was suspended; rice and maize were imported to mix with cornflour; the growth of potatoes was encouraged, and the corn bounties rose continually.

In spite of all this, the war period was a time of great prosperity for landowners and farmers. Enormous sums were spent on the erection of farm buildings, cottages, etc., and on the reclamation and improvement of land. A much higher standard of farming was adopted, and a better class of men was attracted to the land. After the war wages fell, unemployment was rife, and a period of great poverty followed. During the succeeding hundred years the economic importance of agriculture dropped from one-third to one-twentieth in terms of gross national assessment. The breadstuffs grown in 1821 would have supplied double the number of people provided for in 1914, and the agricultural interest, which was paramount in 1814, has now lost the greater part of its political power.

Naturally, these changes have been reflected in the agricultural policy adopted during the recent war. Although the agricultural industry has prospered, its prosperity has been small as compared with the period 1793–1815. The incentive of high gains, which provided the spur for great efforts during the French war, was not allowed to operate fully. During the latter part of the recent war much more was done for the consumers than for the producers, and the great exertions of the farmers in the face of unexampled difficulties were therefore all the more creditable. Fixing a flat maximum price for wheat meant that what was a good price in a good year would be a bad price in a bad year, and the whole loss fell on the farmer. In the French war the poorest consumers were subsidised out of the rates, while in the late war all consumers were subsidised out of the taxes. In all probability the farmer saved the taxpayers about 25,000,000*l.* between the years 1917 and 1919. The farmers experienced further difficulties in the shortage of labour, and to have secured an increased food-supply under these conditions was not only a notable achievement, but also a most valuable contribution to victory.

The labourer was the worst sufferer after the French war, but during the recent war and since the armistice agricultural wages have been increased and the hours of labour have been shortened. It is now universally recognised that the position of agricultural labourers must be improved. If high wages and shorter hours result in greater efficiency, then the industry will prosper; if they do not, then the industry will exist only under conditions which restrict employment. Lord Ernle concludes: "It rests with the men—and their leaders. Unless a new earth is created, there can be no new heaven to inherit."

Experimental Cell Studies.

In an experimental study of cell and nuclear division, especially in *Vicia faba*, Sakamura (Journ. Coll. Sci., Imp. Univ. Tokyo, vol. xxxix., article 11) has made an important contribution, particularly with regard to the factors that may influence the form, size, and number of the chromosomes. He finds, in agreement with most previous investigators, that *V. faba* has twelve chromosomes, the earlier counts of fourteen being due to a constriction which appears constantly at a certain point on the longest pair of chromosomes. Two other species of Vicia have fourteen chromosomes, three have twelve, while *V. unijuga* is tetraploid, having twenty-four.

The investigations of Nemec and others in chloralising root-tips and studying the effects on mitosis and the multiplication of chromosomes have been considerably extended, including treatment with benzene and chloroform vapour, ether, carbon dioxide, high temperature, electric currents, Röntgen rays, plasmolysis, and infection by the Nematode worm Heterodera. The chromosomes often shorten and thicken under this treatment, irregular mitoses occur, and frequently the number of chromosomes is multiplied, but there is no evidence of later reduction divisions in somatic tissues. Irregular reduction divisions in the pollen formation were also obtained by similar treatment.

A study of the chromosomes of wheat gives very different results from those of previous investigators. *Triticum monococcum* is found to have fourteen chromosomes (2×), four derivatives of Emmer wheat are found to have twenty-eight (4×), while three descendants of Dinkel wheat have forty-two (6×). This is a confirmation of the view that *T. monococcum* is the most primitive, while *T. vulgare* belongs to the most advanced, type—a view which is supported also by the phytopathological studies of Wawiloff, the serological tests of Zade, and the evidence from sterility of the various hybrids as obtained by Tschermak. The fundamental importance of cytological studies of agricultural plants is thus apparent.

R. R. G.

University and Educational Intelligence.

Cambridge.—Mr. H. H. Brindley, St. John's College, has been re-appointed demonstrator of biology to medical students; Mr. J. T. Saunders, Christ's College, demonstrator of animal morphology; and Mr. J. Gray, King's College, demonstrator of comparative anatomy. Mr. E. J. Maskell, Emmanuel College, has been appointed to the Frank Smart University studentship in botany.

Graduate research studentships at Emmanuel College have been awarded to E. J. Maskell for research in plant physiology, to C. H. Spiers for research in stereochemistry, and to G. L. Jones for research in Celtic and Frankish institutions.

Dr. Griffith Taylor, at present physiographer in the Commonwealth Weather Service, Melbourne, has been appointed to a specially created position of associate professor of geography in the University of Sydney. He will take up the duties of his new position in the early part of 1921.

A reunion of old students of the Royal College of Science, London, will be held on Tuesday, September 14, at 7 p.m., at the Imperial College Union, Prince Consort Road, South Kensington, London, S.W.7. The president, Sir Richard Gregory, will take the chair at 8 p.m., and Prof. H. E. Armstrong will deliver an address entitled "Pre-Kensington History of the Royal College of Science and the University Problem."

The issue of the *Lancet* for August 28 is a medical students' guide for the session 1920–21. The various curricula are described in detail, and under their respective headings the necessary information concerning the facilities for medical study offered at the different teaching centres of the United Kingdom is given. The regulations for the examinations, both preliminary and professional, at these centres are set out so that the student desiring to obtain a medical degree from a university or a diploma from any medical corporation may ascertain the course of clinical instruction and the conditions under which submission for examination is allowed. The metropolitan medical schools and hospitals are grouped under the University of London; similarly, all hospitals in direct connection with provincial universities are described under the appropriate university. Finally, an account is given of the conditions under which commissions can be obtained in the Navy, Army, Air Force, Indian, and Colonial Medical Services.

We have just received a "Handbook of Lectures and Classes for Teachers," issued by the London County Council. The range of subjects offered is very wide, and all the courses will be conducted by experts. Under the heading of geography, lectures will be given on physical geography, the use of instruments, and regional and historical geography—a course which will extend over two years. In addition, there will be lectures on the past and the future of the great towns of the world, and one lecture on regional surveys. In the department of mathematics the teaching of arithmetic, of mensuration and geometry in junior schools, and of elementary mathematics will be dealt with in five courses of lectures during the year. Science will be represented by courses of lectures on modern theories of time, space and matter, psycho-analysis, psychology, elementary astronomy, the special senses, experimental investigation of children, the industries of the Stone age, insects in relation to agriculture and disease, and laboratory arts, and there will be one lecture on insects as disease-carriers. As usual, there will be a course of single lectures on special subjects: Prof. J. N. Collie will lecture on the rare gases in the atmosphere; Prof. A. Fowler on recent developments in astronomy; Prof. A. Keith on the antiquity of man; Prof. R. Biffen on agricultural botany; Dr. Bateson on the heredity of sex; Dr. Forster on chemical technology; and Sir W. H. Bragg on the romance of science. The lectures will be open to all teachers employed either within or outside the administrative county of London. Full directions for the application for tickets of admission will be found in the handbook.

Societies and Academies.

Paris.

Academy of Sciences, August 9.—M. Henri Deslandres in the chair.—A. **Blondel**: A new optical or electrical apparatus for the measurement of oscillations of velocity and angular deviations. The method is based on the registration on a photographic film moving at a uniform rate of the angular displacements of a disc carrying a series of equidistant slits, the disc being attached to the axis of the machine under examination. An application of the method to the study of an internal-combustion engine is given.—M. **Petot**: Extract from a letter to M. Appell concerning the spherical representation of surfaces.—B. **Delaunay**: The number of representations of a number by a binary cubic form with negative discriminant.—F. **Carlson**: The zeroes of the series of Dirichlet.—C. **Frémont**: Cause of the frequency of breakages of rails at their extremities.—J. **Rey**: Perrot's experiment relating to the movement of rotation of the earth. In 1859 Perrot observed certain rotations in a jet of water flowing from a hole in the base of a cylindrical vessel, and regarded these as due to the rotation of the earth. Laroque, in 1860, concluded that the observed phenomena were not connected with the earth's rotation, but many phenomena in geophysics have since then been explained on the assumption of the validity of Perrot's views. Experiments are described which lead to the conclusion that Perrot's views are erroneous, and fully confirm Laroque's criticisms.—H. **Godard**: Observations of the periodic comet Tempel II. made at the Bordeaux Observatory with the 38-cm. equatorial. The apparent positions of the comet and comparison stars for July 24, 25, and 27 are given.—A. **Buhl**: The symmetries of the electromagnetic and gravific field.—E. **Darmois**: The influence of ammonium molybdate on the rotary power of malic acid. A crystallised compound of malic acid and ammonium molybdate has been isolated. Its rotatory power is very high (+219°), and constant over a wide range of concentrations. There is a probability that this is not the only complex compound formed when ammonium molybdate is added to solutions of malic acid.—A. **Portevin**: The similitudes of micrographic aspect existing in various states between the iron-carbon (steels), copper-tin (tin bronzes), copper-zinc (brasses), and copper-aluminium alloys (aluminium-bronzes).—J. **Bougault** and P. **Robin**: Catalytic oxidation by unsaturated bodies (oils, hydrocarbons, etc.). Dichloroethyl sulphide, which alone or in solution is unaffected by oxygen, in presence of turpentine readily oxidises on exposure to air, the sulphoxide $SO(CH_2.CH_2Cl)_2$ being formed. By a similar oxidation, thiodiglycol in presence of citral is readily oxidised by air to the sulphoxide $SO(CH_2.CH_2.OH)_2$.—R. **Souèges**: The embryogeny of the Compositæ. The last stages of the development of the embryo in *Senecio vulgaris*.—P. **Lesage**: Experiments utilisable in plant physiology on osmosis and on the aspiration due to evaporation.—M. and Mme. G. **Villedieu**: The action of rain on the deposits of copper mixtures on plants.—J. **Amar**: How to determine the output of workmen.—A. **Migot**: The formation of the axial skeleton in *Eunicella (Gorgonia) Cavolinii*.—MM. **Fauré-Fremiet**, J. **Dragoiu**, and Mlle. Du **Vivier de Streel**: The histochemical differentiation of the fœtal pulmonary epithelium in the sheep.—M. **Piettre** and A. **Vila**: Some properties of serine.—C. **Leballly**: The virulence of the milk in apthous fever. The milk is virulent before any appearance of symptoms characteristic of the disease, the high temperature being the only indication of departure from the normal healthy condition.—E. **Alilaire** and E. **Fernbach**: Some observations on the culture of the tubercle bacillus in non-glycerinated media.

ROME.

Reale Accademia dei Lincei, April 11.—A. Ròiti, vice-president, in the chair.—U. **Cisotti**: Integration of characteristic equation of waves in a canal of any depth, iii. Formulæ for the effect of local perturbations are found.—P. **Comucci**: So-called hydrocastorite of Elba. Analysis shows that this is not a definite species of mineral, but rather a product of alteration found as a rule in different minerals of uncertain composition.—G. **Valle**: Interrupted incoherent sounds. An examination of the acoustical effects produced by sirens in which the openings are arranged in groups, the interval between which is not an exact multiple of the interval between the members of a group.—M. **Tenani**: Diurnal oscillations of wind velocity at different heights. Between May and September, 1917, regular observations were made with *ballons-sondes* at different times of the day at the Royal Aerological Station of Vigna di Valle for the purposes of aviation. The mean amplitude of diurnal oscillation decreases upwards, starting with 3 m./sec. at the ground. The oscillations parallel to the shore-line are almost negligible compared with those in a perpendicular direction. An attempt is made to determine a coefficient of correlation between the difference of temperature of earth and sea and the wind velocity perpendicular to the shore, but the mean error is too large to allow of the results being practically applicable up to the present.—C. **Ravenna** and G. **Bosinelli**: The dipeptid of aspartic acid and the function of asparagin in plants. In these experiments the dipeptid was obtained directly in a state of purity by prolonged boiling of a solution of asparagin.—R. **Raineri**: Corallinaceæ of the Tripoli coast, i. A description (accompanied by three figures) of the five species of the genus Lithothamnium found along the floor of the Tripoli Sea, namely, *L. crispatum*, *Haucki*, *Lenormandi*, *Philippii* (encrusting), and *fruticulosum* (lightly branching). Seven other species, to be described later, were also found.—M. **Ascoli** and A. **Fagiuoli**: Sub-epidermic pharmacodynamic experiences, iv. This deals with the action of thyroids and indirect effects.—L. **de Marchi**: Obituary notice of Prof. Vincenzo Reina, with list of works.—The Academy passed a resolution expressing the hope that the Government would secure for the nation the "Villa Gioiello," near Arcetri, in which Galileo spent the last ten years of his life.

April 25.—F. D'Ovidio, president, in the chair.—L. **Tonelli**: Points in the calculus of variations.—E. **Clerici**: A pulverulent mineral from Dorgali, in Sardinia. This mineral produces luminescence when heated. By comparing the corresponding effects with various fluorites it is inferred that this phenomenon arises from the presence of traces of rare earths.—R. **Raineri**: Corallinaceæ from Tripoli, ii. The remaining species are *Lithophyllum expansum*, *lichenoides*, *byssoides*, and *decussatum*, and *Melobesia Lejolisii*. In addition, two corallines with articulate thallus occurred.—L. **Pigorini**: Colouring matters from the eggs of silkworms. One gram of eggs was treated with a mixture of alcohol and acetone and the coloured extract tested with a Duboscq colorimeter. The coefficients of extinction of the various colours were found to differ according to whether the eggs were laid by the white, golden, or yellow type of female, or, again, by crosses of the two latter, and the results were sufficiently marked to be practically useful in testing the variety to which the ova belong.—L. **Pigorini** and R. **Grandiori**: Action of sulphide of lime on Lepidopterous ova. Pigorini found that sulphide of lime dissolves the shell of the egg without damaging the living elements, and Grandiori uses the method in his embryological studies of the eggs of *Bombyx mori*, *B. Yamamai*, and *Orgiya antiqua* with great success.—R. **Grandiori**: Symbiotic micro-organisms in *Pieris brassicae* and *Apanteles glomeratus*. Observations were made on four embryonic stages of the Pieris, in which were found symbiotic forms similar to others previously seen to penetrate the hypoderm of the parasitic Ichneumon.

CAPE TOWN.

Royal Society of South Africa, July 21.—Dr. A. Ogg, vice-president, in the chair.—P. A. **van der Bijl**: The genus Tulostoma, Persoon, in South Africa. This is a widely distributed genus, and in South Africa two species are thus far known, viz. *Tulostoma cyclophorum* and *T. Lesliei*, a new species, which the author describes in this paper.—P. A. **van der Bijl**: A fungus, *Ovulariopsis papayae*, n.sp., which causes powdery mildew on the leaves of the pawpaw plant (*Carica papaya*, Linn.). The author describes a fungus found in Natal on the under-surface of the pawpaw leaves as a new species, for which the name *Ovulariopsis papayae* is suggested.—P. A. **van der Bijl**: South African Xylarias occurring around Durban, Natal. Four species of Xylarias have thus far been collected by the writer around Durban, and of these three have not been previously recorded from South Africa.—W. A. **Jolly**: Note on the spinal reactions of the Platana. The author gives a note of reflex times observed in the spinal preparation of the Platana of the Cape Peninsula (*Xenopus laevis* or an allied species).—J. R. **Sutton**: A possible lunar influence upon the velocity of the wind at Kimberley (third paper). This paper deals with the variations in the speed of the wind when the moon is furthest from the earth. The discussion follows the same lines as the previous one, which dealt with the speed variations at perigee. The results obtained go to confirm the earlier ones. The diagram curves show generally the same turning-points as the perigee curves, but later in time, and the moonrise minimum is not so pronounced. The apogee curves average lower on the scale than the perigee curves. While the velocity of the wind tends to rise at perigee when the moon is above the horizon, it tends to fall at apogee.

SYDNEY.

Royal Society of New South Wales, July 7.—Mr. T. H. Houghton, vice-president, in the chair.—Dr. S. **Smith**: *Aphrophyllum Hallense*, gen. et sp. nov., and Lithostrotion from the neighbourhood of Bingara, N.S.W. The corals are referred by the author to *Lithostrotion arundineum* and *L. Stanvellense*.—J. H. **Maiden**: Descriptions of three new species of Eucalyptus. The first is a dwarf, mallee-like stringybark, from between Port Jackson and Broken Bay, closely allied to a moderately large tree, *Eucalyptus capitellata*. The second species comes from the summit of Mount Jounama, at an altitude of about 5400 ft., thirty miles south of Tumut. It is a large tree, a gum, and the bark falls off in strips as much as 30 ft. long. It is allied to the snow gum, *Eucalyptus coriacea*. and to one of the mountain ashes, *E. gigantea*. The third species comes from the drier parts of Western Australia, and it may be spoken of as the dry country representative of the Yate, *E. occidentalis*.

Books Received.

The Land of the Hills and the Glens: Wild Life in Iona and the Inner Hebrides. By S. Gordon. Pp. xii+223. (London: Cassell and Co., Ltd.) 15*s*. net.

Die Binokularen Instrumente. By Prof. M. von Rohr. Zweite Auflage. Pp. xvii+303. (Berlin J. Springer.) 40 marks.

A Text-book of Electrical Engineering. Translated from the German of Dr. A. Thomälen by Dr. G. W. O. Howe. Fifth edition. (London: E. Arnold.) 28*s*. net.

Einführung (Handbuch der biologischen Arbeitsmethoden). By E. Abderhalden. Pp. 44. (Berlin und Wien: Urban und Schwarzenberg.) 4 marks.

The Advancement of Science, 1920: Addresses delivered at the Eighty-eighth Annual Meeting of the British Association for the Advancement of Science, Cardiff, August, 1920. (London: John Murray.) 6*s*. net.

The Andes of Southern Peru: Geographical Reconnaissance along the Seventy-third Meridian. By I. Bowman. Pp. xi+336. (New York: The Geological Society of New York; London: Constable and Co., Ltd.) 27*s*. 6*d*. net.

Water-Plants: A Study of Aquatic Angiosperms. By Dr. Agnes Arber. Pp. xvi+436. (Cambridge: At the University Press.) 31*s*. 6*d*. net.

A First Course in Nomography. By Dr. S. Brodetsky. Pp. xii+135. (London: G. Bell and Sons, Ltd.) 10*s*. net.

Etude sur le Système Solaire. By Dr. P. Reynaud. Pp. xiv+83. (Paris: Gauthier-Villars et Cie.)

The Sea-Shore. By W. P. Pycraft. Pp. vi+156. (London: S.P.C.K.) 4*s*. 6*d*. net.

A First German Course for Science Students. By Profs. H. G. Fiedler and F. E. Sandbach. Pp. x+99. (London: Oxford University Press.) 4*s*. 6*d*. net.

Science and Labour.

A FORTNIGHT ago the British Association was in session at Cardiff, and men of science were engaged in making and discussing contributions to the world's store of natural knowledge. This week the Trades Union Congress meets at Portsmouth, and representatives of manual labour are asserting their industrial and political claims with no uncertain voice. The spirits of the two bodies are as the poles apart. On one side we have the explorer, animated solely by zeal for discovery and eager to learn of new fields in which pioneers are prospecting: on the other we have workers seeking—no doubt reasonably in some cases—full rights and privileges for particular occupational interests, and aiming to use these interests for political power.

It is not within the province of NATURE to discuss these ambitions of manual labour, or to anticipate the effects of a policy which, to say the least, has little constructive work behind it. We may, however, deal appropriately with the relations of science to labour, especially as the activities of both are essential to human progress and prosperity. Schemes for securing greater pay for less labour occupy most of the attention of the public Press and social platform, while the vastly more important subject of the creation of wealth through scientific discovery and industrial application is almost unheeded by the very people who profit most by it.

Labour alone may build pyramids to-day, as it did four thousand years ago, but it cannot create new industries without new knowledge, and this is obtained by scientific research, whether carried on in an academic laboratory or in the works. Without the aid of science and invention, this country would be in the condition of China, where four-fifths of the population are peasant cultivators of the soil, and the social condition of the people is far below that of any British working class. The fullest encouragement must, of course, be given to the greatest of our industries—agriculture—but it should also be remembered that there are only about as many acres of permanent pasture and arable land together, in the United Kingdom, as there are people in this kingdom, and that we must depend largely for our existence upon foreign trade. By the use of our knowledge and the development of our natural resources we have to be able to offer other countries what they are not yet in a position to produce for themselves, for the lack of either one or the other of these factors of prosperity. Resources can be exhausted, but scientific discovery can continually provide new openings for industry, and the nation which makes the best use of it can be assured of a leading position for its products in the markets of the world.

When, about the end of the eighteenth century, the home demand for corn exceeded the home supply, the population of England and Wales was about nine millions: now it is about forty millions, and we have to look to improved methods of cultivation, and to the production of new varieties of wheat, to enable us to provide more than a week-end supply of food. As a large and progressively increasing proportion of the world's inhabitants feed upon wheat, markets from which we now obtain supplies will also have the demands of other countries to meet, and it will be necessary for us to grow more of our own, as well as to produce goods which other countries will purchase from us.

We now export textile goods to the value of nearly three hundred million pounds annually, and we are able to do so, not because of any specific aptitude on the part of the British manual worker, but because of machinery and of chemical industry, which produces the dyes required for piece goods. Fifty years ago nearly all the cotton grown in the United States was exported to Europe: now, every year more and more raw cotton is being used in the mills of the New England States, and we have to seek fresh sources of supply for our raw material. India is also developing its cotton industry to supply its own needs, and the tendency must always be in this direction when a country concerns itself with progressive industry. China has not yet reached this condition, and therefore it exports raw cotton, wool, and silk, and imports textiles made from them. We are able to send into China cottons and woollens to the value of about ten million pounds annually, solely because we are in advance of that country in science and invention.

We have reached our position as a great industrial nation by the use of scientific knowledge, and we cannot go back to the time when domestic manufactures and home markets were our only concern. China is rich in the very natural products to which our country largely owes its prosperity, and through which a large part of the population secures profitable employment. There is enough coal in the province of Shansi alone to last the world for several thousand years, yet China has not benefited from its riches because of its indifference to progressive knowledge. Two hundred years ago we were in much the same condition. At that time the total quantity of coal raised in Great Britain was not more than a few thousand tons, whereas now the annual output approaches three million tons. Our early coal mines were not more than about 180 ft. deep, and it was the invention of Newcomen's pumping engine that enabled the depth to be extended to about 300 ft. Now, thanks to Watt's steam-engine, and modern methods of ventilation and coal-getting, shafts can be sunk and coal seams worked at ten times this depth. Our buried treasure would have remained hidden in the bowels of the earth to this day, and the million or so miners who derive their living from them would be without an occupation which owes its growth entirely to the steam-engine and other machinery which science and ingenuity have provided.

These workers now number about 5 per cent. of the occupied persons in this country, and they threaten to hold up most of the nation's industries unless certain demands they make are granted. Whether their peremptory action can be justified or not we will not attempt to discuss, but we do ask them to remember that they owe their occupational existence to science, and that men of science really hold the key of power to all industrial positions. A few hundred chemists engaged in dye manufacture, or a few thousand in the production of sulphuric acid, could paralyse almost every industry if they adopted the action by which the coal-miners now challenge the Government of this country.

The closing of the coal mines would mean the stoppage of our iron and steel trade, upon which our industrial greatness has been built, and here again the industry owes its modern development to such men of science as Sir Henry Bessemer, Dr. William Siemens, and Sir Robert Hadfield, to mention three only. Iron ore occurs in China almost as widely diffused as coal, but it is a talent buried in the ground, and the country derives little profit from it, either in employment or in power. The Chinese possess to a supreme degree the conservative spirit which opposes all advance or change, and we should have remained in their position if vested interests, either of employer or of employed, had been permitted to control national development, and industry had failed to take advantage of scientific discovery. Manganese and nickel, titanium, molybdenum, tungsten, vanadium, and other elements now used in steel-making were all products of scientific investigation, and from them wealth has been created and work provided.

It would be easy to show that science has been the source of development of our chief industries and that a single scientific discovery, like that of magneto-electricity by Faraday, for example, contributes far more to human progress than the action of all the politicians and labour leaders put together. The discovery of thorium and cerium made possible the manufacture of incandescent gas mantles, of which about four hundred millions are now produced annually, and from osmium and tungsten have developed the great production of metallic filament lamps. Aluminium, discovered in 1827, has risen from the position of a rare metal to a yearly tonnage exceeded only by iron, lead, copper, zinc, and tin, and it is manufactured exclusively by electrolytic methods, which would never have come into existence but for the investigation by men of science of the chemical effects of the electric current.

The workers are now strong enough to exact their fair share of the profits arising out of the applications of science, and no one wishes to dispute their just claims in this respect. In their deliberations, however, they should occasionally show that they realise the part which science plays in opening up new fields of work without itself sharing in the distribution of the wealth it creates. Probably, if there were a complete levelling of all incomes, wage-earners would not benefit by more than about 5 per cent., yet this is the subject upon which attention is mostly concentrated, while the means of increasing the amount of wealth to divide by creating new industries or increasing the output of individual workers are given little consideration. It should be obvious that the greater the value of industrial production through science and labour, the more will be the profits to be shared, and that the curtailment of productive capacity must mean eventual disaster. The Labour Party has stated that it "has the duty of placing the advancement of science in the forefront of its political programme." We look to it to justify this claim by presenting to the workers in true proportion the relative values of participation in profits and the creation of wealth through science, as determining factors of social improvement and industrial progress.

Development of Higher Education in India.

THE fact that applications are now being invited for seven professorships and five readerships in the University of Dacca will perhaps direct increased attention to the latest development of higher education in India. It is certainly most desirable that the scientific world at home should take an interest in the subject, and do everything possible to help in a movement that is unquestionably of Imperial consequence. For this new university is intended to mark an important departure; it is to be of the residential and teaching type, and both in its government and in its ways is to embody, so it is hoped, what is best in our universities, old and new, at home. The standard of admission of students is to be what is customarily the intermediate examination.

All who have first-hand knowledge of Indian universities, and many of those who have only indirect knowledge, will know how urgent is the need for reform. The situation easily admits of scathing criticism, but it will be more profitable to assist to the extent of our opportunities in this new constructive effort. No more need be said here of the past than that we have in India exactly what we might expect from the attempt to implant in the East, under Government auspices, a system of universities modelled on the London University of early Victorian days. We know at home to what degree our statesmen have been gifted with educational insight and how far their training has qualified them to adjust educational policy to the needs of a new age or of a different race. Those who wish to read in detail the story of Indian university development will do well to refer to the report of the Calcutta Commission, which was noticed at length in these columns on its publication last year (vol. civ., p. 357).

Dacca, as the ephemeral capital of Eastern Bengal, is well provided with all the material elements for making the university a success, and the Bengal Muslims declare themselves intent upon educational advance. If at the outset an academic staff can be assembled that will hold firm to the professed aims of the new university, it may succeed in conferring an incalculable boon upon India. The terms of the appointments will, it is to be hoped, prove sufficiently good to attract men of the necessary quality. A professorship at its best begins at about 1200*l*., rising by annual increments of 60*l*. to 2160*l*., and in addition there may be an allowance of 600*l*. a year. The normal age of retirement is to be fifty-five, when the benefits of a provident fund will accrue.

At the present time there will no doubt be more than the usual difficulty in recruiting first-rate university teachers for India. The abnormal demands of the home universities and the unsettled state of the world come into reckoning, in addition to the usual considerations of exile and climate. On the other hand, there is ground for expecting that in future those who take up educational service in India will not be penalised to the extent they have been in regard to promotion to appointments at home. It is to be hoped that the appointments at Dacca will be seen to afford a very special opportunity of national service and a true educational mission, and that they will appeal not so much to the spirit of adventure as to a real ardour for the advancement of learning by high and creative scholarship. The realisation of the aims of the new university, and the establishment of a compelling example that will lead others to mend their ways, will make a demand on the strength of character and fidelity to principle of its first professors not less than on their intellectual competence. There is surely much here to attract the best type of both character and talent.

As already announced, the first Vice-Chancellor of the new university is Mr. P. J. Hartog, lately Academic Registrar of the University of London. Distinguished in early days as a lecturer in chemistry at Manchester, and most recently by his leading part in the establishment of the School of Oriental Studies in London, Mr. Hartog will approach his task with ample breadth of intellectual sympathy. As a member of the Calcutta University Commission he gained direct knowledge of

Indian university conditions, and co-operated in designing the new institution of which he is to be the chief academic officer. His abundant experience, gained amid the conflicts of London University, will be invaluable for his new duties, for it is the transformation of examining into teaching universities that constitutes the central problem in India. If the difficulties have been great at home, they are still greater there. Nothing seems so urgent, among all the ills that afflict Indian education, than that the strangling grip of university examinations should be released from the throat of learning.

It is true that under the strong and persuasive influence of the Calcutta Commission the aspiration for university reform has received a large measure of native assent, and this is no doubt quite sincere. But the currents of an evil tradition are strong and deep; rights and privileges of very serious social import have become established; a suspicion is apt to arise that attempts at reform are attempts to restrict and deprive, and that they are actuated by a desire to check, rather than to aid, the advance of that kind of learning which will best help the Indian to progress and self-dependence. This hovering distrust will assuredly attend the early labours of Mr. Hartog and his colleagues, but even if they cannot move far towards realising "a fresh synthesis of Eastern and Western studies," which is the stated ideal of their university, they may, with good fortune, inaugurate a salutary and far-reaching reform.

The Foundations of Aircraft Design.

Applied Aerodynamics. By G. P. Thomson. Pp. xx+292. (London: Hodder and Stoughton, Ltd., n.d.) Price 42*s.* net.

MR. THOMSON has made no mention of his own share in the work which he describes, but it is common knowledge that the development of experimental methods, more particularly in full-scale research, owed much to his initiative during the war. At one period, as a member of the experimental staff of the Royal Aircraft Establishment, he took an active part in the now historic debate on "scale effect": at a later date he joined the staff of the Aircraft Manufacturing Company, and there obtained first-hand acquaintance with the routine of a commercial design office. Such varied experience, combined with a considerable amount of actual flying, constitutes the best possible qualification for authorship of a text-book on the practical applications of aerodynamic theory, and the present volume, as we should have expected, abounds in happy illustrations of the interaction of constructional and aerodynamic considerations in design; but it does not of itself tend to ensure clear and systematic presentation of results, and we believe that by devoting a longer period to deliberation and planning Mr. Thomson could have produced a better book.

Let us confess at once that we have found it quite exceptionally difficult to form our judgment of this volume, and that we may have had a wrong idea of the class of readers for which it is primarily intended. Mr. Thomson's preface is not very explicit on this point, but taken in conjunction with Col. O'Gorman's introduction it certainly seems to suggest that he has catered principally for the designer, whilst keeping in view the needs of R.A.F. officers training; in other words, that his book is intended both as a work of reference and as a manual of instruction. But if so, then form and arrangement, we cannot but think, become matters of very real importance, and it is on this score that we venture the foregoing criticism. At our first reading of the text, the difficulties which confront the student impressed us so much as almost to obscure its very real merits; and although on a second examination we were able, with our acquired knowledge of the whole book, to appreciate and enjoy the author's success in compressing so much valuable material into some 280 pages of large type, we cannot help thinking that our first impression was more representative of the view which an uninitiated reader would obtain. We suspect that Mr. Thomson, when he wrote, was too close to the work which he describes to be able to see his subject from the point of view of his readers.

The student, for example, who comes new to the subject ought always to be given the definitions of special terms and the meanings of special symbols used *before* he meets them in the course of the argument: he ought not to find casual references to "interference" scattered throughout chap. iii., and yet be denied a definition, even by implication, of this term until he reaches the very end of the chapter; nor ought he in chap. x. to find himself suddenly confronted by symbols to the meaning of which he is given no clue, save a general reference to two chapters in the second part of the book. In our experience, much of the difficulty of aeronautical literature consists in the sheer number of the symbols which it is found necessary to employ, and we would gladly exchange the glossary of aeronautical terms, which forms an appendix to this volume, for a tabulated list of symbols and their meanings—more especially now, when an excellent scheme for standardising these has been evolved by the Royal Aeronautical Society. The designer who will use the book as a work of reference doubtless has a better initial acquaintance with its notation, but since he will require to read the book piecemeal we suspect that his difficulties will be very much the same. For him it is most important that each several argument shall be as far as possible self-contained, with assumptions clearly stated at the outset. Now in some sections of the chapters on stability we can almost feel Mr. Thomson developing his thought as he proceeds: the discussion of a problem is begun with insufficient data; the scarcity becomes apparent as the analysis proceeds; assumptions have to be made, and are made, sometimes with little justification other than that of necessity. The sequence is typical of engineering as distinct from purely scientific investigations, since "engineering" (we believe the modification of Samuel Butler's epigram is due to Prof. Unwin) "is the art of drawing sufficient conclusions from insufficient premises": but it is not a suitable arrangement when the results of these investigations come to be "written up" for the practical man, who is apt to become bewildered by the steady accretion of assumptions, and even to be doubtful, at the finish, whether any new result has been obtained at all.

One feature of this book will, we believe, be of the very greatest service to its readers: there are practically complete references to original sources of information, even in instances where the reports quoted had not passed from the typewritten to the final form at the time of writing. (Incidentally, their authors' names are somewhat frequently misspelt.) The advantages of this information will be apparent to every serious reader, and of immense service to the designer. The book's own index is not equally successful; at all events, we have not found it of much assistance in compensating for the faults of arrangement which we have noticed above, and of which other instances might be given—such as the inclusion of actual experimental data, and of a carefully reasoned plea for further experiments on body-resistance, in a chapter ostensibly dealing with experimental methods, of a paragraph and three diagrams bearing on the distribution of forces between the upper and lower planes of a biplane under the chapter heading of "centres of pressure and wing-moments," and of Fig. 94, an illustration of experimental apparatus, in a chapter which otherwise is devoted to the discussion and application of experimental data.

We have failed in our intention if the foregoing criticisms suggest that we consider this an unsound or a carelessly written book; on the contrary, we are convinced that readers who have had some first-hand acquaintance with the work of which it treats will read it with real pleasure —and, after all, no better proof of its excellence could be adduced. Our only reason for thus emphasising the importance of arrangement and presentation is that we hope soon to see a second and revised edition in which these aspects have received greater attention: very little labour, we believe, would be required to make this work as satisfactory, regarded as a text-book of design, as it already is in essentials, whereas the impression which it will make upon the ordinary reader as it stands is not likely to do justice to its very real merits.

Food Poisoning.

Food Poisoning and Food Infections. By Dr. William G. Savage. (Cambridge Public Health Series.) Pp. ix+247. (Cambridge: At the University Press, 1920.) Price 15*s*. net.

THE subject of this work is one not only of great importance in medicine, but also of much scientific interest. It necessarily covers a very wide field, for the production of disease by food may depend upon any one of a large number of different conditions. A food may be inherently poisonous, or its ill-effects may depend upon some abnormal sensitiveness on the part of the consumer; it may acquire poisonous properties as the result of putrefactive or other chemical changes on keeping; it may become the vehicle of metallic poisoning from contact with containing vessels, or of bacterial infection resulting from animal disease, or from subsequent contamination with pathogenic organisms. Dr. Savage has rendered a great service, alike to medicine, to public health, and to pure science, in gathering together in a small volume the most recent and authoritative information upon the various ways in which health may be prejudicially affected by food. There is no one who could more fittingly have undertaken the task, for the subject is one of which he has a wide practical experience, and which he has made peculiarly his own. So well has he done the work that scarcely any unfavourable comment suggests itself, and a review must take the form, most pleasant to the reviewer, of a short account of the way in which Dr. Savage has treated his subject.

The first chapter is occupied by a short historical review, and the author then passes on to animal infections transmissible to man, a subject which, apart from the group of diseases due to Gärtner's bacillus and its allies, is dealt with briefly as not falling within the proper scope of the book. In discussing food as a passive vehicle of infection, Dr. Savage gives a very useful summary of experimental work on the temperatures reached in ordinary cooking. Many readers will be surprised to learn how inadequate ordinary boiling and baking are to destroy bacteria in the deeper parts of a large joint of meat, and how little reliance can be placed on cooking as a safeguard against infection. Foods inherently poisonous are the subject of the next chapter: poisonous fish scarcely occur in this country, but an adequate account is given of the effects produced by certain fungi, and of ergotism and lathyrism. Food idiosyncrasy is then discussed: the writer accepts the view, now usually held, that this is a question of anaphylaxis. Certain persons may be so abnormally sensitive to a particular foreign protein as to react against it, with symptoms recalling those of anaphylactic shock, even when it is taken by the mouth—a view which presupposes that some minimal amount escapes digestion and reaches the blood unchanged. The commonest protein against which such hypersensitiveness is exhibited appears to be white of egg, but even milk may be thus poisonous to certain individuals.

The largest section of the book is naturally devoted by the author to those outbreaks of acute gastro-enteritis so commonly described in the newspapers as "ptomaine poisoning," but which are now well known to be instances of infection with some member of the Salmonella group of bacilli. Here Dr. Savage is on his own ground; his report to the Local Government Board on this subject in 1913 is well known. The symptoms, mode of causation, pathology, and bacteriology are fully discussed, and a table is given of 112 outbreaks in this country, with the chief known data concerning each. (It is a pity, by the way, that Dr. Savage persistently uses "data" as a singular instead of as a plural word.) The bacteriology of the Salmonella group is an extremely interesting, but a very difficult, subject. We do not know whether the different food-poisoning bacteria are mere races of one type, or deserve the rank of separate species; it is a most puzzling thing that a single organism should be the cause of paratyphoid fever as a rule, and yet at times produce a gastro-enteritis which is clinically a quite different disease. Into this thorny question Dr. Savage scarcely enters, though he gives an excellent account of the known facts as regards both human and animal infections, together with a full and useful bibliography of the "Gärtner group." It is unfortunate that in many outbreaks of food-poisoning the bacteriological examination has been so insufficient that no certain facts can be gleaned, but the full instructions given in these pages should enable any bacteriologist to carry out an investigation on adequate lines.

Other forms of bacterial food-poisoning receive full discussion, but the weight of evidence seems against their importance, if not against their existence. Botulism, of course, is a well-known condition on the Continent and in America, and receives a chapter to itself. Special types of food-poisoning, such as those due to mussels, cheese, and potatoes, are also dealt with in a separate chapter, and seem to be chemical in their origin.

In a discussion on putrefaction an excellent popular account is given of the chemical and bacteriological aspects of that process, and Dr. Savage has no difficulty in laying the bogey of ptomaine poisoning. This hypothesis dates from a time before the rise of modern bacteriology; ptomaines are unquestionably formed during putrefaction, but their toxicity has been exaggerated, and they are present in any quantity only "when the food is far too nasty to eat."

Chemical poisons in food, unintentionally introduced, are dealt with under two headings—that in which they are introduced in processes of manufacture, and that in which they arise from the chemical action of the food upon the tins or other vessels in which it is put up; a further group is formed by the preservatives used to prevent secondary bacterial action. These subjects are treated in adequate detail, and in conclusion there is a chapter on the prevention of food-poisoning. The book is compact, well printed, and adequately indexed, and should be of signal service to the medical profession and to all engaged in public health work, while it is a mine of information to the bacteriologist, and so clearly written as to be of no small interest to the general reader.

Malaria at Home and Abroad.

Malaria at Home and Abroad. By Lt.-Col. S. P. James. Pp. xi+234. (London: John Bale, Sons, and Danielsson, Ltd., 1920.) Price 25*s.* net.

COL. JAMES'S book appears at an opportune time, when malaria, owing to the Great War and the return of soldiers from highly malarious countries, has acquired a much wider distribution than before. How wide that distribution is at the present time is seen on the map of the world in the frontispiece, and how it affected England in 1919 is shown on map 59, p. 90. It appears that since March 1, 1919, when notification of malaria became compulsory in this country, no fewer than 14,000 demobilised soldiers were, up to November, 1919, notified as suffering from relapses. These figures alone show the importance of the subject at home, while it is no less so abroad, for it is well known that malaria has become even more prevalent abroad than it was when Sir Ronald Ross made his epoch-making discovery as to the *rôle* of the mosquito in the spread of the disease, and wrote his classical work on its prevention.

Col. James has had a large experience of malaria in its endemic and epidemic forms, and he evidently possesses the gift of being able to impart his knowledge in an interesting way.

Lucidity and the maintenance of interest are essential in a book of this kind, for otherwise the many facts and details set forth in connection with the causation, spread, clinical features, pathology, diagnosis, treatment, and prevention of the disease would appeal only to a few specialists, whereas we hope this book will be read by every medical man and by our administrators in tropical countries. The volume is divided into ten chapters. The first is devoted to the life-history of the parasite and to the mode of spread of the disease; the second to the factors concerned in the spread of malaria. The next two chapters deal with the practical work necessary for inquiry into malaria, followed by chapters on a malarial survey in England and the tropics, and epidemiological observations in each. The remaining four chapters give an account of the symptoms, pathology, diagnosis, treatment, and prevention and eradication of malaria.

The illustrations number 104. They are a feature of the book, and very helpful to the reader, leaving less to the imagination than many other monographs. For instance, the photographs depicting the rot-holes in trees; roof gutters with blind ends where water lodges; cut bamboos and a common water plant are likely to give a truer and more lasting impression regarding the nature of certain breeding places of larvæ than any long description.

When giving an account of the clinical onset, course, and termination in ordinary cases of malaria, Col. James very properly points out that the primary illness does not always commence with very characteristic symptoms and signs, and he remarks that an atypical onset has been observed so frequently in primary cases of malaria contracted during the war that it is advisable to keep in mind the possibility of malaria as regards almost every illness in which, after proper clinical examination, some doubt as to the diagnosis remains. This requires to be borne in mind in view of the frequency with which soldiers who have served in the war have not suffered from their first attack of malaria until after their return home. This warning is repeated when describing the pernicious symptoms which may appear in infections with the malignant tertian parasite, and more rarely with either of the other two species of parasites. In such cases there may be in a patient who is obviously very ill an almost complete absence of what are known to be the usual clinical signs of malaria, and unless the blood is examined the malarial attack may be mistaken for sunstroke, alcoholism, acute heart failure, dysentery, cholera, appendicitis, etc. It is because of the protean character of this disease that Sir Patrick Manson, to whom this valuable book is dedicated, states in the preface that "no man has a right to practise in malarial countries or as a consultant in this country who cannot use his microscope in the diagnosis of malaria and other blood parasites."

The Oil Industry.

Animal and Vegetable Oils, Fats, and Waxes: Their Manufacture, Refining, and Analysis, including the Manufacture of Candles, Margarine, and Butter. A Practical Treatise. By Dr. Geoffrey Martin. (Manuals of Chemical Technology, ix.) Pp. x+218. (London: Crosby Lockwood and Son, 1920.) Price 12*s*. 6*d*. net.

SINCE the death of Dr. Lewkowitsch there have appeared quite a number of books on the oil industry, mainly based on his work. The present volume shows the advances made, inasmuch as more attention is devoted to recent industrial developments. Dr. Martin has produced a very valuable compilation of recent patents and improvements, which is well worth the perusal of anyone interested in the oil industry. Excellent chapters on the extraction (including that from waste products), refining, and hydrogenation of oils and fats, and on the candle industry, are given with profuse illustrations. Perhaps too much stress is laid on the volatile solvent process for the extraction of seed oils. Up to a few years ago oils extracted by this process were rarely to be found on the market, due no doubt to the difficulty found in the filtration of the extracted oils.

Coming to the general and analytical sections of the work, we do not find these entirely up to date. The portions dealing with linseed oil (oxidised and polymerised) and with the action of driers take no note of the recent work of Morrell, Ingle (J.S.C.I., 1911 and 1913), and Mackey (J.S.C.I., 1916 and 1917). Under linoleum the author states that linseed oil can be blown in five or six hours, whereas to obtain a suitable product, in our experience, eighteen to twenty hours are necessary. Also in the manufacture of linoleum cements he mentions an amount of kauri gum which is far in excess of that required. His assumption that in the blowing process (Wood and Bedford, and Walton) "superoxidised oil" is formed has not as yet been proved (see Ingle and Woodmansey, J.S.C.I., 1919, p. 101). Otherwise the brief description of the linoleum industry is good.

In discussing the oils used in the cloth trade, while the preparation of distilled oleines, etc., is well treated, the testing of them with regard to their application is too brief. We do not find any reference to the Mackey oil tester, and little mention of the danger of spontaneous ignition or other fire risks.

The analytical chapter is all too brief, though for the most part well done. The present writer has shown (J.S.C.I., 1902, p. 587) that Hubl's solution should be used fresh, and not after twenty-four hours' mixing, as Dr. Martin, copying Dr. Lewkowitsch, states. With regard to the preparation of Wijs's solution, Dr. Martin includes the method from iodine trichloride, a product of doubtful purity, and in this he follows the recommendation of the Government Committee of Analysts (Ministry of Food), but he also gives in the chapter the more trustworthy method by the saturation of glacial acetic acid solution of iodine with dry chlorine. Also one misses the details of the valuable hexabromide test.

With regard to the edible qualities of hydrogenated oils as compared with natural fats, such as butter and lard, it may be pointed out that the assumption of a continuous carbon chain in all the fatty acids has not yet been proved. It is probable that some of the unsaturated oils contain "branched chains" (Verzeigte Ketten), and so in hydrogenation isomeric stearic acids may be formed, and these may have quite different digestibility. Hence it does not follow that a stearine produced by hydrogenation would have the same food value as a natural fat.

The author reprints reports of the Government Committee of Analysts (Oils and Fats Branch, Ministry of Food) which we consider so inadequate that it is surprising that Dr. Martin gives them space.

On the whole, the work should prove of great assistance to the student of the industrial developments of the oil trade, but to the chemically minded it does not go far enough into the discussion of the application of scientific principles and tests to the industry. HARRY INGLE.

Science in History.

Transactions of the Royal Historical Society. Fourth Series. Vol. xi. Pp. v+247. (London: Royal Historical Society, 1919.)

TO scientific readers the most important communication in this volume is that by Sir Richard Gregory, entitled "Science in the History of Civilisation." There are, the author tells us, two methods of approaching the history of science—that of the specialist, who regards it purely as growth of the knowledge of material objects and phenomena in the course of time; and that of the historian of human culture, who dwells on its influence upon social and economic conditions. The object of this paper is to plead for a closer co-ordination of these separate points of view in works of general history. This has been attempted to some extent by Voltaire, Buckle, and Lecky, and in more recent times by Mr. and Mrs. Whetham and by Mr. F. S. Marvin; but some modern speculations have served only to darken knowledge. The late Mr. B. Kidd traced the cause of the evolution of society to the continuous action of religious beliefs, but Dr. Russel Wallace pointed out that the doctrine of progressive ethical impulse does not explain how the rude struggles of 2000 years ending in the sixteenth century could have tended to increase and develop the altruistic and ethical sentiments of early races in their struggle for existence.

The true age of science dates from the era of experimental investigation, advocated by Roger Bacon and advanced by Galileo and the men of his age. It is the scientific scepticism thus created which is responsible for the growth of knowledge and its effects to which all material advance is to be attributed. The question for the future is how to use rightly the power which science gives to modern man; not to teach it as a jumble of isolated facts and theories, but in the history of its development from the earliest times. The necessity of paying increased attention to the history of science has been urged by Sir J. J. Thomson's committee on the position of natural science in the educational system of Great Britain; and on the research side a group of students working with Dr. C. Singer at Oxford has produced the first volume of "Studies in the History and Method of Science," while a second is in the press, to be the basis, it is hoped, of a comprehensive "History of Science," on lines similar to those of the "Cambridge Modern History." This new movement is ably advocated in the paper under notice. C.

Our Bookshelf.

A Critical Revision of the Genus Eucalyptus. By J. H. Maiden. Vol. ii., parts 8–10. Vol. iii., parts 1–8. Vol. iv., parts 1, 3, 5–10. (Parts xviii.–xxviii., xxxi., xxxiii., xxxv.–xl. of the complete work.) (Sydney: W. A. Gullick, 1913–20.) Price 2*s*. 6*d*. per part.

AUSTRALIA, with an approximate area of 3,000,000 square miles, exhibits many peculiarities in its flora, one of which is the presence of large genera distributed practically throughout its full extent. Noteworthy among these are Eucalyptus and Acacia. Eucalyptus comprises species presenting the largest trees of the country down to dwarf bushes. Mr. Maiden's critical revision of the genus Eucalyptus, of which the first part was published in 1903, is now, we believe, approaching completion with the fortieth part. Nearly twenty years is a long time to wait for the termination of a work so greatly needed, yet the author may well be excused, considering his multifarious duties as director of the Botanic Gardens and Government domains; but it is a case of "better late than never." In spite of the pressure of other matter, the author and Government printers succeeded in publishing fourteen parts during the actual war period.

For the purposes of this monograph Mr. Maiden visited Europe to compare his materials with the type-specimens of the species published by earlier European botanists. In fact, he spared himself no trouble to reduce the complicated synonymy of certain species. How far he has succeeded can be discovered only by the student of his great work.

Mr. Maiden defines and figures upwards of 200 species. His illustrations are not artistic pictures, but they are something better, as they represent the specific characters, and are excellently drawn. For example, the leaves of many species of Eucalyptus present a great variety in form in the same species and even in the same individual. The seed vessels, too, differ considerably in shape in different individuals of the same species. These peculiarities are faithfully reproduced, and the origin of each figure is carefully indicated.

Following the descriptions is a more or less lengthy list of specimens belonging to the species in question. Full synonymy, with references to the place of publication, is given, and we understand that the author will deal with the classification of the species, of hybridity, and of other questions concerning the genus in a later part.

W. BOTTING HEMSLEY.

Annual Reports of the Society of Chemical Industry on the Progress of Applied Chemistry. Vol. iv. 1919. Pp. 632. (London: Society of Chemical Industry, 1920.) Price 12*s*. 6*d*. (non-members).

THE first three volumes of the annual reports on the progress of applied chemistry, issued by the Society of Chemical Industry, suffered from the stress of war conditions under which they were produced, and were inevitably incomplete in some respects. In the volume for 1919, the fourth of the series, the publication committee has, however, achieved its purpose of preparing a complete conspectus of progress in the various branches of applied chemistry. Moreover, some of the gaps which occurred in previous volumes have now been filled up. The subject of explosives is dealt with for the first time, the extremely interesting and valuable report covering the period from the beginning of the war until the end of 1919. The reports on ceramics, building materials, and fermentation for 1918, which had to be held over, appear together with the reports for 1919, and a section dealing with analysis, which was omitted from previous volumes, is also included.

The volume includes reports on progress during 1919 in practically all branches of chemical industry. The reports, although of necessity condensed, are generally both comprehensive and complete, and the authors are to be congratulated on the success with which they have accomplished their laborious tasks. The volume will undoubtedly be of the utmost value to technologists, and may fitly find a place on the library shelf beside the annual report of the Chemical Society, to which it is complementary.

Cotton Spinning. By William Scott Taggart. Vol. iii. Fifth edition. Pp. xxviii + 490. (London: Macmillan and Co., Ltd., 1920.) Price 10*s*. net.

THIS well-known and authoritative work on cotton spinning is published in three volumes. It deals with all the processes up to carding; with all appliances up to the end of the fly frame; and, finally, with the theory and processes of spinning and with mill planning, including the important subject of humidity. It has reached, in vol. i., a sixth edition, and in vols. ii. and iii. a fifth, which facts sufficiently mark the popularity and authority of the treatise. Vol. iii. has just been re-issued with important additions. The three volumes include no fewer than 543 detailed drawings descriptive of the sources and characteristics of the cotton fibre and of its treatment by means of the machinery through which it passes until it emerges as marketable yarn. They thus form a complete compendium of the several stages of manufacture of this important textile.

Vol. iii. deals especially with the treatment of the fibre necessary to ensure uniformity in the yarn and regularity of diameter and of length, weight, and strength so vitally essential to the production of a round, solid thread. Useful tables of information are given relative to the indicated horse-power required for the various machines, etc. Much new matter is to be found in Appendix ii., relating to gassing, costing, etc., and a detailed index adds considerably to the value of the volume.

Relativity.

THE relativist position is stated as being "that only relative motions are of physical importance."

If this is meant to apply to rotation as well as to motions of translation, and to deny that rotation is absolute, and independent of the relation of the revolving body to anything outside itself, I would suggest that a relativist should try the following experiment. Let two casks, A and B, of suitable sizes, be placed one within the other (A inside), and so mounted that either can be rotated independently. Now let the believer in relativity place himself inside A so that he can see nothing but its inner surface. So far as appearances are concerned, he will not know whether A is stationary or in motion.

First let A be stationary and let B be made to revolve at, say, 1000 revs. per minute. This will cause no change of any sort in the sensations of the occupant. Next, with B stationary, let A be given the same angular velocity for a minute or two. If the experimenter survives this trial, he will be in a position to assert that the "physical importance" of the angular velocity of A with reference to B is not the same as that of B with reference to A. So far, however, as the geometrical relations of A and B are concerned, it is a matter of indifference which of the two is revolving.

Toads and Red-hot Charcoal.

TOADS are associated with some wonderful myths, and my scepticism was naturally great when my friend Mr. H. Martin Leake assured me, while on a visit to Cawnpore in October of 1915, that toads would eat red-hot charcoal. An after-dinner demonstration, however, soon dispelled my doubts. Small fragments of charcoal heated to a glowing red were thrown on the cement floor in front of several of the small toads (usually *Bufo stomaticus*) which so commonly invade bungalows at that time of year, and, to my surprise, the glowing fragments were eagerly snapped up and swallowed. The toads appeared to suffer no inconvenience, since not only did they not exhibit any signs of discomfort, but, on the contrary, several toads swallowed two or even three fragments in succession. A probable explanation of the picking-up is that the toads mistook the luminous pieces of charcoal for glow-worms or fireflies, the latter being numerous in the grounds of the Agricultural College at Cawnpore in October; but this does not account for the swallowing of the hot particles—the absence of any attempt to disgorge. I repeated the experiment at Allahabad in August, 1916, with the same results (the toads even attempting to pick up glowing cigarette-ends), though I have never observed glow-worms or fireflies in Allahabad at any time of year.

The fact that some toads seized several hot particles in succession would seem to imply either that the heat was not felt (which seems incredible), or that memory is entirely absent in toads; but since toads most certainly come to associate a given time of day with the supply of food, *i.e.* remember, this latter explanation seems to be equally incredible. The truth must be that the incentive to seize an object (a luminous point in this instance) usually associated with an insect is so strong that even acute pain is no deterrent when the experience is limited—the lessons of experience out of the ordinary require to be "burned" into the toad intelligence by sheer repetition, just as the imprisoned shark which repeatedly bruises its snout against the glass of its tank has the lesson "knocked" into it in time. I may add that I unfortunately neglected to examine the toads post-mortem, and that I have recently repeated these experiments with *Bufo vulgaris* in England with entirely negative results.

"Kismet," Lock Mead, Maidenhead.

Active Hydrogen.

IN March last I observed an interesting phenomenon while conducting certain experiments, in the Maharajah's College, Vizianagaram, with detonating mixtures with excess of hydrogen when they are subjected to the silent electric discharge in an ozoniser. In one experiment the oxy-hydrogen mixture, after leaving the ozoniser, was allowed to pass through an alkaline solution of potassium permanganate. In the course of the experiment an electric spark accidentally took place in the mixture, and as a consequence an explosion occurred in which a part of my apparatus was smashed to pieces; but to my surprise I found that the whole of my permanganate solution turned green at once.

It was surmised from this that the instantaneous reduction might be due to the presence of an active modification of hydrogen produced in the circumstances, since molecular hydrogen brings about the same change very slowly. In order to study the problem more conveniently, I filled a Hofmann eudiometer with an alkaline solution of potassium permanganate, and a few cubic centimetres of an explosive mixture with excess of hydrogen (3 vols. of hydrogen and 1 vol. of oxygen) were admitted into the explosion tube and the mixture was sparked; as soon as the spark passed through the solution it turned green.

With the object of testing further the reducing efficiency of this new form of activated hydrogen, its effect was examined in a number of reactions. It was thus found that with this hydrogen an alkaline solution of indigo was converted into indigo white, ferric chloride into ferrous chloride, potassium nitrate into potassium nitrite, arsenious acid into arsine, potassium perchlorate into potassium chloride, and a number of other reactions were also tried with like results.

Some references to the literature relating to this subject of active hydrogen may be of interest. In 1913 Sir J. J. Thomson was led to conclude from examination of the paths of positively charged particles that they "revealed the presence of particles having an atomic weight of 3, presumably triatomic molecules of hydrogen." Duane and Wendt showed, in 1917, that when hydrogen is exposed to the bombardment of α-particles from radium emanation a contraction in volume occurs, a fact which has been incidentally observed by Usher, and confirmed recently by Lind. In 1912 Dr. Langmuir discovered an active modification of hydrogen by heating a metallic filament in hydrogen at low pressures. Again, so late as May last, Gerald and Robert S. Landauer published a paper on triatomic hydrogen in the Journal of the American Chemical Society.

These investigators activated hydrogen in different ways, all the methods being dependent on gaseous ionisation. The hydrogen was activated by the α-rays, by the electrical discharge in a vacuum, by the corona, and by Schumann light, though the last means of activating hydrogen was unsuccessful.

Sir J. J. Thomson found in 1913 (Proc. Roy. Soc., A, lxxxix., 20) that "X_3 disappears when a mixture of it with hydrogen is sparked with sufficient oxygen to give a violent explosion." In my experiments, however, I find that the active hydrogen appears with the explosion; moreover, the fact that under similar conditions with excess of oxygen ozone is produced, and with excess of hydrogen an active form of it makes its appearance, is significant when we consider the nature of the chemical process of the formation of water when explosive mixtures are subjected to an electric spark.

The Organisation of University Education.

THE discussion that has been started by the Government's offer of the Bloomsbury site to the University of London has already opened up a bigger question, namely, that of the vital necessity for re-organising thoroughly the university system—or quasi-system—of this country. It is becoming clear that we must have a regional university system, such that every area of sufficient population shall be provided with a fully equipped and fully staffed university as its educational centre and capital; and more and more it is becoming evident that the duties and services of each university will not by any means be exhausted by the teaching and research carried on therein, but that it must undertake besides the tremendously important work of organising tutorial education for the adult workers hungering after knowledge and the work of aiding and leavening and guiding all the secondary schools in its area. If we take account (1) of these considerations and all that they involve in the way of extra-mural organisation and supervision and teaching, (2) of the demand that the Imperial College of Science shall be elevated to university rank, (3) of the objection raised to the Bloomsbury site that ten times its acreage would be required for a university, and (4) of the recent plea that universities should be decentralised and located in the open so far as possible rather than in a city; it seems to follow that very probably the existing University of London will have to be divided into, or replaced by, some half a dozen or so independent universities, one or two central—as, *e.g.*, in Gower Street, etc., and Kensington—and the others in the outer ring to serve the large populations of the Kent and Surrey and Essex and Middlesex areas; and, if this necessity be made clear, no sentimental attachment to the old University of London ought to weigh against the unquestioned needs of education. Of course, millions would be required from the Government to carry out such a scheme; but perhaps one day we may have a Government that, instead of wasting many tens of millions on wild-cat military expeditions, will invest one or two tens in universities—to the incalculable gain of the country.

It seems to me, however, that, if the universities themselves admit the need for regional division and systematic organisation, they should at least pave the way therefor by such working agreements as will utilise to the best advantage so much regional distribution as at present exists instead of perpetuating a sort of chaos. I have been led to these reflections by a study of the pass-lists of the recent London matriculation, from which I see that nearly 3800 candidates entered. (Incidentally, the fact that under 33 per cent. passed suggests certain very serious criticisms, into which, however, I will not digress.) Now, obviously, we have evidence here of a very serious congestion; and it is clear that the congestion might be very considerably lessened if the regional system were applied at once, as a start, to matriculation candidates. I find that among the first 176 successful candidates there are scholars from (1) Beverley, Chesterfield, Halifax, Huddersfield, Keighley, Leeds, Spalding, and Sunderland; (2) Manchester; (3) Birmingham and Worcester; (4) Cardiff, Merthyr Tydvil, Pontypridd, and Swansea; and (5) Bath, *Bideford, Bridgwater, Clifton, Cheltenham, *Exeter, Sherborne, *St. Austell, and Taunton; and this list is not exhaustive, although it includes most of the names specially relevant to my immediate argument. Now it will be evident at once that candidates from all these places have *deregionalised* themselves, since they belong geographically (1) to the University of Leeds or Sheffield; (2) to the University of Manchester; (3) to the University of Birmingham; (4) to the University of Wales; and (5) to the University of Bristol; and it must be added that, if the proposed South-Western University should come into being, candidates from towns marked * would no longer be in the Bristol region.

Now much of this geographical confusion is already gratuitous, since systematisation has already gone thus far that various matriculations (including the Cambridge Previous and Oxford Responsions) are accepted, with varying qualifications and conditions, by various other universities as exempting from their own matriculations; so that already to a considerable extent a student may matriculate at his own regional university and then proceed to his degree in any one of many other universities; but the reciprocity and interchangeability are not even conditionally complete. It is true that in one important communication with which I have been favoured it is stated that "by the introduction in 1918 of school-leaving certificates *all entrance tests were pooled*"; but on inquiry and examination of the matriculation regulations of the various universities I find that this comforting statement is, unhappily, too sweeping. I will instance the most important exception. One of the newer universities—which is unique in having taken an entirely independent line and in making very practical recognition of the great educational fact (largely ignored by all other universities) that unchangeable inborn aptitudes vary very greatly, and that brains of equal quantitative value have profound qualitative differences—deviates from all the other universities in its matriculation requirements in that, first, and of least importance, it does not limit a candidate to five or six subjects, but merely stipulates for a minimum of two each in two groups and one in a third; secondly, it makes *no subject compulsory*; and, thirdly, it "passes" or "ploughs" by groups apparently instead of by individual subjects, with the very proper proviso that below a certain minimum no marks in any subject shall count towards its group-marks.

Now this scheme involves, to my thinking, an educational advance of tremendous significance, since it recognises the inborn qualitative differences and proclivities of boys' and girls' brains, and refuses to insist that round and square and hexagonal and triangular minds shall all be required to fit into one Procrustean or Chinese examination-gauge; but the apparent difficulty or impossibility of reconciling the requirements of this independent university with those of its far more tradition-bound fellows is obvious; and unless the difficulty can be overcome, either the regional system for matriculation must be abandoned, or those who matriculate at this university will find that they cannot proceed to a degree in various other universities as matriculated students.

Three courses are open:—First, all universities might adopt similar reformed regulations; but this suggestion may be dismissed as a counsel of perfection outside the range of present practical politics. Secondly, this innovating university might abandon its reformed ways and drop into line with subject-marks, instead of group-marks, and several compulsory subjects; but this, to my mind, would be educationally calamitous. Free, untrammelled experiment, spontaneity, and autonomy are essential to educational life and progress, whereas cast-iron uniformity and the repression of individuality in universities and schools are deadly and should be utter anathema. The third course obviates all difficulties. Let each university make its own regulations for its own matriculation, but let it regionally examine students in such wise as to grant the greatest latitude allowed by the most elastic scheme, and issue certificates qualifying for matriculation either in its own domain, or both therein and at various other universities, or at only certain universities, or at only one. Every university in the kingdom could then regionally matriculate students for every other, subject to such regulations as these: "Unless you pass in subjects x and y you cannot proceed to universities A, B, C, D; unless you pass in x and y and z you cannot proceed to E and F; unless you pass in w and x you cannot proceed to G," and so on.

When the pass conformed with the requirements of the examining university a certificate of matriculation at that university would be issued; when otherwise, a certificate entitling the student to matriculate at the universities specified therein. This suggestion assumes, of course, both that the papers set by each university in any subject reach the same standard, and that the percentages of marks qualifying for a pass are the same; and I believe that approximately such uniformity in England has already been obtained, except that the Previous and Responsions are apparently easier than the matriculation examinations of the other universities, although, with qualifications and conditions, they are, curiously enough, accepted by these.

Subject, then, to such very practicable working arrangements, and in view of the extent to which co-ordination already obtains, surely the universities should take another step forward and agree to delimit their respective areas and to refuse candidates for matriculation from another "region," and similarly, of course, to refuse to undertake tutorial classes for adults and extension-lectures in another region. As things are at present, London figures as a sort of poacher on the preserves of all its neighbours, since it holds its matriculation examinations at provincial centres all over the country, and sweeps into its net the natural matriculation prey of its sister (or daughter) universities—at the cost of the shocking congestion already described. Here clearly we find pre-regional practices surviving anachronistically in regional times. The explanation is that (1) originally there were no provincial universities, and therefore London most properly consulted the convenience of provincial students; and (2) the London matriculation long since attained a *kudos* that does not attach in the lay mind to the matriculations of the newer universities. The trouble, I suspect, lies not so much with those who intend to proceed to their degrees—since so many of the matriculations will secure their entrance to any of the universities, and the Final degree eclipses utterly any matriculation *kudos*—as with the large number who intend to go no farther, but desire the matriculation certificate as a proof that they have reached a certain standard of school education. Now, however, all these matriculations have been approximately standardised with the precise object of rendering these "First School certificates" equivalent; and all that is necessary in order to bring the lay public up to date is that the universities should proclaim this fact by delimiting their regions and refusing extra-regional matriculation candidates.

I anticipate no agreement with my views, but only contemptuous contradiction, from those who think in traditional grooves and have not realised the difference between 1920 and 1890 or 1860; but I submit that universities must play a vastly larger part in national life henceforward than in the past, must lead and direct and inspire education and research of all sorts and all grades, and must function as the pulsating heart and controlling brain, each of its own region; that their extra-mural activities in several directions must be enormously increased; and that only by covering the country with a network of regional universities, each responsible for its own region, can we enable each fully to develop its functions of guiding and inspiring secondary education and adult education and research *of all sorts* in its region.

I most specifically confine my proposals for regional distribution of candidates to the matriculation examination, not only because it will frequently happen that after schooldays a change of residence will bring the undergraduate into another region, but also because it has rightly been urged that each university, besides covering the general courses, should aim at making some one "school" a specialty, and that education would be hindered rather than helped, and energy dissipated, if every university sought to collect a few students in each of several uncommon subjects—*e.g.* tropical medicine or palæobotany—instead of bidding all the comparatively few students of each such subject betake themselves to whichever university may have been led to establish a special school or department for the study thereof; and because, as I have said, free experiment and varied curricula are eminently to be desired—given, of course, that all standards should be approximately equal in the sense that a given degree should always imply equivalent brains and equivalent training, and that educationally cheap and nasty degrees should be unknown—and every matriculated student from whatever part of the country should be free to enter whatever university best fitted his own inborn proclivities and mental bent.

In fine, I suggest that *divide et impera* must be the motto of the universities if education in its very widest sense is to hold true imperial sway.

Age and Growth Determination in Fishes.

By ROSA M. LEE.

FOR centuries past it has been known that the scales of fishes showed concentric rings, and later observers have concluded that from the number of these rings the age of the fish could be ascertained.

This discovery was, however, not developed to any great extent until the last ten or twenty years, during which several scientific observers definitely traced the connection between the number of rings on the scales and the number of years of life of certain fishes, the carp amongst freshwater fishes and certain Gadidæ amongst salt-water fishes having been intensively examined and providing a first proof of the correctness of the general theory. The salmon is another fish the economic value and the intrinsic interest of which led to particular attention being paid to its scales in connection with its life-history by many observers, both of professional and amateur status.

But it was the activities of the International Council for the Exploration of the Sea that gave the greatest impetus to the investigation of the age of fishes, and most systematic researches have been carried out with the purpose of correlating the knowledge gained from scale investigations as to the life-history of fishes with that derived from other methods of investigation undertaken by the Council. Amongst the workers of all the nations who have investigated this subject, the Norwegians stand pre-eminent for the very exhaustive researches they have carried on and for the original developments they have made in the methods used, both practical and theoretical. They have concentrated largely on investigating this question in the herring and salmon races, and their contributions to the knowledge of the age distribution and growth of these species have been very valuable.

A great deal of work on the same lines has been carried on by the other countries (including Great Britain) participating in the work of the Council, not only in Europe, but also in America, and the data now collected in regard to various species are extensive enough to enable us to judge the validity of the methods used and the importance of the results obtained.

The theory of age determination, briefly enunciated, is that the periodic quickening and slackening of growth in the fish brought about by the annual changes in the external conditions of their life, viz. summer and winter temperatures, with their accompanying abundance and scarcity of food, or of appetite for food, are reflected in the formation of the scales, and are mainly evident as rings marking the winter growth when development of the scale either slackens or wholly ceases. Such rings can be seen easily with the naked eye or with a low-power lens on the scales of many fishes, and those on the salmon scale illustrated in Fig. 1 furnish an example of the general appearance of winter rings.

Such rings are caused by the definite patterns into which the lines on the upper surface of the scale are formed under changing conditions. The arrangement varies for every species of fish, those of the same family being somewhat alike. Indeed, fish can be identified by their scales alone, as has been done on tinned fish purporting to be salmon.

There are striking differences in the appearance of the winter rings in the scales of certain well-known fishes. In the herring scale the striæ (surface lines) are close and equidistant; they pass from side to side, and appear to be broken by narrow, concentric, transparent rings. In the haddock there are small quadrilaterals arranged concentrically, occurring in zones of wide and narrow growth. In the smelt and the eel this state

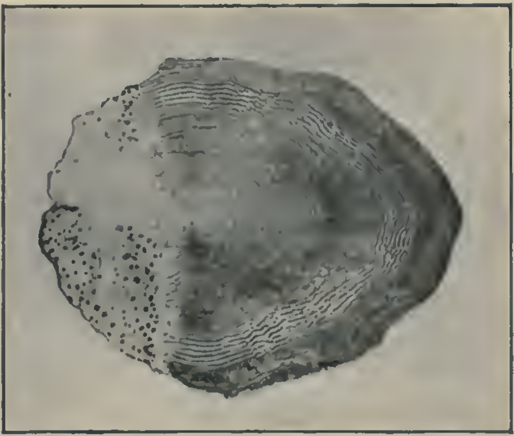

FIG. 1.—Winter rings on a salmon scale.

of wide and narrow zones can be traced, but only with difficulty, and the winter growth is indicated by clear concentric spaces, where the markings are either incomplete or wholly absent. In certain river fish also the winter growth can be traced by the unfinished lines rather than by the narrowing or closing in of the lines, which often marks winter growth.

Underlying all the differences in the patterns on the scales of the various fish a common principle of formation can be traced, and this is undoubtedly due (in normal circumstances) to the annual slackening or cessation of growth associated with winter conditions.

A study of many scales at all times of the year has shown that the discontinuity or incompleteness of the markings (striæ or platelets) may be a temporary characteristic of nearly all stages of growth, and that when growth is active (summer growth) the lines ultimately become complete, but that in the winter they remain incomplete, and therefore the discontinuity serves to mark out the winter growth, because the discontinuity becomes permanent, and leaves on the scales the blank spaces or broken lines which are the characteristic winter rings of certain species in addition to the narrowing of the spaces between the lines.

By counting the rings formed on the scale, the age of any individual fish can be ascertained. When large numbers of any one species are examined they can be grouped into "age classes" or "year groups" according to the number of rings. The average size of each group can be determined, and the difference between these sizes gives the first approximation to the amount of annual growth.

This general theory has been confirmed for several species, first by an examination of the growing edge of the scale throughout the season, when the rings have been seen in the course of development, and secondly by marking experiments on the fish (salmon, plaice, cod, etc.), when additional rings corresponding in number to the winters elapsed in the interval between marking and recapture have in every case been seen to be formed on the scales.

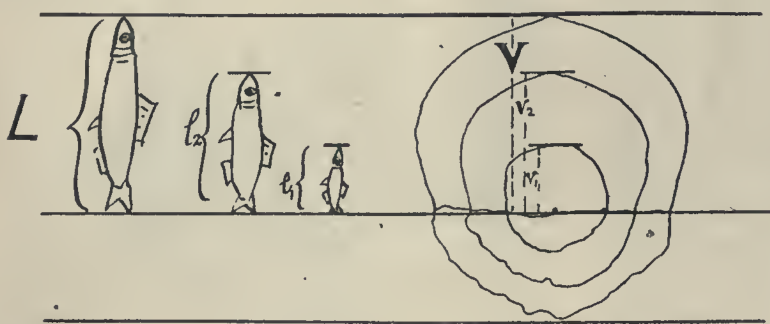

FIG. 2.—Proportional growth of a fish and its scale.

In practice there are, however, certain modifications and exceptions to the general theory which must be looked for and taken into account. What are known as "false rings" may occur. These bear a resemblance to winter rings, and are probably caused by sudden changes in environment, such as a change of temperature, lack or abundance of food, or even by the fish migrating from one part of the sea to another. These rings can generally be distinguished from true rings in the scales of fishes the habits of which are known. For instance, in salmon there is frequently a grouping of close lines in the middle of the third summer, known as a "summer check."

In very old fish the rings are close together near the edge, and it is difficult to make out their number with exactitude. It may sometimes happen that the latest rings become fused together, and the total number then appears less than those shown on the bony and opercular structures of the same fish.

Results of age determinations of many samples of fish have been studied from the mathematical probability point of view to ascertain whether such groups have a probable or natural variation of size, and whether groups of fish of the same ascertained number of rings taken under similar conditions are sufficiently alike in size grouping to give a high probability of being of the same age. These mathematical tests have confirmed the theory that on the average the age determinations of certain species of fish (salmon and herring) are correct up to five or six years of life—that is, those years when they are of most economic importance.

These methods of age determination enabled observers to deduce the approximate growth rates of fish by comparing the sizes of fish of known age. Growth curves so deduced generally rose rapidly from zero for the first two or three years of life, and then the rate of increase fell off rapidly as the fish grew older.

Later researches have demonstrated that this falling off in the growth rate in such fish as herring and plaice and others is not wholly due to a normal slackening in the development, but is made greater by the fact that in several species a segregation according to size takes place, the larger fish of the youngest groups leaving their associates and joining shoals of older fish, generally in deeper water. Such a segregation has been found to take place at the onset of maturity in certain species. Thus it follows that the youngest year groups in the samples are represented only by the larger individuals of those groups, and their average length is higher than those of the complete year group.

When such selection of size occurs, the average sizes of successive age groups are not strictly comparable with one another.

Norwegian investigators developed the method of ascertaining the growth of individual fish by measuring the comparative distances between the rings on the scales, on the assumption that the scale grows in length in proportion to the length of the fish. Fig. 2 shows a fish of length L with an enlarged image of its scale. The scale is measured from its centre along the main axis, and also to the edge of the winter rings, giving the values V (length of scale), v_1, v_2, etc. (lengths from centre to end of first, second winter rings, etc.). If exact proportional growth is assumed between the fish and its scale, it is evident from the parallel lines in the diagram that $l_1 : v_1 :: L : V$, and the lengths at previous winters (l_1, l_2, etc.) are found from the simple formulæ

$$l_1=\frac{v_1}{V} . L, \quad l_2=\frac{v_2}{V} . L, \text{ etc.}$$

Such a method enables the data as to growth to be multiplied to a very great extent, and should therefore be most valuable in detecting good and bad years of growth, which can be associated with known physical conditions, with the onset of maturity or even with migrations into different waters, and as such they have enormous value.

But, after studying the results obtained, certain investigators have doubted the validity of this method of ascertaining growth. It was noticed that in all species so investigated the calculated lengths for the first and succeeding winters became successively less and less as they were found from older and older fish, and other apparent discrepancies were pointed out by different observers. As a matter of fact, the above method gives only a first approximation to the actual lengths to which the fish grows at the end of each winter of life. It is based on the assumption that the lengths of the scale are themselves proportional to the length of the fish—a closer approximation (but still an approximation), for the calculation is given by taking the increments of growth of the scale as proportional to the increments of growth of the fish, starting from the point at which the scale first appears, which is in most cases an amount sufficiently appreciable to affect the calculations of the first two or three winter lengths considerably.

In Fig. 3 the average relations in the observed lengths of the scale and the corresponding fish, and in the observed lengths of the fish and the corresponding scales, are shown by the dots and crosses respectively.

A mathematical relation can be found by combining all the corresponding measures of scales and fish. This is known as a correlation coefficient, and in the case depicted was very high, viz. $r=0.95$. The points lie very nearly on straight lines, known as "regression lines," the mathematical equations to which are $L=4.8V+3$ and $V=0.19L-0.36$. From the first of these equations the length of the fish can be calculated when the length of the scale is known from measurements.

The general form of this equation for any series of measurements of fish and their scales is $L=aV+c$, the constant term c corresponding to the length at which the scale begins to grow. In the case of North Sea herring c is about 3 cm.

As in practice only relative lengths of the winter rings are measured on the scale, the constant a in the equation can be eliminated, and the calculated lengths to any previous winter (L_1, L_2, etc.) derived from the equation put in the form

$$L_1=c+\frac{v_1}{V}(L-c), \text{ etc.}$$

The results obtained by the use of this formula approximate more closely to values derived from observation than in the case of the original formula when c is not taken into account, and the growth measures calculated in this way can therefore be assumed to be a closer approximation to the truth.

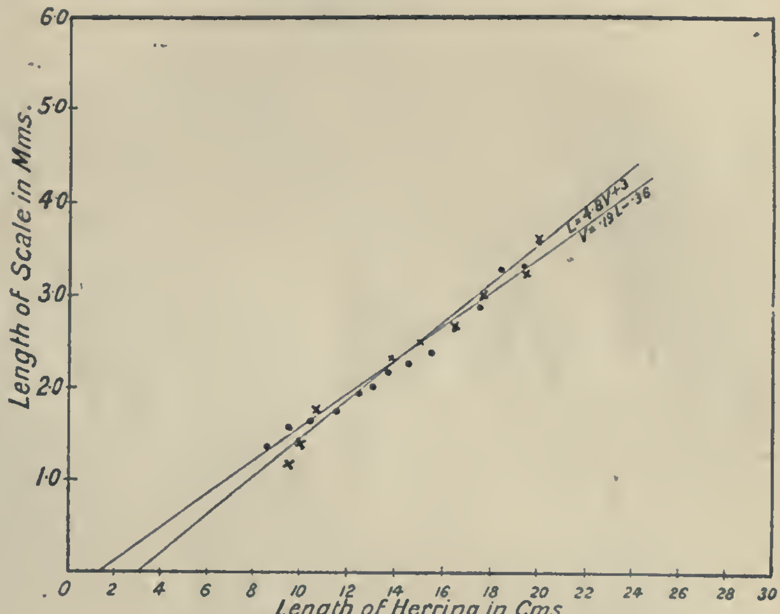

Fig. 3.—Showing average relations between measurements of fish and their scales.

In all cases of age and growth determination individual records may be wrong, owing to one or other of many difficulties that may occur in deciphering the scale, but the latest work on the subject has shown that *average* values, both of age distribution in a sample and of amount of growth, are approximately correct.

The Structure of the Atom.

By C. G. Darwin.

I.—*Atomic Number.*

The study of the interior structure of the atom was initiated about twenty-five years ago by J. J. Thomson's discovery of the electron. Electrons are particles of negative electricity of charge 4.77×10^{-10} electrostatic units and mass 9.0×10^{-28} gr., and they were shown to be constituents of every type of matter. Some years previously Thomson had shown on theoretical grounds that any charged body should possess extra mass on account of its charge, and these two facts taken together suggested the possibility of an electrical theory of matter, whereby all mass should be electromagnetic in origin, and all the properties of matter should be reproduced by the interactions of electrons and positive charges, the latter at that time quite unknown. It is not possible to dwell here on the earlier atom models (such as those of Thomson or Ritz) which were devised on these lines. They had a certain measure of success in explaining some of the properties of matter; but we can now see that there was insufficient experimental knowledge at that time, and also that no theory could possibly work which was based on the old classical ideas of dynamics, as these are certainly inadequate to deal with atomic problems.

As electrons were known to be common to all matter, it was natural to ask how many were contained in each type of atom. The mass of an electron is about 1/1840 of that of a hydrogen atom, and therefore this atom cannot contain more than 1840 electrons. For other elements the corresponding upper limit is given by multiplying the atomic weight by 1840. Thus in all cases a very wide field of choice is left. The attack on the problem was not possible until the development of X-rays and radio-activity had reached a certain stage of advancement, for ordinary chemical and physical methods are quite incapable of penetrating beyond the surface layers of the atom, whereas both X-rays and the radio-active particles are so powerful that they can go right through the atom, and from their behaviour in passing we can deduce a certain amount about its interior. With both the method consists in observing the phenomenon of scattering; that is to say, a narrow parallel beam is sent through a plate, and the amounts are found which are thrown off at various angles. Theory tells us how much a single electron should scatter, the number of atoms in the plate is known with some accuracy, and so we can count the number of electrons in each atom, if we assume that the scattering is due to them alone. When this method is applied with either X-rays or β-particles (the latter are simply electrons moving at a high speed), certain theoretical complications make the results rather inaccurate, but in both cases the experiments clearly indicated that the number of electrons in the atom was of the same general magnitude as the atomic weight. This was found for several elements ranging in weight between carbon and gold. So our first upper limit to the number of electrons in the atom was vastly in excess, and no considerable fraction of the mass of an atom is contributed by its electrons.

The experiments with α-particles were far more definite. An α-particle is simply a helium atom, carrying a positive charge equal to that of two electrons, and moving at a very high speed. As the atomic weight of helium is 4, it is seven thousand times as heavy as an electron. When an α-particle passes an electron the attractive force sets the electron in motion, and the reaction of this force gives the α-particle a small deflection and reduces its velocity slightly. On account of the smallness of the effect of a single electron, great uniformity is obtained in the average, and the number of electrons in an atom can be counted by observing either the scattering of the beam or else the rate at which the particles lose their velocity. Both give the same result, that the number of electrons in an atom is approximately half its atomic weight.

But the experiments on the scattering of α-particles contained the germ of far more important information. For in the course of them it was observed that a certain small fraction of the α-particles underwent large deflections. A few even were thrown right backwards. Now this fraction, though small in itself, was out of all proportion large compared with what could be given by the cumulative effect of a large number of collisions with electrons. Rutherford showed that the only reasonable hypothesis to account for this type of scattering was to suppose that the large deflections were produced in a single step. In this way he was led to put forward the nucleus theory of the atom, now universally accepted. According to this theory practically the whole mass of the atom is carried by a nucleus of very small dimensions (at most 10^{-12} cm.) which has a charge of positive electricity equal to some multiple of the electronic charge. This nucleus is surrounded by a cloud of electrons of just such a number as to neutralise its charge. Each element has a different nuclear charge, and (to anticipate some results that we shall come to later) the value of this nuclear charge completely determines all the chemical characters of the element. Radioactive properties belong to the nucleus, as well as mass, while chemical and spectroscopic properties are attributed to the electrons of the cloud, and are only indirectly controlled by the nucleus because it determines the number and arrangement of these surrounding electrons. The dynamical structure of this planetary system was left unspecified, and remains to this day almost unknown.

Now consider the bearing of this theory on the question of scattering. The α-particle is itself the nucleus of a helium atom. In passing through matter most of the particles will not go very near any nucleus, and so will behave in the way we have already discussed. But the paths of a few will take them near some nucleus, and large repulsive forces will be developed between the two positive charges. Most atoms are much heavier than α-particles, and so the latter will describe hyperbolas according to Newton's laws, and pass off in new directions. It is a simple matter to calculate the number of particles to be expected at any inclination to the original beam in terms of their initial velocity and the charge on the nucleus. The comparison with experiment, therefore, first furnishes a test as to whether the law of force has been taken correctly, and then provides a value for the nuclear charge. In both particulars the experiments fully bore out the prediction, and it was found that the nuclear charge (measured with the electronic charge as unit) was about half the atomic weight for the lighter elements, and rather less than half for the heavier.

Table of Atomic Numbers of the Elements.

	Hydrogen **1.** H, 1·008 1·008									
Helium **2.** He, 4·00 4	Lithium **3.** Li, 6·94	Beryllium **4.** Be, 9·1	Boron **5.** B, 10·9 10, 11	Carbon **6.** C, 12·00 12	Nitrogen **7.** N, 14·01 14	Oxygen **8.** O, 16·00 16	Fluorine **9.** F, 19·00 19			
Neon **10.** Ne, 20·2 20, 22	Sodium **11.** Na, 23·00	Magnesium **12.** Mg, 24·32	Aluminium **13.** Al, 27·1	Silicon **14.** Si, 28·3 28, 29	Phosphorus **15.** P, 31·04 31	Sulphur **16.** S, 32·06 32	Chlorine **17.** Cl, 35·46 35, 37			
Argon **18.** A, 39·88 36, 40	Potassium **19.** K, 39·1	Calcium **20.** Ca, 40·07	Scandium **21.** Sc, 44·1	Titanium **22.** Ti, 48·1	Vanadium **23.** V, 51·06	Chromium **24.** Cr, 52·0	Manganese **25.** Mn, 54·93	Iron **26.** Fe, 55·85	Cobalt **27.** Co, 58·97	Nickel **28.** Ni, 58·68
	Copper **29.** Cu, 63·57	Zinc **30.** Zn, 65·37	Gallium **31.** Ga, 69·9	Germanium **32.** Ge, 72·5	Arsenic **33.** As, 74·96 75	Selenium **34.** Se, 79·2	Bromine **35.** Br, 79·92 79, 81			
Krypton **36.** Kr, 82·92 78, 80, 82, 83, 84, 86	Rubidium **37.** Rb, 85·45	Strontium **38.** Sr, 87·83	Yttrium **39.** Y, 88·7	Zirconium **40.** Zr, 90·6	Niobium **41.** Nb, 93·5	Molybdenum **42.** Mo, 96·0	— **43.**	Ruthenium **44.** Ru, 101·7	Rhodium **45.** Rh, 102·9	Palladium **46.** Pd, 106·7
	Silver **47.** Ag, 107·88	Cadmium **48.** Cd, 112·4	Indium **49.** In, 114·8	Tin **50.** Sn, 118·7	Antimony **51.** Sb, 120·2	Tellurium **52.** Te, 127·5	Iodine **53.** I, 126·92			
Xenon **54.** Xe, 130·2 128, 130-1-3-5	Cæsium **55.** Cs, 132·81	Barium **56.** Ba, 137·37	Lanthanum **57.** La, 139·0	Cerium **58.** Ce, 140·25	Praseodymium **59.** Pr, 140·6	Neodymium **60.** Nd, 144·3	— **61.**			
	Samarium **62.** Sa, 150·4	Europium **63.** Eu, 152·0	Gadolinium **64.** Gd, 157·3	Terbium **65.** Tb, 159·2	Dysprosium **66.** Ds, 162·5	Holmium **67.** Ho, 163·5	Erbium **68.** Er, 167·7			
	Thulium **69.** Tu, 168·5	Ytterbium **70.** Yb, 173·5	Lutecium **71.** Lu, 175	Keltium **72.** Kt	Tantalum **73.** Ta, 181·5	Tungsten **74.** W, 184·0	— **75.**	Osmium **76.** Os, 190·9	Iridium **77.** Ir, 193·1	Platinum **78.** Pt, 195·2
	Gold **79.** Au, 197·2	Mercury **80.** Hg, 200·6 197–204	Thallium **81.** Tl, 204·0 IV.	Lead **82.** Pb, 207·2 XI.	Bismuth **83.** W, 208·0 V.	Polonium **84.** VII.	— **85.**			
Emanation **86.** III.	— **87.**	Radium **88.** Ra, 226·0 IV.	Actinium **89.** Ac II.	Thorium **90.** Th, 232·15 VI.	U.X₂ **91.** II.	Uranium **92.** U, 238·2 II.				

The atomic numbers were mostly fixed by the less direct method of Moseley, which will be described later. For convenience the "isotopes" (also to be discussed later) are given in the table. Thus, as an example, read:—Chlorine, atomic number **17**, symbol Cl, atomic weight by chemical methods 35·46, composed of two isotopes 35 and 37. In the case of the radio-elements (**81–92**) the evidence is of a different kind, and the roman numeral gives the number of them believed to exist. The nomenclature of some of the rare earths (**69–72**) is not yet standardised. The names here are those used by Moseley. Some of these elements, though detected by their X-ray spectra, have never been isolated. As points of some interest, observe that in three cases (A and K, Co and Ni, Te and I) the order of atomic weights is wrong, while the periodicity of the chemical properties corresponds to the atomic number Observe also the five missing elements—**43, 61, 75, 85, 87**; the properties of which can be predicted with fair confidence from the Periodic Law. A curious relation, pointed out by Rydberg, is that the atomic numbers of all the inert gases are given by taking the series $2(1^2+2^2+2^2+3^2+3^2+4^2+\dots)$ and stopping the summation at any term.

This method of determining the number of electrons in the atom is by far the most direct yet devised, as the interpretation of the experiments does not involve the rather difficult averaging necessary for the compound scattering produced by the electrons.

Now if we make a table of all the elements arranged in order of atomic weights, as is done by chemists for the study of the Periodic Law, and if we number them in this order, starting with hydrogen at 1, helium at 2, and so on, as on p. 53, it will be seen that the resulting numbers are always in the neighbourhood of half the atomic weight. The nuclear charge is by hypothesis some multiple of the electronic charge, and by experiment is about half the atomic weight, and so we are almost forced to suppose that the ordinal number of an element in the table is the same as the number of electronic charges on its nucleus. We do not anticipate an exact correspondence throughout the table, because there may be (and in fact are) gaps in it which represent hitherto undiscovered elements. But apart from this we arrive at the conception of an *atomic number* for each element. The atomic number of an element is defined as the number of positive electronic charges carried by its nucleus, or, which is the same thing, as the number of electrons surrounding this nucleus.

(To be continued.)

Obituary.

CANON C. H. W. JOHNS.

BY the death of the Rev. C. H. W. Johns, Master of St. Catharine's College, Cambridge, and Canon of Norwich, Assyriology has lost another of its most prominent representatives in this country. It was almost exactly a year after the death of Prof. L. W. King that Canon Johns passed away. He had been noted as an Assyrian scholar for many years past; held the post of lecturer in Assyrian at his college of Queens', in the University of Cambridge, for fourteen years; and preceded Prof. King as Assyrian reader at King's College, London. These lectureships he vacated on his appointment as Master of St. Catharine's in 1909. The duties of the head of a college in no way interfered with the continued prosecution of his Assyrian studies, and to the last Dr. Johns was at work on the cuneiform inscriptions to which he had devoted a large part of his life. He was an excellent decipherer of the tablets, and had had much experience as a student of Ashurbanipal's library in the British Museum, to the officials of which, and especially to the late Prof. King, he was always *persona grata* and a valued colleague in science. His most notable publication is probably his "Assyrian Deeds and Documents," published in 1898—a series of copies and translations of a large number of cuneiform legal and other records preserved in the British Museum. He also wrote on the famous legal code of Hammurabi, delivered the Schweich Lectures on the relations between the Laws of Babylonia and the Laws of the Hebrew peoples, and contributed articles on Mesopotamian law and history to various scientific journals and dictionaries, notably to the "Encyclopædia Biblica." His death is a great loss to the scientific study of Mesopotamian archæology.

H. R. HALL.

PROF. ADAM POLITZER, whose death has just been announced from Vienna, was recognised in all lands as the leading specialist of his time in diseases of the ear. He was born in Hungary on October 1, 1835, and, taking his medical degrees at the University of Vienna in 1859, went abroad to study the anatomy and diseases of the ear, coming to London to work at the pathology of the ear under Mr. Joseph Toynbee, F.R.S. Returning to Vienna, he quickly established himself as the leading exponent of the newest learning concerning the organ of hearing and its defects, and his growing fame drew medical men to Vienna from all parts of the civilised world. The secret of his success was that he founded his methods of treatment on a first-hand knowledge of the structure, action, and pathology of all parts of the ear. He sought to give to the practice of the aural surgeon a foundation on fact, and not the least of his discoveries were made in the fields of normal anatomy.

THE death of SIR CHARLES LYALL leaves a gap in the ranks of the older school of Orientalists, in which field he will be remembered rather than as an eminent Indian administrator. Sir Charles became a member of the Civil Service in the United Provinces of Agra and Oudh in 1867, and, without much experience of district work, he was absorbed in the Provincial Secretariat, and then went to Simla and Calcutta. Much of his service was passed in Assam, of which province he became Chief Commissioner. Transferred to the Central Provinces, his training in administration failed to prepare him for the emergency of the great famine of 1897, and he was removed to the India Office as Secretary of the Judicial and Public Department. Here he was able to resume his work on Indian languages, particularly Hindustani, and he showed his profound knowledge of Arabic by numerous translations of its poetic literature, which he discussed in successive editions of the "Encyclopædia Britannica." Sir Charles Lyall was a tower of strength to the Royal Asiatic Society, of which he was vice-president, working with Orientalists like James Kennedy and Vincent A. Smith, both of whom recently died. His services to literature were rewarded by several honorary degrees, and by the coveted distinction of fellowship of the British Academy.

Notes.

On August 31 and September 1 the centenary of the discovery of electromagnetic action by the Danish physicist, Hans Christian Oersted, was celebrated at Copenhagen. Meetings were held in the Town Hall and University, at which many Scandinavian men of science were present, and the occasion was marked by the publication of some of Oersted's scientific correspondence. It was during the winter of 1819–20 that Oersted observed that a wire uniting the ends of a voltaic battery affected a magnet placed in its vicinity, and after prosecuting his inquiries some months longer, in July, 1820, he published his Latin tract, "Experimenta circa effectum Conflictus Electrici in Acum Magneticum." The importance of his discovery received instant recognition. Ampère, Arago, and Davy all seized on the idea, and four months after the publication of his tract Oersted was elected a foreign member of the Royal Society and awarded the Copley medal. Efforts to connect magnetism with electricity had hitherto met with little success, and Wollaston, in his discourse as president of the Royal Society, referring to Oersted's discovery, expressed the hope that "the gleam of light which thus beams upon us may be the dawn of a new day, in which the clouds which have hitherto veiled from our sight the hidden mysteries of light and heat, of electricity and magnetism, may be dispelled." Oersted, who was the son of a country apothecary, originally studied medicine, but turning his attention to chemistry and physics while at Copenhagen University, he was in 1806 appointed to the chair of physics, and he held that position until his death in March, 1851, at the age of seventy-three. Known alike for his genial and kindly nature and for his scientific labours, he was the author of some two hundred memoirs, and received many honours at home and abroad. Twenty-five years after his death a bronze statue of him was erected on the old fortification of Copenhagen.

The joint committee appointed by the Illuminating Engineering Society to inquire into the subject of eye-strain in kinema theatres has now presented an interim report to the London County Council. The committee consisted of representatives of the Illuminating Engineering Society, the Council of British Ophthalmologists, the Physiological Society, and the kinema industry, and also received the help of various officers of the London County Council. Its main conclusions are concerned with the undue proximity of seats to the screen as a cause of eye-fatigue. The committee expresses the opinion that a high angle of view is one of the most important causes of eye-strain. It is accordingly recommended that the angle between the horizontal plane passing through the observer's eye and the plane containing the observer's eye and the top edge of the picture should not exceed 35°. This is, roughly, equivalent to specifying that the ratio between the distance of the nearest seats from the screen and the height of the top of the picture above eye-level should not be less than 1 : 43. A second recommendation limiting to 25° the obliquity of view from the sides of the theatre is also made. The conclusions are based on actual experience in a number of kinemas in London, and will doubtless be accepted as moderate in scope. Various other matters, such as the origin of flicker, the effect of imperfect films and apparatus, and the conditions of artificial lighting to be provided in halls, are also dealt with, although formal conclusions are not presented at this stage. With proper precautions it appears that the provision of a low general illumination in halls is consistent with a satisfactory image on the screen. Such inquiries, besides being in the public interest, should ultimately also be for the benefit of the kinema industry, and we are glad to note that several representatives of the industry shared in the investigation.

Prof. J. B. Farmer, professor of botany in the Imperial College of Science and Technology, has been appointed by an Order of Council to be a member of the Advisory Council to the Committee of the Privy Council for Scientific and Industrial Research.

We learn from *Science* of August 20 that Dr. George Ellery Hale, director of Mount Wilson Observatory, has been elected a foreign member of the Società Italiana delle Scienze, Rome, in succession to the late Lord Rayleigh.

Severe earthquake shocks occurred at Milan, and in other parts of Northern and Central Italy, shortly before eight o'clock on September 7. The centre of the disturbance seems to have been in the province of Massa Carrara, where several villages have been much damaged and the small town of Villa Collemandina has been destroyed.

The next meeting of the Association of Economic Biologists will be held on Friday, September 24, at the Royal Botanic Gardens, Kew. At 2.30 p.m. a discussion will be opened on problems of susceptibility or immunity to disease in plants, the following being the principal speakers :—A. Howard, The Relation of Soil Aeration and Soil Temperature to Disease in Plants; E. S. Salmon, The Relation of Climatic Factors to Disease in Plants; and F. T. Brooks, Immunity to Disease in Plants as a Mendelian Factor.

At a meeting of delegates appointed by the scientific academies of the Allied nations held in Brussels in July, 1919, an International Research Council was formed for the co-ordination of work and effort in the various branches of science and its applications. Each country, by means of its national academy or national research council or its Government, can take part in the scheme. We gather from an address on the organisation of research delivered before the Association of American Universities by Dr. J. R. Angell, and reproduced in the July number of the *Scientific Monthly*, that the United States has established a National Research Council to deal with the organisation and conduct of research in that country. While in Germany the work was done most effectively by an autocratic Government, it was felt that in a democratic country an enterprise of this type could only meet with conspicuous success if freed from Government control. The funds are provided from the Rockefeller Foundation and other private sources, and arrangements with the universities for the training of research workers, for the organisation of research, and for the supply of information regarding current research have already been made.

THE Nile Projects Commission, appointed to consider the proposals of the Egyptian Ministry of Public Works for improving the regulation of the Nile discharge with the view of extending the cultivable area of Egypt, has issued an interim report, in which, dealing first with the ethical charges brought by Sir William Willcocks and Col. Kennedy against Sir Murdoch Macdonald, the Adviser to the Egyptian Ministry of Public Works, the Commission states that on a careful consideration of all the evidence the members are unanimously of opinion that there has been no falsification or intentional suppression of records or any fraudulent manipulation of data. A study of the projects as described in "Nile Control," the official statement by Sir Murdoch Macdonald, has further led the Commission to the conclusion that, considered strictly from an engineering point of view, the White Nile dam, the Gezireh irrigation scheme and Blue Nile (Sennar) dam, and the Nag Hammadi barrage should be carried out at once. A final report is promised, in which will be considered at length the Commission's observations made in Egypt, the character of the data, the criticisms received and an examination of the evidence given on oath, and other matters. The members of the Commission are Mr. F. St. John Gebbie (president), Prof. H. T. Cory, and Dr. G. C. Simpson.

MR. J. J. JOICEY has acquired for the Hill Museum, Witley, the collection of Lepidoptera formed by Mr. H. J. Elwes, as well as the large collection of Heliconius formed by the late H. Riffarth. The museum has lately also received large collections of Lepidoptera from Central Africa, obtained by Mr. and Mrs. T. A. Barns, who have recently returned from a twelve months' trip undertaken on behalf of Mr. Joicey. Mr. Barns has recorded many interesting observations on the bionomics of the Lepidoptera collected. Some remarkable kinematograph films were taken *en route* of both geographical and entomological interest. A report on the results of this expedition is in progress. The museum has also in preparation papers on the Lepidoptera of Hainan, of the Schouten Islands, of Dutch New Guinea, Misol, Aru, Key, Tenimber, Obi, and Sula Islands, and a report on the Lepidoptera collected by Messrs. Pratt in the mountains of Central Ceram. Mr. Joicey has now sent the three brothers Pratt to Dutch New Guinea. They have reached the mountains in an area south of Geelvinck Bay, entomologically unexplored, and a consignment of specimens has already been dispatched. It is expected that important zoological results will be obtained by this expedition.

IN the Journal of the Royal Anthropological Institute (vol. xlix., July–December, 1919) Mr. S. Hazeldine Warren records the discovery at Graig-lwid, Penmaenmawr, of an important prehistoric site where the manufacture of axes of the Neolithic type was extensively carried on. Penmaenmawr Mountain and Graig-lwid form an oval intrusion of igneous rock, which is extensively quarried for road-metal and building stone. Neolithic remains are generally scarce in North Wales, but Sir John Evans records the discovery of some axes at Dwygyfylchi, in Carnarvonshire, the adjoining village to Penmaenmawr. The axes were made of scree material—that is to say, angular blocks of rock broken up by frost along its natural joint-planes. It is certain that there was a very large output of axes from this factory, and some of them must have passed to long distances in the course of barter and along trade routes during hunting expeditions or hostile raids, tribal migrations, and the like. It is possible that some examples in collections made of felsite or felstone may ultimately be traced to this factory.

IN the Journal of the Torquay Natural History Society (vol. ii., No. 6, 1920) Mr. H. J. Lowe discusses "The Needles of Kent's Cavern with reference to Needle Origin." He thinks that the modern implement originated in prehistoric times in the course of attempts made to sew skins together for use as clothing. The simplest method is to attempt to push the thread through when piercing the hole for it, and the advance made was by getting the idea of a hole in the awl through which the thread could go and be thrust through the skin with the awl or bodkin. In support of this theory a bone needle has recently been found in Kent's Cavern, which Mr. Lowe regards as "an unique specimen of Palæolithic man's bone implement, made for use as a needle." In this specimen "its blunt end will permit strong pressure and twisting by the end of the thumb without abrading the skin or causing a sore, and with one thread passing before the thumb, to be held taut with the other by the closed three fingers, the implement could be held firmly to the thumb and vertically to the skin by one hand, while the other would be free for holding and adjusting the skin while the needle was being pushed through it." It will be interesting to ascertain whether other examples of such an implement are available in collections, and if Mr. Lowe's view is correct.

WE have recently received the first volume (124 pp.) and Nos. 1–2 (32 pp.) of the second volume of *Bollettino della Società Italiana per lo Studio della Alimentazione*, published from the Museum of Natural History in Florence. The bulletin contains original articles on problems connected with food and nutrition —*e.g.* the milk-food of infants, the present soldier's ration in Italy, the culture of carp, and the preservation of hen's eggs. About half of each issue is devoted to abstracts of memoirs on the chemistry and physiology of nutrition, the analysis of food, adulteration, dietetics, the production and preparation of food, the nutrition of animals, and diseases of man and animals arising from food, *e.g.* deficiency diseases.

IN the *Lancashire and Cheshire Naturalist*, vol. xiii., No. 2, August, 1920, Miss Annie Dixon reports on the gatherings of protozoa made from a pond in Didsbury, from September, 1918, to March, 1919, and appends a table of the species found, about 100 in number, showing in which months they occur. A previous report dealt with the protozoan fauna of this pond during the period March to September, 1918. Among the more noteworthy species recorded may be mentioned *Archerina Boltoni*, which was very common during one week in April, 1918, but has not reappeared; and *Mastigamoeba aspera*, which was found in small numbers in September and October, 1918. It is to be hoped that the study of the protozoa of this pond and the recording of the seasonal occurrence of the various species will be continued.

ZOOLOGISTS, and especially field-naturalists, will be interested in a short paper on the occurrence of Protohydra in England, by Prof. S. J. Hickson, in the current issue of the *Quarterly Journal of Microscopical Science* (vol. lxiv., part 4). *Protohydra Leuckartii* was discovered rather more than half a century ago, and, although apparently very rarely met with since, it has always been regarded with especial interest as one of the simplest—though not necessarily the most primitive—of the Cœlenterata, being, in fact, a Hydra without any tentacles. It has now turned up in abundance in pools in the tidal marshes of the River Hamble, near Southampton, and has also been recorded from the Laira River, near Plymouth. Unfortunately, though it has been observed by Prof. Hickson and Mr. Herbert Ashby for four successive years, no new light is forthcoming as to its life-history, no medusoids and no sexual method of reproduction, but only transverse fission, having been observed.

A MONOGRAPH of the South Asian, Papuan, Melanesian, and Australian frogs of the genus Rana, by Dr. G. A. Boulenger, forms vol. xx. (226 pp., June, 1920) of the Records of the Indian Museum. Dr. Boulenger has grouped the series, so far as possible, according to their probable phylogenetic relationships, and in order to do this has laid down the characters which might be expected to occur in a theoretical prototype from which phyletic lines may be drawn up. Among Asiatic species he regards *Rana hexadactyla* as the nearest approach to the ideal prototype. He groups the 125 species considered into seven natural sections, the first of which is the *hexadactyla*-section from which three others can be derived. The remaining three sections are derived from other ancestral sources. A table of the characters of the nine subgenera of Rana and excellent synoptic keys of the species are given. Detailed descriptions of the species follow, and tables are supplied giving measurements of the different parts of the body of adult and half-grown specimens in order to convey exact information on these important matters, and also to show the amount of individual variation.

PAMPHLET No. 11 of the Economic Series published by the British Museum (Natural History) has recently appeared. It is written by Dr. Gahan, the keeper of the entomological department, and deals with furniture beetles, their life-histories and preventive measures. Not infrequently articles of furniture, or some part of the woodwork in the house, are seriously damaged by the larvæ of certain beetles, of which we have about five species in this country. The common furniture beetle (*Anobium punctatum*, De G.) is the most usual enemy; the death-watch beetle (*Xestobium rufovillosum*, De G.) seldom attacks movable furniture, and more usually affects the timbers of old houses, etc.; while the powder-pest beetles (Lyctus) mostly affect sapwood, and, unless treated with a preservative beforehand, this part is unsuitable for furniture-making. The above types of beetles are well described in this useful little brochure, and clearly figured. Wherever it can be safely applied, treatment by heat is one of the best methods of dealing with affected furniture. In other cases resort has to be made to fumigation with a poisonous gas or vapour. As a third alternative, direct application of a liquid, such as benzene, carbon tetrachloride, or terebene, may be adopted. Anyone troubled with these pests is advised to obtain this pamphlet, which can be purchased at the Museum for the sum of 6*d*.

M. MEUNISSIER has published (*Journal of Genetics*, vol. x., No. 1) a short account of some genetic results obtained by the late M. Philippe de Vilmorin on the colour of the hilum or point of attachment of the pea. One variety of garden pea has a black hilum or "eye," and in crosses with other varieties and species this was found to behave as a simple dominant. In several crosses of varieties in which both parents had an uncoloured hilum, the black hilum appeared in the offspring—in some cases in all the offspring, in others in only a portion of them, and in still others only a few seeds developed the black hilum. Whether such cases are to be looked upon as variations, or, in the latter case, as bud mutations, can only be determined by further breeding experiments. They represent an interesting departure from the usual Mendelian behaviour.

BEFORE the war the medical opium trade was largely in the hands of Turkey, and the Indian opium poppy, although belonging to the same species (*Papaver somniferum*) as the Turkish, was found to have a lower morphine content. In order to replace the foreign product by one produced within the Empire, an effort is being made to produce by breeding experiments a race with a high content and a good yield. Messrs. H. Martin Leake and B. Ram Pershad (*Journal of Genetics*, vol. x., No. 1) expect, by selection and crossing of the numerous Indian varieties of opium poppy, to produce a race with the desired qualities. The preliminary paper deals with the numerous colour varieties. The colour patterns are independent of opium content, but are a useful index of purity in the various races. Chemical investigations have disclosed races yielding as much as 18 per cent. morphine.

THE first of the Memoirs of the Botanical Survey of South Africa has been issued by the Union Department of Agriculture. It comprises an account of the Phanerogamic flora of the Divisions of Uitenhage and Port Elizabeth by Dr. S. Schonland. In July, 1918, an Advisory Committee for the Botanical Survey of the Union was appointed by the Minister of Agriculture, consisting of botanists from each of the four provinces, with the chief of the division of botany and plant pathology as director of the Survey. The botanists comprising the Committee are each in charge of different administrative areas into which the Union has been divided for purposes of the Survey. It was agreed that as a basis of the Survey the preparation of regional floras should be taken in hand and local vegetation surveys prepared, and the present contribution is the first of these regional floras.

PROF. J. C. BRANNER has furnished a much-needed summary of the geology of Brazil, together with a coloured map on the scale of 1 : 5,000,000 (Bull. Geol. Soc. America, vol. xxx., p. 189; second ed., April, 1920). The included bibliographies enable the reader to supplement on any special line the immense amount of material here brought together in a condensed form from the author's own experience. Among the plates is a handsome photograph of a striated boulder from the Permian beds of São Paulo.

MR. H. P. WHITLOCK (*Amer. Journ. Sci.*, vol. xlix., p. 259, 1920) has constructed and described a model for the demonstration of any point-system in atomic spacing within crystals, the atoms being represented by perforated wooden beads, which are obtainable in six colours from dealers in kindergarten requisites. Glass rods are used for their support, and these are passed through holes appropriately punched in two horizontal plates of tin set in a frame. Only two types of frame are required by the crystallographic systems.

WE know, from such valuable publications as Collet's "Alpes calcaires entre Arve et Rhône," that geology is honoured by the *Société de Physique et d'Histoire Naturelle de Genève*. In the *Compte rendu des séances* for April to July, 1920, various authors discuss such topics as details of Alpine structure; the glacial origin of the Petit Lac of Geneva, involving the question of the capture of the Rhône Valley ice by the Arve basin, and the end of the struggle between the Arve and Rhine for the possession of the waters of the upper Rhône; the green rocks of the southern Urals (to which M. L. Duparc brings his experience); and the classification of felspar twins, by M. R. Sabot. It is clear that geologists must keep even the minor publications of this society within their scope.

CAPTAINS and officers of vessels traversing the North Atlantic will find much of value and interest to them in the series of "Monthly Meteorological Charts" issued by the Meteorological Office. The chart for September gives the distribution of winds and ocean currents at this season of the year, and the mean values of the barometer are indicated by isobars over the sea as well as over the adjacent land. Mean temperatures of air and sea surface are also given. The normal conditions show a large area of high barometer readings centred in mid-Atlantic, around which there is a general circulation of winds. A smaller region of high barometer embraces New York and the neighbouring land and sea. Areas of low barometer occur to the south of Greenland and near the equator, as well as over North America and Central Africa, all of which materially influence the normal wind circulation. The extension of the "Gulf Stream" is very evident on the eastern side of the Atlantic to as far as 50° or 55° N. latitude. The southern limit of the north-east trade, and the northern limit of the south-east trade, winds embrace an area centred in about 10° N. latitude. On the reverse of the chart a brief description is given of the different types of atmospheric systems which produce certain and distinct kinds of weather, and illustrations are given which will be helpful to the navigator in constructing a weather chart for himself with the aid of wireless reports he may receive.

THE *Meteorological Magazine* for August shows that every effort is being made to improve the Daily Weather Report. Sea- and air-temperatures and the weather in home waters are now incorporated, whilst since August 1 a small map is given showing "barometric tendency" for the three hours from 4h. to 7h. For the special advantage of aeronauts a method of obtaining the degree of visibility on cloudy nights is suggested by Capt. W. H. Pick. The use of the grease-spot photometer of Bunsen is advocated, calibrated in accordance with the visibility-scale adopted by the Meteorological Office and allied authorities. The apparatus consists of a drop or two of molten grease on a sheet of writing paper and a candle placed behind the grease spot. The observer faces the spot and moves backward, noticing the exact position at which the spot of grease becomes indistinguishable on the paper. The distance of indistinguishability in feet is given in a tabular form for the respective units of the visibility-scale. Careful examination of the suggestion by independent workers is desirable before its final adoption. At best it seems that the method must be rough. July is stated to have been generally a wet month over the British Isles, and the Thames Valley rainfall map shows some areas having a fall of more than 6 in. The general July rainfall for England and Wales was 161 per cent. of the average, Scotland 104 per cent., and Ireland 153 per cent.

IT has long been known that the sensitiveness of photographic bathed plates can be increased by the addition of ammonia to the dye-bath, though at the expense of keeping qualities and freedom from chemical fog. Mr. S. M. Burka has critically studied, at the American Bureau of Standards, the action of ammonia on commercial plates, hoping thereby to increase their sensitiveness and facilitate aerial photography. His communication to the Franklin Institute on the subject is reproduced in the *British Journal of Photography* for August 6, 13, and 20. He finds that ordinary and orthochromatic plates are not much, if at all, affected by bathing them in weak ammonia, but panchromatic plates may be increased in sensitiveness to as much as five times. More usually the increase is to about twice, but even then the sensitiveness to red may be increased to five times and be extended 100 or more Ångström units. Plates which show irregular curves of spectrum sensitiveness have their minima raised, and in many cases smoothed out entirely. It is preferred to add alcohol to the ammonia bath, because without it the plates must be used as soon as they are dry, although if it is omitted the sensitiveness is increased to a still greater extent. The communication is illustrated by numerous spectrum and other curves and diagrams, and some aerial photographs in which a comparison can be made between the effect of using the treated and the untreated plates.

PROF. LUIGI PALAZZO, director of the Meteorological Office at Rome, has sent us a separate copy of his discussion in the *Annali del R. Ufficio Centrale di Meteorologia e Geodinamica* (vol. xxxvii., part 1) of comparisons made of magnetic instruments at Terracina in 1901, 1911, and 1913. On the first occasion the instruments of the Meteorological Office at Rome were compared with those used in the Polar expedition of the Duke of the Abruzzi. On the other occasions the comparison was between the Roman instruments and others belonging to the Carnegie Institution of Washington. Prof. Palazzo himself observed with the Roman instruments. The American observers were Mr. W. H. Sligh in 1911 and Mr. W. F. Wallis in 1913. Terracina was selected as being free from the artificial disturbances which for some time have rendered Rome unsuitable as a magnetic station. It is interesting to note that all the dip-circles used were of English construction. The magnetometers were of different patterns. The comparisons with the Washington instruments are of most general interest. In the case of declination the mean difference between the Rome and Washington instruments was only 0·2′ in 1911 and 0·1′ in 1913—differences which are probably too small to rely on. In both years the Washington instruments gave the smaller dip and the larger value for the horizontal force. But the apparent differences between them and the Roman instruments were substantially different on the two occasions. Consistency to 0·1′ in dip and to 1γ in horizontal force is probably too much to expect from ordinary dip-circles and unifilar magnetometers.

THE University Tutorial Press, Ltd., announces that it has in preparation a new series of text-books for use in agricultural schools and colleges. The first book of this series, which it is hoped will be issued next month, is "The Chemistry of Crop Production," by Prof. T. B. Wood, head of the Cambridge University School of Agriculture. This will be followed later by "Animal Food Production" by the same author. A volume on "Chemistry for Agricultural Students," by Mr. R. H. Adie, is also in active preparation.

WE learn from Mr. Wilson L. Fox that the statement made in NATURE for August 26 (p. 837) with reference to the rainfall at Falmouth for August 18 is incorrect. The Daily Weather Report gives the rainfall as 6 mm. between 7 a.m. and 6 p.m., and not 2·21 in. between 8 a.m. and 7 p.m., as was reported.

Our Astronomical Column.

THE NEW STAR IN CYGNUS.—Mr. Denning writes that this nova declined in brightness very quickly after its maximum on August 24, but at the end of that month maintained its light for a few days, so that its magnitude remained at about 4·2, and the nova was a little brighter than the star 33 Cygni. The magnitude on August 24 was 1·8. Since that date the estimated magnitudes at Bristol have been:

August	25 ... 2·7		September	1 ... 4·1
	26 ... 2·9			2 ... 4·2
	28 ... 3·5			3 ... 4·5
	29 ... 3·9			4 ... 4·7
	31 ... 4·2			

RADIATION PRESSURE NEAR THE SUN.—Radiation pressure has been freely invoked in recent years to explain various celestial phenomena. Prof. Eddington, who was one of the first to suggest that it may play a very important part in the interior of the giant stars, contributes a note to Mon. Not. R.A.S. for June, in which he examines the maximum effects that it could produce outside the sun. Assuming a temperature of 10,000° C. at the surface of the photosphere (which is purposely taken considerably in excess of the most probable value), then the radiation just outside the photosphere is equivalent to a wind-pressure of 30 dynes per sq. cm., which could not support a greater mass than 1 milligram against the solar gravitation. Thus if a prominence 10,000 km. deep were upheld by radiation, its mass could not exceed a milligram per sq. cm. of its base, implying a density of 10^{-12}, which is difficult to accept, in view of the fact that the prominences are visible in spectrograms as dark markings on the solar disc. Prof. Eddington estimates the maximum density of the corona and the tails of comets (on the radiation theory) as 10^{-18}. These are less difficult to accept, as it is known on other grounds that their density is extremely small.

DISTRIBUTION OF INTENSITY IN SOLAR AND STELLAR SPECTRA.—Mr. Bertil Lindblad, of Upsala Observatory, has made an important study of effective and minimum wave-lengths in grating spectra of the sun and stars (Upps. Univ. Årsskrift, 1920, Mat. och Naturvetenskap 1). He claims that the method affords an independent determination of absolute magnitude without making use of the spectral lines, being thus a check of the method of Adams and Joy. In particular, stars are giants the effective wave-length of which exceeds 426 $\mu\mu$. The effective temperature of the solar photosphere is found to diminish from 6200° at the middle of the disc to 5430° at the limb. The difference is ascribed to the lower depth from which we receive light in the former case. Detailed measures of the spectra of sixty stars of known spectral type and luminosity are then given, and curves drawn connecting minimum wave-length with absolute magnitude for the various spectral types.

A detailed examination of a special region in Cepheus is then given, in which the data previously acquired are utilised. It contains the extreme dwarf Krüger 60; two other stars are found to be dwarfs, B.D. 57° 2514 and 56° 2779. Their spectral parallaxes are given as 0·03″ and 0·04″, and an annual P.M. of 0·5″ is suspected in each case from comparison with the B.D. places.

On the other hand, there are several red giants in the region, the distance of which is given as 4700 light-years; this is suggested as the distance of the galactic star-cloud which occupies the region.

Scientific Studies of Non-ferrous Alloys.*

By C. T. HEYCOCK, M.A., F.R.S.

THE production of metals and their alloys undoubtedly constitutes the oldest of those chemical arts which ultimately expanded into the modern science of chemistry, with all its overwhelming mass of experimental detail and its intricate interweaving of theoretical interpretation of the observed facts. Tubal-cain lived during the lifetime of our common ancestor, and was "an instructor of every artificer in brass and iron"; and although it may be doubted whether the philologists have yet satisfactorily determined whether Tubal-cain was really acquainted with the manufacture of such a complex metallic alloy as brass, it is certain that chemical science had its beginnings in the reduction of metals from their ores and in the preparation of useful alloys from those metals. In fact, metallic alloys, or mixtures of metals, have been used by mankind for the manufacture of implements of war and of agriculture, of coinage, statuary, cooking vessels, and the like from the very earliest times.

In the course of past ages an immense amount of practical information has been accumulated concerning methods of reducing metals, or mixtures of metals, from their ores, and by subsequent treatment, usually by heating and cooling, of adapting the resulting metallic product to the purpose for which it was required. Until quite recent times, however, the whole of this knowledge was entirely empirical in character, because it had no foundation in general theoretical principles; it was collected in haphazard fashion in accordance with that method of trial and error which led our forerunners surely, but with excessive expenditure of time and effort, to valuable results.

To-day I purpose dealing chiefly with the non-ferrous alloys, not because any essential difference in type exists between the ferrous and non-ferrous alloys, but merely because the whole field presented by the chemistry of the metals and their alloys is too vast to be covered in any reasonable length of time.

The earliest recorded scientific investigations on alloys were made in 1722 by Réaumur, who employed the microscope to examine the fractured surfaces of white and grey cast-iron and steel. In 1808 Widmanstätten cut sections from meteorites, which he polished and etched. The founder, however, of modern metallography is undoubtedly H. C. Sorby, of Sheffield. Sorby's early petrographic work on the examination of thin sections of rock under the microscope led him to a study of meteorites and of iron and steel, and in a paper read before the British Association in 1864 he describes briefly (I quote his own words) how sections "of iron and steel may be prepared for the microscope so as to exhibit their structure to a perfection that leaves little to be desired. They show various mixtures of iron, and two or three well-defined compounds of iron and carbon, graphite, and slag; these constituents, being present in different proportions and arranged in various manners, give rise to a large number of varieties of iron and steel, differing by well-marked and very striking peculiarities of structure." The methods described by Sorby for polishing and etching alloys and his method of vertical illumination (afterwards improved by Beck) are employed to-day by all who work at this branch of metallography.

From 1854–68 Mattheisen published in the Reports of the British Association and in the Proceedings and Transactions of the Royal Society a large number of papers on the electrical conductivity, tenacity, and specific gravity of pure metals and alloys. He concluded that alloys are either mixtures of definite chemical compounds with an excess of one or other metal, or solutions of the definite alloy in the excess of one of the metals employed, forming in their solid condition what he called a solidified solution. This idea of a solidified solution has developed into a most fruitful theory upon which much of our modern notions of alloys depends. Although, at the time, the experiments on the electrical conductivity did not lead to very definite conclusions, the method has since been used with great success in testing for the presence of minute quantities of impurities in the copper used for conductors. In the *Philosophical Magazine* for 1875 F. Guthrie, in a remarkable paper quite unconnected with alloys, gave an account of his experiments on salt solutions and attached water. He was led to undertake this work by a consideration of a paper by Dr. J. Rea, the Arctic explorer, on the comparative saltness of freshly formed and of older ice-floes. Guthrie showed that the freezing point of solutions was continuously diminished as the percentage of common salt increased, and that this lowering increased up to 23·6 per cent. of salt, when the solution solidified as a whole at about 22° C. He further showed, and this is of great importance, that the substance which first separated from solutions more dilute than 23·6 per cent. was pure ice. To the substance which froze as a whole, giving crystals of the same composition as the mother-liquor, he gave the name "cryohydrate."

In the *Philosophical Magazine* for 1876 Guthrie gave an account of his experiments, using solvents other than water, and states that the substances which separate at the lowest temperature are neither atomic nor molecular; this lowest melting-point mixture of two bodies he names the eutectic mixture. In the same paper he details the methods of obtaining various eutectic alloys of bismuth, lead, tin, and cadmium.

We have in these papers of Guthrie's the first important clue to what occurs on cooling a fused mixture of metals. The researches of Sorby and Guthrie, undertaken as they were for the sake of investigating natural phenomena, are a remarkable example of how purely scientific experiment can lead to most important practical results. It is not too much to claim for these investigators the honour of being the originators of all our modern ideas of metallurgy. Although much valuable information had been accumulated, no rapid advance could be made until some general theory of solution had been developed. In 1878 Raoult first began his work on the depression of the freezing point of solvents due to the addition of dissolved substances, and he continued at frequent intervals to publish the results of his experiments up to the time of his death in 1901.

In a paper in the *Zeit. Physikal. Chem.* for 1888 on "Osmotic Pressure in the Analogy between Solutions and Gases," van't Hoff showed that the experiments of Pfeffer on osmotic pressure could be explained on the theory that dissolved substances were, at any rate for dilute solutions, in a condition similar to that of a gas; that they obeyed the laws of Boyle, Charles, and Avogadro; and that on this assumption the depression of the freezing point of a solvent could be calculated by means of a simple formula. He also showed that the exceptions which occurred to Raoult's

* From the opening address of the President of Section B (Chemistry) delivered at the Cardiff meeting of the British Association on August 24.

laws, when applied to aqueous solutions of electrolytes, could be explained by the assumption, first made by Arrhenius, that these latter in solution are partly dissociated into their ions. The result of all this work was to establish a general theory applicable to all solutions which has been widespread in its applications. From this time the study of alloys began to make rapid progress.

The experiments of Laurie, Tannman, and Neville and myself in 1888 and 1889 helped to establish the similarity between the behaviour of metallic solutions or alloys and that of aqueous and other solutions of organic compounds in organic solvents. That our experiments were correct seemed probable from the agreement between the observed depression of the freezing point and the value calculated from van't Hoff's formula for the case of those few metals the latent heats of fusion of which had been determined with any approach to accuracy.

Our experiments, afterwards extended to other solvents, led to the conclusion that in the case of most metals dissolved in tin the molecular weight is identical with the atomic weight; in other words, that the metals in solution are monatomic. This conclusion, however, involves certain assumptions. Sir William Ramsay's experiments on the lowering of the vapour pressure of certain amalgams point to a similar conclusion.

So far our work had been carried out with mercury thermometers, standardised against a platinum resistance pyrometer, but it was evident that, if it was to be continued, we must have some method of extending our experiments to alloys which freeze at high temperatures. The thermo-couple was not at this stage a trustworthy instrument; fortunately, however, Callendar and Griffiths had brought to great perfection the electrical resistance pyrometer (Phil. Trans., A, 1887 and 1891). Dr. E. H. Griffiths kindly came to our aid, and with his help we installed a complete electrical resistance set. As at this time the freezing points of pure substances above 300° were not known with any degree of accuracy, we began by making these measurements:—

Table of Freezing Points.

[1] Contaminated with silicon. [2] Known to be impure.

With the exception of silver and gold, these metals were the purest obtainable in commerce.

During the period that the above work on non-ferrous alloys was being done, great progress was being made in the study of iron and steel by Osmond and Le Chatelier. In 1890 the Institution of Mechanical Engineers formed an Alloys Research Committee. This committee invited Prof. (afterwards Sir William) Roberts-Austen to undertake research work for it. The results of his investigations are contained in a series of five valuable reports extending from 1891 to 1899, published in the Journal of the institution. The fifth is of especial importance, because, besides a description of the thermal effects produced by carbon, which he carefully plotted and photographed, he described the microscopical appearance of the various constituents of iron. The materials of this report, together with the work of Osmond and others on steel and iron, provided much of the material on which Prof. Bakhuis Roozeboom founded the iron-carbon equilibrium diagram. Reference should also be made to the very valuable paper by Stansfield on the present position of the solution theory of carbonised iron (Journ. Iron and Steel Inst., vol. xi., 1900, p. 317). It may be said of this fifth report, and of the two papers just referred to, that they form the most important contribution to the study of iron and steel that has ever been published. Although the diagram for the equilibrium of iron and carbon does not represent the whole of the facts, it affords the most important clue to these alloys, and undoubtedly forms the basis of most of the modern practice of steel manufacture. Many workers, both at home and abroad, were now actively engaged in metallurgical work—Stead, Osmond, Le Chatelier, Arnold, Hadfield, Carpenter, Ewing, Rosenhain, and others too numerous to mention.

In 1897 Neville and I determined the complete freezing-point curve of the copper-tin alloys, confirming and extending the work of Roberts-Austen, Stansfield, and Le Chatelier; but the real meaning of the curve remained as much of a mystery as ever. Early in 1900 Sir G. Stokes suggested to us that we should make a microscopic examination of a few bronzes as an aid to the interpretation of the singularities of the freezing-point curve. An account of this work, which occupied us for more than two years, was published as the Bakerian lecture of the Royal Society in February, 1903. Whilst preparing a number of copper-tin alloys of known composition we were struck by the fact that the crystalline pattern which developed on the free surface of the slowly cooled alloys was entirely unlike the structure developed by polishing and etching sections cut from the interior; it therefore appeared probable that changes were going on within the alloys as they cooled. In the hope that, as Sorby had shown in the case of steel, we could stereotype or fix the change by sudden cooling, we melted small ingots of the copper-tin alloys and slowly cooled them to selected temperatures and then suddenly chilled them in water. The results of this treatment were communicated to the Royal Society and published in the Proceedings of February, 1901.

To apply this method to a selected alloy we first determined its cooling curve by means of an automatic recorder, the curve usually showing several halts or steps in it. The temperature of the highest of these steps corresponded with a point on the liquidus, *i.e.* when solid first separated out from the molten mass. To ascertain what occurred at the later halts, ingots of the melted alloy were slowly cooled to within a few degrees above and below the halt and then chilled.

The method of chilling also enabled us to fix, with some degree of accuracy, the position of points on the solidus. If an alloy, chilled when it is partly solid and partly liquid, is polished and etched, it will be seen to consist of large primary combs embedded in a matrix consisting of mother-liquor, in which are disseminated numerous small combs, which we called "chilled primary." By repeating the process at successively lower and lower temperatures we obtained a point at which the chilled primary no longer formed, *i.e.* the upper limit of the solidus.

Although we made but few determinations of the physical properties of the alloys, it is needless to say how much they vary with the temperature and with the rapidity with which they are heated or cooled.

From a consideration of the singularities in the liquidus curve, coupled with the microscopic examination of slowly cooled and chilled alloys, we were able to divide the copper-tin alloys into certain groups having special qualities.

So far I have directed attention to some of the difficulties encountered in the examination of binary alloys. When we come to ternary alloys the difficulties of carrying out an investigation are enormously increased, whilst with quaternary alloys they seem almost insurmountable; in the case of steels containing always six, and usually more, constituents we can hope at present to get information only by purely empirical methods. Large numbers of the elements and their compounds, which originally were laboriously prepared and investigated in the laboratory and remained dormant as chemical curiosities for many years, have, in the fullness of time, taken their places as important, and indeed essential, articles of commerce. I may remark that even during my own lifetime I have seen a vast number of substances transferred from the category of rare laboratory products to that which comprises materials of the utmost importance to the modern metallurgical industries. A few decades ago aluminium, chromium, cerium, thorium, tungsten, manganese, magnesium, molybdenum, nickel, calcium and calcium carbide, carborundum, and acetylene were unknown outside the chemical laboratory of the purely scientific investigator; to-day, these elements, their compounds and alloys, are amongst the most valuable of our industrial metallic products. They are essential in the manufacture of high-speed steels, of armour-plate, of filaments for the electric bulb lamp, of incandescent gas mantles, and of countless other products of modern scientific industry. All these metallic elements and compounds were discovered, and their industrial uses foreshadowed, during the course of the purely academic research work carried out in our universities and colleges; all have become the materials upon which great and lucrative industries have been built up. Although the scientific worker has certainly not exhibited any cupidity in the past, and has been content to rejoice in his own contributions to knowledge and to see great manufacturing enterprises founded upon his work, it is clear that the obligation devolves upon those who have reaped in the world's markets the fruit of scientific discovery to provide from their harvest the financial aid without which scientific research cannot be continued.

The truth of this statement is well understood by those of our great industrial leaders who are engaged in translating the results of scientific research into technical practice. As evidence of this I may quote the magnificent donation of 210,000*l*. by the British oil companies towards the endowment of the school of chemistry in the University of Cambridge; the noble bequest of the late Dr. Messel, one of the most enlightened of our technical chemists, for defraying the cost of scientific research; the gifts of the late Dr. Ludwig Mond towards the upkeep and expansion of the Royal Institution, one of the strongholds of British chemical research; and the financial support given by the Goldsmiths' and others of the great City of London Livery Companies (initiated largely by the late Sir Frederick Abel, Sir Frederick Bramwell, and Mr. George Matthey) to the foundation of the Imperial College of Science and Technology. The men who initiated these gifts have been themselves intimately associated with developments in both science and industry; they have understood that the field must be prepared before the crop can be reaped. Fortunately, our great chemical industries are, for the most part, controlled and administered by men fully conversant with the mode in which technical progress and prosperity follow upon scientific achievement; and it is my pleasant duty to record that within the last few weeks the directors of one of our greatest chemical manufacturing concerns have, with the consent of their shareholders, devoted 100,000*l*. to research. Doubtless other chemical industries will in due course realise what they have to gain by an adequate appreciation of pure science. If the effort now being made to establish a comprehensive scheme for the resuscitation of chemical industry within our Empire is to succeed, financial support on a very liberal scale must be forthcoming from the industry itself for the advancement of purely scientific research. This question has been treated recently in so able a fashion by Lord Moulton that nothing now remains but to await the results of his appeal for funds in aid of the advancement of pure science.

In order to prevent disappointment and a possible reaction in the future in those who endow pure research, it is necessary to give a word of warning. It must be remembered that the history of science abounds in illustrations of discoveries, regarded at the time as trivial, which have in after-years become epoch-making. In illustration I would cite Faraday's discovery of electro-magnetic induction. He found that when a bar-magnet was thrust into the core of a bobbin of insulated copper wire, the terminals of which were connected with a galvanometer, a momentary current was produced; while on withdrawing the magnet a momentary reverse current occurred—a purely scientific experiment destined in later years to develop into the dynamo and with it the whole electrical industry. Another illustration may be given: Guyton de Morveau, Northmore, Davy, Faraday, and Cagniard Latour between 1800 and 1850 were engaged in liquefying many of the gases. Hydrogen, oxygen, nitrogen, marsh gas, carbon monoxide, and nitric oxide, however, resisted all efforts until the work of Joule and Andrews gave the clue to the causes of failure. Some thirty years later, by careful application of the theoretical considerations, all the gases were liquefied. The liquefaction of oxygen and nitrogen now forms the basis of a very large and important industry.

Such cases can be multiplied indefinitely in all branches of science.

Perhaps the most pressing need of the present day lies in the cultivation of a better understanding between our great masters of productive industry, the shareholders to whom they are in the first degree responsible, and our scientific workers; if, by reason of any turbidity of vision, our large manufacturing corporations fail to discern that, in their own interest, the financial support of purely scientific research should be one of their first cares, technical advance will slacken, and other nations adopting a more far-sighted policy will forge ahead in science and technology. It should, I venture to think, be the bounden duty of everyone who has at heart the aims and objects of the British Association to preach the doctrine that in closer sympathy between all classes of productive labour, manual and intellectual, lies our only hope for the future. I cannot do better than conclude by quoting the words of Pope, one of our most characteristically British poets:

> By mutual confidence and mutual aid
> Great deeds are done and great discoveries made.

Economic and Educational Aspects of Zoology.*

By Prof. J. Stanley Gardiner, M.A., F.R.S.

Great as have been the results in physical sciences applied to industry, the study of animal life can claim discoveries just as great. Their greatest value, however, lies, not in the production of wealth, but rather in their broad applicability to human life. Man is an animal, and he is subject to the same laws as are other animals. He learns by the experience of his forbears, but he learns also by the consideration of other animals in relationship to their fellows and to the world at large. The whole idea of evolution, for instance, is of indescribable value; it permeates all life to-day; and yet Charles Darwin, whose researches did more than any others to establish its facts, is too often known to the public only as "the man who said we came from monkeys."

Whilst, first and foremost, I would base my claim for the study of animal life on this consideration, we cannot neglect the help it has given to the physical welfare of man's body. It is not out of place to direct attention to the manner in which pure zoological science has worked hand-in-hand with the science of medicine. Harvey's experimental discovery of the circulation of the blood laid the foundation for that real knowledge of the working of the human body which is at the basis of medicine; our experience of the history of its development gives us good grounds to hope that the work that is now being carried out by numerous researchers under the term "experimental" will ultimately elevate the art of diagnosis into an exact science. Harvey's work, too, mostly on developing chicks, was the starting-point for our knowledge of human development and growth. Instances in medicine could be multiplied wherein clinical treatment has been rendered possible only by laborious research into the life-histories of certain parasites preying often on man and other animals alternately. In this connection there seems reason at present for the belief that the great problem of medical science, cancer, will reach its solution from the zoological side. A pure zoologist has shown that typical cancer of the stomach of the rat can be produced by a parasitic threadworm (allied to that found in pork, Trichina), this having as a carrying host the American cockroach, brought over to the large warehouses of Copenhagen in sacks of sugar. Our attack on such parasites is made effective only by what we know of them in lower forms, which we can deal with at will. Millions of the best of our race owe their lives to the labours of forgotten men of science who laid the foundations of our knowledge of the generations of insects and flat-worms, the modes of life of lice and ticks, the physiology of such lowly creatures as Amœba and Paramecium, and of parasitic disease—malaria, Bilharziasis, typhus, trench fever, and dysentery.

Of immense economic importance in the whole domain of domestic animals and plants was the rediscovery early in the present century of the completely forgotten work of Gregor Mendel on cross-breeding, made known to the present generation largely by the labours of a former president of this Association, who, like a true man of science, claims no credit for himself. We see results already in the few years that have elapsed in special breeds of wheat, in which have been combined with exactitude the qualities man desires. The results are in the making—and this is true of all things in biology—but can anyone doubt that the breeding of animals is becoming an exact science? We have got far, perhaps, but we want to get much further in our understanding of the laws governing human heredity; we have to establish immunity to disease. Without the purely scientific study of chromosomes (the bodies which carry the physical and mental characteristics of parents to children) we could have got nowhere, and to reach our goal we must know more of the various forces which in combination make up what we term life.

In agricultural sciences we are confronted with pests in half a dozen different groups of animals. We have often to discover which of two or more is the damaging form, and the difficulty is greater where the damage is due to association between plant and animal pests. Insects are, perhaps, the worst offenders, and our basal knowledge of them as living organisms—they can do no damage when dead, and perhaps pinned in our showcases—is due to Redi, Swammerdam, and to Réaumur in the middle of the eighteenth century. Our present successful honey production is founded on the curiosity of these men in respect to the origin of life and the generation of insects. The fact that most of the dominant insects have a worm (caterpillar or maggot) stage of growth, often of far longer duration than that of the insects, has made systematic descriptive work on the relation of worm and insect of peculiar importance. I hesitate, however, to refer to catalogues in which perhaps a million different forms of adults and young are described. Nowadays we know, to a large degree, with what pests we deal, and we are seeking remedies. We fumigate and we spray, spending millions of money, but the next remedy is in the use of free-living enemies or parasitics to prey on the insect pests. The close correlation of anatomy with function is of use here in that life-histories, whether parasitic, carnivorous, vegetarian, or saprophagous, can be foretold in fly-maggots from the structure of the front part of their gut (pharynx); we know whether any maggot is a pest, harmless, or beneficial.

I will not disappoint those who expect me to refer more deeply to science in respect to fisheries, but its operations in this field are less known to the public at large. The opening up of our north-western grounds and banks is due to the scientific curiosity of Wyville Thomson and his *confrères* as to the existence or non-existence of animal life in the deep sea. It was sheer desire for knowledge that attracted a host of inquirers to investigate the life-history of river-eels. The wonder of a fish living in our shallowest pools and travelling two or three thousand miles to breed, very likely on the bottom in 2000 fathoms, and subjected to pressures varying from 14 lb. to 2 tons per square inch, is peculiarly attractive. It shows its results in regular eel-farming, the catching and transplantation of the baby eels out of the Severn into suitable waters which cannot, by the efforts of Nature alone, be sure of their regular supply. Purely scientific observations on the life-histories of flat-fish—these were largely stimulated by the scientific curiosity induced by the views of Lamarck and Darwin as to the causes underlying their anatomical development—and on the feeding value and nature of Thisted Bredning and the Dogger Bank, led to the successful experiments on transplantation of young

* From the opening address of the President of Section D (Zoology) delivered at the Cardiff meeting of the British Association on August 24.

plaice to these grounds and the remarkable growth-results obtained, particularly on the latter. Who can doubt that this "movement of herds" is one of the first results to be applied in the farming of the North Sea so soon as the conservation of our fish supply becomes a question of necessity?

The abundance of mackerel is connected with the movements of Atlantic water into the English Channel and the North Sea—movements depending on complex astronomical, chemical, and physical conditions. They are further related to the food of the mackerel, smaller animal life which dwells only in these Atlantic waters. These depend, as indeed do all animals, on that living matter which possesses chlorophyll for its nutrition, and which we call plant. In this case the plants are spores of algæ, diatoms, etc., and their abundance as food again depends on the amount of the light of the sun—the ultimate source, it might seem, of all life.

A method of ascertaining the age of fishes was sought purely to correlate age with growth in comparison with the growth of air-living vertebrates. This method was found in the rings of growth in the scales, and now the ascertaining of age-groups in herring shoals enables the Norwegian fishermen to know with certainty what possibilities and probabilities are before them in the forthcoming season. From the work on the blending together of Atlantic with Baltic and North Sea water off the Baltic Bight and of the later movements of this "bankwater," as it is termed, into the Swedish fjords can be understood, year by year, the Swedish herring fishery. It is interesting that these fisheries have been further correlated with cycles of sun-spots, and also with longer cycles of lunar changes.

The mass of seemingly unproductive scientific inquiries undertaken by the United States Bureau of Fisheries thirty to fifty years ago was the forerunner of their immense fish-hatching operations, whereby billions of fish-eggs are stripped year by year and the fresh waters of that country made into an important source for the supply of food. The study of the growth-stages of lobsters and crabs has resulted in sane regulations to protect the egg-carrying females, and in some keeping up of the supply in spite of the enormously increased demand. Lastly, the study of free-swimming larval stages in Mollusca, stimulated immensely by their similarity to larval stages in worms and starfishes, has given rise to the establishment of a successful pearl-shell farm at Dongonab, in the Red Sea, and of numerous fresh-water mussel fisheries in the southern rivers of the United States, to supply small shirt-buttons.

Fishery investigation was not originally directed to a more ambitious end than giving a reasonable answer to a question of the wisdom or unwisdom of compulsorily restricting commercial fishing, but it was soon found that this answer could not be obtained without the aid of pure zoology. The spread of trawling—and particularly the introduction of steam trawling during the last century—gave rise to grave fears that the stock of fish in home waters might be very seriously depleted by the use of new methods. We first required to know the life-histories of the various trawled fish, and Sars and others told us that the eggs of the vast majority of the European marine food species were pelagic—in other words, that they floated, and thus could not be destroyed, as had been alleged. Trawl-fishing might have to be regulated all the same, for there might be an insufficient number of parents to keep up the stock. It was clearly necessary to know the habits, movements, and distribution of the fishes, for all were not throughout their life or at all seasons found on the grounds it was practicable to fish.

But why multiply instances of the applications of zoology as a pure science to human affairs? Great results are asked for on every side of human activities. The zoologist, if he be given a chance to live and to hand on his knowledge and experience to a generation of pupils, can answer many of them. He is increasingly getting done with the collection of anatomical facts, and turning more and more to the why and how animals live. We may not know in our generation or in many generations what life is, but we can know enough to control that life. The consideration of the fact that living matter and water are universally associated opens up high possibilities. The experimental reproduction of animals, without the interposition of the male, is immensely interesting; where it will lead no one can foretell. The association of growth with the acidity and alkalinity of the water is a matter of immediate practical importance, especially to fisheries. The probability of dissolved food-material in sea- and river-water, independent of organised organic life and absorbable over the whole surfaces of animals, is clearly before us. Is it possible that that dissolved material may be even now being created in Nature without the assistance of organic life? The knowledge of the existence in food of vitamines, making digestible and usable what in food would otherwise be wasted, may well result in economies of food that will for generations prevent the necessity for the artificial restriction of populations. The parallel between these vitamines and something in sea-water may quite soon apply practically to the consideration of all life in the sea. Finally, what we know of the living matter of germ-cells puts before us the not impossible hope that we may influence for the better the generations yet to come.

So far I have devoted my attention primarily, in this survey of the position of zoology, to the usefulness of the subject. Let us now note where we stand in respect to other subjects and in meeting the real need for wide zoological study.

Let me give a few facts which have their sweet and bitter for us who make zoology our life-work. During the war we wanted men who had passed the honours schools in zoology—and hence were presumably capable of doing the work—to train for the diagnosis of protozoal disease. We asked for all names from 1905 to 1914 inclusive, and the average worked out at under fourteen per year from all English universities: an average of one student per university per year. In the year 1913–14 every student who had done his honours course in zoology in 1913 could, if he had taken entomology as his subject, have been absorbed into the economic applications of that subject. Trained men were wanted to undertake scientific fishery investigations, and they could not be found. Posts were advertised in animal breeding, in helminthology, and in protozoology, three other economic sides of the subject. The Natural History Museum wanted systematists, and there were many advertisements for teachers. How many of these posts were filled I do not know, but it is clear that not more than one-half—or even one-third—can have been filled efficiently. Can any zoologist say that all is well with his subject in the face of these deficiencies?

The demands for men in the economic sides of zoology are continually growing, and it is the business of universities to try to meet these demands. There are Departments of Government at home and in our Colonies which, in the interests of the people they govern, wish to put into operation protective measures, but cannot do so because there are not the men with the requisite knowledge and common sense required for inspectorates. There are others that wish for research to develop so as to conserve existing industries as well as to discover new ones, and they, too, are compelled to mark time.

In default, or in spite, of the efforts of the schools of pure zoology, attempts are being made to set up special training schools in fisheries, in entomology, and in other economic applications of zoology. Each branch is regarded as a science, and the supporters of each suppose they can, from the commencement of a lad's scientific training, give specialised instruction in each. The researcher in each has to do the research which the economic side requires. But he cannot restrict his education to one science; he requires to know the principles of all sciences; he must attempt to understand what life is. Moreover, his specialist knowledge can seldom be in one science. The economic entomologist, however deep his knowledge of insects may be, will find himself frequently at fault in distinguishing cause and effect unless he has some knowledge of mycology. The protozoologist must have an intimate knowledge of unicellular plants, bacterial and other. The animal-breeder must know the work on cross-fertilisation of plants. The fisheries man requires to understand physical oceanography. The helminthologist and the veterinary surgeon require an intimate knowledge of a rather specialised "physiology." All need knowledge of the comparative physiology of animals in other groups beyond those with which they deal, to assist them in their deductions and to aid them to secure the widest outlook. It is surely a mistake, while the greatest scientific minds of the day find that they require the widest knowledge, to endeavour to get great scientific results out of students whose training has been narrow and specialised. Such specialisation requires to come later, and can replace nothing. This short cut is the longest way round. The danger is not only in our science, but in every science.

Surely the time has now come for us to lift our eyes from our tables of groups and families, and, on the foundations of the knowledge of these, to work on the processes going on in the living body, the adaptation to environment, the problems of heredity, and at many another fascinating hunt in unknown country. Let us teach our students not only what is known, but, still more, what is unknown, for in the pursuit of the latter we shall engage eager spirits who care naught for collections of corpses. My own conviction is that we are in danger of burying our live subject along with our specimens in museums.

As a result of the wrong teaching of zoology, we see proposals to make so-called "Nature-study" in our schools purely botanical. Is this proposal made in the interests of the teacher or of the children? It surely cannot be for "decency" if the teaching is honest, for the phenomena are the same, and there is nothing "indecent" common to all life. "The proper study of mankind is man," and the poor child, athirst for information about himself, is given a piece of moss or duckweed, or even a chaste buttercup. Is the child supposed to get some knowledge it can apply economically? Whatever the underlying ideas may be, this course will not best develop the mind to enable it to grapple with all phenomena, the aim of education. If necessary, the school teacher must go to school; he must bring himself up to date in his own time, as every teacher in science has to do; it is the business of universities to help him, for nothing is more important to all science than the foundations of knowledge.

Native Races of the Empire.

AMONG the resolutions adopted by the General Committee of the British Association during the recent meeting at Cardiff, several dealt with problems connected with the native races of the Empire. Of these one referred to the deplorable conditions now prevailing among the aboriginal tribes of Central Australia, of which an account was recently given in these columns (see NATURE, July 8, p. 601). The Association urged upon the Federal Government and the Governments of Western Australia and South Australia the desirability of establishing an absolute reservation upon part of the lands now occupied by the tribes within the jurisdiction of these Governments in order that they might be preserved from extinction. The resolution further emphasised the necessity of establishing a medical service for the natives in order to check the ravages of disease by which they are now rapidly being reduced in numbers. It may be hoped that the influence of the Association will add force to the movement which has already been set on foot in South Australia, and induce the Governments concerned to take action in this matter.

A second resolution of the Association dealt with the desirability of initiating an anthropological survey of the natives of Western Australia. In this State the natives are under the control of Protectors of Aborigines, and are, for the most part, either located on Government farms or stations, or, if employed by private owners, the conditions of their employment are strictly regulated by the Protectors. Notwithstanding the measures taken for their well-being and preservation, which include a medical service and an organised system of food-supply for times of scarcity, they are dwindling in numbers. At the same time, in the changed conditions, the memory of their tribal customs and traditions is being lost. In the interests of science it is, therefore, highly desirable that some record should be made of their language, customs, traditions, and beliefs, as well as of their physical characters, before the older members of the tribes die out.

During the past summer, it will be remembered, Gen. Smuts introduced into the South African Parliament a Bill dealing with the native population. This Bill has been described as embodying the most important proposals in reference to the native problem since the Glen Grey Act. Briefly stated, its main provisions aim at improving the position of the native, and at the same time meeting his claim to a voice in the regulation of his own affairs by developing a system of local government based upon the tribal social organisation. A further resolution of the Association pointed out that any attempt to bring the native population into closer touch with the social and economic development of the country as a whole —the crucial problem of native legislation in South Africa—could hope to be successful only if it were based upon an intimate knowledge of native psychology and customs, and to this end it urged upon the Government of the Union the necessity for the establishment of an Ethnological Bureau for the collection of data and the study of native institutions.

Relativity.

DR. C. E. ST. JOHN gives in the *Observatory* for July some remarks on the search for the Einstein effect in the solar spectrum which was made last year by L. Grebe and A. Bachem at Bonn, and alluded to with approbation in a letter from Dr. Einstein, quoted in NATURE for January 29 last. Dr. St. John thinks that the dispersion of their spectrograph, 1 mm. per Å.U., was too low for work of this character, especially where the lines are so close together; further, the comparison spectrum was not photographed simultaneously, but before and after. The arrangements for eliminating the solar rotation are also not considered to have been exact enough.

Dr. St. John then goes on to criticise their suggested explanation for the failure of some other observers to detect the Einstein shift, which was, in short, that unsymmetrical emission lines become symmetrical in absorption. He shows that this neglects the light radiated by the vapour itself; since the absorbing vapour is at various depths in the sun, the probable result is shown to be an unsymmetrical absorption line. The further argument is made that many of the iron lines are unsymmetrical in the reverse direction to the carbon lines in question, so that if the explanation were true, these lines should give too large an Einstein effect, which they do not.

Dr. St. John concludes by saying that the object of his note is not to deny the existence of the Einstein effect, but merely to throw doubt on the completeness of the proof put forward by Messrs. Grebe and Bachem.

Astr. Nach., 5051, has an article by K. F. Bottlinger in which a possible astronomical test is suggested to distinguish between the relativist view of the speed of light and the earlier view of the stationary æther. He notes the very high radial velocities of the spiral nebulæ and clusters, and concludes that it is, *a priori*, likely that the velocity of our stellar system relatively to the æther is of the same order. If we take it as 1000 km./sec., and also assume that the direction of motion is not distant from the plane of the ecliptic, then eclipses of Jupiter's satellites will be alternately accelerated and retarded by some 14 sec., according as Jupiter lies towards the apex or antapex. The eclipses observed at Harvard make it pretty certain that there is no residual of this amount in the eclipse times; so that either the fixed-æther doctrine of light transmission is wrong or the speed of our system in the æther is only a small fraction of 1000 km./sec. This proposed test differs from the Michelson-Morley experiment in being a first-order effect, while that is of the second order.

University and Educational Intelligence.

Science of August 20 reports that the Harvard University School of Medicine has received 70,000*l.* from the Rockefeller Foundation for the development of psychiatry, and 60,000*l.* for the development of obstetric teaching.

THE *Chemist and Druggist* announces that the chair of chemistry in Berlin University, rendered vacant by the death of E. Fischer, will be filled by Prof. Haber, who will retain also his present position of director of the Emperor William Institute for Physical and Electro-Chemistry.

THE governors of the Northern Polytechnic Institute, Holloway, N.7, are, on September 27, opening a school of rubber technology. There will be day and evening courses designed mainly to train those who have already acquired a thorough knowledge of chemistry and physics and are now desirous of taking up responsible positions of a scientific and technical nature in rubber factories. The school will be in close touch with the industry, as it will be under an advisory committee composed of representatives of the manufacturers, producers, merchants, rubber engineers, etc. The director of the courses is Dr. P. Schidrowitz, who is a leading authority on rubber.

FROM the Simla correspondent of the *Pioneer Mail* for August 6 we learn that the text of the Muslim University Bill has been published. It is proposed to dissolve the Muslim University Association and the Mohammedan Anglo-Oriental College, Aligarh, and to transfer the property of these societies to a new body called "The Aligarh Muslim University." The Bill secures to the Government powers of control, and to the University the assurance of a permanent endowment. The University will be of the teaching and residential type, and its degrees will be recognised by the Government. Special features of the institution will be the instruction of Muslims in Muslim religious education, and the inclusion of departments of Islamic studies.

THE calendar of the Edinburgh and East of Scotland College of Agriculture for the year 1920–21 contains a detailed account of the courses of instruction available at this centre for the degree of B.Sc. of Edinburgh University, for the college diploma in agriculture, and for the college diploma in horticulture. Short courses in agriculture are provided during the winter months for the benefit of farmers and others who are unable to attend the full diploma course; these last for five weeks and extend over two years. In addition, a short course in forestry lasting four weeks may be given during the summer of 1921. The college also acts in an advisory capacity to farmers in the central and south-eastern counties of Scotland. Epidemics of insect or other pests on crops, trees, or live-stock are investigated, and information on farm and dairy management is always available. Manures and seeds for experimental work are tested at specially low rates with the idea of encouraging farmers to conduct experiments and trials in collaboration with the college staff.

THE current issue of the *British Medical Journal* is the annual educational number. As usual, it is addressed mainly to two classes: those who need information as to the course which must be followed in order to become legally qualified practitioners of medicine, and those who, having obtained qualifications to practise, are doubtful as to what particular branch of medicine they should choose as a career. The student is advised to aim at a university degree in medicine at the outset of his career, though it may be desirable to take also a diploma or licence. Warning is also given with regard to the question of expenses. The outlay involved in completing a medical curriculum varies, but 1500*l.* is reckoned to be the minimum for which the training can be accomplished at the present time. For the medical graduate, diplomate, or licentiate, once his name is on the Register of the General Medical Council, many paths are indicated; but he is reminded that whatever the branch of practice chosen, the main reward of medical life is the knowledge of good work well done. Against this it is urged that the spirit of the times is all in favour of the extension and co-ordination of the public health services. This has occasioned an increase in the official medical services, but their position is not well defined at present, and prospects of promotion are uncertain.

THE new session of the Sir John Cass Technical Institute, Aldgate, will commence on Monday, September 27. The courses of instruction provided are especially directed to the technical training of those engaged in chemical, metallurgical, and electrical industries and in trades associated therewith. Special courses of higher technological instruction form a distinctive feature of the work of the institute. The curriculum in connection with the fermentation industries includes courses of instruction in brewing and malting; in the history, cultivation, and use of the hop; and in the micro-biology of the fermentation industries. These courses are arranged for persons engaged in the practical and scientific control of breweries, maltings, and other fermentation industries who desire to acquire a knowledge of the technology and principles underlying their daily operations. A connected series of lectures on fuel and power is also included in the syllabus of the chemistry department for the forthcoming session. In the department of physics and mathematics special courses of lectures will be given in colloids, the methods employed in their investigation and their relation to technical problems; in differential equations and vector analysis; and in the theory and application of mathematical statistics. Full details of the courses are given in the syllabus of the institute, which can be had on application at the office of the institute or by letter to the principal.

ALTHOUGH the scientific study of human and animal nutrition is of even greater importance to this country than to the United States of America, it has attracted fewer workers and received far less financial support here than on the other side of the Atlantic. Consequently, the public-spirited munificence of Mr. John Quiller Rowett in contributing 10,000*l.* towards the endowment of an Institute for Research in Animal Nutrition in connection with the University of Aberdeen and the North of Scotland College of Agriculture is especially to be commended. The new institute, which will appropriately be named the Rowett Research Institute, has already secured the services of two first-rate investigators. Dr. J. B. Orr, the director, was recently associated with Prof. E. P. Cathcart in the conduct of a very important study of the energy output of soldiers, while Dr. R. H. A. Plimmer, chief biochemist in the institute, has had a distinguished career as a research worker in the Physiological Institute of University College, London. An agricultural correspondent, writing in the *Aberdeen Daily Journal* of July 9, directs attention to the enormous economic loss, estimated at 30 millions sterling per annum, due to diseases of animals and plants, while the unsatisfactory state of knowledge respecting problems of human nutrition and food-supply was the subject of a criticism by a committee of the Royal Society. It is obvious that no single institute can cope with the mass of work which urgently needs to be done, but the precedent just established is valuable, and the scientific colleagues of Drs. Orr and Plimmer will look forward with confidence to their future successes in a field of research so far inadequately cultivated.

Societies and Academies.

PARIS.

Academy of Sciences, August 2.—M. Henri Deslandres in the chair.—The president announced the death of Armand Gautier.—G. **Humbert**: The representation of an integral by indefinite Hermite forms in an imaginary quadratic body.—M. **Michkovitch**: Observations of the periodic comet Tempel II. made at the Marseilles Observatory with the Eichens equatorial of 26-cm. aperture. Positions for July 20 and 21 are given, with those of comparison stars. The comet was circular, diameter 5 to 6 seconds of arc, and magnitude 10·2. The nucleus was well defined.—R. **Jarry-Desloges**: Contribution to the study of telescopic images.—P. **Ditisheim**: The determination of the difference of longitude between Greenwich and Paris by chronometers carried by aeroplane. The regular aeroplane service between London and Paris was utilised for the transport of twelve chronometers. The general mean of sixty-one operations was 9m. 20·947s. ±0·027s. for the difference of longitude between Greenwich and Paris.—J. **Villey**: The application of Righi's method to the discussion of Michelson's experiment.—G. **de Rocasolano**: The ageing of colloidal catalysts (platinum, palladium). In the decomposition of hydrogen peroxide solutions by colloidal solutions of platinum, the velocity constant increases with the time between the preparation of the catalyst and its use, reaches a maximum, and then falls. Hydrosols of palladium exhibit similar phenomena.—Er. **Toporescu**: The removal of copper oxide and nickel oxide from solutions by precipitates of ferric oxide.—Ch. **Depéret** and P. **Mazeran**: The Bresse of Chalon and its Quaternary terraces.—L. **Mayet**, P. **Nugue**, and J. **Dareste de la Chavanne**: The discovery of a skeleton of *Elephas planifrons* in the Chagny sands at Bellecroix, near Chagny (Saône-et-Loire). This species has not, up to the present, been identified amongst the Pliocene elephants of Western Europe.—G. **Zeil**: Tectonic earthquakes and variations of latitude.—O. **Mengel**: Tectonic of the secondary synclinal of Amélie-les-Bains.—H. **Colin**: Crystallisable sugar and free acids in plants.—R. **Anthony** and J. **Liouville**: The characters of adaptation of the kidney of Ross's seal (*Ommatophoca Rossi*) to the conditions of aquatic life. The kidney of this seal presents the maximum of characters of specialisation, with respect to its aquatic life, met with amongst Pinnipeds. It is comparable with the kidney of Cetaceans of a primitive type, such as Mesoplodon.—L. M. **Bétancès**: The existence of thrombocytes in *Astacus fluviatilis*.—C. **Gessard**: A pyocyanic culture.—J. **Danysz** and Mme. St. **Danysz**: Attenuation of the pathogenic effects of certain micro-organisms by mixture with dead organisms of the same race.—M. **Fouassier**: The micro-organisms persisting in milk after pasteurisation: their *rôle* in the decomposition of hydrogen peroxide.

SYDNEY.

Linnean Society of New South Wales, June 14.—Mr. J. J. Fletcher, president, in the chair.—A special general meeting "in commemoration of the centenary of the birth of Sir William Macleay." The meeting was devoted to the presidential address, "The Society's Heritage from the Macleays," followed by an exhibit of mementoes of the Macleays. The many claims which the memory of Sir William Macleay has on the members of the society were recalled; details of the development of their interest in science of the direct line of the family, and the history of the Macleay collections up to 1874, were given. The mementoes exhibited consisted of portraits and copies of books and drawings of zoological interest, most of which had been presented to members of the Macleay family by their authors. Later, Prof. J. T. Wilson unveiled the society's Honour Roll, on which are inscribed the names of members who served abroad during the Great War.

June 30.—Mr. J. J. Fletcher, president, in the chair.—H. J. **Carter**: Notes on some Australian Tenebrionidæ, with descriptions of new species; also of a new genus and species of Buprestidæ. Thirty-three species of Tenebrionidæ belonging to eighteen genera (of which one is proposed as new) are described as new. As a result of the comparison by Mr. K. G. Blair of specimens with the types in the British Museum, a number of mistaken identifications are corrected and further synonymy is suggested. A re-examination of the species of the closely allied genera Dædrosis, Licinoma, Brycopia, and their allies has led to considerable modifications of tabulations previously published.—G. H. Hardy: The male genitalia of some robber-flies belonging to the sub-family Asilinæ (Diptera). The results of a study of a number of species of Australian robber-flies belonging to the subgenus Asilus indicate that the male genitalia afford a satisfactory basis for identifying the species. Eleven species (of which one is described as new) are dealt with and their male genitalia figured.

The British Association and National Life.

WE published a fortnight ago (Sept. 2, p. 13) some observations made by Dr. R. V. Stanford, our local correspondent for the recent meeting of the British Association at Cardiff, upon "the apathy of local people of the educated classes to the presence of the Association" in the city, and the neglect of the opportunity which such a meeting may afford of stimulating public interest in scientific achievements and their applications. There is, we believe, a feeling among many members of the Association that efforts should be made to increase its usefulness by bringing it into closer contact with thoughtful members of all classes of the community and encouraging a fuller representation of the new generation of scientific workers. Institutions, like organisms, must be adapted to their circumstances, or suffer eventual extinction. The British Association is still in a state of strong vitality, but it is not making progress; and not to be in touch with advancing times signifies retrogression.

It is easy to be satisfied with this condition, and to consider that all is of the best in the best of all scientific organisations, but that is not the spirit of development. There is no need for scientific men now to work in secret cells, and carry on their discussions in conclaves; on the contrary, the world is more eager than ever it was to learn and to use the results of scientific research. Whatever apathy exists on the part of the general public as regards these advances is due largely to the neglect of national bodies like the British Association to adjust themselves to changing national needs. The public does not understand the Association, and the Association makes little endeavour to show the bearing of scientific methods and principles upon most subjects of vital importance in national polity and industrial affairs.

When the Association was founded, in 1831, one of its first purposes was stated to be "to obtain a greater degree of national attention to the objects of science"—a phrase which in the present rules reads "to obtain more general attention for the objects of science." Whether the change was deliberate or not we do not know, but we prefer to think that "national attention" is what was originally intended, and we desire to urge that this aspect of the Association's activities should be given more consideration than it now receives, instead of concentrating upon the work of the sections. There were no sections when the Association began its existence, but only committees upon various branches of science. At the Cambridge meeting in 1833 the sections were: (1) Mathematics and Physics; (2) Philosophical Instruments and Mechanical Arts; (3) Natural History, Anatomy, Physiology; (4) History of Science. Chemistry, with Mineralogy, became a section in the following year, and Statistics formed a sixth section. Then came in succession Geology and Geography, Zoology and Botany, Mechanical Science, and various other changes, leading to the present denomination of sections. Anthropology became a section in 1884, Physiology ten years later, Botany in 1895, Educational Science in 1901, Agriculture in 1912, and at the recent Cardiff meeting the General Committee recommended that Psychology be promoted from a sub-section to a section, making thirteen in all. Each section is autonomous, and there is no co-ordinating committee to make them part of a composite organisation, or suggest how they may combine their forces for the common good. The Association is like a great industrial works in which each shop produces what it pleases, and no one has the duty of building up a noble structure from the various parts.

Two separate functions may be distinguished in the work of each section. One is the presentation of papers for discussion by workers in the particular fields to which they refer, and half-a-dozen such allied workers gathered together can gain more from one another by informal conversation than can possibly be elicited when their remarks are addressed to an audience without special knowledge of the subjects under consideration. If, however, a section is to be regarded purely as an assembly of specialists, and papers read are prepared on this assumption, then fifty sections would not be sufficient to meet the present-day differentiation of scientific subjects. As such subdivision is impracticable, intensive discussion is usually impossible, and very few members of a section are able to make profitable comments upon papers of a specialised kind. Authors ought not, indeed, to assume that a section as a whole consists of specialists in their own minute fields, but should address themselves rather to workers generally in a broad department of scientific activity. Members who attend any particular section do not expect to learn much that is new of their own special subjects, but they do want to know the chief lines of progress in related branches of work. A section ought not, in fact, to be addressed as a scientific or technical society, but as a Royal Institution assembly. Its main function should not be technical discussion by specialists for specialists, but the enlightenment of an extensive group of workers as to main lines of advance in fields not specifically their own.

We know, of course, that there are practical difficulties in ensuring generally intelligible discourses from men whose main interest is in actual research. Genius for discovery is not often associated with the art of literary or of vocal expression, so that it is not uncommon to find readers of papers and openers of discussions in sections offending the most elementary principles of public speaking. They converse with themselves instead of addressing the back row of their audience; if they use a lantern their slides are often mixed, and are usually changed by the irritating instruction "Next, please," long ago discarded by every public lecturer of any reputation; and if they use a blackboard, what they scribble upon it can be read by the front row only. All these sins of commission, as well as others of omission, may be forgiven when a circle is small and those who compose it are familiar with the details of the subject, but an audience which fills a section room has a right to expect its interests to be considered, and not to leave the room with a feeling of disappointment or in a more confused state than when they entered it.

There would not be the slightest difficulty in securing large audiences for joint meetings of several sections, interested in different aspects of broad scientific subjects, provided that reasonable care were devoted to the selection of the subjects and the opening speakers. The success of the symposia arranged by the Faraday Society through Sir Robert Hadfield's enterprise shows how keen scientific workers are to occupy a common platform and understand each other's contribution to a common cause. The organising committees of related sections of the British Association would perform a much greater service to the scientific community by united action on these lines than by accepting as their separate programmes a variety of papers of which few are novel or of wide interest. The separate action of sections upon matters of common interest was exemplified by four resolutions brought before the General Committee at Cardiff. The Section of Zoology condemned the views of the "Investigators" of the Secondary Schools Examination Council of the Board of Education that zoology was not so suitable as botany as a school subject; the Section of Geography asked that geography should be recognised by the Board as a subject for advanced courses in secondary schools; and that of Anthropology urged that work of a regional survey type should receive official encouragement and anthropometric measurements should be made of pupils in continuation schools. There is an Educational Science Section of the Association where all these subjects could be considered appropriately in joint session with the sections which brought them forward, yet the action was taken independently and without consultation with the very members who are supposed to be concerned with the development along scientific lines of all schools and scholars. A joint meeting of several sections on "Science and the School," or similar subject, might have suggested a means of adjusting the various claims made upon the curriculum and the resources of schools, and such a meeting should obviously have been held before the Council was asked to father resolutions of individual sections upon subjects which concern other sections also.

We mention this episode merely as an example of the fissiparous tendency of the sections, and as a reason for more frequently dissolving the membrane which separates contiguous cells. When joint meetings are arranged, however, it should be remembered that the larger the intended appeal the more general must be the subject selected, and that the greatest common factor of knowledge possessed by the audience will be correspondingly lower. Huxley once said that in a public lecture he addressed himself to the least intelligent member of his audience, and though it may not be essential for a speaker at a joint meeting of sections to accept this standard, yet if he wishes to claim the close attention of most of his hearers he should not soar so much above it as is commonly done.

What we have said as to the intensive and extensive functions of sections of the Association is on behalf of the general members, who are engaged in scientific education or research. No one waits for an annual meeting of the Association in order to describe a new discovery or announce a development, and as the Association does not publish papers, except by special resolution, there is nothing to induce authors, if they wish their work to be recorded, to make new communications to the sections. The chief aim should be, therefore, not a miscellany of papers of interest to a few specialists, but clear expositions of broad advances which appeal to the many. Beyond this duty of the Association to the general body of scientific workers is the even more important relation of the Association to national life and public interest. When the Association first met, and for many years afterwards, it was the only national peripatetic organisation of a scientific or technical kind. Now, however, the Institution of Naval Architects, Iron and Steel Institute, Royal Sanitary Institute, Society of Chemical Industry, Museums Association, Institute of Metals, and other bodies concerned with pure or applied science, hold their annual meetings at different places each year, and the Association no longer occupies a unique position in this respect. Notwithstanding this fact, the Association remains the only body which can represent the contributions of research to the whole field of progressive natural knowledge—whether applied or not—and we believe that a much larger public, in any place of meeting, would take active part in its work if greater consideration were given to wide national questions and the bearing of local conditions upon them.

The Association has come to be regarded as a technical or professional organisation, like the British Medical Association and similar bodies, with the result that the intelligent public in the locality where it meets takes little interest in it—at any rate, not so much as it did at one time. At the recent meeting in Cardiff, the total attendance was 1378; in 1891 it was 1497; and at almost every meeting in recent years the numbers have been less than at the previous meeting in the same place. Scientific workers are much more numerous than they were in the earlier years of the Association, and the fact that the attendance at meetings does not show a corresponding increase, but a decrease, is a sign that should not be disregarded by an organisation that desires to expand.

Unlike the other societies and institutions mentioned above, the British Association looks for members and support to the public in the locality in which its annual meeting is held. It cannot expect, however, to meet with the response desired unless it does much more to create and foster interest in local and national subjects with which science may be concerned, and by securing for the meetings the presence of prominent public men. Distinguished statesmen, great captains of industry, and leading representatives of labour should be approached, and we believe that many of them would be glad to range themselves on the side of scientific workers and testify to the national significance of contributions to national knowledge. There is no lack of subjects with which such men may be appropriately associated. What is lacking is the eloquent advocacy which well-known public men can give.

We are not alone in suggesting that a change of policy and of programme is needed to bring the Association into line with present conditions. Two of the technical journals—the *Electrician* and the *Chemical Age*—have each recently expressed regret that at the Cardiff meeting evidence of progress in electrical science, engineering, and chemistry was not prominently displayed by the papers presented to the sections devoted to these subjects; and they consider that the Association is now out of touch with the times. The former journal suggests that to make the annual meeting of greater interest to the public generally there should be a series of communications on the latest discoveries in physical science, the problems of electric traction, advances in wireless communication, domestic uses of electricity, and related matters in contact with daily life; and it remarks, "We do feel that at a time when electrical science is being more and more applied to the solution of industrial and domestic problems it is a pity that an opportunity such as the annual meeting of the British Association affords of placing what is being done in simple and, so far as possible, in non-technical language before the general public should have been so conspicuously missed."

Even technical men, therefore, do not look to the Association for specialised work, but for broad surveys of large regions and descriptions of outstanding peaks in scientific fields. Above all, they ask for attention to subjects of vital interest to the community, and this plea is the main object of the present article. The Association should stand not for esoteric, but for exoteric, philosophy, and thus bring within its sphere all who believe that progressive thought, with accurate knowledge, form the only sure foundation upon which man can build a structure that will withstand the polemic storms of the present and the world shocks which promise to assail it in the future.

Ewing's "Thermodynamics."

Thermodynamics for Engineers. By Sir J. A. Ewing. Pp. xiii+383. (Cambridge: At the University Press, 1920.) Price 30*s*. net.

ONE of the chief fascinations of thermodynamics is the way in which it ramifies into other branches of science, following the manifold transformations of energy. The fundamental laws reappear in so many different aspects in relation to the quantities which are the subject of measurement in the different branches, such as chemistry, electricity, radiation, etc., that it affords one of the most interesting standpoints from which to view the growth of natural philosophy and to study the correlation of its parts. For the same reason it is difficult for the worker in any one branch to follow the applications of thermodynamics to other subjects with the principles of which he is unfamiliar; and he is apt to find that the discussion of his own subject in a general survey is necessarily lacking in the practical details and numerical data which would be required to enable him to make any use of it for his special purpose. Accordingly it is usual in treatises on special subjects, such as steam turbines, or petrol motors, or refrigerating machines, to include one or more chapters on the principles of thermodynamics in relation to the subject discussed. This is a very natural compromise, but involves a great deal of repetition of elementary principles, while it frequently fails, owing to limitations of space or lack of generality, in providing a sufficiently solid foundation for further research. So much effort has been wasted in the past, and is still being wasted, by inventors and experimentalists, in pursuit of fancied improvements which a wider knowledge of thermodynamics would have shown to be illusory, that such knowledge should be regarded as an essential part of the equipment of the scientific engineer, however abstract and theoretical it may appear to the practical man at first sight.

Among English treatises on thermodynamics, few, if any, appear to have been written primarily from the point of view of the engineer. We are therefore all the more disposed to welcome a book with this object from a master of clear exposition, whose books on kindred subjects are already so well known and appreciated by engineers. The method adopted by the author of the present work is to begin with the elementary notions and their interpretation in practice, and to defer the mathematical relations until the reader may be supposed to have become familiar with the fundamental ideas as physical realities, and is presumably able to apply them to practical problems.

In pursuance of this general scheme, the first six chapters of the book deal with general principles, explained in the first instance in relation to ideal gases, and then applied to practical problems in discussing the properties of actual fluids, the theory of the steam-engine and of refrigeration, jets and turbines, and internal-combustion engines. Since the general principles of thermodynamics have not changed in the last few years, it naturally follows that most of the material employed in this part of the work is the same as in the author's previous books on "The Steam-engine and Other Heat-engines" and on "The Mechanical Production of Cold." But the material has been rearranged as a connected exposition of the principles, and brought up to date in minor particulars, such as the adiabatic equation for dry steam, and the effect of supersaturation on the discharge through a nozzle. Most of the problems discussed are so well worked out that there is little room for difference of opinion, and so clearly explained that it would be difficult to suggest any improvement. It is only when we come to more recent or debatable problems, especially where the experimental data are still uncertain, that it becomes possible in a few cases to criticise the author's views.

The importance of devoting adequate consideration to the properties of the working fluid as affecting the operation of a heat-engine has been more fully recognised in recent years. Accordingly the author has included in the chapter on internal-combustion engines a discussion of the effect of increase of specific heat at high temperatures, and has added an appendix on the molecular theory of gases, which should serve as a useful introduction to the theory of the variation of specific heat. In discussing this subject the author naturally follows in the main the views of his successor at Cambridge, Prof. B. Hopkinson, whose work he did so much to inspire. Prof. Hopkinson's view that the loss of efficiency, as compared with the ideal air-standard for a given compression-ratio, could be attributed entirely to the increase of specific heat, provides an effective working hypothesis, but the experiments of Sir Dugald Clerk on the variation of specific heat, and on the composition of the mixture shortly after the attainment of maximum pressure, appear to show that the question is not quite so simple. The later development of Hopkinson's own experiments on radiation in gaseous explosions by W. T. David indicates other factors which have to be considered in framing a complete theory, and may have an important influence on the design of engines for large units of power or for high speeds. The completeness or otherwise of combustion at the moment of maximum pressure may fairly be regarded as still an open question and a fit subject for further experiment.

In developing the general thermodynamic relations between the various properties of a substance, the chief difficulty is to make a selection among the many possible permutations. It need scarcely be said that the author makes a very judicious selection for the purpose in view, and develops chiefly those relations of the energy, entropy, and total heat, and of their coefficients, the specific heats and the cooling-effects, which are required in applying the principles of thermodynamics to the correlation of the properties of the working fluids employed in heat-engines. In the next chapter he proceeds to apply the general relations to particular fluids, defined by well-known forms of characteristic equation, showing how the equation selected determines the necessary relations between the coefficients. In this connection the author discusses the general properties of gases and vapours, as illustrated by Amagat's experiments at high pressures, and Van der Waals's equation for the critical state. But most of the numerical illustrations are drawn from the properties of steam at moderate pressures, as being the most important for engineering purposes and the most accurately determined by experiment. He shows how the formulæ employed secure exact thermodynamic consistency between the various properties, but he refrains from discussing the experimental evidence with regard to the particular values selected for the constants, because this is a separate question beyond the scope of pure thermodynamics.

At the same time the book is not without some bearing on physical experiment, because no modern experimentalist can afford to represent his results by purely empirical formulæ without inquiring how far they are consistent with other measurable properties of the substance investigated. This requires a knowledge of the thermodynamical relations, and the ability to apply them, which this book is intended to teach. Thus one of the practical uses of the thermodynamic relations is to find the form and slope of lines on diagrams, such as the Mollier diagram, which are becoming so popular among engineers. Mollier had great difficulty in constructing his diagram for carbonic acid near the critical point, owing to the scarcity and uncertainty of the experimental data. Most of the missing data have since been supplied by the experiments of Prof. Frewen Jenkin and Mr. D. R. Pye, who made great use of thermodynamic relations in constructing their diagram, and incidentally showed that some of Mollier's lines were of an impossible shape. They had some difficulty, however, in fixing the form of the saturation line for the liquid, which appeared to show a point of inflexion a few degrees below the critical point. The author suggests that the point of inflexion should be at the critical point itself. This is in some ways an attractive suggestion, but the proof does not seem to be quite conclusive, and would be difficult to reconcile with the orthodox view of the critical state, according to which the critical isothermal itself possesses this property. It is possible that the singularity at the critical point may be of a nature different from that commonly assumed. It would be difficult to decide such a point by experiment, but it is just in such cases where experiment fails that thermodynamics is most useful.

H. L. C.

Forensic Medicine.

A Handbook of Medical Jurisprudence and Toxicology for the Use of Students and Practitioners. By Dr. W. A. Brend. Third edition, revised. (Griffin's Medical Pocket-book Series.) Pp. xiii+317. (London: Charles Griffin and Co., Ltd., 1919.) Price 10s. 6*d*. net.

THIS edition has been revised and enlarged. The chapter on the legal relationships of insanity and other abnormal states of mind, which has been entirely rewritten, gives a very good account in a brief and concise form of a branch of forensic medicine which usually presents difficulties to the medical student and practitioner. Chap. xvii., dealing with "Medical Privileges and Obligations," is excellent, and gives in a collected form the duties and responsibilities which may devolve upon a medical practitioner as a result of his registration by the General Medical Council. This subject has been much neglected in most of the existing text-books on forensic medicine, and the present edition of this work supplies a much-needed want by providing valuable advice on the line of conduct to be adopted by medical men in the many difficult situations which are likely to arise in medical practice.

The various chapters on forensic medicine and toxicology are well written, but a few points need correction and revision in a future edition. For example, in reference to "exhumation" it is stated that disinfectants should be freely used. The use of disinfectants in exhumations should, on the contrary, always be avoided, since in suspected poisoning, which is a common reason for exhumation, the use of disinfectants is likely seriously to complicate the analysis. A classical example of this was the Crippen case, where the sprinkling of a disinfecting powder containing carbolic acid and traces of arsenic on the remains added considerably to the difficulties of the analysis.

In the chapter dealing with blood-stains reference should have been made to the benzidine test. Also sufficient importance is not attached to the serum test for human blood, which must now be regarded as being trustworthy, and one of the routine tests which should always be adopted in the examination of blood-stains in order to determine with certainty that they are those of human blood and not of other animals, such as sheep, horse, ox, etc.

We do not find any account of the influence of status lymphaticus in cases of sudden death. In the chapter on abortion there is no mention of the effect of quinine and pituitary extract, which are powerful abortifacients. Reference should have been made to the changes introduced during the war with regard to the procedure in coroners' courts. In the chapters on toxicology one would wish to have seen some description of the poisons, such as tetrachloroethane, trinitrotoluene, etc., which were responsible for so many cases of fatal jaundice amongst munition workers.

The book claims to be a handbook of medical jurisprudence, and as such it has certainly justified its publication, for it will be most useful to students for examination in forensic medicine and to medical practitioners.

Industrial Administration.

Industrial Administration: A Series of Lectures. By A. E. Berriman and Others. (Publications of the University of Manchester. No. cxxxi.) Pp. vii + 203. (Manchester: At the University Press; London: Longmans, Green, and Co., 1920.) Price 7*s*. 6*d*. net.

THE lectures published in this volume were delivered in the department of industrial administration in the College of Technology, Manchester, during the session 1918–19, by various well-known authorities on subjects relating to industrial administration. Mr. Seebohm Rowntree discourses on the "Social Obligations of Industry to Labour," and endeavours to fix the minimum wage compatible with the maintenance of a working man and his family in decency and moderate comfort. In answer to the question: "Can industry afford to pay the minimum wages indicated?" he believes that the principal source to which we must look for increased wages is increased efficiency in the organisation and administration of industrial enterprises. Many British factories are run on very inefficient lines, with antiquated machinery and ill-trained staff and workers, and in such cases the profits are inconsiderable even when wages are low.

A most interesting and striking lecture on "Occupational Diseases" was given by Dr. T. M. Legge, who, in his capacity as Medical Inspector of Factories, has been largely responsible for the precautions taken to abate the evils of certain industrial processes. The success of the precautions may be judged from some of the figures he quotes. Whilst in 1900 there were 358 cases of lead poisoning among white-lead workers, and 200 among pottery workers, in 1913 the cases were reduced to 29 and 62 respectively. Of more recent interest are the cases of trinitrotoluol poisoning, which developed with alarming frequency in the latter half of 1916. There were 43 fatal cases in the six months, and another 32 fatal cases in the first six months of 1917, but by that time the chief cause of the poisoning—viz. absorption through the skin—was tracked down, and suitable precautions were taken. In the next six months fatal cases fell to 12, and in the following year to 10.

Other lectures deal with the applications of psychology to industry, industrial fatigue, and education in factory management and administration, whilst Dr. L. E. Hill gives an interesting account of his well-known investigations on "Atmospheric Conditions and Efficiency" by means of the katathermometer. Perhaps the lecture of most general interest is that on "Industrial Councils," by Mr. T. B. Johnston. The national council recently formed in the pottery industry is described in some detail, and it is to be hoped that in course of time similar councils will be formed in all the other staple industries. Equal numbers of representatives of the manufacturers and of the operatives sit on all committees, and they not only consider questions relating to wages, employment, and the conditions of production, but also encourage research into the industry, and consider inventions and improvements designed by the workpeople. Most important of all, the employers disclose full details of wages and profits, so that the workpeople can determine whether they are being fairly treated or not, and at the same time the consumer can ascertain whether the prices he is charged are due in any degree to profiteering. As Mr. Johnston rightly points out, "the first essential to a better understanding between Capital and Labour is that all the cards should be laid on the table."

H. M. V.

Fuel Economy.

The Use of Low-grade and Waste Fuels for Power Generation. By John B. C. Kershaw. Pp. x+202. (London: Constable and Co., Ltd., 1920.) Price 17s. net.

THE great increase in the cost of coal has naturally directed the attention of users of fuel to the question of fuel economy, the possibilities of which lie in two directions—the utilisation of lower-grade fuels and waste combustible material, and the more efficient utilisation of all fuels. Mr. Kershaw's book deals adequately with both these aspects of this important question. His earlier chapters are devoted to the consideration of peat, wood waste, small coal and washery waste, and other minor combustibles. In his second section he deals with fuel sampling and analysis and with the scientific control of combustion in practice.

Mr. Kershaw defines low-grade solid fuel as containing more than 25 per cent. of ash and 10 per cent. of moisture, or, in all, 35 per cent. of incombustible material. The cynic may remark that such a definition covers most of the coal at present marketed! Small coal, however, no matter what its ash and moisture content, is also "low grade," and the author includes all coal and coke passing a ½-in. mesh sieve.

Means are available, and Mr. Kershaw describes them clearly and discusses their merits lucidly, by which the lower-grade fuels may be utilised, but possibly, because of present economic conditions, the more general utilisation of low-grade coal and colliery refuse will be confined to the large, centralised power schemes which have been recommended, and individual consumers will more specifically seek economy in the better utilisation of the class of fuel they have been accustomed to use, and for which their plants can be adapted with but little expenditure. Mr. Kershaw's treatment of this side of the question is adequate and practical, and he is to be congratulated on producing this small volume at this opportune moment, for it is one to command the attention of all interested in the use of fuel for every industrial purpose.

Text-books of Chemistry.

(1) *An Introductory Course in Quantitative Chemical Analysis, with Explanatory Notes, Stoichiometrical Problems, and Questions.* By Prof. G. McPhail Smith. Pp. x+206. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1919.) Price 9s. net.

(2) *Quantitative Analysis by Electrolysis.* By A. Classen, with the co-operation of H. Cloeren. Revised, rearranged, and enlarged English edition by Prof. W. T. Hall. Pp. xiii+346. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1919.) Price 17s. 6d. net.

(3) *Industrial Organic Analysis: For the Use of Technical and Analytical Chemists and Students.* By Paul S. Arup. Second edition, revised and enlarged. Pp. xi+471. (London: J. and A. Churchill, 1920.) Price 12s. 6d. net.

(4) *A Foundation Course in Chemistry: For Students of Agriculture and Technology.* By J. W. Dodgson and J. Alan Murray. Second edition, thoroughly revised. Pp. xii+241. (London: Hodder and Stoughton, Ltd., 1920.) Price 6s. 6d. net.

(5) *Chemistry in Everyday Life: Opportunities in Chemistry.* By E. Hendrick. Pp. xii+102. (London: University of London Press, Ltd., 1919.) Price 3s. 6d. net.

IN the multiplicity of text-books one naturally looks for evidence of the trend of progress as demonstrated in new editions and new volumes. We want to find the aim of the author and why he has considered it desirable to add one more to the books that are already so many that the teacher and the student find it difficult to select the one that will suit them best.

(1) Prof. Smith says of his manual that it is for those who have completed courses in elementary chemistry and qualitative analysis and are beginning work in quantitative analysis. We are glad to see, so far as this is evidence of it, a return to the natural sequence of quantitative following qualitative work. The student at this stage ought to be able to appreciate the introductory section in which the author, after some excellent advice, proceeds to consider the balance, its use and care, methods of weighing, the calibration of weights, various errors and their elimination; the precipitation, filtering, and washing of precipitates, in which he uses the theories of modern physical chemistry; drying, ignition, evaporation, and the use and calibration of volumetric apparatus. The student is thus well prepared to work intelligently, but throughout the book, although the instructions are definite, almost every direction is accompanied with the

reason for the procedure. So the student is helped to study and not merely to perform. One evidence of progress is the appreciation of the filter-pump at its true value: "When paper filters are employed, the use of a vacuum pump to promote filtration is of doubtful advantage in quantitative analysis"; its disadvantages "more than offset the possible gain in time." While the volumetric section is more extended than usual, the number of gravimetric exercises of a simple kind seems to us unduly few. After the determination of chlorine, iron, and sulphuric acid in simple salts, we pass to sulphur in an ore, phosphoric anhydride in a phosphate rock, and so on. Still it is better to do little thoroughly than much superficially. The ten pages devoted to the electrolytic determination of copper (1) with stationary electrodes, (2) with a rotating anode, is a part in which we think a few more practical exercises might have been introduced with advantage, but perhaps time does not permit of this in the laboratories of the University of Illinois.

(2) Prof. Hall has prepared this edition of "Classen," from the translation made six years ago, without further reference to the German text. Some new procedures have been added, and the order and the theoretical explanations have been somewhat modified. He says: "A simple application of the modern electronic theory seems to clarify rather than befog the vision of the beginner. An attempt, therefore, has been made to apply this theory a little more closely than has been done in most of the other well-known books on the subject." After 100 pages of introductory matter which describes in general terms electrolysis and the various details that affect it and its applications in analysis, the practical methods of determining twenty-nine metals are described, then methods of separating thirteen of the commoner metals from great varieties of other metals, and finally the electrolytic analysis of a considerable number of industrial products. The comparisons of various methods of depositing the different metals are often tabulated, so that a great amount of information is given in a comparatively small space, and the references to original communications being numerous, the student can turn at once to the full accounts of investigations if he wishes to pursue any particular matter. This edition of an authoritative treatise will be welcomed by all who are interested in the subject.

(3) In preparing the second edition of "Industrial Organic Analysis" Mr. Arup has added a chapter on sugars, some recently published methods, and references to the literature of the subject-matter. This last is an especially valuable feature, because the author has prepared the volume for those who have had a "thorough training in chemistry and physics," and are therefore able to take full advantage of such assistance. The author not only gives methods of analysis, but also describes the details of manufacture or treatment of the material dealt with so far as is necessary to carry out with intelligence the analytical process and to interpret usefully the results. The subjects treated of are coal and coke, coal-tar and its distillation products, fatty oils and fats, soap, petroleum and its distillation products, milk and butter, starch and its decomposition products, flour, barley, and malt, sugars and alcohol, and preservatives and colouring matters in foods. These headings are interpreted liberally; for instance, we have under one or the other infants' foods, margarine, cocoa, the sterilising and pasteurising of milk, and so on. The author is eminently practical, but in no sense merely empirical.

(4) It will probably long remain a debatable matter whether a student's elementary course in chemistry should be pursued with a definite aim as to the use he is ultimately to make of it. This means more or less passing over subjects that appear to be of little or no importance to him, and expanding the treatment of matters that appear to bear specially upon his future work. But the future may bring into prominence the very subjects that are scantily treated. The authors in their "Foundation Course" include, besides general chemistry and a consideration of various inorganic materials, a little organic chemistry, devoting forty-four pages to aliphatic compounds and five pages to aromatic compounds. Physical chemistry is dealt with in twenty pages. To this extent the book provides a good general introduction to these subjects.

(5) Mr. Hendrick, with few exceptions, gives sound information and good advice in his little volume, but it is marred by a familiar style and such statements as "the temperature of the electric arc, which is about as hot as sizzling sinners getting their reward." C. J.

Oil Geology.

Popular Oil Geology. By Prof. Victor Ziegler. Pp. viii+149. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1918.) Price 11*s.* 6*d.* net.

TO render any scientific subject into easy reading, to make such reading void of technical details while keeping strictly within the limits of accuracy and precision, is a problem tackled by many, but overcome only by few. To this few we may add the name of Victor Ziegler, who, in his

"Popular Oil Geology," has produced a remarkably neat and illuminating little volume which may be confidently recommended to all interested in the subject of petroleum technology.

Prof. Ziegler has condensed a very large subject into a comparatively small space, and it must be admitted that in but few instances have the principles of the science suffered from this treatment. The author has the obvious knack of extracting the real substance of the various branches of oil geology, and of presenting this without unnecessary "padding," so that the book really achieves its purpose of being an introduction to larger volumes dealing in more detail with the principles of the subject.

The chapters on the laws of the migration and accumulation of oil and gas, on oil structures and oil fields, and on prospecting are particularly good, while the final remarks on oil investments, culminating in a parody of John Hammond's rules for investors, are quite as amusing as they are apposite.

The book is profusely illustrated, a great many of the maps and diagrams being taken from the U.S. Geological Survey publications, as acknowledged in the preface. While this practice of reproduction is useful within limits, it is one that can be very easily overdone. To say that it shows lack of originality is possibly an exaggeration, but when such diagrams as that included on p. 77 occur again and again in various American publications we have examined, it seems disappointing that a new rendering of the same subject cannot be invented. But for that and the price (which for a book of this description is rather excessive), this little volume deserves a place on the bookshelf of the layman, student, and expert alike.

H. B. Milner.

Our Bookshelf.

Ozone. By Prof. E. K. Rideal. (A Treatise of Electro-chemistry.) Pp. ix + 198. (London: Constable and Co., Ltd., 1920.) Price 12*s*. net.

In recent years ozone has attracted increasing interest on account both of its value as an aid to research in organic chemistry, and of its actual or possible applications on the industrial scale. The literature of the subject is, however, widely scattered, hence in compiling this monograph, which forms a section of the treatise on electrochemistry in course of production under the editorship of Mr. Bertram Blount, the author has done good service to chemists.

An interesting introductory portion, which deals with the early history, the general properties, and the occurrence of ozone, is followed by five chapters in which the methods of production—chemical, thermal, and electrolytic—and in particular production by means of ultra-violet radiations and of the silent electric discharge, are adequately described. These are succeeded by a summary of the principal investigations on the catalytic decomposition of ozone, and in the next chapter its more important industrial applications—*e.g.* in the sterilisation of water, the "purification" of air, the bleaching of oils and fats, and the manufacture of vanillin—are discussed in some detail. The last chapter contains an account of the methods of detecting and estimating ozone.

The author has been distinctly successful in his effort to collect and correlate the various references to ozone which occur in chemical literature, and his monograph will be welcomed if only for that reason. In addition, it contains a valuable summary of what is known—after all not very much—about ozone, and by indicating problems which remain to be solved should also serve to promote investigation. It is therefore all the more regrettable that several of the pages of an otherwise praiseworthy book are disfigured by grammatical errors, or by sentences so carelessly constructed as to be obscure in their meaning.

Microscopy: The Construction, Theory, and Use of the Microscope. By Edmund J. Spitta. Third edition. Pp. xxviii + 537 + xxviii plates. (London: John Murray, 1920.) Price 25*s*. net.

The first edition of this work was reviewed in Nature for February 6, 1908. The work has gained a well-deserved popularity, and two further editions have since been called for. In each of these the opportunity has been taken to bring the subject-matter so far as possible up to date, and to indicate important new developments. In the present edition may be noted especially the reference to low-power objectives designed to give great depth of focus and a flat field, valuable especially for the photography of relatively large specimens of appreciable thickness, where good definition has to be obtained of parts lying in different planes. To illustrate the use of these, a considerable number of new plates have been added, which include some admirable reproductions of photographs obtained with modern objectives of this type.

Mention must also be made of the photographs added to illustrate the use of the term "critical definition." Unfortunately, the term, though no doubt convenient, is not one to which a precise significance can be given, and it thus always presents difficulties to the learner, who comes to appreciate only by experience the sense in which it is employed.

The "Addenda," amounting to more than twenty pages, contain useful notes of some recent improvements, with a few convenient tables. Attention is directed especially to the use of the newer Kodak filters for obtaining blue light with a powerful illuminant, details being given. The index has been improved and additional references have been inserted, notably those to the pages of the text in the descriptions of the plates, which are of material assistance. In short, the third edition exhibits throughout the same careful attention to detail as its predecessors, and the work fully maintains its position as the most valuable handbook to the practical use of the microscope as an optical instrument.

Oil-Finding: An Introduction to the Geological Study of Petroleum. By E. H. Cunningham Craig. Second edition. Pp. xi+324+xiii plates. (London: Edward Arnold, 1920.) Price 16*s.* net.

THE second edition of this work has been enlarged to nearly double the bulk of the first, the scheme remaining the same, and there is little to add to the review which appeared in NATURE of August 8, 1912, except to say that the revision of the work has distinctly improved its quality. The author is still insistent on the importance of the theory of the origin of petroleum, and for him that of vegetable origin and subsequent concentration, controlled by geological structure, is supreme. The treatment of this subject, regarded as of vital importance, is inadequate, in so far that less than six pages are devoted to theories of inorganic origin, and thirty-four to a polemical examination of the hypotheses of animal or vegetable origin; yet there are many facts in the known distribution of petroleum more easily explicable on the supposition of inorganic than on that of organic origin. At present there are grave difficulties in the way of regarding either as even approximately complete, and there is this to be said for the theory and principles of application advocated by the author, that they will lead to correct conclusions in about nine cases out of ten, and in the tenth success will depend mainly on luck, instinct, or intuition. The chapters on field-work are very distinctly improved, the approximate and imperfect methods indicated being relegated to their proper place, as expedients which may have to be resorted to by force of circumstances, and not, as inexperienced readers of the first edition might easily be led to believe, preferable to more exact and thorough methods.

Keys to the Orders of Insects. By Frank Balfour-Browne. Pp. vii+58. (Cambridge: At the University Press, 1920.) Price 7*s.* 6*d.* net.

MR. BALFOUR-BROWNE has placed students under an obligation by publishing this useful series of tables, founded on notes drawn up for those who have the advantage of attending his courses of entomology at Cambridge. The twenty orders of insects recognised are first distinguished by means of a "key," and then the families of those six orders that may be regarded as of greatest economic importance—the Orthoptera, Rhynchota, Lepidoptera, Coleoptera, Diptera, and Hymenoptera—are further discriminated. The characters given are those of adults only; but in later editions the author proposes to deal with some of the larval forms. It is to be hoped that these tables will serve to familiarise the rising generation of entomologists with the Comstock system of nomenclature for wing nervuration, and to hasten its use—perhaps with the modifications rendered necessary by Dr. Tillyard's recent researches—among special students of all orders of insects. Some points of detail in the tables need correction. It is implied that all Thysanura have the jaws retracted within the head; this is not the case with the two most conspicuous families, Machilidæ and Lepismidæ. Palps are not present in the Anoplura and Rhynchota; probably "absent" was meant, but "present" has been printed. In a new edition it would be well, if possible, to break up the unnatural group "Polymorpha" among the beetles, and it is to be hoped that the sale of the book may enable the publishers to reduce the price, which must be considered high, although blank interleaved pages have been considerately provided for students' notes.

G. H. C.

Catalogue of the Lepidoptera Phalaenae in the British Museum. Supplement. Vol. ii.: *Catalogue of the Lithosiadae (Arctianae) and Phalaenoididae in the Collection of the British Museum.* By Sir George F. Hampson. Plates xlii–lxxi. (London: British Museum (Natural History), 1920.) Price 32*s.* 6*d.*

THE present volume is supplementary to vol. iii. of the great Catalogue of Lepidoptera Phalænæ. Owing to the European War it has remained in manuscript since 1915, but has been brought up to date so far as possible. It includes no references to German publications which have appeared since August, 1914, for the reason just mentioned. Two families of Lepidoptera are dealt with—the Lithosiadæ (Arctianæ) and the Phalænoididæ. Of the former, vol. iii. included 147 genera and 845 species, and to these are added in the present work twenty-five genera and no fewer than 1215 species. Of the second family (Agaristidæ of many authors), the original numbers are increased by seven genera and eighty species. In his selection of family and generic names Sir George Hampson has adopted views on nomenclature which have been largely rejected by most systematists, but he has wisely adhered to the system utilised in the already issued volumes. We need only add that the book is well printed and up to the standard of the previous parts of the catalogue.

Historical Geography of Britain and the British Empire. (In two books.) Book I. *The Making of England; The Making of Empire; The Establishment of Empire:* B.C. 55 *to* A.D. 1815. By T. Franklin. Pp. viii+216. (Edinburgh: W. and A. K. Johnston, Ltd.; London: Macmillan and Co., Ltd., n.d.) Price 2*s.* net.

BOOK I. is divided into three sections; the first deals with the growth of England from the time of the Roman invasion to the beginning of the sixteenth century, the second with the building-up of the British Empire during the two succeeding centuries, and the third with the establishment and consolidation of the Empire. Geography plays a minor part in the book, and the title is therefore likely to be misleading. Nevertheless it is refreshing to find a school history in which the author has departed from the time-honoured custom of subdividing his work according to the number of monarchs with whom he intends to deal.

Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of Nature. *No notice is taken of anonymous communications.]*

"Spiranthes autumnalis" in Scotland.

Great is the debt which British botanists—experts and amateurs alike—owe to the authors of the "Handbook of the British Flora." It is scarcely possible to imagine a simpler or more convenient key to the natural orders. But a good deal has been added to our knowledge of British plants since the last revision of the work by Sir Joseph Hooker forty years ago, and it is to be regretted that before the latest edition was published in 1918 it was not passed through the hands of a competent editor to bring the work up to date. For instance, it is stated that the little orchid, *Spiranthes autumnalis*, is found nowhere north of Yorkshire and Westmorland. I had always accepted this as gospel until last August, when, while exploring a wood on Speyside for *Linnaea borealis*, I came upon a little colony of "lady's tresses." Since then I have received trustworthy information that Spiranthes grows in the valley of the Nairn.

I do not know whether this addition to our Scottish flora has been recorded hitherto.

Herbert Maxwell.

Monreith.

Associated Squares and Derived Simple Squares of Order 5.

The six different types shown below are distinguished by the position of the complementary numbers (1, 25; 2, 24; 3, 23, etc.):

Constant 65.

A is an associated square, and by means of Dr. Planck's method of complementary differences it has been found that there are 3034 squares of this type, and each one can have sixteen inversions, making a total of 48,544 squares.

B. By exchanging the first and second numbers in both rows and columns of A, type B is obtained. There are thus 48,544 squares of type B.

C. By exchanging the first and fourth numbers in both rows and columns of A, type C is obtained. There are thus 48,544 squares of type C.

D. Every associated square cannot be converted into type D, but by means of Dr. Planck's method of complementary differences the number can be found. It is 972, and each one can have one inversion, making a total of 1944.

E. But 36 of these 972 can be converted into type E, and each one can have three inversions, making a total of 144.

F. Also the same 36 of type D can be converted into type F, and each one, again, can have three inversions, making a total of 144.

In the last three types, squares can be constructed for each type by taking the columns as the rows and *vice versa*, and I have included these in the totals. This obviates the necessity of including types of squares when these three types are turned round through a quarter of a circle.

Totals:

A	...	48,544
B	...	48,544
C	...	48,544
D	...	1,944
E	...	144
F	...	144
		147,864

These are only six out of thirty-four types of 5th order, making a total of nearly 700,000 squares.

J. C. Burnett.

Barkston, near Grantham, Lincs.

The Spectrum of Nova Cygni III.

Cloudy and hazy nights have seriously interfered with spectroscopic observations of this nova at Stonyhurst, but some good photographs of the spectrum were obtained with the Whitelow short-focus prismatic camera on the nights of August 29 and 30 and September 6 by Father J. Rowland. The spectrum, the bright band spectrum characteristic of the second stage in the progressive spectra of novæ, remained practically the same during that interval. The bright hydrogen bands extended, on the average, over 20 Å. units, and consisted each of two components. There was a bright extension on the violet edge of H_ζ, about λ 3870, which was possibly the first sign of the incoming of the nebular band.

Besides hydrogen, the most prominent radiations were due to enhanced iron lines, 5316, 5169, 5019, and 4924. On September 6, 4924 alone of the four radiations named left an impression on an isochromatic plate. Between H_β and H_γ were two prominent and very broad bright bands, the first extending from λ 4703 to 4628, and the other marked by three maxima corresponding to the iron lines λ 4584, 4550, and 4516. Between H_γ and H_δ were three very prominent radiations, λ 4303 iron, 4228, and 4170, the last being almost as intense as H_δ. The K calcium band was also doubled, and extended over about 15 Å. units. On August 29 the spectrum extended far into the violet. On September 6 the visual magnitude was estimated as lower than the fifth. No obvious change in the spectrum could be detected on a weak impression secured on September 10. The iron line 4924 was still present. H_ϵ was very brilliant.

A. L. Cortie.

Stonyhurst College Observatory, Blackburn.

The Timbers of Commerce.[1]

A BOOK dealing with timbers in general is very welcome. The text-books in English on this subject give, as a rule, little information on the uses and commercial aspects of the numerous species which are imported into this country. There is one exception—Laslett's small book on "Timber and Timber Trees," which is still valuable, though in some respects out of date, the last edition having appeared in 1894. Other works, good as regards the microscopical structure of a considerable number of woods, fail to throw much light on their manifold uses and special properties.

Mr. Howard's work consists mainly of a descriptive account of the commercial uses of a great number of timbers, which are listed in alphabetical order, the botanical and vernacular names being indiscriminately used. This arrangement is open to criticism, as it occasionally mingles together species which have little in common but their trade name, and disjoins others which belong to the same genus—*e.g.* basswood (p. 23) and lime (p. 122), species of Tilia. Two indexes do away, however, with this difficulty. The title is somewhat misleading, as the timbers enumerated and described are not world-wide, but are practically confined to those imported into London and Liverpool. No attention is paid to any others. One fails to find, for example, an account of interesting woods like that of the nettle-tree (Celtis) in France, or of the sandarac wood (Tetraclinis) of Algeria, the latter remarkable for its subterranean burrs, out of which beautiful articles of cabinet-ware have been made from the time of the Cæsars to the present day.

Oak Grove, Kyre Park, Worcestershire. (From "A Manual of the Timbers of the World.")

Mr. Howard was, however, wise in limiting his subject to the timbers of which he has first-hand knowledge, and this inspires confidence in the facts that he discloses. With more than forty years of experience in the timber trade he is able to give his own personal opinion upon the merits and characteristics of a great number of species. The book, in short, is excellent on the commercial side. A scientific treatise on timbers in general has yet to be written. Such a work would contain a clear account of the structure of the woods concerned, and of their provenance, properties, and defects, and would point out how and why each species is adapted to the special purposes for which it is used. Mr. Howard's book is incomplete in these respects, and is, moreover, devoid of references to the numerous special papers and publications that have appeared on many species. Nevertheless, it is a valuable addition to the library of the merchant, the engineer, the architect, and the student at the present juncture. The British Empire Timber Exhibition, lately held, showed the wealth of timbers possessed by our Dominions, Colonies, and India, many of which are totally ignored by manufacturers and little known in the trade. Mr. Howard's book will awaken interest and disseminate valuable information.

"The Timbers of the World" is attractive in appearance, being illustrated by a series of repro-

[1] "A Manual of the Timbers of the World, their Characteristics and Uses." By A. L. Howard. Pp. xvi+446. (London: Macmillan and Co., Ltd., 1920.) Price 30s. net.

ductions from excellent photographs of timber operations and forest scenes in many parts of the British Empire. The inclusion in the work (pp. 328–84) of the tables of strengths of woods, which were published by Laslett, is probably justified by the fact that Laslett's book is out of print. These tables are of considerable value, but as Laslett had not at his disposal apparatus for determining the moisture contents of the woods examined, the figures are not so trustworthy as they seem. It would certainly be preferable in future, as Mr. Howard admits, to conduct experiments on woods "with some named and specific percentage of moisture." Moreover, we are now aware, thanks to the numerous tests carried out of late years at the Forest Products Laboratory, Madison (U.S.A.), that there is a remarkable variation in the properties of timbers of the same species from different logs and from different localities. That timbers are in no way comparable with metals in the uniformity of their physical characteristics is of course well known.

A chapter on the artificial seasoning of timber, with a note on laboratory and working tests, contributed by Mr. S. Fitzgerald, will prove useful.

There are errata and misstatements in this book, but they are not of a kind to detract much from its real value, which consists in the thoroughly practical nature of the information given on the uses, conversion, and utilisation of so many kinds of timber. Some of the inaccuracies may, however, be pointed out. It is, unfortunately, not true that, as stated on p. 118, "larch disease has practically disappeared." The explanation of the name "sycamore" on p. 266 is entirely erroneous, and is an instance of the strange fascination that wrong etymology has for many people. The word "sycamore" was originally applied in Greece to a species of Ficus, and is now transferred in England to the large-leaf maple, *Acer pseudoplatanus*, and in America to the Western plane, *Platanus occidentalis*. A whole page—p. 164—is devoted to the etymology of the term "wainscot oak," about which there is no doubt. It could have been expressed in three lines. "Wainscot" is derived from a Dutch word (fourteenth century) which means "oak wood with a wavy grain"; in other words, "wainscot oak" is "figured oak." Mr. Howard misquotes Skeat, who ("Concise Etymological Dictionary," p. 597) expressly warns the reader against the wrong derivation attributed to him by Mr. Howard. A regrettable error occurs on p. 211, where *Abies pectinata*, the European silver fir, is called "silver spruce." As is pointed out on pp. 262–63, the latter name can be applied only to the Sitka spruce (*Picea sitchensis*). Endless

Fine example of African mahogany curl. (From "A Manual of the Timbers of the World.")

embarrassment to the landowning class resulted during the war from the confusion between the names "silver spruce" and "silver fir."

The Structure of the Atom.[1]

By C. G. DARWIN.

II.—*Atomic Number (continued.)*

IT would involve very prolonged work to get the atomic numbers accurately by direct experiment with scattered α-particles. Fortunately, this is not necessary, as there exist much more convenient indirect means of determining them. The invention of a powerful method of studying X-ray spectra enabled Moseley to examine the spectra from a sequence of elements. Whereas visual spectra have a highly complicated structure, and exhibit the same periodicity as do chemical pro-

[1] Continued from p. 54.

perties, for the X-rays this periodicity disappears, and is replaced by a perfectly orderly progression from element to element. Each spectrum can be derived from the last by a reduction of the wave-lengths according to a simple rule. . Thus an examination of a sequence of spectra reveals the true order of the elements, and gaps are shown by a missing term in the sequence. It will be seen that Moseley's method only gives differences of atomic number, and not the numbers themselves. To determine these we must find one of them in some other way. This is not difficult, for we know from observation on α-particles that helium must have atomic number 2; and though X-rays have not been observed for the first dozen elements, the periodic table is perfectly regular in that region, and it is impossible to believe that it could contain any gaps. More remarkable still, if the formula for the wave-length of the X-ray spectrum is extrapolated right back to hydrogen, it reproduces the fundamental line of the famous Balmer series. The numbers which were given in the table are therefore certainly correct.

In formulating the principle of atomic number we said that it, and not the weight, completely determines the chemical character of the element. This statement is justified by a line of evidence which we must now consider. The process of radio-active transformation consists in the emission of an α- or a β-particle from the nucleus, and this emission transmutes the atom into a new element. From a study of the chemical behaviour of these successive elements it was concluded that the emission of an α-ray shifts the element two places to the left in the periodic table, while the emission of a β-ray shifts it one place to the right. This fits in exactly with the conception of atomic number, for when the nucleus loses an α-particle (that is, a helium nucleus of atomic number 2) its own number must be reduced by two, whereas the loss of a β-particle out of the nucleus must raise the number by one, since the β-particle is an electron and has a negative charge. By a study of all the radio-elements we can work out chains of transformations such as are shown in Fig. 1. These chains start at uranium 92 and thorium 90, and, so far as we know, all end at lead 82. It will be seen that most of the numbers are occupied several times over. For example, 90 has ionium, the parent of radium, as well as thorium and several others. It has been found that the spectra of ionium and thorium are exactly the same, and that all chemical methods are quite powerless to separate them from each other. They are chemically identical because they have the same atomic number, but they differ in the nature of their nuclei, as witnessed by the difference in their radio-active behaviour. Such substances are called *isotopes*.

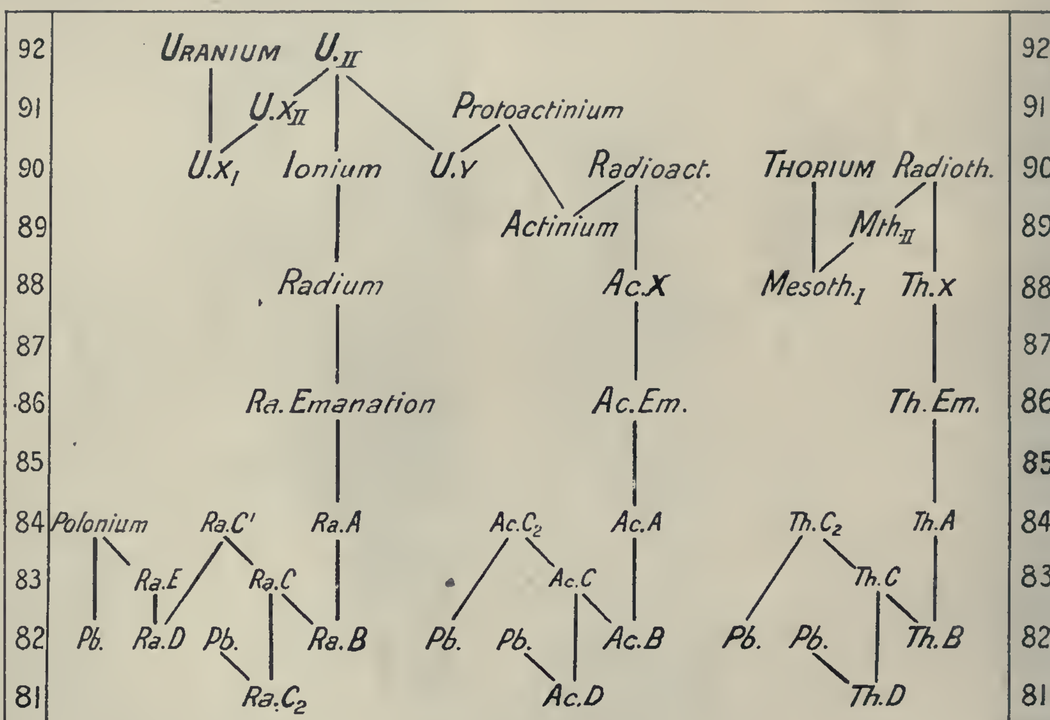

FIG. 1.—The Radio-active Transformations. In every case a step two downwards is accompanied by the emission of an α-particle, and one upwards by a β-particle. Actinium is derived from uranium or an isotope, but the connection shown is rather conjectural. Thorium C has a third branch about which little is known. The final products in all cases are believed to be lead, but as they are not radio-active it is uncertain how many of the isotopes are really different. In the Table of Atomic Numbers they were counted as all different, and one was added on to allow for the existence of common lead. One was also added there for 81 and 83 to represent the non-radio-active types of thallium and bismuth.

The existence of isotopes was first proved from radio-active evidence. But besides possessing the radio-active characteristics of the atom, the nucleus also carries its mass, and this suggests that isotopes may differ in mass. The first evidence for this can be derived from the study of the figure. For example, uranium at 92 loses an α-particle and two β-particles, and thus returns to 92; and the loss of the particles must have reduced its weight from 238 to 234. The same principle has been experimentally verified by finding that the atomic weight of lead from radium is perceptibly different from that of ordinary lead. We shall see in the next article that ordinary elements also have isotopes; for convenience, these have been given in the table, in so far as they have been yet discovered. It should perhaps be here mentioned that the mere difference of atomic weight theoretically implies certain minute differences in chemical behaviour, but it can be shown that these are out of all proportion less than those between substances of different atomic number, so much so that it is an almost impossibly laborious task to separate isotopes by ordinary chemical or physical processes.

The general outcome of our argument has therefore been that atomic number, and not atomic weight, is the determining factor in the behaviour of an element. There are exceptions to this rule—for example, specific heat depends directly on the weight of the atom—but apart from these exceptions the importance which in the past the chemist and spectroscopist have given to atomic weight must in the future be attached to atomic number.

(To be continued.)

Obituary.

PROF. WILHELM WUNDT.

WITH the death on September 1, at the advanced age of eighty-eight years, of Prof. W. Wundt a remarkable and striking personality passes away from the scientific world. If, as a philosophic thinker, he did not possess either the speculative genius or the insight of a Herbart or a Lotze, he was yet a mind of extraordinary versatility, whose comprehensive acquaintance with vast fields of knowledge has rarely, if ever, been rivalled. His amazing activity as a writer has been for long a source of wonder to his contemporaries; year after year books, pamphlets, and articles have issued from his pen in steady succession, and there was no department of philosophy which he thus left untouched. Naturally, this tremendous literary output is not all of equal worth, but almost everything he wrote exhibits a surprising mastery of detail and power of turning it to account in reaching theoretical conclusions. As a teacher, too, his influence has been extremely wide and far-reaching; students from all parts of the world met in his class-room, and worked in the Institute of Experimental Psychology at Leipzig, the foundation of which was due to him.

Wilhelm Wundt was born on August 16, 1832, at Neckarau, near Mannheim. In 1851 he began the study of medicine at Heidelberg, and in subsequent semesters pursued his medical studies further in Tübingen and Berlin. Fr. Arnold and E. Hasse, of both of whom he always spoke with great respect, were his teachers in Heidelberg; while in Berlin Johannes Müller was then at the height of his fame, and in the great man's laboratory Wundt was for some time busily engaged. On the completion of his career as an undergraduate, he turned his attention first of all to pathological anatomy, and took his degree in Heidelberg in 1886, his *Arbeit* being a thesis on the condition of the nerves in inflamed and degenerated organs. In the following year he habilitated in the Faculty of Physiology of the same university, and remained in Heidelberg for some years as Helmholtz's assistant in the physiological laboratory. During that period he published two monographs on physiological subjects—the "Beiträge zur Lehre von den Muskelbewegungen" (1858) and the "Beiträge zur Theorie der Sinneswahrnehmung" (1859–62)—in the long Introduction to the latter of which he first outlined his conception of the scope of empirical psychology as a natural science, and insisted upon the necessity of using experimental methods in the observation of mental processes. It was in consequence of his being occupied with the problems of sense-perception that the young physiologist was induced to enter the domain of metaphysical inquiry, and started to read, "ziemlich ziel- und planlos," as he tells us, the works of Kant, Herbart, and Leibniz. The first fruits of these and of his more strictly psychological labours saw the light in the "Vorlesungen über Menschen- und Thierseele" of 1863—a volume in which, as he afterwards expressed it, he set about his task with more zeal than discretion, and which he came to look upon as containing the wild oats of his youthful days. There followed in 1865 a text-book of "Human Physiology" (which apparently had a large circulation, a fourth edition appearing in 1878), and in 1867, when he was already a professor in Heidelberg, a voluminous treatise on what he called "Medicinische Physik," intended to acquaint medical students with the exact physical methods needful in medical investigation. Probably the most elaborate piece of experimental research undertaken by himself was that of which account is given in his "Untersuchungen zur Mechanik der Nerven und Nervencentren," the first part of which was published in 1871 and the second in 1876. The bold and ingenious hypothesis, which he here put forward, of reflex phenomena has not been sustained by later investigation, but it was a resolute effort to explain a large group of facts of which an adequate theory is still to be sought, and it led incidentally to not a few interesting observations, some of which are referred to by Sherrington in his book on the nervous system.

Wundt succeeded F. A. Lange as professor of "Inductive Philosophy" in Zürich in 1874. In the same year the "Grundzüge der physiologischen Psychologie" was published in two volumes (increased to three volumes of huge proportions in the fifth edition of 1902). His sojourn in Zürich, however, was of short duration. In 1875 he removed to Leipzig, on his appointment to one of the philosophical chairs in the university; and, despite several attempts on the part of other centres of learning to draw him away, Leipzig continued to be his home for the last forty-five years of his life.

In his "Antrittsreden" of 1874 and 1876 Wundt sketched the view which, as professor in Leipzig, he consistently maintained of the function of philosophy, and of the influence which philosophy, as he conceived it, should exert upon the empirical sciences. Philosophy, he contended, is based upon the results reached by the empirical sciences, and forms their necessary supplement and completion. It has for its main purpose to consolidate into a coherent system the generalisations of the special sciences and to trace back to their ultimate grounds the principles and presuppositions which the special sciences are compelled to use. But, he insisted, if philosophy is dependent for its material upon the special sciences, the latter are no less dependent upon philosophy for a justification of the fundamental concepts without which scientific explanation would be impossible. And great as had been the influence of Kant, Hegel, and even Schopenhauer upon the science of their time, he foresaw that the influence of exact philosophical thought upon the science of the future would be greater and more significant still. From this point of view it was natural that, as a philosophical inquirer, his attention should be directed at the outset to the problems of knowledge. His "Logik," the first volume of which was devoted to "Erkenntnislehre," was published in 1880, and the second, dealing with the methods of scientific investigation, in 1883 (in later editions the "Methodenlehre" expanded into two volumes), is undoubtedly a work of considerable importance, and may justly be said to occupy a distinct place in the history of logical science. In the first volume the author tries to steer a middle course between the purely formal view of logic on the one hand and the metaphysical view of it on the other, while in the second volume he undertakes by far the most accurate and detailed examination in existence of the principles, methods, and results of the special sciences. The study of logic in this country has suffered much through want of an English translation of a book which in its way is unique. The next of Wundt's larger works to be published was the "Ethik" (1886)—an investigation, as he described it, of the facts and laws of the moral life. Although not, I think, on the same level of value as the "Logik," it is a suggestive and stimulating treatise, basing an ethical system upon the doctrine of evolution, which here takes form for him especially in the ideas of human progress and of the "Gesamtwille." Finally, as the culmination of his attempt at philosophical construction, the "System der Philosophie" appeared in 1889, in many respects the most original of all his writings, and that by which his position in the development of philosophical thought is most definitely established.

The position is not one that can be indicated in a few words. Wundt took his departure from the point of view of what he called "immediate experience"—experience as he conceived it would be prior to the elaboration of it by reflective thought, which is itself evolved from it. The data of such primordial experience might be classified under the three heads of presentations, affective processes, and conative activities. Originally, presentations are, he insisted, for the experiencing subject not different from objects; they are *Vorstellungsobjecte,* wholes which contain the elements, as yet undifferentiated, which thought in the course of time distinguishes. The development of thought means that presentations come to be separated from the objects to which they are taken to refer; and, when the attempt is further made to conceive these objects as freed from contradiction, they have to be represented as destitute of such attributes as sense-qualities, which, as intuitively experienced, must belong to the subject. The world of physical science is, therefore, wholly conceptual in character; for physical science the ultimate constituents of objects are material points. On the other hand, a psychological treatment of the subjective factors leads to the notion of activity and passivity as mutually involved in every mental state. But we are compelled to conceive of activity as that which is essentially characteristic of our conscious being and to ascribe the passivity we experience to the objects which affect us and thereby counteract our activity. The pure activity which he thus took to be characteristic of the subject Wundt designated will; will he regarded as the essence of subjective existence. Ontologically, however, there was no stopping short of a monistic view of the universe. In the long run the concept of object rests upon an effect which the will experiences, and what thus limits the will is not in itself immediately known. We can only conclude, on the basis of our own experience, that what occasions passivity must in itself be active; and, since will is the only activity known to us, we are justified in ascribing our passivity to another will. Presentations, then, are to be traced back to the reciprocal action of different wills. A further step brought the author to his final contention. Our personal individual wills are not, he argued, elementary will-units, but units of a higher order comprising many elementary will-units. And these units of higher order may be thought of as in turn uniting to form higher unities still (*e.g.* the collective will of society), until in the end we reach the thought of a world-will including within itself the multiplicity of individual wills.

Many of Wundt's psychological theories—such, for example, as his well-known doctrine of apperception—only become intelligible in the light of his general view of Nature. Emphatic as he was in claiming for psychology a position of its own as an empirical science, he never ceased to regard it as standing in the closest and most intimate relation with philosophy. Even in the "Grundzüge," which is a storehouse of facts largely accumulated in his own laboratory, he turns again and again to the discussion of problems essentially philosophical in character. That work has often been severely criticised, yet when all is said it remains one of the great and permanent contributions to the modern science. The Leipzig Institute was started in a humble way in 1878, but it grew by rapid strides, and Wundt lived to see one of his early desires realised—namely, that the time would come when in every German university a psychological laboratory would be deemed a part of the necessary equipment. The "Philosophische Studien," of which he was the editor, served as a medium of publication for the work of his pupils, and many valuable articles of his own are likewise contained in the twenty volumes that appeared from 1883 to 1903. The last years of his life saw also the realisation of another of his early dreams. In 1900 the first volume of his "Völkerpsychologie" was published, and five other bulky volumes followed. Here, again, to some extent he was breaking new ground, where, however, he was entirely dependent for his material upon the labours of others.

Wundt married shortly after leaving Heidelberg; his son is distinguished as an authority in Greek philosophy, and to his daughter, his companion "im Urwald der Mythen und Märchen," one of the volumes of the "Völkerpsychologie" is dedicated. In private life he was a man of many lovable qualities. His old students look back to many delightful hours spent with him in the midst of his family, and remember with gratitude his kindly interest in them and their work. Slender in build, never of strong physique, and troubled with failing eyesight, it seems well-nigh incredible that he got through the multitudinous labours of which I have spoken, and survived so many of his former pupils. He was wonderfully effective as a lecturer; without a note, and usually to audiences of more than three hundred students, he would handle in a concise and lucid manner themes of notorious difficulty. Absorbed in his scientific pursuits, allowing himself little leisure, but content and happy in his modest and simple home, his life was a rounded whole, the memory of which one would not willingly let die.

G. Dawes Hicks.

Armand Gautier.

By the death of Emile Justin Armand Gautier, at Cannes, in his eighty-third year, France loses one of her most distinguished chemists. Born at Montpellier, the son of a medical man, Gautier appears to have been destined to follow his father's profession, and to his early training is to be attributed, in all probability, the direction of much of his subsequent life's work in science, notably in biological chemistry. As a youth he obtained a post, under the Faculty of Montpellier, first as *aide-préparateur* and then as *préparateur* in the chemical laboratory, where he remained five years, and where he acquired that power and facility of manipulation which characterised his experimental work. In the early 'sixties he seems definitely to have decided to attach himself to chemistry as a career. At that period the science was experiencing profound changes, and chemical theory was developing with remarkable rapidity, more particularly owing to the progress in organic chemistry. Wurtz was everywhere recognised as one of the pioneers and leaders of the new movement, and accordingly young Gautier repaired to Paris to work under his inspiration and direction. At Paris he remained, becoming, in 1869, a member of the Faculty of Medicine, in 1872 director of the first laboratory of biological chemistry instituted in France, and in 1884, on the death of Wurtz, professor of medical chemistry. He was elected a member of the Academy in 1889.

During the fifty years of his scientific activity Armand Gautier published an extraordinary number of memoirs—upwards of 600, it is said. They range over every department of the science and practically every sub-section of it. Many of them, of course, are not of first-rate importance, but, collectively, they serve to show his breadth of sympathy, his receptivity, his intellectual keenness, his versatility, and the many-sidedness of his interests.

Here we can deal only with his more noteworthy contributions to the literature of chemistry. The influence of Wurtz is stamped on the earliest of them—as in his work on cyanogen derivatives, on the nitriles and their isomerides, the carbylamines—which mostly appeared in the Bulletin of the French Chemical Society and served to establish Gautier's position as one of the foremost investigators of the new French school. His appointment as director of the laboratory of biological chemistry, already referred to, gave a fresh impetus and a new departure to his work as an investigator. In 1872 he signalised the existence of a class of cadaveric alkaloids, termed by Selmi *ptomaines,* and presumed to be products of putrefaction. Earlier investigators, such as Panum, Dupré and Bence Jones, Marquardt, Schmidt, Bergmann and Schmiedeberg, Zuelzer and Sonnenschein, had obtained so-called putrefaction bases which occasioned physiological effects similar to certain vegeto-alkaloids. Selmi's term was adopted by Gautier to denote alkaloidal substances formed in the putrefaction of proteins. The earlier literature relating to the ptomaines—a term now fallen into disuse in scientific nomenclature—is full of errors, and there is practically no evidence that what is called "ptomaine poisoning" is due to poisonous alkaloids: it is rather to be attributed to bacterial infection and is caused by bacterial toxins. Gautier found in fresh tissues a number of basic substances, related to uric acid and creatinine, which he regarded as the products of ordinary metabolism, and to which he gave the name of *leucomaines*, to distinguish them from the products of bacterial action.

A subject which engaged Gautier's attention for some time, and to which he occasionally returned, was the widespread diffusion of arsenic in the animal organism, which led to work on improved methods of detecting and estimating that element in micro-chemical quantities. His speculations concerning the *rôle* played by arsenic, as well as by iodine, in our organism may be said to be at the basis of modern therapeutics. The question of the influence of the infinitely little on hygiene had, in fact, a special attraction for him. It is seen in his work on the action of the impurities of the air of towns on the public health. He detected the constant presence in air of iodine, as well as of hydrogen; the former, he imagined, was due to the presence of microscopic algæ, the latter to emanations from primitive rocks, volcanoes, and thermal springs.

Gautier, as a biochemist, also engaged himself in questions of plant physiology and on the chemical transformations of various products in the life-history of vegetable organisms. These studies occasionally took a practical turn, as, for example, in his inquiries into the colouring matter of the grape and the detection of the fraudulent colouring and dilution of wine, and into the influence of "plastering," "collage," and fortifying on the weight of the dry extract. The nature of tobacco-smoke also attracted his attention. He found that when tobacco is smoked in a pipe the volatile liquid products consist mainly of basic compounds, among them nicotine, a higher homologue, $C_{11}H_{16}N_2$, which pre-exists in tobacco leaf, and a base, C_6H_9NO, which appears to be related to picoline. Hydropyridines and other alkaloids are also present, resulting from the decomposition at relatively low temperatures of the carbopyridic and carbohydropyridic acids present in the leaf.

Gautier was a fellow-worker with Maxwell Simpson in Wurtz's laboratory, and the two collaborated in the study of the action of hydrocyanic acid upon aldehyde. He was an occasional visitor to this country, and represented France at various academic gatherings in London. He was a genial soul, and, as was said of him by M. Deslandres, president of the Academy of Sciences, when pronouncing his *éloge*, remained young in spirit and young of heart until the end.

T. E. THORPE.

BY the death of MR. HENRY BASSETT, F.I.C., at the age of eighty-three, on August 30, we have lost one of the few remaining survivors of that ardent band of young chemists who studied under Dr. A. W. Hofmann at the Royal College of Chemistry. Handicapped at the start by the death of his father when he was only nine years old, Mr. Bassett had an uphill fight all his life; but he was animated by the same spirit which often enables the poet and the artist to produce good work under most unfavourable conditions. For a time he acted as assistant to Brodie at Oxford, but most of the best years of his life were taken up in testing anthracene as assistant to Mr. F. A. Manning. In 1894, at an age when men more fortunately situated are thinking of retiring, he started a consulting practice of his own, first at St. Andrew's Hill and then at 104 Queen Victoria Street, specialising in non-ferrous alloy and anthracene work. Never lacking in ideas, Mr. Bassett always had some research work in hand, and at intervals, from 1863, he published some seventeen papers and short notes, mainly in the Journal of the Chemical Society or the *Chemical News*. Several of these had reference to anthracene testing, into which he introduced some improvements, and on which he was a recognised authority. His most important research was certainly that on ethyl orthocarbonate, which he prepared by the action of sodium on a mixture of chloropicrin and absolute alcohol. This was published in the Journal of the Chemical Society for 1864, and may give him a permanent place in chemical literature. Several short papers on chlorides of carbon and one on eulyte and dyslyte may also be mentioned. During the course of his consulting practice Mr. Bassett carried out a considerable amount of research work, notably on the corrosion of manganese and other bronzes by sea water, which was never intended for publication. Of recent years he had been doing some very interesting work on graphite, and until within a fortnight of his death had been trying to get his results into a form suitable for publication.

WE regret to note that the death of Mr. ISHAM RANDOLPH on August 2, at seventy-two years of age, is announced in the *Engineer* for September 10. Mr. Randolph's most prominent work was on the Chicago drainage canal, of which he was chief engineer from 1893 until 1907, and was thereafter its consulting engineer until 1912; this great work cost about 12,000,000*l*., and has a hydro-electric plant of 40,000 h.p. He was a member of the international board of consulting engineers for the Panama Canal, and occupied many other important public posts. Mr. Randolph was a member of many engineering societies, including the American Society of Civil Engineers. The Franklin Institute awarded him the Elliott Cresson Medal for distinguished achievements in civil engineering, and the University of Illinois conferred upon him the degree of Doctor of Engineering in 1910.

Notes.

THE earthquake felt on September 7 in the north of Tuscany proves to have been much more serious than the early accounts indicated. Many towns and villages are completely destroyed. The epicentre seems to have been near Fivizzano, a small town, now a heap of ruins, on the slope of the Apennines, and about twelve miles north of Carrara. The area within which buildings were damaged is evidently extensive, as it includes both Viareggio and Pistoia, the latter town being about forty-five miles south-east of Fivizzano. The number of deaths so far reported is 327, but the real number is probably much higher. The earthquake appears to be the most violent known in this part of Italy, which is fortunate in possessing a meagre seismic history. On April 11, 1837, an earthquake, with its centre about five miles south-east of Fivizzano, caused some damage in that town. On September 10, 1878, a strong shock, with its centre close to Fivizzano, again injured a few houses there. Indeed, the recent wholesale destruction of villages is evidence of their long immunity from violent earthquakes, for the buildings were not of that resisting type the construction of which is now enforced in the rebuilt towns of Italy.

IN the detailed exploration of the coasts of Greenland Danish explorers have taken a leading part. Plans of a new expedition under the leadership of Mr. Lauge Koch have been sent to us by Dr. M. P. Porsild, of the Danish Arctic Station in Disko, Greenland. In order to commemorate the voyage of Hans Egede to Greenland in 1721, which began the systematic settlement of the west coast by Denmark, Mr. Koch's expedition is known as the Bicentenary Expedition to the North of Greenland. The Danish Government has provided a vessel and part of the funds, the remainder of the cost being met by subscription in Denmark. The expedition left Copenhagen on July 15 for Robertson Bay in Inglefield Gulf, where a wintering station is to be established. From there a depôt is to be laid in Warming's Land. It is hoped that this will be done in the late summer with the help of motor-tractors. The journey to the depôt will be repeated next year with dog-sledges, and the main work of the expedition will then begin. This includes journeys to the interior of Peary Land and to the north of Adam Biering's Land, where an advanced base will be established. Independence Fjord, Böggild's Fjord, and the unknown parts of Wulff's Land and Warming's Land will be mapped. In the following spring the expedition will travel along the coast from its winter quarters through Kennedy and Robson Channels, round the north of Peary Land into Independence Fjord. The return journey will be made by the main depôt to Robertson Bay. Mr. Koch is accompanied by Mr. C. F. Slott and several Eskimo.

THE *British Medical Journal* for September 11 announces that the International Society of Surgery, at its recent meeting in Paris, elected Sir William Macewen, of Glasgow, as its president for the next congress, to be held in Great Britain—probably in London—during the summer of 1923.

THE British Launderers' Research Association has been approved by the Department of Scientific and Industrial Research as complying with the conditions laid down in the Government scheme for the encouragement of industrial research. The secretary of this association is Mr. J. J. Stark, 162–65 Bank Chambers, 329 High Holborn, W.C.1.

THE Royal Academy of Science of Turin has sent us a leaflet announcing the offer of two Bressa prizes of 9000 lire for the greatest work in almost any branch of science during the past four years. Candidates may submit printed (not written or typed) works to the Secretary before December 31, 1922. Members of the Turin Academy are not eligible to compete for the prizes.

THE eighth annual Indian Science Congress will be held in Calcutta from January 31 to February 5, 1921. His Excellency the Right Hon. the Earl of Ronaldshay has consented to be patron of the meeting, and Sir R. N. Mukerjee will be president. Members intending to read papers should send them, together with a short abstract, to Mr. P. S. MacMahon, Canning College, Lucknow, before November 30.

THE Secretary for Scotland has appointed an Advisory Committee to advise him on matters connected with the administration of the Wild Birds Protection Acts. The Committee consists of Mr. Hugh S. Gladstone (chairman), Dr. W. Eagle Clarke, Dr. Walter E. Collinge, Mr. H. M. Conacher (representing the Board of Agriculture for Scotland), Mr. H. J. Crowe (representing the Fishery Board for Scotland), and Prof. J. Arthur Thomson.

THE widespread, popular belief in the use and value of the divining rod gives considerable interest to a recent publication of the United States Geological Survey on the subject. "The Divining Rod," by Mr. A. J. Ellis (Water-supply Paper 416), is a condensed history of water-witching, to which is added a bibliography with many hundred entries. The origin of the divining rod is lost in antiquity, but a belief in its value for a variety of purposes besides water-finding has persisted until the present day. The U.S. Geological Survey considers that for all practical purposes the matter is thoroughly discredited and of no value whatever in locating either water or mineral ores. Mr. Ellis adds a note on various mechanical "water-finders," most of which are magnetic or electrical instruments. He dismisses the claims of all these contrivances as being purely speculative and quite unsound in principle.

THE *Geographical Journal* for July (vol. xvi., No. 1) gives a summary by Dr. Hamilton Rice of his recent expedition to the headwaters of the Orinoco. Dr. Rice's route was from the Amazon up the Rio Negro to the Orinoco. Esmeralda was reached at the end of last year. The Orinoco was then ascended to the rapids of Guaharibos, where Dr. Rice's party of ten was attacked by a big band of Guaharibos and compelled to fight. Material has been obtained for a map traverse on a scale of 1 : 125,000 of the route from Manáos to the Guaharibos rapids. The traverse is checked by more than forty astronomical stations, where time was obtained by field wireless from Darien and Washington. Magnetic observations were taken at more than twenty of the stations. Meteorological readings were taken four times daily in conjunction with similar readings at the same hours at Para. Much attention was paid to geological research. Finally, Dr. Rice says that the survey of the diseases encountered will form one of the not least valuable results of the expedition.

THE problem of suitable maps for aviators continues to attract much attention and is far from being satisfactorily solved. In the *Geographical Journal* for August (vol. lvi., No. 2) Capt. H. A. Lloyd has a short paper, illustrated by many admirable photographs, on the classification of the ground from the air. Experience on the Western front during the war convinced Capt. Lloyd that the whole area could be divided into distinctive zones differentiated by the shapes of fields or by the industries carried on in particular localities. A recognition of these types of terrain was found to enable a pilot to determine his approximate position. This was particularly valuable in the case of a pilot losing his way owing to clouds or in flight over the country for the first time. Thirteen types of ground were recognised and taught to pilots in the area of the Western front between the sea and the River Oise. Under war conditions this classification had its limitations because the destructive effect of battle, as a rule, removed all features visible to the eye and generally to the camera. It is also noted that, under normal conditions, while the shape of the fields and other features remain constant, the height of the vegetation affects the appearance of the photograph. Thus a field of ripe corn may look almost as dark as a row of trees. These seasonal variations would need to be taken into account in making use of such a classification in map-construction. Capt. Lloyd also discusses the classification of landmarks, and insists that small-scale maps, such as are used in flying, should portray the chief features of towns so that a glimpse of a town would be enough for an aviator to locate his position. These considerations entail the omission of much of the detail shown on maps for land use, so that the features conspicuous from the air may stand out boldly.

A PROSTRATE variety of potato has been found in the breeding experiments of Messrs. R. N. Salaman and J. W. Lesley (*Journal of Genetics*, vol. x., No. 1), which, it is suggested, may be useful for potato-growers in semi-arid climates, since the foliage, lying on the ground, has a considerable effect in conserving the soil moisture. This variety breeds true, and is shown to differ from the upright type in a failure to form secondary xylem in the stem. A procumbent variety, the stems of which turn up at the end, has also appeared. Anatomically, it agrees with the prostrate variety. In both these types the crop of tubers is unaffected.

IN an interesting further study of melanism in moths, Mr. J. W. H. Harrison (*Journal of Genetics*, vol. x., No. 1) discusses crossing experiments with *Tephrosia bistortata*, *T. crepuscularia*, and their melanic varieties. The melanic variety of *T. crepuscularia* behaves as a simple Mendelian dominant to the type, and the same has been shown to be true of various other melanic varieties. But in crosses of *T. bistortata* with the melanic form of the other species a great range of colour forms was obtained in F_1 and F_2, with no indication of Mendelian segregation. The results are interpreted as showing that the unit factor for melanism has been modified, and in some cases broken up so that it has practically disappeared.

As a first study of inheritance of egg-weight in fowls, Philip Hadley and Dorothy Caldwell (Bull. 181, Rhode Island Agr. Expt. Station) make an analysis of the normal distribution of egg-weight in White Plymouth Rocks. Egg records from a flock of thirty-nine hens through eight years showed that individual hens differed markedly in the weight of eggs laid in any period. The first eggs of any year are smaller, increasing to a maximum in April, then falling to a minimum in July or August, followed by another maximum and minimum in September and November respectively. After the second laying year these maxima appear less clearly, and after the fourth there is a progressive decrease in the weight of eggs produced each year. There appears to be a slight tendency for heavier hens to lay larger eggs.

THE attention of workers on Diptera is directed to Mr. E. Brunetti's catalogue of Oriental and South Asiatic Nemocera, which has been published as vol. xvii. (300 pp., June, 1920) of the Records of the Indian Museum. Mr. Brunetti states that he has included in his catalogue all the names of species available up to the middle of 1919. In nomenclature his policy has been to retain the names employed by the principal dipterologists of the last century; he believes in "continuity before priority," and does not agree with the general overturning of generic and specific names, suggested by strict priorists, which arises out of the much discussed "1800 paper" of Meigen. For each species the author gives the essential bibliographical references and synonyms, and indicates the distribution. The location of the type-specimen, where this is known, is stated. The Culicidæ (mosquitoes) receive careful consideration, and the list of these extends over ninety-six pages of the catalogue.

IN view of the present scarcity in the supply of cotton, the attempts now being made to establish cotton-growing on a large scale in Mesopotamia are of particular interest. Cotton has been grown in Mesopotamia from very ancient times, and is still cultivated in small quantities by the Arabs in conjunction with food-crops along the banks of both the Tigris and Euphrates. The fibre is used locally for spinning and as a stuffing material for pillows and mattresses. The country possesses a soil and climate favourable to the production of large yields of excellent cotton, and in course of time it should add materially to the world's supply. Since 1917 experiments have been conducted by an expert from the Indian Agricultural Service with the view of discovering the most suitable kinds to grow, and the results of the work done in this connection and the prospects of establishing a cotton-growing industry are fully dealt with in the current number of the Bulletin of the Imperial Institute. So far, American types of cotton seem to be the most suitable for cultivation in Mesopotamia. The members of a deputation of the British Cotton Growing Association which visited the country towards the end of last year were very favourably impressed with its possibilities for cotton production.

THE July-August issue of the *Scottish Naturalist* (Nos. 103 and 104, pp. 99–144) is devoted to a report on Scottish ornithology in 1919 by Miss Leonora Jeffrey Rintoul and Miss Evelyn V. Baxter—a careful piece of work in which many contributors have assisted. The most interesting feature of 1919 is the extension of the breeding range of certain species. Of these the most important is the reappearance of the Whooper swan as a Scottish breeding species. Migration ran a fairly normal course; the cold spring seemed to have no effect on the arrivals of summer visitors. A very large movement took place in the first half of May, but no very big migrations are recorded in autumn, the only one of any magnitude being a weather movement in mid-November caused by the very hard frost and snow at that time. No new birds were added to the Scottish list, but a good many uncommon visitors and new records for particular faunal areas are noted, *e.g.* a blue-headed wagtail at Fair Isle, a red-backed shrike in Moray, two reed-warblers from Lerwick, a bee-eater at Lentran, two American widgeon from Tay and Clyde, and a spotted crake from Ross-shire. The garden-warbler and the pied flycatcher were both found nesting in the Moray area. The report deals also with the decrease of certain species in various areas, with varieties of plumage, with the noteworthy phenomena of the various seasons, and with peculiarities of habit, such as carrion-crows acting as foster-parents. It is cheering to read that on October 5, at Swordale, East Ross, a golden eagle, two buzzards, and a peregrine falcon were all seen in the air together. The authors are to be congratulated on the continuation of their valuable series of annual reports.

IN Professional Paper 98–L of the U.S. Geological Survey, Messrs. G. C. Matson and E. W. Berry provide the first description of a North American Pliocene flora. This comes from the Citronelle formation of the Gulf coastal plain, extending from western Florida to eastern Texas, and indicates climatic conditions in late Pliocene time similar to those of the present day. The modern forest flora is well illustrated in its habit as it lives, to furnish a picture of the Pliocene period.

MR JOHN PARKINSON introduces the term "lak" into geography in his "Report on the Geology and Geography of the Northern Part of the East Africa Protectorate" (Colonial Reports—Miscellaneous, No. 91, 1920). A lak is a drainage-channel that may carry water periodically; it is often a guide to the capacity of an area for development. On the banks of some laks in East Africa the abundance of molluscan shells indicates the former existence of extensive lakes, and the water-supply found in the wells may be a relic of these lakes in a region that has clearly suffered from desiccation.

DRUMLINS, kames, and eskers play a large part in the topography of northern temperate lands in Europe and America, and their relations are well illustrated in maps and landscapes in Mr. W. C. Alden's important memoir on "The Quaternary Geology of South-eastern Wisconsin" (U.S. Geol. Surv., Prof. Paper 106, 1918). The distribution of the drumlins of the Green Bay glacier west of Lake Michigan, and of the subglacial eskers, is a very striking feature of the large "surficial" map. Would the U.S. Survey consider the folding of its maps with the printed side outwards, as is done by the Ordnance Survey of the British Isles, following the plan adopted by so many travellers in their field-work?

A CATALOGUE of the Mesozoic and Cenozoic Plants of North America, by F. H. Knowlton, has been issued as Bulletin 696 of the United States Geological Survey. It contains 815 pages, and should form a useful work of reference. The catalogue is an alphabetically arranged list of the genera and species that have been described. For each American form that is known only in a fossil state the original date and place of publication are given; then follow all or the most important references, especially such as refer to descriptions and figures. For each Old World form that is recognised in North American strata the original date and place of publication are given; a reference to the publication in which the form is first recorded as American follows, and then in chronological order the American references. For living species found fossil only the authority is given, followed by the first reference to the species in a fossil state, and then by other important references. The synonymy is placed under the species to which it belongs, but each synonym occurs in its proper alphabetical place with a reference to the form to which it is now referred. The catalogue is supplemented by a systematic arrangement of the genera and an index of genera and families. There are also a list of the North American Mesozoic and Cenozoic plant-bearing formations, with the plants found in each alphabetically arranged, and a bibliography.

THE Report issued by the United States Geological Survey of the world's production of copper in 1917 has recently been published. For many years the U.S.A. has been the largest producer of this metal. In 1913 its production was about 57 per cent. of the world's output of just under one million tons. During the war there was a greatly increased use of this metal, and the demand of the belligerent countries was satisfied principally by a very large increase in American production. The high-water mark was reached in 1917, when a grand total of 1·454 million tons was extracted. Of this the U.S.A. produced 0·855 million tons. Japan and Chile also increased their smelter production to a little more than 100,000 tons. Then follow Canada, Mexico, and Peru. It will be seen, therefore, that by far the greater part of the world's copper was derived from the western hemisphere. It is evident that the U.S.A. is the largest single factor in nearly every phase of the industry. At present it is not only much the largest producer and consumer, but it also excels in both imports and exports. At the beginning of 1917 the producing capacity was the largest in the history of the industry, and was almost wholly utilised. The principal producing State was Arizona, followed by Montana, Michigan, and Utah. These four States provided 79 per cent. of the total American output in 1917.

MR. T. SHEPPARD, whose careful record of William Smith's maps and memoirs has just been published by Messrs. Brown and Sons of Hull, chose "The Evolution of Topographical and Geological Maps" as the subject of his address to the Delegates of Corresponding Societies at the British Association meeting in Cardiff. He showed how incomplete our collections are of county maps, while such publications are occasionally used by dealers for the wrapping of book-parcels. Great credit is very properly assigned to John Cary's work in England from 1787 to 1832; his large road-map, with the coach-roads coloured in blue, is on the scale of five miles to one inch, not ten as stated, and, with its index of every village, is still of great value in a private library. In citing maps published after the initiation of the Ordnance Survey, those of Scotland by Faden and Wyld, on the basis of surveys by General Roy and John Ainslie (1839), and by Arrowsmith, scale four miles to one inch (1840), used as the basis of MacCulloch's fine geological map, are worthy of mention. MacCulloch seems to have completed his share in this map in 1834. The second and most authoritative edition of Griffith's map of Ireland was issued in 1855, not 1853, as given in the address. Attention is well directed to the "soil-maps," in reality precursors of our "drift-maps," published in connection with agricultural and statistical surveys about the beginning of the nineteenth century. That of Londonderry by Sampson in 1802, with its blue boulder-clay and pink sands and gravels, interestingly anticipates our modern colouring. Mr. Sheppard's address as now printed is a welcome work of reference.

MONTHLY results of magnetical, meteorological, and seismological observations at the Royal Alfred Observatory, Mauritius, to April, 1920, have been received. Hourly observations of the magnetic declination, horizontal force, and vertical force are given from the photographic records. There are similar observations for each hour of atmospheric pressure, direction and velocity of wind, temperature of the air and evaporation, amount of cloud, duration of bright sunshine, and rainfall, most of which are from self-registering instruments. Monthly rainfall totals are given for about 100 stations in Mauritius, grouped according to the river systems. The monthly and yearly means and extremes of the meteorological elements at the Royal Alfred Observatory for 1919 are tabulated. July had the highest mean atmospheric pressure, and February and March the lowest. The absolute highest temperature was 34·9° C. in January, and the lowest night minimum 13·0° C. in August. The mean of the daily maxima was highest, 32·1° C., in January, and lowest, 23·4° C., in July. The mean of the night minima was lowest, 16·3° C., in August, and highest, 23·3° C., in February. The degree of humidity, saturation 100, was highest, 78, in March, and lowest, 69, in November. The amount of rain was greatest, 202·7 mm., in March, and least, 24·3 mm., in May, the total for the year being 1001·6 mm.

"NOTES on the Ground Day Visibility at Cranwell, Lincolnshire," by Capt. W. H. Pick, published by the Meteorological Office as Professional Notes No. 11, is an attempt to find the relations existing between visibility and wind direction, wind velocity, and distribution of pressure. The period dealt with is from February 1 to April 8, 1920, and for hourly observations from 9h. to 17h. G.M.T. It is shown that winds in the south-west quadrant brought the best visibility, winds between west and east through north a considerably lower degree, and winds in the south-east quadrant the lowest degree. It is pointed out that visibility with winds greater than 12 m.p.h. was much higher than it was with winds less than or equal to 12 m.p.h. Classification according to pressure distribution shows that the mean visibility in front of a depression is 5·1 of visibility-scale (0–9), in the rear of a depression 5·0, and in a secondary depression 4·9. In an anticyclone or wedge it is 3·9 of scale, in a col 4·7, and with straight isobars south to north 3·2, west to east and south-west to north-east 5·5. The period of observation discussed—sixty-eight days of nine consecutive hours each—is far too short. The situation of Cranwell and its proximity to hills would render the conditions found quite different from those in many other parts of the British Isles, or on the open sea contiguous to our coasts. The relations between visibility and pressure distribution seem open to doubt. No attempt has been made to ascertain the relation of visibility to time of day.

THE August issue of the Journal of the Society of Glass Technology contains the paper on the properties of the raw fireclays found in this country which was communicated to the meeting of the society in April by Miss E. M. Firth, Mr. F. W. Hodkin, and Dr. W. E. S. Turner. Twenty-seven clays were examined, only five of them falling within the specification of the Refractories Research Committee of the society as suitable for glass-furnaces. The results show no correlation between the physical properties and chemical compositions of the clays, and the authors conclude that the classification of clays according to chemical composition is premature, and should be replaced by one according to their shrinkage and porosity. Most of the clays tested show expansion at some part of the firing range, owing probably to the allotropic changes in the silica present. In general, clays with high alumina content show a wide range of porosity, but there are notable exceptions. From the tables of the properties of the various clays given by the authors it is possible to calculate the properties of a mixture of them when fired to a given temperature.

CONTINUING his researches on the alloys of iron with chromium and tungsten, Prof. Honda has recently published in the Science Reports of the Tôhoku Imperial University an investigation on the structural constitution of high-speed steels containing these elements. He concludes that in an annealed steel containing 5 per cent. of chromium, 18 per cent. of tungsten, and 0·6 per cent. of carbon the alloy consists of a solution of iron tungstide in iron, together with free tungstide and the carbides Cr_4C and WC. On heating such a steel above Ac_1 the carbides dissolve, and the chromium carbide Cr_4C is converted into Cr_3C_2 and metallic chromium. The higher the temperature, the more the change proceeds in this direction. On cooling, the reverse change takes place only slightly, and the result is that at the ordinary temperature a steel is produced containing the carbides, chromium, and the tungstide all in solid solution. This, according to him, is the constitution of the hardened steel. The self-hardening property is conveniently studied by the temperatures of the transformations, while the degree of tempering on later heating is best studied by means of magnetic heating curves. The tempering takes place in two steps—one at about 400° and the other above 700°. Prof. Honda concludes that self-hardening and resistance to tempering depend primarily on the quantity of Cr_3C_2 dissolved in iron containing chromium and tungstide. These properties increase both with chromium and carbon and with rise of temperature. The function of tungsten appears to consist in lowering the temperature, at which self-hardening begins to be manifest. When this element exceeds 12 per cent. it exists as fine globules of tungstide Fe_2W, and these are directly related to the cutting efficiency of the tool.

WE have just received from W. Heffer and Sons, Ltd., of Cambridge, a catalogue of their library of second-hand books. Science and mathematics are well represented by a number of the bigger text-books, and several collections of bound volumes of scientific journals are also offered for sale.

THROUGH the omission of the word "hundred" from line 28 of the first column of page 38 of last week's NATURE, the annual production of coal in Great Britain was erroneously stated to approach "three million" instead of "three hundred million" tons. It is shown in the article upon the proceedings of the Section of Economics and Statistics of the British Association, printed elsewhere in this issue, that the output in 1913 was 287,000,000 tons.

Our Astronomical Column.

TEMPEL'S COMET.—This comet is now fading, but may still be visible for some weeks. The following ephemeris, for Greenwich midnight, is by M. Ebell:

	R.A. h. m. s.	S. Decl. ° ′		R.A. h. m. s.	S. Decl. ° ′
Sept. 17 ...	3 1 5	8 27	Oct. 3 ...	2 51 44	10 53
21 ...	2 59 45	9 8	7 ...	2 47 59	11 21
25 ...	2 57 42	9 46	11 ...	2 43 50	11 44
29 ...	2 55 0	10 22	15 ...	2 39 24	12 1

Values of log *r*, log Δ: September 21, 0·2364, 9·9411; October 15, 0·2737, 9·9730.

A photograph obtained at Bergedorf on August 15 showed a well-defined nucleus and a fan-shaped tail which could be traced for about 1′. The corrections indicated to Ebell's ephemeris were +23s., S. 3·0′.

NOVA CYGNI.—The position of this star referred to the equinox of 1920·0 is R.A. 19h. 56m. 24·77s., N. decl. 53° 24′ 1·3″; annual precession, +1·50s., +9·7″. Examination of past photographs shows no trace of a star in this place on plates taken by Dr. Wolf and Mr. Franklin Adams some fifteen and twelve years ago. They go down to mag. 17 and 15 respectively. Two plates taken at Harvard on 1920 August 9 with a 1-in. lens fail to show it, and it must have been fainter than 9·5. A plate taken by Mr. Nils Tamm in Sweden on August 16 shows it of mag. 7, and a Harvard one of August 19 indicates mag. 4·8. Since the maximum was not reached until August 24, the rise in light occupied more than a week. The total increase in light was at least 15 magnitudes, while that of Nova Aquilæ 1918 was only 11 magnitudes (Harvard Bulletin, 729; *Astr. Nachr.*, 5060).

THE PERTH SECTION OF THE ASTROGRAPHIC CATALOGUE.—The publication of the great Astrographic Catalogue has fallen far behind the expectations that were formed when the scheme was initiated some thirty years ago, but many new observatories have stepped in to fill gaps left in the zones, and these are showing much energy in pushing on their share of the work. The Perth Observatory, under the direction of Mr. N. B. Curlewis, undertook the region from −31° to −41°. The Catalogue will be completed in thirty-six volumes, each containing six hours of R.A. in a single degree of declination. Vols. xvii. to xxiv. have recently been issued. The following table gives the number of stars in each volume and the ratio to the number in C.P.D.:

Plate centre	R.A. 0h.–6h. No. of stars	Ratio	R.A. 6h.–12h. No. of stars	Ratio	R.A. 12h.–18h. No. of stars	Ratio	R.A. 18h.–24h. No. of stars	Ratio.
−36°	7,740	4·7	21,923	2·5	20,766	4·1	19,832	5·0
−37°	7,664	4·4	21,883	2·6	20,667	3·5	14,562	3·8

It will be seen that the ratio varies considerably, being, on the whole, lowest where the star-density is greatest.

The radius of the image is given for stars not fainter than magnitude 8. The fainter stars have their magnitudes indicated by a letter (from A to L) referring to a specially constructed scale; approximately A is of magnitude 8½, and the letters are half-magnitudes apart, so that L is 13½.

The *étoiles de repère*, of which there are about fifteen on each plate, have recently been re-observed with the Perth meridian-circle, and proper motions deduced where necessary. The measured rectangular co-ordinates of all the stars are given to 0·001 of a *réseau* interval. The usual plate-constants and tables for reduction to R.A. and declination are also given, with a note that the constants are deduced on a somewhat different plan from that followed at Greenwich.

Geographers and the Reconstruction of Europe.*

By JOHN MCFARLANE, M.A.

IN the rearrangement of European States which has taken place geographical conditions have, perhaps, not always had the consideration which they deserve, but in an inquiry such as that upon which we are engaged they naturally occupy the first place. It is to the land within the frontier, and not to the frontier itself, that our main consideration should be given. The factors which we have to take into account are those which enable a people to lead a common national life, to develop the economic resources of the region within which they dwell, to communicate freely with other peoples, and to provide not only for the needs of the moment, but so far as possible for those arising out of the natural increase of the population. The principle of self-determination has likewise played an important, if not always a well-defined, part in the rearrangement of Europe. The basis upon which the new nationalities have been constituted is, on the whole, ethnical, though it is true that within the main ethnical divisions advantage has been taken of the further differentiation in racial characteristics arising out of differences in geographical environment, history, language, and religion. But no more striking illustration could be adduced of the strength of ethnic relationships at the present time than the union of the Czechs with the Slovaks, or of the Serbs with the Croats and the Slovenes. Economic considerations, of course, played a great part in the settlement arrived at with Germany, but, on the whole, less weight has been attached to them than to ethnic conditions.

When we come to examine the application of the principles which I have indicated to the settlement of Europe we shall, I think, find that the promise of stability is greatest in those cases where geographical and ethnical conditions are most in harmony, and least where undue weight has been given to conditions which are neither geographical nor ethnical.

The restoration of Alsace-Lorraine to France had always been treated as a foregone conclusion in the event of a successful termination of the war against Germany. From the geographical point of view, however, there are certainly objections to the inclusion of Alsace within French territory. From the economic point of view, however, the great deposits of iron ore in Lorraine constitute its chief attraction for France to-day, just as they appear to have constituted its chief attraction for Germany half a century ago. But the transfer of the province from Germany, which has built up a great industry on the exploitation of its mines, to France, which does not possess in sufficient abundance coal for smelting purposes, together with other arrangements of a territorial or quasi-territorial nature made partly at least in consequence of this transfer, at once raises questions as to the extent to which the economic stability of Germany is threatened. In regard to coal the position is serious. We need not, perhaps, be unduly impressed by the somewhat alarmist attitude of Mr. Keynes, who estimates that on the basis of the 1913 figures Germany, as she is now constituted, will require for the pre-war efficiency of her railways and industries an annual output of 110,000,000 tons, and that instead she will have in future only 100,000,000 tons, of which 40,000,000 tons will be mortgaged to the Allies. In arriving at these figures Mr. Keynes has made an allowance of 18,000,000 tons for decreased production, one-half of which is caused by the German miner having shortened his shift from eight and a half to seven hours per day. This is certainly a deduction which we need not take into account. Mr. Keynes also leaves out of his calculation the fact that previous to the war about 10,000,000 tons per year were sent from Upper Silesia to other parts of Germany, and there is no reason to suppose that this amount need be greatly reduced, especially in view of article 90 of the Treaty of Versailles, which provides that "for a period of fifteen years Poland will permit the produce of the mines of Upper Silesia to be available for sale to purchasers in Germany on terms as favourable as are applicable to like products sold under similar conditions in Poland or in any other country." We have further to take into account the opportunities for economy in the use of coal, the reduction in the amount which will be required for bunkers, the possibility of renewing imports from abroad—to a very limited extent indeed, but still to some extent—and the fact that the French mines are being restored more rapidly than at one time appeared possible. (On the basis of the production of the first four months of 1920 Germany could already reduce her treaty obligations to France by 1,000,000 tons per year.) Taking all these facts into account, it is probably correct to say that when Germany can restore the output of the mines left to her to the 1913 figure, she will, as regards her coal supply for industrial purposes, be in a position not very far removed from that in which she was in 1910, when her total consumption, apart from that at the mines, was about 100,000,000 tons. Our general conclusion, then, is that the territorial arrangements which have been made do not necessarily imperil the economic stability of Germany. The economic consequences of the war are really much more serious than the economic consequences of the peace. Germany has for ten years to make good the difference between the actual and the pre-war production of the French mines which she destroyed. Her own miners are working shorter hours, and as a result her own production is reduced, and as British miners are doing the same she is unable to import from this country. For some years these deductions will represent a loss to her of about 40,000,000 tons per annum, and will undoubtedly make her position a serious one. But to give her either the Saar or the Upper Silesian coalfields would be to enable her to pass on to others the debt which she herself has incurred. The reduction of her annual deliveries of coal to France, Belgium, and Italy was, indeed, the best way in which to show mercy to her.

The position of Poland is geographically weak, partly because its surface features are such that the land has no well-marked individuality, and partly because there are on the east and west no natural boundaries to prevent invasion or to restrain the Poles from wandering far beyond the extreme limits of their State. Polish geographers themselves appear to be conscious of this geographical infirmity. It is, then, to racial feeling rather than to geographical environment that we must look for the basis of the new Polish State, but the intensity with which this feeling is likely to operate varies considerably in different parts of the region which it is proposed to include. The population is sufficiently large and the

* From the opening address of the President of Section E (Geography) delivered at the Cardiff meeting of the British Association on August 24.

Polish element within it sufficiently strong to justify its independence on ethnical grounds. Moreover, the alien elements which it contains are united neither by racial ties nor by contiguity of settlement. Considered as a whole, Poland is at least as pure racially as the United States. When we consider the economic resources of Poland we see that they also make for a strong and united State. It is true that in the past the country has failed to develop as an economic unit, but this is a natural result of the partitions and of the different economic systems which have prevailed in different regions. Even now, however, we can trace the growth of two belts of industrial activity which will eventually unite these different regions. One is situated on the coalfield running from Oppeln in Silesia by Cracow and Lemberg, and is engaged in mining, agriculture, and forestry; while the other extends from Posen by Lodz to Warsaw, and has much agricultural wealth and an important textile industry. Moreover, the conditions, geographical and economic, are favourable to the growth of international trade. If Poland obtains Upper Silesia she will have more coal than she requires, and the Upper Silesian fields will, as in the past, export their surplus produce to the surrounding countries, while the manufacturing districts will continue to find their best markets in the Russian area to the east. The outlets of the State are good, for not only has it for all practical purposes control of the port of Danzig, but it is able to share in the navigation of the Oder and it has easy access to the south by way of the Moravian Gap. It seems obvious, therefore, that Poland can best seek compensation for the weakness of her geographical position by developing the natural resources which lie within her ethnic frontiers. By such a policy the different parts of the country will be more closely bound to one another than it is possible to bind them on a basis of racial affinity and national sentiment alone. Moreover, Poland is essentially the land of the Vistula, and whatever is done to improve navigation on that river will similarly tend to have a unifying effect upon the country as a whole. The mention of the Vistula, however, raises one point where geographical and ethnical conditions stand in marked antagonism to one another. The Poles have naturally tried to move down-stream to the mouth of the river which gives their country what little geographical individuality it possesses, and the Polish corridor is the expression of that movement. On the other hand, the peoples of East and West Prussia are one and the same. The geographical reasons for giving Poland access to the sea are no doubt stronger than the historical reasons for leaving East Prussia united to the remainder of Germany, but strategically the position of the corridor is as bad as it can be, and the solution arrived at may not be accepted as final. Lastly, we may consider the case of East Galicia, which the Poles claim not on geographical grounds, because it is in reality part of the Ukraine, and not on ethnical grounds, because the great majority of the inhabitants are Little Russians, but on the ground that they are, and have for long been, the ruling race in the land. It may also be that they are not uninfluenced by the fact that the region contains considerable stores of mineral oil.

Czecho-Slovakia is in various ways the most interesting country in the reconstructed Europe. Both geographically and ethnically it is marked by some features of great strength, and by others which are a source of considerable weakness to it. Bohemia by its physical structure and its strategic position seems designed by Nature to be the home of a strong and homogeneous people. Moravia attaches itself more or less naturally to it, since it belongs in part to the Bohemian massif, and is in part a dependency of that massif. Slovakia is Carpathian country, with a strip of the Hungarian plain. Thus, while Bohemia possesses great geographical individuality, and Slovakia is at least strategically strong, Czecho-Slovakia as a whole does not possess geographical unity, and is in a sense strategically weak, since Moravia, which unites the two upland wings of the State, lies across the great route which leads from the Adriatic to the plains of Northern Europe. The country might easily, therefore, be cut in two as the result of a successful attack, either from the north or from the south. Later I shall endeavour to indicate certain compensations arising out of this diversity of geographical features, but, for the moment at least, they do not affect our argument. We have, further, to note that the geographical and ethnical conditions are not altogether concordant. In Bohemia we feel justified in arguing that here at least the governing factors are and must be geographical. To partition a country which seems predestined by its geographical features to be united and independent would give rise to an intolerable sense of injustice. In Slovakia also there are racial differences. Within the mountain area the Slovaks form the great majority of the population, but in the valleys and on the plains of the Danube, to which the valleys open out, the Magyar element predominates. Moreover, it is the Magyar element which is racially the stronger, and before which the Slovaks are gradually retiring. Geographical and ethnical conditions, therefore, unite in fixing the political frontier between Magyar and Slovak at the meeting place of hill and plain. But on the west such a frontier would have been politically inexpedient because of its length and irregularity, and economically disadvantageous because the river valleys, of which there are about a dozen, would have had no easy means of communication with one another or with the outside world. Hence the frontier was carried south to the Danube, and about 1,000,000 Magyars were included in the total population of 3,500,000. The danger of transferring territory not on geographical or ethnical, but on economic, grounds could not be more strikingly illustrated. With regard to economic development, the future of the new State would appear to be well assured. Bohemia and Moravia were the most important industrial areas in the old Austrian Empire, and Slovakia, in addition to much good agricultural land, contains considerable stores of coal and iron. But if Czecho-Slovakia is to be knit together into a political and economic unit, its communications will have to be developed. We have already suggested that the geographical diversity of the country offers certain compensations for its lack of unity, but these cannot be taken advantage of until its different regions are more closely knit together than they are at present. The north of Bohemia finds its natural outlet both by rail and water through German ports. The south-east of Bohemia and Moravia look towards Vienna. In Slovakia the railways, with only one important exception, converge upon Budapest. The people appear to be alive to the necessity of remedying this state of affairs, and no fewer than fifteen new railways have been projected which, when completed, will unite Bohemia and Moravia more closely to one another and to Slovakia. Moreover, it is proposed to develop the waterways of the country by constructing a canal from the Danube at Pressburg to the Oder. If these improvements are carried out the position of Czecho-Slovakia will, for an inland State, be remarkably strong. It will have through communication by water with the Black Sea, the North Sea, and the Baltic, and some of the most important land routes of the Continent already run through it. On the other hand, its access to the Adriatic is handicapped by the fact that in order to reach that sea its goods will have to pass through the territory of two, if not three, other States, and however well the doctrine of economic rights of way may sound in theory there are undoubted drawbacks to it in practice. It is probable, therefore, that the development of internal communications will in the end be to the advantage of the German ports, and more especially of Hamburg. But the other outlets of the State will certainly tend towards the preservation of its economic independence.

The exent to which Rumania has improved her position as a result of the war is for the present a matter of speculation. On one hand she has added greatly to the territory which she previously held, and superficially she has rendered it more compact; but on the other she has lost her unity of outlook, and strategically at least weakened her position by the abandonment of the Carpathians as her frontier. Again, whereas before the war she had a fairly homogeneous population—probably from 90 to 95 per cent. of the 7,250,000 people in the country being of Rumanian stock—she has, by the annexation of Transylvania, added an area of 22,000 square miles of territory, in which the Rumanians number less than one and a half millions out of a total of two and two-third millions. In that part of the Banat which she has obtained there is also a considerable alien element. It is in this combination of geographical division and ethnic intermixture that we may foresee a danger to Rumanian unity. The position in the Dobruja is also open to criticism. Geographically the region belongs to Bulgaria, and the Danube will always be regarded as their true frontier by the Bulgarian people. Ethnically its composition is very mixed, and, whatever it was originally, it certainly was not a Rumanian land. But after the Rumanians had rather unwillingly been compelled to accept it in exchange for Bessarabia, filched from them by the Russians, their numbers increased and their economic development of the region, and more especially of the port of Constanza, undoubtedly gave them some claims to the northern part of it. As so often happens, however, when a country receives part of a natural region beyond its former boundaries, Rumania is fertile in excuses for annexing more of the Dobruja. To the southern part, which she received after the Balkan wars, and in the possession of which she has been confirmed by the peace terms with Bulgaria, she has neither ethnically nor economically any manner of right. Her occupation of it will inevitably draw Rumania on to further intervention in Bulgarian affairs. The arrangements which have been made with regard to the Banat must be considered in relation to the Magyar position in the Hungarian plain. The eastern country of the Banat, Krasso-Szörény, has a population which is in the main Rumânian, and as it belongs to the Carpathian area it is rightly included with Transylvania in Rumanian territory. In the remainder of the Banat, including Arad, the Rumanians form less than one-third of the total population, which also comprises Magyars, Germans, and Serbs. But Rumania has been permitted to descend from the mountains and Jugo-Slavia to cross the great river which forms her natural boundary, and both have obtained a foothold on the plain, where it may be only too easy for them to seek occasion for further advances. For the extension of Jugo-Slavia beyond the Danube two pleas have been advanced, one ethnical and the other strategic. Neither is really valid. The Danube is certainly a better defensive frontier than the somewhat arbitrary line which the Supreme Council has drawn across the Hungarian plain.

In fact, it is in the treatment of the Hungarian plain that we feel most disposed to criticise the territorial settlements of the Peace Treaties. Geographical principles have been violated by the dismemberment of a region in which the Magyars were in a majority, and in which they were steadily improving their position. Ethnical principles have been violated, both in the north, where a distinctly Magyar region has been added to Slovakia, and in the south, where the western part of the Banat and Bačka have been divided between the Rumanians and the Jugo-Slavs, who together form a minority of the total population. For the transfer of Arad to Rumania and of the Burgenland to Austria more is to be said, but the position as a whole is one of unstable equilibrium, and can only be maintained by support from without. In this part of Europe at least a League of Nations will not have to seek for its troubles.

When we turn to Austria we are confronted with the great tragedy in the reconstruction of Europe. Of that country it could once be said, "Bella gerant alii, tu felix Austria nube," but to-day, when dynastic bonds have been loosened, the constituent parts of the great but heterogeneous empire which she thus built up have each gone its own way. And for that result Austria herself is to blame. She failed to realise that an empire such as hers could only be permanently retained on a basis of common political and economic interest. Instead of adopting such a policy, however, she exploited rather than developed the subject nationalities, and to-day their economic, no less than their political, independence of her is vital to their existence. The entire political reorientation of Austria is necessary if she is to emerge successfully from her present trials, and such a reorientation must be brought about with due regard to geographical and ethnical conditions. The two courses which are open to her lead in opposite directions. On one hand she may become a member of a Danubian confederation, on the other she may throw in her lot with the German people. The first would really imply an attempt to restore the economic position which she held before the war, but it is questionable whether it is either possible or expedient for her to make such an attempt. A Danubian confederation will inevitably be of slow growth, as it is only under the pressure of economic necessity that it will be joined by the various nationalities of south-eastern Europe. Moreover, Austria has in the past shown little capacity to understand the Slav peoples, and in any case her position in what would primarily be a Slav confederation would be an invidious one. For these reasons we turn to the suggestion that Austria should enter the German Empire, which, both on geographical and on ethnical grounds, would appear to be her proper place. Geographically she is German, because the bulk of the territory left to her belongs either to the Alpine range or to the Alpine foreland. Ethnically, of course, she is essentially German. Now, although my argument hitherto has rather endeavoured to show that the transfer of territory from one State to another on purely economic grounds is seldom to be justified, it is equally indefensible to argue that two States which are geographically and ethnically related are not to be allowed to unite their fortunes because it would be to their interest to do so. And that it would be to their interest there seems little doubt. Austria would still be able to derive some of her raw materials and foodstuffs from the Succession States, and she would have, in addition, a great German area in which she would find scope for her commercial and financial activities. Not only would Austria find a market for her industrial products in Germany, but she would also become the great trading centre between Germany and south-east Europe.

The absorption of Austria in Germany is opposed by France, mainly because she cannot conceive that her great secular struggle with the people on the other side of the Rhine will ever come to an end, and she fears the addition of 6,500,000 to the population of her ancient enemy. But quite apart from the fact that Germany and Austria cannot permanently be prevented from following a common destiny if they so desire, and apart from the fact that politically it is desirable they should do so with at least the tacit assent of the Allied Powers rather than in face of their avowed hostility, there are reasons for thinking that any danger to which France might be exposed by the additional man-power given to Germany would be more than compensated for by the altered political condition in Germany herself. Vienna would form an effective counterpoise to Berlin, and all the more so because she is a great geographical centre, while Berlin is more or less a political creation. The South German people have never loved the latter city, and to-day they love her less than ever. In Vienna they would find not only a kindred civilisation with which they would be in sympathy, but also a political leadership to which they would readily give heed. In such a Germany, divided in its allegiance between Berlin and Vienna, Prussian animosity to France would be more or less neutralised. Nor would Germany suffer disproportionately to her gain, since in the intermingling of northern efficiency with southern culture she would find a remedy for much of the present discontents. When the time comes, and Austria seeks to ally herself with her kin, we hope that no impassable obstacle will be placed in her way.

The long and as yet unsettled controversy on the limits of the Italian kingdom illustrates very well the difficulties which may arise when geographical and ethnical conditions are subordinated to considerations of military strategy, history, and sentiment in the determination of national boundaries. The annexation of the Alto Adige has been generally accepted as inevitable. It is true that the population is German, but here, as in Bohemia, geographical conditions appear to speak the final word. Strategically also the frontier is good, and will do much to allay Italian anxiety with regard to the future. Hence, although ethnical conditions are to some extent ignored, the settlement which has been made will probably be a lasting one.

On the east the natural frontier of Italy obviously runs across the uplands from some point near the eastern extremity of the Carnic Alps to the Adriatic. The pre-war frontier was unsatisfactory for one reason, because it assigned to Austria the essentially Italian region of the Lower Isonzo. But once the lowlands are left on the west, the uplands which border them on the east, whether Alpine or Karst, mark the natural limits of the Italian kingdom, and beyond a position on them for strategic reasons the Italians have no claims in this direction except what they can establish on ethnical grounds. In Carniola the Slovenes are in a large majority, and in Gorizia they also form the bulk of the population. On the other hand, in the town and district of Trieste the Italians predominate, and they also form a solid block on the west coast of Istria, though the rest of that country is peopled mainly by Slovenes. It seems to follow, therefore, that the plains of the Isonzo, the district of Trieste, and the west coast of Istria, with as much of the neighbouring upland as is necessary to secure their safety and communications, should be Italian, and that the remainder should pass to the Jugo-Slavs. The so-called Wilson line, which runs from the neighbourhood of Tarvis to the mouth of the Arsa, met these requirements fairly well, though it placed from 300,000 to 400,000 Jugo-Slavs under Italian rule to less than 50,000 Italians, half of whom are in Fiume itself, transferred to the Jugo-Slavs. Any additional territory must, by incorporating a larger alien element, be a source of weakness and not of strength to Italy. To Fiume the Italians have no claim beyond the fact that in the town itself they slightly outnumber the Croats, though in the double town of Fiume-Sushak there is a large Slav majority. Beyond the sentimental reasons which they urge in public, however, there is the economic argument, which, perhaps wisely, they keep in the background. So long as Trieste and Fiume belonged to the same empire the limits within which each operated were fairly well defined, but if Fiume becomes Jugo-Slav it will not only prove a serious rival to Trieste, but will prevent Italy from exercising absolute control over much of the trade of Central Europe. Its development is more fully assured as the one great port of Jugo-Slavia than under any other form of government. With regard to Italian claims in the Adriatic little need be said. To the Dalmatian coast Italy has no right either on geographical or on ethnical grounds, and the possession of Pola, Valona, and some of the islands gives her all the strategic advantages which she has reason to demand.

Of the prospects of Jugo-Slavia it is hard to speak with any feeling of certainty. With the exception of parts of Croatia-Slavonia and of southern Hungary, the country is from the physical point of view essentially Balkan, and diversity rather than unity is its most pronounced characteristic. Ethnic affinity forms the real basis of union, but whether that union implies unity is another matter. It is arguable that repulsion from the various peoples—Magyars, Turks, and Austrians—by whom they have been oppressed, rather than the attraction of kinship, is the force which has brought the Jugo-Slavs together. In any case, the obstacles in the way of the growth of a strong national feeling are many. Religious differences are not wanting, and cultural conditions show a wide range. To build up out of elements in many respects so diverse a common nationality without destroying what is best in each will be a long and laborious task. Economic conditions are not likely to be of much assistance. It is true that they are fairly uniform throughout Jugo-Slavia, and it is improbable that the economic interests of different regions will conflict to any great extent. On the other hand, since each region is more or less self-supporting, they will naturally unite into an economic whole less easily than if there had been greater diversity. What the future holds for Jugo-Slavia it is as yet impossible to say; but the country is one of great potentialities, and a long period of political rest might render possible the development of an important State.

This brings me to my conclusion. I have endeavoured to consider the great changes which have been made in Europe, not in regard to the extent to which they do or do not comply with the canons of boundary-making—for, after all, there are no frontiers in Europe which can in these days of modern warfare be considered as providing a sure defence—but in regard rather to the stability of the States concerned. A great experiment has been made in the new settlement of Europe, and an experiment which contains at least the germs of success. But in many ways it falls far short of perfection, and even if it were perfect it could not be permanent. The methods which ought to be adopted to render it more equable and to adapt it to changing needs it is not for us to discuss here. But as geographers engaged in the study of the ever-changing relations of man to his environment we can play an important part in the formation of that enlightened public opinion upon which alone a society of nations can be established.

Economics and Statistics at the British Association.

THE meetings of Section F (Economics and Statistics) at the recent meeting of the British Association at Cardiff were characterised by the greater part taken in the programme by the younger students of economics, and the result augurs well for the future of the science. What some of the readers of papers may have lacked in experience and authority they gained in freshness of outlook, in readiness to face the new facts of the post-war situation, and in refusal to be bound by the views of the older generation. It would have been interesting had some of the older representatives of the science been present to see the clash of the old ideas and the new; in their absence some of the less orthodox views went almost unchallenged.

In the first meeting of the Section the application of the co-operative method to economic life was urged in two connections. Mr. L. Smith Gordon (arguing from his experience of Irish conditions, in which he has been associated with Sir Horace Plunkett) dwelt on the necessity of treating agriculture as an industry to be organised on a scientific basis if its psychological and economic demands were to be reconciled with modern conditions. Such a scientific basis could only be found in co-operation. In his view, the undoubted advantages of large-scale farming lay not in the actual work of production, but in the handling and sale of the goods produced; and this thesis he maintained in an examination of the economies open to agriculture. But such advantages do not necessitate the existence of large farmers; the same results can be obtained through the adoption by small men of the co-operative methods already applied in Denmark, Belgium, and Germany, and this has the further advantage of building up a numerous race of independent, prosperous small farmers.

Mr. J. Lassen, a Dane, with twenty years' experience of England, argued for the introduction into this country of the Danish system of credit corporations, and supported his case by a detailed examination of the Danish method. The unique point of the system is that, whereas most financing is usually carried out through corporations of lenders (banks, trust companies, etc.), the Danish system begins with a corporation of borrowers. The borrowers, mainly belonging to one locality, and being known to each other, give joint security for loans, and the general public are asked to lend on this first-class mortgage security. That the system has worked well in Denmark was obvious from its history, but the writer was unable entirely to satisfy the sceptics on two points: first, how, if the system were introduced here, the hard-headed Englishman could be induced to accept unlimited liability; and, secondly, how the public could be induced to subscribe to bonds which are liable to depreciation and do not yield an abnormally high rate of interest. There seemed to be some subtle difference in the psychology of the Dane and the Englishman which remained unexplained.

From co-operation the Section passed to the consideration of coal. Mr. J. O. Cheetham analysed the present coal situation with special reference to its effects on the shipping interests of Cardiff. His main subject was the falling output, an examination of its causes and results, and suggestions for increasing production. In 1913 the coal produced in the United Kingdom amounted to 287,000,000 tons, in 1919 to 229,000,000 tons—a fall of 58,000,000 tons. In the same period the numbers employed in the industry increased from 1,128,000 by 63,000 to 1,191,000; and the output per person employed in the industry fell from 262 tons to 193 tons per annum. Thus an increase of 6 per cent. in the numbers employed synchronised with a decrease of 20 per cent. in total output. The writer also estimated (though from an *ex parte* statement by employers) that labour costs had increased from 63 per cent. of selling price in 1914 to 75 per cent. of selling price in 1919. Thus the period of Government control of the coal industry was also the period of the decline in total production and in production per head, and of increase in relative labour costs of production. The special causes to which the decline in output was attributed were the introduction of the seven-hours' day and the failure of transport to convey the coal from the pit-head owing to the lack of trucks. In addition, the employers accused the miners of restricted production, and the employees in turn accused the owners of a deliberate holding-up of the development of mines. Mr. Cheetham seemed to hold both charges well grounded, but to think that what was a sin against the community on the part of the miners was natural and justifiable on the part of the owners—a distinction in which it was difficult to follow him. The president of the Section, Dr. Clapham, directed attention to the necessity of discovering to what extent the decreased output was attributable to the employment of a large amount of labour, not in getting coal, but in improving the state of the mines which had been inevitably neglected during the war period.

Mr. R. F. Adgie, in a paper entitled "The Conduct of the Mining Industry," distinguished between the economic and the psychological aspects of the problem of nationalisation. His thesis was that while from the purely economic point of view the argument for nationalisation was inconclusive, from the psychological viewpoint the balance of evidence pointed to the necessity of social ownership and control. On the economic side he pointed out that there had been an undefined amount of waste connected with the conduct of the industry under private ownership in the past. There was a good deal in distribution, since coal sold at the pit-head for 23*s*. 5*d*. was sold to the London consumer at 44*s*., the distribution charges thus amounting to 47 per cent. This leakage, however, could be stopped by large-scale or unified distribution. In some other directions the economic defects of the industry in recent years (reduced output, inefficient working, etc.) were exigencies of the war period, and were rapidly disappearing; and in others uncoordinated effort and inadequate capital resources had been at fault. But on the economic ground alone the analysis of the existing system had not revealed any advantages arising from social ownership and control which could not be achieved under capitalism. From the psychological point of view the case was different. While granting that the best organising ability might not be forthcoming in a socialised mining industry, he contended that in coal-mining the absence of the best trained direction was of less importance than in other industries. On the other hand, the technical staffs were willing to work under a socialised industry, and the miners would co-operate in no other. Without the technical staffs and the manual workers the industry could not function at all, and therefore, on the balance, the introduction of socialised ownership and control was, from the psychological aspect, inevitable.

The third sitting of the Section was devoted to financial problems. The address of Mr. A. H. Gibson covered a wide field, and was mainly historical in its treatment of its subject, "Credit: Inflation and Prices." After a survey of the development of credit institutions, Mr. Gibson pointed out that banks having by common consent collectively become custodians of the available purchasing power, this imposed on them the duty of not expanding credit at a rate proportionately greater than the increasing supplies of commodities, otherwise inflation would necessarily follow. In theory there was no limit to the expansion of bank credit, subject to the banks being able to obtain sufficient legal tender to meet current demands. He explained that "ways and means advances" by the Bank of England had had the effect of increasing the cash reserves of the banks during the war, and therefore banks were compelled to stop expansion of credit. He expressed the opinion that the banks would meet all the demands made on them for legitimate trade requirements. Traders would find that after a time the restriction of credit would enable them (by causing a fall in prices) to conduct their businesses on a lesser amount of floating capital than at present. He reviewed the necessary steps to be taken for deflation, the chief of which, he maintained, was the increase of production without a further increase in wages or profits. Other remedies were the reduction in the purchasing power of the community, the funding of the present floating debt by direct subscriptions from the public and not from the banks, and further retrenchment in public expenditure. The purchasing power of the community was now 1,800,000,000*l.* greater than before the war, and 85 per cent. of this represented bank credit expansion.

One of the worst evils of inflation was that it considerably reduced the export trade of the country because of higher costs of production. Under these conditions high prices would remain, for this country would have little to offer in exchange for imports of foodstuffs and raw materials from foreign countries. Thus the inflation, which appeared of little consequence to the Government during the war, had all the seeds of disruptive forces within it in the case of a country situated like the United Kingdom, dependent for its existence on foreign trade. It had been a suicidal policy, and the harvest was yet to be reaped. High prices, discontent, labour troubles, and the probable loss in the future of a considerable part of our former volume of export trade were some of the fruits of this monetary inflation policy. The Government and the banks would make every effort to make the deflation as gradual as possible, but the process was bound to be accompanied by severe labour troubles and social discontent. He held, however, that however bitter the pill might be, it would be to the ultimate benefit of Labour to accept the inevitable reduction of wages and exert the maximum combined effort with Capital to increase production. A considerable increase in production might even allow the present level of wages to remain. Labour consumed probably 90 per cent. of the fruits of production, and had everything to gain by intensified output and everything to lose by wilfully diminished production.

At the last sitting of the Section the chief contribution was a paper by Mrs. Wooton on "The Future of Earning." Mrs. Wooton's thesis was that there is nothing inherently sacred in the notion of earning; that in recent times the payment of subsidies which had no relation to the value of work done had taken an increasing part in the remuneration of the worker; and that the time had come to recognise the new ground of remuneration and to pay subsidies avowedly as such and not disguised as wages. As evidence of the tendency she pointed to the increased acceptance of the idea of a minimum wage and the growing favour of time- as distinguished from piece-wages. When the minimum wage paid exceeded the value of the work done for which it was paid, then it was no longer earned, but it was really a subsidy to the worker, and it was incompatible with the continuance of payment of a wage.

In the course of the last two or three years research has been carried on by sub-committees of the Section into problems of credit and currency and into the place taken by women in industry during the war. Already several printed reports have been issued by these committees. The Committee on Women in Industry will probably issue a final report, and the Committee on Credit and Currency has been continued for another year and will issue its report in the summer of 1921.

The International Congress of Physiologists.

AMONGST the results of the outbreak of war in 1914 was the making of it impossible for physiologists to assemble together as was their wont every three years. But now that Europe is recovering from the conflict, physiologists from different countries have been able to assemble, and they did so in Paris on July 15–20.

The congress was under the presidency of Prof. Richet, of the chair of physiology at the Sorbonne, who was assisted by the vice-president, Prof. Gley, of the chair of general biology at the Collège de France. It was informally opened on the evening of Wednesday, July 14, by a *réunion amicale* in the laboratories of physiology at the Sorbonne. This conversazione gave opportunities for old friends to forgather and to make arrangements for the congress-week.

At ten o'clock on the following morning the congress was formally opened by a convocation in the great lecture-hall of chemistry at the Sorbonne. The amphitheatre had been transformed by means of crimson curtains and gilded chairs into a *salle d'honneur* for the occasion. Prof. Richet occupied the chair, and was supported by the Minister of Public Instruction, Prof. Gley, Prof. Fano, Prof. Fredericq of Liége, Profs. Sir E. Sharpey Schafer, Langley, Sherrington, Waller, and others.

The presidential address was simple, dignified, and impressive. The president began by recalling the names of those physiologists who had passed away from their labours since the last congress at Groningen in 1913. No sooner had he finished this part of his discourse than the whole assembly rose to their feet and remained standing in silence for some short time. It was quite spontaneous, so French, so exactly the thing to do at the moment, yet without a trace of anything theatrical or insincere.

The latter part of the address was an interesting survey of such advances in physiology since 1913 as have necessitated changes in our views regarding certain problems. In particular, reference was made to the value of the researches of the American physiologists under Benedict into metabolic exchanges at rest—the so-called "basal metabolism." Prof. Fano, the new occupant of Luciani's chair at Rome, was the next speaker, the subject of his discourse being the two cerebral attributes of volition and inhibition. He made use of data obtained through injuries to the human brain in the late war.

The afternoon was devoted to the reading of papers and to witnessing demonstrations, for which purposes the congress was divided up into five sections, which had to meet simultaneously.

At half-past eight the members were invited to witness a display of scientific kinematography at the Institute of Oceanography in the Rue St. Jacques. At this *séance* the Prince of Monaco and his suite were present. The demonstrations were exceedingly interesting, those of the amœboid movements of the leucocytes in frog's and in human blood being particularly instructive. The rate of reproduction of the films had been accelerated to sixty or eighty times the normal, so that, instead of seeing leucocytes advance on bacilli in the leisurely fashion of their own positive chemiotaxis, they appeared to bolt in and out amongst the *rouleaux* of red discs like so many rabbits amongst the bracken of a warren. Another set of illustrations was equally remarkable: men and animals had been photographed walking, running, and leaping, not only at the rate necessary for the normal reproduction of these movements, but also so rapidly that the transit of the pictures could be brought down to a very slow rate without, however, producing any flicker.

The illusion in the artificially retarded series was very curious; one saw, for instance, a man with a pole in his hand approach a high gate, slowly place the pole on the ground, rise leisurely into the air, float slowly over the gate, and then, having left the pole upright behind him, sink slowly down on the other side. The pole meanwhile fell on one side with a dignity and grace that would not have shamed a Vere de Vere. As a physiological study of the various groups of muscles co-ordinated in actions of this kind, the demonstrations were very valuable. Other series were: the cure of avian beri-beri; the heart and lungs in action in the opened thorax of the cat; hydromedusæ in their tanks; a cat let fall back downwards rotating itself so as to alight on the ground on all fours; and the flying of birds and butterflies in artificially retarded action.

The secretion of pancreatic juice after the injection of secretin into a dog was clearly demonstrated, as also the artificial digestion of a cube of albumen by activated pancreatic juice in presence of the necessary controls. This last demonstration was very remarkable, for in a few moments we were shown the chemical disintegration of the protein into soluble substances, which in reality occupies more than nine hours.

Saturday, July 17, until six o'clock, was given up to the scientific work of the congress. At nine in the evening Prof. and Mme. Richet received the members in their large and handsome house in the Rue de l'Université. It was fortunately a fine, warm evening, so that we were able to stroll about the illuminated garden, where the conversations were not exclusively on scientific subjects.

On the Sunday no scientific work was undertaken, but an excursion was made to the park and château at Chantilly, a place best known to many Englishmen as the site of a racecourse. This proved a very enjoyable visit; the interior of the château is decorated in the stately and gorgeous style of the Renaissance, and the house contains some fine paintings, besides miniatures, valuable gems, and other treasures.

Monday, July 19, saw the congress busily at work again until five o'clock, when there was a large reception at the Hôtel de Ville. This was given by the Mayor of Paris and the City Council; it was a full-dress affair, as might be interred from the costumes of the ladies and from the uniforms and cocked hats of the attendants by whom we were ushered up marble staircases to painted halls. There were speeches of welcome and speeches of thanks in response, as well as generous entertainment.

At nine o'clock the same evening a *soirée* was given by the Club de la Renaissance française in the Rue de Poitiers. This consisted of a concert of chamber music, in which piano, 'cello, and harp all took part. Not for long had some members of the congress, they said, enjoyed an evening so much, for they were enabled for an hour or two to escape from the auditory discords of the streets and to live in an atmosphere of pleasing sounds.

On Tuesday, July 20, the congress was at its work again until half-past two, when the *séance de clôture* took place. At nine o'clock the same evening the Rector of the University of Paris gave a formal reception to the congress in the magnificent salons of the Sorbonne. This was a full-dress conversazione, the entertainment provided, besides some singing, being a recitation by a young actor of one of Alfred de Musset's poems.

During the week several dinner-parties and lunches were given, both the president and Prof. Gley acting frequently as hosts. The number of ladies who as physiologists participated in the congress was larger than at any previous meeting, Great Britain being particularly well represented in this respect.

Not many American or Canadian physiologists attended the congress. American physiology was, however, represented by Prof. Neil Stewart, of Cleveland University, Ohio; Prof. Frederick S. Lee, of Columbia University, New York; Prof. Graham Lusk, of Cornell University, New York; and Dr. L. G. Henderson, of Harvard University.

From Canada there were only Prof. J. J. R. Macleod, of Toronto University, and Prof. Fraser Harris, of Dalhousie University, Halifax, N.S.

The subjects discussed at the congress are too numerous to be dealt with in the detail they deserve. The physiology of adrenalin was the subject of prolonged debate. In particular, doubt was cast upon the trustworthiness of some of the methods for the detection of that hormone in the blood and upon the alleged rapidity with which adrenalin is increased in a very large number of different conditions, some accompanied and some not by emotional factors.

The topics of diabetes, the psycho-galvanic phenomenon of Waller, human calorimetry, the transport of carbon dioxide in the blood, and the condition of the respiratory centre in shock were all discussed at as great length as the overloaded state of the programme permitted.

The congress was too short to deal adequately with all the difficult problems presented for solution. Some of us were just beginning to know one another and to discuss subjects of mutual interest when it was time to part. It was all too short for any lover of Paris, for no lover of brightness and beauty leaves Paris without regret. Some departed for the shell-scarred battlefields of the greatest war in history; others, ere they returned to the routine of their lives, gave one more glance at the gardens of the Tuileries lying in the golden sunshine of the perfect July afternoon as it brought out all the vivid colours of the flowers grouped with such unerring taste.

Memories of the past had been crowding in all that week; did not the word "Sorbonne" at one time import everything that strove against scientific enlightenment, and connote everything that stood for the obscurantism of the Middle Ages?

The historically minded could not but recall that it was in the gardens of the Tuileries one day in 1819 that Laennec devised the first stethoscope. He had been watching some children place their ears on logs of wood to hear sounds conveyed through them, and, seizing on the principle underlying the children's play, he soon invented the stethoscope, one of the earliest instruments of modern medicine.

As we strolled across the gardens we gave a parting glance at the sun-bathed roofs of the Louvre, the most magnificent palace in Europe, a building the history of which is an epitome of the wonderful story of France herself—of her glories, her triumphs, her crimes, and her sorrows. D. Fraser Harris.

University and Educational Intelligence.

The Patent Office Library is open to the public daily except on Sundays, Good Friday, Christmas Day, Whitsun Eve, and Bank Holidays. On and after October 1 the hours of opening will be from 10 a.m. to 9 p.m., except on Christmas Eve and Easter Eve, when the library is closed at 4 p.m.

Dr. R. M. Caven has been appointed to the chair of inorganic and analytical chemistry in the Royal Technical College, Glasgow. This vacancy was caused by the transfer of Dr. F. J. Wilson to the chair of organic chemistry in succession to Dr. I. M. Heilbron, who was recently appointed professor of organic chemistry in the University of Liverpool. Dr. Caven was for many years lecturer in chemistry at University College, Nottingham, a position he resigned to become Principal of the Darlington Technical College.

The new session of the Battersea Polytechnic opens on Tuesday, September 21. A general introductory course has been arranged for students desiring either to qualify for the scholarship or entrance examinations of any of the diploma courses, or to take the Matriculation Examination of London University before taking up a science or engineering degree course. Day and evening courses are provided for those desirous of taking the Intermediate and Final Examinations of London University in science (pure and applied) and in music. Day courses are also available in engineering and other technical subjects, including teachers' courses in sanitary and domestic science. Evening courses are wider in scope; engineering, physics, photography, languages, music and domestic science are among the subjects with which the lectures will deal. Full particulars of all the courses will be found in the Polytechnic Calendar, which can be obtained from the secretary.

A combined effort is at present being made by students and friends of the City and Guilds Engineering College, the Royal School of Mines, and the Royal College of Science in support of the Imperial College War Memorial scheme. The first object in view is the erection in the college buildings of simple memorial tablets bearing the names of the old students—some three hundred in all—who fell in the war. Closely connected with this purpose, and arising out of the desire of ex-Service men and relatives of the fallen to do something of permanent practical value for the students of the college, is the scheme for the acquisition of a sports field. This particular provision for physical development has hitherto been lacking at the Imperial College, and the enterprise now on foot aims at supplying what is generally admitted to be an essential part of the equipment of an educational institution. In response to an appeal issued in May last for 12,000*l*. to enable the scheme to be carried out in its entirety, a sum of more than 6000*l*. has already been subscribed or promised. This has been considered sufficiently encouraging to warrant the acquisition of a suitable ground over which an option had been secured, and the committee is now appealing to all old students and other friends of the Imperial College who have not so far subscribed to take their share in providing the balance of the purchase price and the cost of equipment.

Societies and Academies.

Paris.

Academy of Sciences, August 17.—M. Henri Deslandres in the chair.—G. **Humbert**: The expression of a non-Euclidean area of the fundamental domain related to an indefinite Hermite form.—T. **Carleman**: Singular integral equations with a real and symmetrical nucleus.—M. **Galbrun**: The deformation of a helical spring the extremities of which are constrained.—L. **Barbillion** and M. **Dugit**: A new class of measuring apparatus for the direct evaluation of magnitudes which are functions of two variables. Forms of apparatus now in use, based on the determination of the position of intersection of two rectilinear needles with reference to a curve, are liable to errors of parallax which are difficult to reduce. The type now described is based on the use of a rectilinear needle and a curved needle rotating on a common axis. Two examples of application of the method are suggested: speed indicators for aeroplanes and control of carburettor in internal-combustion motors.—C. **Nordmann**: The absorbing powers of the atmospheres of stars. A method of comparing them and of determining the minimum numerical values.—H. **Gault** and R. **Weick**: A case of isomerism in the series of the aromatic α-keto-acids. In addition to the two isomers of phenylpyruvic acid described by the authors in a recent paper, a third isomer has now been isolated, and the conditions under which these isomers can be transformed into the other forms have been worked out. A study of the reactions of these three compounds leads to the conclusion that two are stereo-isomers possessing the enolic form, and the third is the ketone.—R. **Fosse**: The synthesis of a second diamide, oxamide, by the oxidation of sugar and ammonia. Oxamide has been isolated as one of the products of oxidation of cane-sugar in presence of ammonia by calcium permanganate.—MM. **Tiffeneau** and **Orékhoff**: The hydrobenzoin transformation. The influence of the nature of the reagent. With the exception of the case of triphenylglycol, which reacts in the same manner with different dehydrating agents, according as strong or dilute sulphuric acid is employed, the dehydration of the alkylhydrobenzoins may take place in various ways.—H. A. **Brouwer**: The nature of the diamond-bearing conglomerate of Diamantina, Brazil.—P. W. **Stuart-Menteath**: The tectonic of the Western Pyrenees.—J. **Kunstler**: A treatment preventive of oidium. A handful of sulphur is distributed round the roots of the vine at a depth of 10 to 20 cm.—P. **Wintrebert**: The time of appearance and mode of extension of the sensibility at the surface of the tegument in fishes and amphibians.—C. **Levaditi**: An attempt at the culture of the organism of syphilis in symbiosis with the cellular elements. The culture *in vitro*, in contrast with the virus of poliomyelitis and rabies, not only did not grow, but rapidly lost its vitality and virulence.—F. **Grenet**: The appearance of alcoholic yeast in vineyards. It was noted by Pasteur in 1878 that although mould-spores could be found on the stems of the vines and in the soil at all periods of the year, alcoholic yeast appeared only at the time the grape ripened. The cause of this has now been traced to the fly, *Drosophila melanogaster*, which carries the yeast-spores, and appears in the vineyards only when the grapes are ripe. The origin of the fly has not been traced, nor is it known whence it obtains the yeast-spores.—E. **Joltrain**: The value of Bordst's fixation reaction in the diagnosis of plague. This reaction has rendered great service in cases of doubt in convalescents, and when search for the bacillus has given negative results.—C. **Gessard**: Sub-races of the pyocyanoid bacilli.—L. **Scheffler**, A. **Sartory**, and P. **Pellissier**: The use of silicate of soda in intravenous injections: physiological and therapeutical effects. Sodium silicate solutions may be utilised for intravenous injection in doses worked out empirically. The treatment is beneficial in cases of arterio-sclerosis, in cardio-renal troubles, and in chronic rheumatism. The treatment of tuberculosis by this method is under consideration.

ROME.

Reale Accademia dei Lincei, May 2.—A. Róiti, vice-president, in the chair.—S. **Pincherle**: Complete iteration of x^2-2. The problem has not been resolved for a non-linear function except in very limited cases, of which this is an example.—O. **Tedone**: Some other formulæ of inversion connected with Riemann's method of integration. These formulæ have applications to certain mechanical problems, such as finite wave-motion in an elastic fluid.—F. **Millosevich**: Blödite and other minerals of the saline deposits of Monte Sambuco, in the territory of Calascibetta, Sicily. The salt deposits on the southern face of the mountain, which is in the province of Caltanisetta, are worked by three tunnels, of which the upper cuts through a deposit of hard salt containing local aggregates of the present mineral, which is synonymous with astrakanite, and occurs in two forms, one of which is coloured by iron oxide. The crystallographic data are given, and the analysis indicates the composition $Na_2SO_4.MgSO_4.4H_2O$.—E. **Bompiani**: Point transformations between varieties which satisfy Levi-Civita's parallelism.—R. **Raineri**: Tripoli Corallinaceæ, iii. The species dealt with are *Corallina officinalis*, L., *C. mediterranea*, Areschoug, and *Peyssonelia rubra*, Grev.—Anna **Foà**: Excretory system of the silkworm. The peri- and endo-cardiac and peritracheal glands form a system for the excretion of certain substances probably having an acid reaction. A figure is given of a silkworm injected with carmine and Chinese ink.—A. **Pais**: Convalescence of chronic malaria by X-rays.—Commenting on the foregoing paper, Prof. B. **Grassi** concludes that in the sequelæ of malaria these rays, when opportunely used, have an almost marvellous curative effect, when other remedies, such as quinine, arsenic, iron, diet, and change of air, are much more tardy and uncertain in their action. On the other hand, these remedies can be usefully employed, especially in rebellious cases, in conjunction with ray treatment, but the latter has been shown to be suitable for adoption in every malarial district.—G. **Amantea**. Spermatic secretion, x. The elimination of the sperm in the cavy and rat.—Profs. **Róiti** and **Castelnuovo** referred to the deaths of Theodore Reye, Zeuthen, and Hurwitz; and Prof. Levi-Civita presented reports by C. **Guidi** on the strength of dykes, and by M. **Panetti** on the aerodynamic laboratory adjoining the Polytechnic of Turin.

May 16.—F. D'Ovidio, president, in the chair.—A. **Angeli**: Reactions of some ortho- and para-substitute derivatives of benzol.—Anna **Foà**: Excretory system of the silkworm, ii. The rectal portions of the Malpighian tubes (with three illustrations).—G. **Cotronei**: Identity of metamorphoses of Amphibia anura and urodela.

The Re-challenge to the Ocean.

WE are glad to notice the general approval with which Prof. Herdman's suggestion of a renewed *Challenger* deep-sea expedition has been received, and we hope that men of science will not fail to take immediate advantage of the present very favourable opportunity for urging upon the Government the renewal of the great enterprise of 1872. Never, unhappily, had the population of these islands to think so much and so anxiously of maritime affairs as during the four years that began in August, 1914. We believe that this concern did not die away when peace was arranged, and we may be sure that very many people are now interested, not only in the further development of our mercantile marine and deep-sea fisheries, but also in the exploration of the ocean as a matter of pure scientific research.

It was, therefore, very fortunate that this was the subject of the Presidential Address at Cardiff, and that the latter succeeded in arousing public interest in a remarkable manner. Politically, also, the time is opportune. Never has the naval supremacy of this country been so unquestioned as it is at the present time, and for this we have to thank the high level of character and resource that has been exhibited by all grades of seagoing men, not only professional sailors but also fishermen and yachtsmen. These qualities must be our best defence in the unforeseeable dangers that may yet threaten us as a nation, and we can think of no better way of cultivating them than by endeavouring to arouse a general interest in everything connected with the sea. Here, then, we have a way, by giving the people the opportunity of following with interest the progress of a great national voyage of deep-sea exploration.

Thus, both from the point of view of national security and that of the development of our marine resources, much is to be said in favour of a renewed *Challenger* expedition, but here our predominant interest ought to be that of pure scientific investigation. It is fifty years since the original proposal for a national oceanographical voyage of exploration was made, and at that time the difficulties of fitting out a ship for that purpose were much greater than they are now: thus, the officers of the *Challenger* hesitated for a long time as to whether they ought to use the recently adopted steel wire for sounding and dredging in preference to hempen rope, and finally they decided upon the latter. In almost every respect the details of oceanographic methods have been improved almost out of recognition. It took several hours then to make a deep sounding, and a whole day to work a dredge for an hour or so in very deep water, and then the results were often uncertain. Now these operations can be carried out expeditiously, and with every prospect of complete success, so greatly have the cable ships improved sounding apparatus and the steam trawlers fishing gear. Plankton methods have been so intensively studied during the last twenty years that it should now be possible to arrange a programme that may solve many theoretical questions with the indispensable economy of labour. Physical and chemical methods for the determination of temperature, density, and other sea-water variables have been developed to a remarkable degree by the international organisation for fishery investigations.

There may possibly be suggestions for new methods of research in the study of the artifices adopted in anti-submarine warfare. We may be certain that with the perfected apparatus now at the disposal of an ocean-going marine-biological and hydrographic expedition results may be obtained much more quickly and accurately than in 1872. It is true that various deep-sea expeditions have been made since the time of the *Challenger*, and that the new methods have been employed. Still, those expeditions were mostly rather small ones, and what is wanted now is a voyage of, at the very least, the duration and scope of that of the *Challenger*. It is also true that all the recent expeditions have been foreign, and that Great Britain has, ever since 1872, lagged behind in this respect. It is owing to our present condition of naval superiority and commercial progress that we should do our share in oceanographical research.

In many ways the outlook is now markedly different from what it was in 1872, and so much more evident is the need for renewed investigation. The detailed study of the results obtained by the *Challenger* herself, and the discussion which these have now received, point to the need for renewed investigation, both on more intensive and more extensive scales. It cannot be said that the recent expeditions afford data for the settlement of most questions. One must never forget what a very insignificant fraction of the whole area of the ocean bottom has been touched by *all* the deep-sea expeditions. There is an enormous tract, said Mr. Tate Regan at the British Association discussion, lying round the Falkland Islands and up as far as Montevideo, which is almost unknown. All this lies within the 100-fathom contour line, and it may be the region of lucrative fisheries. Yet over it all there are only some eight trawling records—two by the *Challenger* and six by the *Albatross*. In these days, when trawler-owners are seeking new grounds, when the British fishery industry looks like being world-wide in its scope, and when steam fishing-vessels can cross the ocean and can fish commercially at depths of 100 to 200 fathoms, such a suggestion cannot be ignored.

All such investigations carried out with the object of discovering fishing-grounds, charting unknown sea-bottoms, or investigating tides and currents from the point of view of the navigator are, of course, utilitarian. But they employ scientific methods and they obtain a great surplus of data to be worked out from a purely scientific point of view. We have not the space here to advert to the enormous importance and theoretical interest of a study of the ocean from the point of view of meteorology. Nor can we insist, as we ought to do, on the reflex value of an arousal of popular interest in marine science. Immersed, as we are at present, in the problems of commerce and industrial production, one is apt to forget how curious are all people connected with the sea in the results of marine research. That popular curiosity and interest is something that scientific organisation ought legitimately to attempt to satisfy.

Philosophical Aspects of Nature.

(1) *The Concept of Nature: Tarner Lectures delivered in Trinity College, November, 1919.* By Prof. A. N. Whitehead. Pp. ix + 202. (Cambridge: At the University Press, 1920.) Price 14*s*. net.

(2) *Lectures on Modern Idealism.* By Josiah Royce. Pp. xii + 266. (New Haven: Yale University Press; London: Humphrey Milford; Oxford University Press, 1919.) Price 12*s*. 6*d*. net.

IT may seem that in bringing together two such widely divergent views and methods as those represented by the present professor of pure mathematics in the Imperial College of Science and Technology, and by the late genial and kindly Harvard professor and leader of modern idealism, the problem with which each of these courses of lectures deals is in danger of being prejudged. Prof. Whitehead's method is severely practical, that of Royce speculative and theoretical. It is, however, in contrasts that the profounder meaning of antithetical theories is revealed. These two courses of lectures—very similar in form and in aim—separated in time by an interval of thirteen years, both deal with the same subject, the concept of Nature, and both are conscious, despite a fundamental divergence, of an identical problem.

(1) The Tarner Lectures of Prof. Whitehead consist of a core of constructive work. Certain kinds of entities are posited for knowledge in sense-awareness. The classification of these, and the investigation of the sorts of relations they can have to one another, form the constructive work undertaken. The most fundamental of these entities are events, and the first kind of relation examined is time. The factors in Nature represented by the conception of space are next brought under review, and the method by which they are analysed is named "extensive abstraction." Space and motion are then considered, and lead to the formulation of a theory of congruence—that is, of measurement in space and time. This plunges us into the relativity controversy, and enables the author to define his position in regard to the theory of Einstein. Finally, we have a theory of "objects," which are described as "the elements in Nature which do not pass." Objects are "recognised," events happen; an event occurs once and is unique, but objects have the character that they can "be again." This core of constructive work has a prologue and an epilogue in the two introductory and the two concluding chapters. It is in these that the problem underlying the concept of Nature is acknowledged, the principle which must rule scientific inquiry discussed, and the issue between the divergent

methods, the *a priori* and the experimental, decided.

Prof. Whitehead sees very clearly and expresses very boldly the philosophical problem of Nature. It is admirably expounded in his chapter on "Theories of the Bifurcation of Nature." By bifurcation he means that Nature is presented first in sense-awareness and then in a conceptual activity of thought. Though the two consequent forms, sense-images and concepts, are inseparable, they are so absolutely distinct that when we reflect on them they present themselves as two totally different kinds, or orders, of facts, between which the relation, so far from being obvious and transparent, is literally incomprehensible. For not only is our sense-awareness fragmentary, requiring an activity of conception to complete it—as when, for example, we conceive another side of the moon—but also the fragmentary appearances themselves are referred to another kind of reality, conceived as existing in itself and called Nature. Physical science treats of electrons, æther waves, and such like, as existent entities, sense-awareness being a special form of the relation of these to the mind. This old philosophical problem has recently forced itself on the attention of physicists by reason of the startling nature of Einstein's special and general relativity principle. In fact, Einstein may truly be said, adapting the famous phrase of Kant, to have roused physicists from their dogmatic slumber. Prof. Whitehead treads the new ground confidently, but yet with caution. He will not have the "curvature of space," and he insists that the concept of Nature shall concern the reality of the observation, unconfused with any question concerning its relation to the observer and his system. To deny the possibility of this detachment is in his view not simple scientific scepticism, but destruction of the basis on which any physical science can be constructed.

(2) The lectures of the late Prof. Royce, originally entitled "Aspects of Post-Kantian Idealism," were first delivered in 1906, and therefore antecede the apparition of the Principle of Relativity. This is not very important, because that principle propounded nothing in the least strange and unfamiliar to philosophers. It is, indeed, essentially one and identical with the principle of idealism. It is its confirmation by experiments which has brought it home with such force to the scientific worker. Although, therefore, the lectures are largely historical, and deal with a philosophical movement and speculation a century old, they are vitally relevant to our present problem. The problem of post-Kantian idealism was essentially the problem of Nature, in particular the fact that while Nature is a concept brought to birth by the mind itself in its intellectual activity, under the stimulus and out of the material provided for it by sense-awareness, yet this concept stands before the mind as necessarily independent and alien in its existence, and as the ground of the existence of the mind itself.

It is curious how, in the historical retrospect of the important philosophical movement which followed Kant, Hegel overshadows all his contemporaries. One of the most interesting portions of this book is the account of the wonderfully brilliant work of Schelling, especially in his early period. No physicist has grappled the problem of Nature with greater zeal or with keener insight than this philosopher.

It is not our purpose to pass judgment, but we commend these two books—both remarkable for their lucidity and intellectual honesty—to all who wish to have a comprehensive grasp of the physical and metaphysical problem of the concept of Nature.

H. Wildon Carr.

The Vehicles of Hereditary Qualities.

The Physical Basis of Heredity. By Prof. T. H. Morgan. (Monographs on Experimental Biology.) Pp. 305. (Philadelphia and London: J. B. Lippincott Co., 1919.) Price 10*s.* 6*d.* net.

So far as the study of heredity means formulating and explaining the resemblances and differences between successive generations great progress has certainly been made, and Prof. Morgan thinks it is mock modesty to refrain from saying that many problems have been solved. The present book is a masterly account of recent work on the physical basis of inheritance, which means, for practical purposes, the chromosomes of the germ-cells. The general evidence in support of the chromosomal theory is once more discussed; its fundamental propositions are clearly stated and abundantly illustrated; and numerous recent subtleties, at varying levels of probability, are explained. The book is indispensable to serious students of biology.

The first general principle is Mendel's law of segregation. The fertilised ovum contains paired factors or genes, causally linked with certain characters; these come into relation to each other, but separate off cleanly in the germ-cells of the offspring, one member of each pair going to one daughter-cell, the other member to the other cell. It is during maturation that the conjugation of homologous (paternal and maternal) chromosomes occurs and is followed by their subsequent segregation. In all probability, apart from hybrids altogether, the germ-plasm of each immature germ-cell is made up of pairs of elements or genes which segregate during maturation. In recent years an entirely unexpected and important discovery has been made in regard to segregating pairs of genes (allelomorphs). In an ever-increasing number of cases it has been found that there may be more than two distinct characters that act as allelomorphs to each other. For example, in mice, yellow, sable, black, white-bellied grey, and grey-bellied grey are allelomorphs—*i.e.* any two may be present (as a pair) in an individual, but never more than two. It may be noted, too, that at an early stage in his argument the author rejects the criticism that Mendelian characters are necessarily superficial characters. He also points out what critics of Mendelism sometimes fail to understand, that species differ from one another, not by a single Mendelian difference, but by many.

Mendel's second law describes the free and independent assortment of the genes. If an immature germ-cell contains the factors or genes—"tall," "short," "colour," "white"—then at maturation the genes "tall" and "colour" (*sit venia verbis*) will go to one daughter-cell, "short" and "white" to the other, or "short" and "colour" to one, and "tall" and "white" to the other. Now the cytological evidence is that each pair of chromosomes, just before the reduction division, consists of a maternal and a paternal member, and there is a free or random assortment of some maternal chromosomes to one pole and some to the other, and similarly for the paternal chromosomes.

But further investigation is disclosing an increasing number of cases in which free assortment does *not* occur. Many characters have been found to keep together in blocks in successive generations instead of assorting freely. This is what is called *Linkage,* one of the post-Mendelian elaborations.

Correlated with the idea of linkage is that of *Crossing Over,* which means an interchange of blocks of genes between homologous pairs of chromosomes. It may be frequent or rare; it may occur in the germ-cells of one sex, but not in those of the other; the size of the blocks may vary at different temperatures and for internal reasons; and a break in one region of the chromosome may interfere with a break in another region. It is altogether very curious and intricate. The genes of a pair do not jump out of one chromosome into the other, so to speak, but are changed by the thread breaking as a piece in front of them or else behind them, but not in both places at once. It is possible that there is a limiting value for crossing over, and if this can be established it may lead to the discovery of the lower limit of the size of the gene. It seems that the crossing over may be effected at the time of the conjugation.

The data in regard to linkage and crossing over lead to the conclusion that the genes are arranged in linear order, standing at definite levels in the chromosomes and definitely spaced. Another interesting suggestion is that the correspondence seen in *Drosophila melanogaster* between the number of linkage groups and the number of chromosomes may hold good generally. Yet another suggestion is to be found in the curious fact, too frequently illustrated to be a coincidence, that one species may have twice as many chromosomes as a closely related one.

In regard to the view that the difference between the sexes is connected with the distribution of particular chromosomes, Prof. Morgan discusses two opposing interpretations. In certain species a female organism develops from a fertilised ovum with two X-chromosomes, while a male organism develops from a fertilised ovum with only one X-chromosome, with or without a Y-chromosome in addition. The question is whether the presence of the two X-chromosomes causes a female to develop, or whether XX is merely an index of sex. According to the author the evidence is now conclusive that sex follows the chromosomes, not the other way round. He shows ingeniously how the chromosome theory of sex may be applied to the interpretation of inter-sexes, gynandromorphs, and allied phenomena.

The conception of a gene or factor seems to become increasingly complex. A gene is to be thought of as a certain amount of material in the chromosome that may separate from the chromosome in which it lies, and be replaced by a corresponding part (and none other) of the homologous chromosome. But it is now becoming clear that a gene is causally associated with *manifold* effects; that different genes may produce characters that are indistinguishable, such as whiteness in poultry; that each character is the product of many genes, and so on. Moreover, the variability of a character is not necessarily due to variability in the gene; much may be due to variability in the environmental conditions of development. Critics of Mendelism must read this book, not necessarily to criticise less, but to criticise more wisely.

There are so many illuminating discussions in Prof. Morgan's book that we find it difficult to stop. Regarding mutations it is pointed out that they are of infrequent occurrence, that the change is definite from the beginning, that some at least are recurrent, and that the difference between the old character and the new is small in some cases and greater in others. But their origin remains obscure. As to their supposed "chance" character, it is pointed out, very usefully we think, that the degree of development of any character increases the probability of further stages in the same direction. Species are to be thought of as groups of genes, and related species have a good many genes in common. Thus similar mutations are likely to occur in different but related species. Of this, indeed, studies on Drosophila have furnished experimental evidence.

We do not know how many books on heredity Prof. T. H. Morgan has written. Their succession marks the rapid advance of a department of science to which his personal investigations have made very important contributions.

New County Histories.

The Victoria History of the Counties of England: Hampshire and the Isle of Wight. Part i., pp. 46+2 maps. Part xv., pp. 409–470+1 plate: *Buckingham.* Parts iv. and vi., pp. 177–205+map and plate. Part xxiii., pp. 312–372+5 plates: *Hertford.* Parts ii. and iii., pp. 43–221+map: *Berkshire.* Part ii., pp. 27–68+map. Part iv., pp. 173–196+map and 12 plates: *Surrey.* Parts i.–iv., pp. 254+4 maps and 2 plates. (London: Constable and Co., Ltd., 1920.) Prices various.

"THE Victoria History," finely conceived and excellent in performance, at the outset in 1900 largely disdained plebeian methods of advertisement. Wealthy country gentlemen were often left in ignorance of its existence, and slender purses were mocked by the high cost to be pledged for the history of any single county. A more considerate policy has now been adopted. Essays by eminent specialists can be purchased separately. Comparison with earlier county histories shows a surprising advance in recognising the importance of natural knowledge.

Since Nature makes merry with man's artificial boundaries, a work taking all our English counties in detail cannot avoid some overlapping and repetition in dealing, for example, with botany and butterflies, with mice and their alliterative contrast, men. The difficulty is enhanced in zoology by the hordes of insects. Records stating when, where, and by whom each species was captured in a particular county become rather appalling. It is a relief to read in the "History of Surrey" that out of 3000 British flies (Diptera) only a miserable tale of 360 can be credited to the county. Yet this luck is "solely due to the paucity of collectors of this order of insects" (p. 151). Though Diptera be few, "the Phytophagous hymenoptera, *i.e.* saw-flies, wood-wasps, and gall-flies, are abundant throughout Surrey." Avoid, however, speaking disrespectfully of saw-flies. "Saw-flies can easily be bred and reared in captivity, and it is only by doing this in large numbers that we can hope to arrive at the laws which control that most mysterious phenomenon, parthenogenesis." Mr. Chawner further declares that a common species, *Poecilosoma puteolum*, produces females only, arguing from the experience that several thousands have been bred for six years in succession, and all turned out to be of that sex (p. 91). Still, it is hard to prove a negative, even for broods to which Sir Ray Lankester's term "impaternate or fatherless" would seem appropriate.

The botanists agree that "the best division of a country for botanical purposes is into river-basins" ("Hertfordshire," Hopkinson, p. 48); to explain the distribution of the flora of Berkshire, "various botanical districts essentially based on the river drainage" are used by Mr. Druce (pp. 29, 51); so also for Surrey Mr. Beeby accepts the division into districts founded on the river-basins "as the most desirable in all respects," with exceptions. The grand exception is, as he explains, that "the geological strata run in such remarkably parallel bands from east to west, while the streams run transversely to them, so that each of the principal rivers has its share of each of the formations." For Surrey Mr. Lamplugh says, "the geological structure of the county is so simple, and its existing features depend so closely upon this structure, that it forms an ideal tract for the study of the elementary principles of the science." The same might be said of the geology of Hampshire as displayed in the late Mr. Clement Reid's luminous treatise. The map of Surrey shows how you may "walk east and west upon the same formation along the line of 'strike' from one end of the county to the other; while if we go southward we soon cross to underlying, and if northward, to overlying beds."

Space permits only bare notice of an important historical disquisition on "Forestry and the New Forest," by Nisbet and Lascelles; and of the profusely illustrated essays on Early and Anglo-Saxon Man in Berks and Bucks by Shrubsole, Clinch, and Reginald Smith; while no attempt can be made to discuss the interesting local history of the "Aylesbury Hundred" of the latter county. In the botany of Surrey the late George Massee leaves a curious note of chronology by saying (p. 65): "The edible boletus (*Boletus edulis*) has a cap corresponding in size and colour to a penny bun." When will the penny bun once more rival the cap of a boletus?

Practical Organic Chemistry.

The Preparation of Organic Compounds. By E. de Barry Barnett. Second edition. Pp. xv+273. (London: J. and A. Churchill, 1920.) Price 10*s*. 6*d*. net.

THE work which the universities were invited to undertake in preparing synthetic drugs and "poison gases" in more than usual laboratory quantities forced them to replace their costly glass and porcelain apparatus, wherever possible, by larger and stronger vessels of tinned iron and by earthenware basins of cheap material. This experience has been wisely turned to account in the new edition of Mr. Barnett's book, in which a description of such apparatus is given. Although it is desirable for the beginner to use transparent vessels, in which reactions can be easily watched and controlled, and to manipulate quantities which do not demand too great an expenditure of time, the knowledge of how to apply larger scale methods he may later be called upon to adopt will prove invaluable. Moreover, the habit of discarding, as occasion demands, the usual laboratory vessels in favour of less elegant but more serviceable utensils is a good mental and moral exercise. With the exception of the above-mentioned description and the addition of a few new preparations, no fundamental change has been made in the size and scope of the new edition. It takes the form made familiar by Gattermann's and Freundler's well-known treatises, and by many other books dealing with this subject.

Which of the two systems is the more satisfactory, namely, discussing general methods and apparatus first, and then referring to them in the later preparations, or allowing the student to familiarise himself with them by actual examples involving their use, must be left to the individual teacher to decide. He must also determine what amount of detail he thinks it desirable to supply in his account of the preparations. There is no doubt that some simple modification in the conduct of a reaction which additional details would supply will often convert failure into success, with a corresponding economy in the student's time. On the other hand, advantage may be gained by the student having to surmount his own difficulties.

There is, on the whole, not much to choose between the two methods. The present writer is inclined to think that, as the purpose of the practical work is mainly to assist the student in developing his general knowledge of organic chemistry, the greater the variety of reactions he can perform during his course, which is often not too long, the more he will profit by it. Later research will afford ample opportunity for the exercise of his ingenuity in meeting and overcoming difficulties.

J. B. C.

Our Bookshelf.

The Essentials of Histology: Descriptive and Practical. For the Use of Students. By Sir E. Sharpey Schafer. Eleventh edition. Pp. xii+577. (London: Longmans, Green, and Co., 1920.) Price 14*s*. net.

"THE Essentials of Histology" preserves, in its eleventh edition, the well-known characteristics of the previous editions of this standard work. The volume is growing in size, but the additions are mainly of new illustrations. These are uniformly good, and conform to the general tendency of successive editions to present photographic representations of actual preparations, as well as semi-diagrammatic drawings emphasising points which the artist deems of special import. The latter are of great service to the beginner, but carefully selected photographs mean more to the advanced student. Both varieties are utilised in the "Essentials," and monotony in the figures is avoided by a pleasing use of colour. Although mainly a descriptive work, the practical side is better represented than a cursory glance would reveal, and the directions briefly given at the head of each lesson are amply sufficient, if exactly followed, to enable the student to obtain the preparations desired. Further practical directions are given in the appendix, which is a synopsis of general and special histological methods.

A Naturalist on the Amazons. By H. W. Bates. Abridged and edited for schools by Dr. F. A. Bruton. (English Literature for Secondary Schools.) Pp. xix+182. (London: Macmillan and Co., Ltd., 1920.) Price 2*s*. 6*d*.

IN this abridged edition selections from Bates's original work have been chosen which deal mainly with the natural history of the forests of the Amazon. A short account of the more remarkable forest trees is included, but the bulk of the book consists of selections describing the fauna of the country. Illustrations from photographs are given of most of the animals mentioned. Dr. Bruton contributes an interesting introduction and some helpful notes. We are glad that Bates's vivid descriptions of Nature and man are made available for appreciation by young people in schools by the issue of this abridged edition of his masterpiece.

The Advancement of Science: 1920. Addresses delivered at the 88th Annual Meeting of the British Association for the Advancement of Science. Cardiff, August, 1920. (London: John Murray, n.d.) Price 6*s*. net.

IN this volume are published the presidential addresses delivered at the recent meeting of the British Association at Cardiff. Such a collection, representing, as it does, the views of the leading authorities on progress made in various departments, and discussing some problems of prime interest, will be welcome to all students of science as well as to many members of the educated public. We hope the demand for the volume will justify the attempt of the Association to secure a wider circle of readers for the most interesting contributions to its annual meeting.

A Handbook of Physics and Chemistry. By H. E. Corbin and A. M. Stewart. Fifth edition. Pp. viii+496. (London: J. and A. Churchill, 1920.) Price 15*s*. net.

THE requirements of the new syllabus for the First Examination in physics and chemistry of the Conjoint Board of the Royal Colleges of Physicians and Surgeons have made it necessary to double the size of the volume issued in 1899. Short articles on statics, hydrostatics, expansion, refraction, absorption spectra, current electricity, ionisation, and radio-activity have been added in order to meet the new syllabus, and much new matter has been inserted with the view of making the book more useful to students preparing for other elementary examinations in physics and chemistry.

Common Diatoms. By Thos. K. Mellor. Pp. 16 + plates. (London: William Wesley and Son, 1920.) Price 6*s*. net.

THIS little pamphlet consists of eight pages of introduction, followed by a general index and seven plates of diatoms. The author's intention is to illustrate such diatoms as are usually found on "circle" slides sold by opticians, from such districts as England, Japan, Hungary, New Zealand, Istria, Samoa, the Adriatic Sea, Maryland, etc. The seven plates contain about 400 figures, and are fairly well drawn.

The introductory remarks are of a popular description, and do not profess to deal with diatoms from a scientific point of view.

Problems in Physical Chemistry: With Practical Applications. By Dr. Edmund B. R. Prideaux. Second edition, revised. Pp. xii+294. (London: Constable and Co., Ltd., 1920.) Price 18*s*. net.

DR. PRIDEAUX's book, in its first edition, was found useful by teachers and students of physical chemistry, and served a very important purpose by assisting in directing the teaching of the subject into practical and intelligible channels. The new edition has been carefully revised and improved in many respects. The high price of the book, which is somewhat poorly bound and printed on not very good paper, will be the main drawback to its popularity among students.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The British Association.

THE Cardiff meeting of the British Association was pleasant and profitable in various ways, but the membership in an important and prosperous city like Cardiff might have been larger, and a certain amount of apathy on the part of the public in general to the presence of the Association was noticed. The Press did its best, but perhaps an influx of material prosperity has rendered folk temporarily callous to other forms of activity. My recollection of the Cardiff meeting in 1891 is that it excited more local interest—perhaps because it was the first in the city; perhaps also because the meeting included the week-end, extending from Wednesday to Wednesday, instead of ruthlessly encroaching on the four chief working days of the week and beginning sectional operations ten hours before the president's opening address. It is understood that future meetings will return to pre-war conditions in this and other respects. Other improvements may be desirable, so the manifesto of your Cardiff correspondent, Dr. R. V. Stanford, on p. 13 of NATURE of September 2 is opportune and timely.

The British Association differs from other learned societies in that it does address the general public, and travels from place to place in order to reach a wide constituency. In so far, therefore, as it takes the easier course and caters merely for specialists, it is not fully executing its mission. Its function might be described as bringing the general public into personal contact with a scientific discoverer and giving them some inkling of his methods and results. Technicalities are not always inappropriate, so they be suitably expounded; for no one can suppose that scientific work is a simple and easy matter readily understanded of the people.

If the public were treated to nothing but the superficial froth they would rightly feel defrauded; they wish to realise that a plenitude of coherent material lies beneath the surface, much of it necessarily rather deep. The enthusiasm of a scientific worker is, or should be, contagious; and an impression of real value and interest can be produced, in spite of a plentiful lack of understanding.

Moreover, though it is difficult to overestimate the ignorance of the bulk of the population, there are likely to be in every civic community a few young minds, instinctively eager and unconsciously able, who may be stimulated by a discourse from a great man and become themselves disciples, and ultimately even co-workers. The awakening of one such youth per meeting would be well worth while; nor is it too much to expect. No one can tell beforehand what particular seed will come to fruition, and instances of such awakening in the past are historic. What is called science-teaching at schools has been known before now to have a depressing effect; direct aiming at a result may not achieve it; unorganised and indirect impersonal instruction, coupled with unconscious personal influence, may occasionally be far more stimulating.

To come to details, avoiding every sort of contemporary allusion and speaking quite generally:

The President's Address should, as a rule, deal with some comprehensive and enlightening theme; but the president is an individual liable to be overweighted by the opportunity for a responsible, more or less ponderous, utterance, and it is useless to legislate for an individual.

The function of the two evening lectures is fairly understood, and great trouble is sometimes taken over their illustration. They can be approximately on the lines of a Friday evening discourse at the Royal Institution, but should be still more popular, because the audience, for the most part, will not be so experienced and specifically cultivated. They should not, of course, be of the mere elementary "popular lecture" type, and the manner of presentation should be such as to arouse admiration even in those specialists who are learned in the particular subject treated of. But whereas at the Royal Institution it is customary to hear a man discourse on his own investigations, no such tradition naturally exists at the British Association; the work of a foreigner or of a recluse may be described, or any other topic dealt with which either is in the public mind already or may be conveniently introduced there. These lectures are also an opportunity for interesting not only the general public, but also the working members of the Association belonging to other sections, who are glad of an opportunity of hearing something authoritatively and well expounded by an expert in some branch of science other than their own.

If examples are permissible, Clerk Maxwell's discourse on "Molecules" in 1873 at Bradford was not only profoundly, absorbingly, interesting at the time of delivery, but was a genuine elucidation of the molecular problems of that day and of the kinetic theory of gases; and Huxley's discourse on "Animal Automatism," the year afterwards at Belfast, was a marvel of eloquence free from adventitious aids or accessories of any kind.

So far agreement may be expected; difficulties begin when we contemplate the work of the sections. Here a certain amount of specialisation is inevitable, and the public who attend the sections expect, and on the whole enjoy, proceedings rather out of their depth. Yet still there are ways of interesting experts without being wholy unintelligible to everyone else. Dullness, indistinctness, inaudibility, and the absence of clarity, are not appreciated even by experts, though much may be forgiven when the matter is new or important. But liveliness and suggestiveness are specially appropriate at sectional meetings, attended as they are by kindly hosts who are anxious to get some glimmering of what science "feels like" to those engaged in it, whom they are for the nonce entertaining. It is probably unwise to limit the proceedings to the delivery of set papers according to a prearranged and rigid programme.

Of late years there has been a tendency to curb and curtail discussions for the sake of completing each item of a programme so far as possible to time. But in the old days discussions were often the most lively, and sometimes the most instructive and suggestive, part of the meeting. Kelvin and Stokes, Maxwell and Rayleigh, FitzGerald and Larmor—these were men worth hearing; and, whether they happened to contribute papers or not, their presence was stimulating and their remarks encouraging to the younger men. It was at one of these meetings long ago that the then unknown J. P. Joule was "discovered," and many another young man was brought into notice by the enthusiasm of Sir William Thomson and the giants of his era. Then again, Cayley and Sylvester, H. J. S. Smith, W. K. Clifford, and one or two still living, shone brilliantly in pure mathematics; and there were the Astronomers as well. Blackboards full of equations were far more frequent than the dim and depressing atmosphere required for lantern-slides, and the audience found this manner of exposition exhilarating in its own peculiar way. To see physical results emerging from chalk and duster is always an astonishing and edifying spectacle. The realities of physical investigation, and their obviously recondite character, contribute to respect. Brilliant mathematical exposition is both cheaper and easier, in a peripatetic society, than brilliant experimenting; and if both are forbidden, the true atmosphere of science is not represented. Diagrams are more trouble than lantern-slides, but are in many respects better.

I see I am speaking of the *personnel* of Section A only—it is inevitable—but I suppose that something of the same sort must have been occurring in other of the older sections; certainly a large *clientèle* assembled whenever Huxley was expected to speak, and sometimes he was quite reasonably technical in substance as well as literary in form. Are we to conclude that there were giants in those days, and despair of maintaining the standard? There is splendid work being done now, but the conditions somehow seem less attractive.

Let me be not misunderstood as making any complaint! The proceedings in Section A were brilliant this year, from the president's address downwards, and one came away full of admiration for the work of the present generation; but the programme was rather too full. So it used to be long ago also, though four hours were then given to it instead of three, and no kind of time-table was attempted. When Sir William Thomson got into his stride few presidents had the hardihood to check him or to curtail his sometimes rambling eloquence; while his young disciples were conscious of enthusiasm and enlightenment, commingled with occasional boredom, and the audience was often delighted with his vivacity, however little they were able to follow.

I feel sure that among the younger men now there are some whose more frequent contributions to a discussion would be most welcome, but the incubus of a set programme and limited time, together with apparently an over-modest expectation of hypercriticism from their immediate fellows, seems to restrain them. The secretaries of Sections used not to limit their activities to providing for the revelations of others; they shed a light of their own. No self-denying ordinance was inflicted on the president, the vice-presidents sat on the platform, and when a lively discussion seemed to be beginning the exigencies of the programme were ignored. The discussions I speak of were not formally arranged; they arose spontaneously. I remember, for instance, a lively passage-of-arms between Herbert Spencer and Clerk Maxwell on a thermodynamical subject. Sometimes there were real controversies, and occasionally some dissipation of energy in the form of heat. The modern prearranged discussions are an innovation—possibly a good one—but in organising such a discussion it has turned out to be a mistake to fire off a group of more or less allied papers by way of an opening. Disconnected and separately conceived papers do not really open; they are apt to dissipate interest and stop real discussion, partly by too extended a range, partly by consumption of time.

The procedure of a "debate," one proposer and one opposer, followed by spontaneous and unprepared speeches which really deal with the points raised, would seem a not impossible ideal.

It must be admitted that the more elastic and semi-random procedure of old days sometimes entailed disappointment, especially among the butterfly visitors who flitted from section to section trying to be present wherever a well-known speaker was on his feet. A rather futile proceeding it usually was, and yet there was merit in it from the missionary point of view. But the butterflies must take their chance; it is the more steady and persevering insects for whom we should aim at providing honey.

How to do it I confess I know not with any certainty; yet it must be known beforehand, in a general way, that one or two subjects will in all probability prove attractive, and it is a pity when, through lack of collaboration between the sections, a number of such attractions compete for attention on a single day.

The General Secretaries have striven this year to unite the office-bearers of the different sections, and generally to carry forward or renew the old traditions so far as possible. It may be hoped that their efforts will have a good effect in the future.

Oliver J. Lodge.

Normanton, Lake, Salisbury, September 10.

P.S.—Since writing the above I have seen your leading article in Nature of September 16. I perceive that you hold views similar in many respects to my own, and I anticipate that many readers of Nature will be in agreement, now that you have given them an opportunity of reconnoitring the whole position. O. J. L.

September 17.

Allow me to express my concurrence in the view presented in the leading article in Nature of September 16 as to the necessity for a re-organisation—a re-adjustment to the needs of the day—of the British Association for the Advancement of Science. The Association has been allowed to develop and grow in various directions without sufficient control or consideration as to how it may best serve the purpose for which it exists. It was at first a society of a missionary character, aiming at spreading in the dark regions of these islands a knowledge of and interest in science. Soon it added to this purpose that of an annual picnic and friendly gathering of workers in science. Then followed the gathering of funds by fees for membership; the application of those funds to pay, here and there, for research. Later ensued an extended and overwhelming creation of "sections," so as to give all sorts of people a meeting ground for discussion and, incidentally, for self-advertisement. The result of the last step was an embarrassing demand for meeting-rooms and committee-rooms to be provided by the town which had invited the Association to give it a visit. At the same time the subdivision of subjects led to a dilution of quality, and a free bid for popularity and newspaper notice—which has rendered the proceedings of the Association of diminishing interest and value to the educated classes, not only in the locality of its meeting, but also throughout the country. Serious workers in science are now well provided in our great cities with societies and journals by aid of which new work may be discussed. No one is particularly anxious to follow the lengthy, and frequently non-authoritative, disquisitions which the sectional meetings, as at present organised, tend to promote.

The annual meetings of the Association might be carefully arranged beforehand by the executive so as to secure the consideration and clear exposition to the public of a few definite matters of actual moment. The "sections" of the meeting could with great advantage be reduced to four, and the addresses to be given by the president of each section, and also the "papers" accepted for consideration, limited to subjects chosen by the executive of the Association. The individuals chosen to preside or to introduce a subject should be men whose names and works are such as to command the attention and presence of the leaders of thought and social life in the district where the meeting is held.

The only wise alternative to this reconstruction seems to me to be a frank restriction of the meetings of the Association to men from all parts engaged in scientific work, glad to meet one another once a year in pretty and suitable spots (such as our old university towns and smaller cathedral cities), there to exchange in more or less intimate meeting—without the disturbing influence of newspaper reporters and notoriety hunters—recitals and exhibitions of the progress of their researches. Such are (or were) some of the associations of scientific workers in Continental countries. Meetings of this class involve little or no expense or trouble to their participants. The use for a week of a "refreshment hall" and public garden is all that is needful for the gatherings of the hundred or two *savants* who alone are eligible as members or anxious to be present. These meetings are often delightful, and lead to informal and productive discussions and personal friendships of permanent value.

I think that our "British Association" is in an unhealthy condition owing to the attempt made by it—not deliberately, but by constitutional looseness of purpose—to combine the features of a friendly picnic and smoking debate with the work of a national conference dealing (under the disadvantage of public ignorance and journalistic inaccuracy) with great questions of national importance. A choice must be made between "picnic" and "conference." I should prefer the picnic. E. Ray Lankester.

September 17.

Your criticism of the British Association, that it fails to touch our national life, is most opportune; but whereas you imply merely that it is decadent, to me it seems to be practically defunct. An active worker on its behalf in the past, I have little hope of its resuscitation and doubt if it can ever again fulfil the desires of its early promoters, who undoubtedly held its primary function to be that of advancing public appreciation of scientific discovery. I have always deplored our failure to appeal to the public. Seemingly, the spirit of sacrifice is gone out of science; strange to say, the herd instinct is altogether wanting in our society, so uncontrolled is our individuality. The assumed author of "The Beggar's Opera," after remarking of his characters, "There's not an honourable man among them, nor an honest woman," proceeds to say, "but they are all human." So are the present exploiters of the British Association, though were it not human to be selfish some might even dub them inhuman on account of the narrowness of their outlook and their disregard of public needs.

The neglect of science by the nation has long been the favourite text of the scientific preacher; it occurs to none to consider how complete is the neglect of the nation of which scientific workers have long been consistently guilty. Few seem to realise how great has been our failure of late to make any concerted effort to enlighten the man in the street, how little right we have to despise his ignorance. Scientific jargonese so fills the air that it would be refreshing to go back to Babylon and the Tower of Babel; scarce a readable book, fit for general consumption, is written on any branch of our scientific work. We ever walk on stilts; little wonder that the public does not reach up to us.

Like every other institution, the Association is a failure for want of leaders; and as discipline is gone out of society and children in these days think themselves superior to their parents—as demonstrated recently in the columns of the *Morning Post*—it is doubtful if, in the future, leaders will be recognised. Men with the Olympic genius of Huxley and with his profound belief in truth are creations of great rarity; even men like Michael Foster, his body-slave, are no longer to be found. Though not gifted with any high degree of imagination, Foster's was a sympathetic nature; he was ever on the look-out for suggestions and ever ready, when a good purpose was mooted, to help in bringing people together to accomplish it. The Royal Society has been a lifeless body since it lost his guiding hand; it has allowed its proper functions to be abrogated in every direction. Nothing, for example, could be more lamentable than its abandonment of the control of scientific research to the bureaucrats.

The British Association no longer has any real influence either on science or on the public. It has ceased to count, more especially since it lost the services of the late Mr. George Griffith, who rendered it such signal service while secretary. Griffith was the ideal official; he had feeling for every subject and his contagious influence in bringing about an understanding between elements often diverse in character was very great. He enticed all its members into active co-operation; his one desire was ever to make the Association of avail.

Of late years the secretariat has been a forbidding rather than an attracting institution; it has not only lacked imagination and "go," it has also had no ideals; and yet it has monopolised control, with the aid of a few elderly amiables who have been persuaded into the belief that they were bosses of the show.

The young man has been too little noticed; being afraid to speak out, feeling that his elders resent any expression of opinion, he has had no reason to take an active interest in the Association. The young man must be more cared for in future.

If the Association be continued, its constitution must be entirely changed. It is, perhaps, significant that at Cardiff the general committee relegated to a committee the appointment of a new treasurer—really a matter to be dealt with by the council. In point of fact, the council exists only in name; control rests with the official ring, who resent every criticism and any intervention with ideas. I would suggest that the two secretaries and the treasurer should each be appointed for three years, not more, so that every subject might be represented in turn; if only one of the three were appointed in any one year, the remaining two would always be men who had some previous experience of office. The council might consist of the officers, together with the president, the president of the previous year, the president-designate and a single delegate from each of the sections, half of these delegates being chosen afresh either each year or every other year. The business of the Association should be entirely carried out at meetings of the council, not settled previously by an official caucus. The delegate from a section should each year present a report to his sectional committee so as to bring the proceedings of the council under discussion.

The functions of the general committee need to be more clearly defined and perhaps limited; the "freak" has too great a chance at present and as no one knows what topic is to come under consideration, the discussions are rarely representative of the real state of opinion.

Of late the Association has lost what little hold it had on the public generally, owing to the commercialisation of the Press; even the *Times* is now given over to tit-bit-ery and the reports it prints of the Association meetings are worthless for all practical purposes. Some new method of running the scientific publicity campaign must be thought out. It may be worth while for the Association to spend its annual income on advertising in two or three of the chief papers, arranging that between them these report the proceedings in full. Money for research can now be had from other sources and the public has the right to demand that, being taxed for research, its contribution to the Association shall be used largely on its own behalf.

As to the work of the annual meeting, I am entirely with you in thinking that the sections should unite in treating subjects broadly on lines such as the Faraday Society has followed. Instead of a dozen separate sections sitting each year, it would be far better to have at most four.

The discourse delivered by Prof. Eddington may be referred to as an example of the address which appeals to specialists; it is of enthralling interest, yet far too technical; many of the conclusions arrived at need explanation to make them clear to the scientific mind not specially versed in the subject. Such an address, in fact, needs considerable working up to make it of avail even to the instructed reader.

Subjects can always be found on which we need posting up which are of general as well as of special interest; for example, what precisely is the present state of the evidence in favour of evolution? "General" Bramwell Booth scoffs at the conception as "stuff and nonsense." With what case can we confront him and literary quibblers like Mr. G. K. Chesterton? It is long since Huxley discussed the horse in public; in the interval much new evidence has been brought to light which should be presented. The chalk has told an undeniable story, yet how many know it? It is our own fault that the ecclesiastically minded, in their ignorance, speak of us as though we were mere speculators in knowledge, constantly shifting hypotheses without ever arriving at clear conclusions.

To mention other subjects, at the moment the fuel problem is one of the greatest importance; only the food problem is of greater urgency. On matters such as these the public stands much in need of enlightenment. Obviously, each town visited would be interested in having some particular subject special to itself treated exhaustively.

To make the meeting of more than local and passing value, the essays brought forward in the sections for criticism and discussion should be printed in advance and published, with the considered discussions, without any delay. Such a book of authoritative opinion could not but find a ready sale.

If something serious were attempted, something serious would be done. Now everything is attempted and little, if anything, done. Insisting, as we constantly do, on the value of education, it is imperative that we show ourselves educable and ready to read the signs of the times.

HENRY E. ARMSTRONG.

THE leading article in NATURE of September 16 gives articulation to notions which have been very prevalent of late. One does, indeed, occasionally hear the suggestion made that the British Association has outlived its period of usefulness, but most of us, I think, are of opinion that the virility of this nonagenarian institution is such that it should effect even more during its next ninety years than in its past to promote the objects laid down in clause 1 of chap. i. of its rules. One feels, however, that some infusion of modernity is necessary if the best possible future is to be built up upon the fine traditions of our Association. With your permission I will remark on certain impediments to progress resulting from the present form of organisation, and suggest, with some diffidence, a possible means for their removal.

The Association is really run by the general secretaries and the treasurer, with the technical members of the council as auxiliaries; these gentlemen are always chosen from the most eminent scientific talent of the country, and they constitute a body even more exclusive than the council of the Royal Society. None will doubt the thoroughly representative composition of the council, or that its members are doing less than their very best to promote the objects of the Association.

No executive body intervenes between the council and the sectional committees, and the latter meet only to settle the details of sectional procedure at the annual meeting; the general committee is merely a confirming body. In this detail of organisation seems to reside a notable defect. We should probably progress more rapidly if an intermediate set of men, chosen from among the more promising and active of the junior scientific men, were appointed to enunciate questions of policy, of initiative, and of action, and to put a definite scheme for each annual meeting before the council. The president-elect might act as chairman of this advisory body.

The council, meeting several times a year, cannot itself produce such a scheme. Its members are men who have filled most public offices in their respective professions and are distracted by a thousand calls upon their thought and time; they can, however, bring experience to bear towards amending and perfecting a well-thought-out plan of campaign laid before them.

The presentation of papers to sections as to an ordinary scientific society should, I venture to think, be definitely discouraged. The morning session of each section would be better occupied by a discussion upon some topic of immediate interest to the subject concerned; most large topics concern several sections of the Association, and these should amalgamate for a mutual exchange of views. If this mode of working were adopted as a general, rather than as an exceptional, practice, we should be spared audiences numbering about a dozen suffering under the vagaries of a lantern dimly burning.

The real feature of the meeting might well be made the delivery of semi-popular addresses by competent people on subjects of general interest. I have seen British Association evening lecturers, great authorities on their own subjects, but incapable of making themselves heard to a company outnumbering twenty, grappling with an audience of several thousands; the comments of these non-auditors have informed me of the extent to which such an exhibition promotes the objects of the British Association, and I can imagine the torments of the lecturer. One episode of this kind —it did not occur this year—does so much harm to science as to counterbalance the good results accruing from a dozen British Association meetings, and its recurrence should be made impossible. No professional class is, on the average, so competent to expound a good case as is that of the scientific man; anyone who has been in the habit of attending the Friday evening discourses at the Royal Institution will realise that this is a true statement. No class but ours, however, would commit the folly of inviting an incompetent exponent, of no matter what eminence, to address a general audience in the name of the community at large.

Dr. R. V. Stanford's view, that we ought to go to the British Association with a programme of fifty addresses to the non-scientific public, is, I believe, entirely sound. Such a programme could have been carried out at Cardiff; there were many present who combine high scientific achievement with marked expository power, but, apart from delivering themselves of a few impromptu remarks before sparse sectional attendances, these gentlemen perforce confined themselves to the object of their journey to Cardiff, and, like all the rest of us, thoroughly enjoyed their annual chat about scientific affairs with the many friends whom they had not seen since the meeting at Bournemouth last year.

If it be possible to construct such an aggressive plan of campaign as is foreshadowed by Dr. Stanford, some concrete object of attack must be selected. The following is merely a suggestion.

We are meeting next year in the intellectual centre of Scotland, in the capital town of a vast number of public-spirited and wealthy people. The University of Edinburgh is making a great effort to extend its science schools so as to bring them into line with present-day requirements. The objects of the Association would be well served by an intensive educational propaganda for the purpose of bringing home to wealthy Scotsmen what humanity, science, and the British Empire have to gain by the extension of liberal financial support to the University of Edinburgh.

WILLIAM J. POPE.

The Chemical Laboratory, University of Cambridge, September 20.

I CERTAINLY agree in the main with the views expressed in the leading article in NATURE of September 16 on "The British Association and National Life." No one seems to be satisfied with the Association as it is, and the advance of the times has left it decadent just when it ought to be entering into its heritage. Any detailed criticism of the last meeting could scarcely fail to be invidious, but it could have given to few the impression that scientific men themselves are aware of the position science now holds in the community or realise that the vast body of the general public, disillusioned by the war, looks to them to provide a way of escape from the evils that threaten our civilisation. The Association provides an annual opportunity to honour by rotation and seniority a few scientific men by making them officials and inviting them to preside over its deliberations; to advance the numerous schemes competing for public money one or two at a time; to study human nature, another city and the surrounding scenery; but it makes no attempt to come to grips with the real enemy or to take the position already conceded by the general public to the spirit and service of science as almost the only disinterested and effective agency in a cannibalistic and corrupt society.

Surely ever so much more now than in 1831, when the Association started and when the broader implications of scientific discovery and thought upon human life were not dreamt of, is there need for an Association to insist upon a greater degree of national attention to the objects of science, and, it may be added, to its long over-ripe fruits neglected in order that everything old and out-of-date may be scrupulously retained. It is not too much to say that whole fields of government in the real sense, which is not the conventional sense of party politics, now fall wholly within the ascertained realm of science. A remark of Mr. H. G. Wells from his "Outline of History" concerning ethnologists, geographers, and sociologists may be generalised. All the monstrous turmoil and waste, the wonderful attitudes, deeds, and schemes of the "great men" deemed famous by the unscientific historian, might very well be avoided if Europe had the sense to instruct a small body of ordinarily honest scientific men to take over the work.

Whether the British Association can be of any real help in enforcing proper respect for the public position of science or not, it is clear enough to the man in the street that figs are not gathered from thorns. When he wants his appendix removed he does not brief an advocate to get up the subject for his particular case to persuade him that he has not got an appendix or, if he has, that it would kill him to have it removed. Neither are the national appendices rendered less painful by the men who talk of them as the essential parts of the British Constitution, which, with their felicitous assumption of office, has at length reached its final and perfect expression. The public, if not scientific men, know that scientific government is inconceivable without scientific men at the head of affairs.

It is amazing that, as in the example of the director of research to the Glass Research Association, science should be served by men with less respect for science and understanding of its powers apparently than the ordinary common-sense citizen. The peculiar thing is that one may attend learned societies and British Association meetings regularly without taking any part in the important work of selecting the officials, who apparently descend upon them in some mysterious fashion from heaven.

Unless the British Association becomes democratic and acts as a real bond of union between scientific men and the thinking public, rather than as a periodic platform for personages, it does not seem to fulfil any function worth continuing. The public application of science is a totally different thing from applied science. This scientific synthesis and the direction of the unique mental attitude, induced only by the actual discovery of new knowledge, to the conduct of public affairs are the real and peculiar functions of the Association if it is to regain its national position. Curved space, isotopes, and the economics of life on the floor of the ocean are topics of great interest to hundreds of the public. The standards of truth which science has set up, and the elevation of its pursuit above sophistry, chicanery, and the monotonous motives of self-interest, inspire the imagination of hundreds of thousands. The British Association seems to be attacked by senile paralysis just as a belief in science and in the power of its methods is arising in the world phœnix-like from the ashes of its old self.

FREDERICK SODDY.

THE interesting criticism by Dr. R. V. Stanford in NATURE of September 2 tempted me to write. Your leading article of September 16 makes me yield to the temptation. There are two lines on which comment may run: broad and narrow gauge. Taking the broad or general view first, we have to appreciate the fact that the changed attitude of the public to the Association is part of a widespread change in social life. Science is more taught in our schools, elementary scholars and others are introduced to it in our museums, and yet the number of keen naturalists in our local societies is decreasing, and the help of amateurs is a diminishing quantity. The opportunity of the war period and the subsequent economic pressure have driven all but a few to earn their living. Those really interested in science become professional workers therein; the others pass into their own special professions. Consequently, a body like the British Association has to rely more on professed workers in science and less on the amateurs and "camp followers," whose attendance the *Times* actually deprecates. But of the scientific workers many have had their fill at the end of a year's work, not to mention the society and committee meetings that accompany it. All they want is a holiday, and one as remote as possible from their daily avocation and surroundings.

Here we switch on to the narrow gauge. If you hold a meeting in August when one man is on the moors, another sea-bathing off the Land's End, and a third climbing the Alps, can you expect them to go to Cardiff? An attempt to facilitate the attendance of junior students was on the right lines and in harmony with the general trend; we may hope for a better response at a more convenient season. The local naturalists played up all right, but the other inhabitants were more interested in the tram strike and the coal strike than in hearing about aeroplanes or a grain of wheat, and so Sir Richard Glazebrook and Sir Daniel Hall delivered their popular lectures to benches two-thirds empty. Possibly Cardiff is more concerned with shipping than with aviation and agriculture. Again, the mid-week meeting, now tried for two years, seems less convenient than the old system.

Now for the sections. It is difficult to suggest practicable reforms. If you restrict the papers to popular expositions you may have the president and his faithful recorder confined to listen to what they know already, while the other constituents of the section flit dispersedly round other rooms. You ought to give the local workers a chance, anyhow; and there will always be a few people who wish to test some novelty on an audience of experts. How would it do to have one day for the more technical papers, one day for inter-sectional meetings, one day for broader expositions, and one day for the president's address, reports of committees, and what may be called scientific politics? These days should differ for the different sections, and certainly all the sectional presidents should not be addressing at the same hour. The Oxford Parliament of Recorders, held this year, effected some admirable arrangements on these lines, though the printing of the Journal beforehand set an ideal before sectional officers which they could not always live up to—and hence confusion to the public. Yet another suggestion comes from a camp-follower. Why not have "Section X, Popular Science," in continuous session, with a jolly president, a lantern that will work, and as many "star" performers as you can get? I think there's something in that. Of course, it must be properly advertised, and with figures more attractive than the aged dodderer who symbolises science for the Cardiff School of Art.

F. A. BATHER.

I WAS very glad to see the leading article in NATURE of September 16. You have directed attention with great force and point to the need for altering the methods of the British Association if its meetings are to retain the interest and attention of the public.

I doubt if at any time there existed a larger number of persons interested in science and with a keen appreciation of the practical value of science to mankind. But the excessive specialisation of British Association meetings has repelled instead of attracting their interest, and they have felt that they could not "see the wood for the trees."

After all, as you point out, one of the most important functions of the Association is to obtain the attention of the nation to the objects of science. It cannot do this unless it is willing to popularise its meetings, and I feel sure that your suggestions to associate with the meetings public men, whether of local or national distinction, and by grouping sections to obtain a broader outlook upon the scientific questions of the day, form a practical contribution towards the problem of how to revive public interest in the Association. I trust they will be seriously considered by the council. NEVILLE CHAMBERLAIN.

Westbourne, Edgbaston, Birmingham,
September 20.

THE stress laid in the leading article in NATURE of September 16 on "The British Association and National Life" on the importance of the "enlightenment of an extensive group of workers as to main lines of advance in fields not specifically their own" emboldens me to repeat a suggestion which I have often made and never found acceptable. It is that the presidential addresses in the sections should be placed in the foreground of the work of the Association, and so timed that an individual member could hear them all if he felt so disposed. The president of a section may safely be assumed to know his own subject, and he is usually able to express his views in language sufficiently explicit to be clear to everyone interested in any department of science. It is of vital importance to every scientific worker to know how his brethren are heading, were it only in order to see which lines are converging on his own, and which in the light of new knowledge may seem to be diverging from it. HUGH ROBERT MILL.

September 18.

I WISH, as a mere layman, to support the plea in your leading article of September 16 for more energetic and *popular* action by the British Association.

I am afraid that the responsibility both for the indifference, or even hostility, to science of Governments (of which Prof. Soddy complained in a recent letter), and for the lack of financial support from the general public, lies at the door of men of science themselves, who do not understand that they ought to carry on systematic educational propaganda as to the value of science in terms of the things that interest the ordinary man.

I will give three pieces of evidence:

(1) I am thirty-four years of age. I have never been directly appealed to for a subscription to any scientific society, and I have never been asked to join one.

(2) I have just recently looked through the file containing letters appealing for subscriptions addressed to a certain business firm during the twelve months ended August 31, 1920. I find there are just over 150 appeals, or say three a week. They range from hospitals to choral societies. Not one is for aid to scientific research. Most exceptionally, there is one for an educational institution, and part of the large gift made in response *may* go to research.

(3) I happened to remark to a well-educated and intelligent man who takes great interest in public affairs that I was glad to see that a large sum of money had been given for biochemistry. My friend replied that no doubt it was a good thing, but he was sorry that the donor had not rather given the money to reduce the National Debt! I think I managed to convince him that the money given to biochemistry would probably yield the nation thousands per cent. in mere cash, to say nothing of other benefits, *e.g.* health.

But this is what the average man—very naturally—thinks of scientific research, and will continue to think until men of science, or more properly their officials specially trained for the work, carry on systematic propaganda in the same way as hospitals, political organisations, and trade bodies do.

The love of science for its own sake is a special taste, like an interest in heraldry or stamp-collecting. If the men of science want the support of those who do not happen to share that taste, they must show the non-scientific man that science (unlike stamp-collecting) can confer real benefits, moral or material, on the world at large.

Governments move as they are pushed; if they have not moved to support scientific research, it is because there is no strong body of public opinion pushing them.

My practical suggestions are these:

Creation of a "Propaganda and Finance Department" of the British Association, with a permanent staff consisting of a director (responsible to the council of the B.A.); under him a publicity manager controlling a staff of journalists and a staff of lecturers, a financial agent controlling a staff of travelling collectors, with the necessary typists and clerks.

The working would be somewhat as follows: The publicity manager tells his journalists to "write up" the life and experiments of Faraday, showing the present results; particulars of the industries and benefits that have resulted from them; number of men employed; dividends paids; number of tramcars running; and need of financial support for "our modern Faradays." This to be embodied in (i) lectures—for the travelling lecturers; (ii) posters; (iii) booklets and pamphlets for the use of the travelling collectors; and (iv) letters to the Press, especially the provincial and local Press.

After a certain district had been well "treated" with this propaganda, a travelling collector to be sent to interview individuals, firms, chambers of commerce, trade unions, and so on. These collectors would have to be men of high capacity and tact. They would endeavour to get (1) subscriptions and (2) new members of the B.A.

A few thousands a year spent in this way would produce easily an income of 500,000*l.* a year in subscriptions and donations, to say nothing of the other advantages that would flow in.

One useful means of propaganda would be a "Science Day" on the lines of Lifeboat Saturday. Another would be a "Review of the Year's Work" in each branch of science in non-technical language.

Relativity.

THE examples considered by the theory of relativity appear to have become somewhat stereotyped, and to deal mainly with problems of optics and electrodynamics. The specification of "simultaneity" seems to be regarded as necessarily involving the use of rays of light. The following suggested examples may perhaps be of interest. They are not put forward as possible "objections" to the theory, but with the same intention as prompted the supposed "exceptions" to the second law of thermodynamics. The latter, although they did not disturb the application of the law in its proper sphere, led to drastic limitations to its general validity (*e.g.* the "sorting demons" of Maxwell).

Consider first a cube of unit volume, constructed of rigid material absolutely impervious to heat. Suppose the cube contains a gas the temperature of which, measured by an observer rigidly attached to the box, is T. What will be the temperature as measured by another observer moving relative to the first with a uniform velocity v in the direction of one of the edges of the cube? The volume of the cube as measured by the second observer will, according to the theory of relativity, be reduced to $1/\sqrt{1-v^2/c^2}$. If the same laws hold for the gas for both observers, the temperature of the gas would seem to be $T(\sqrt{1-v^2/c^2})^{\gamma-1}$. We note in passing that this depends on γ, the ratio of specific heats, and thus on the structure of each of a definite number of molecules of gas contained in the cube. If the gas is supposed to be the mixture $2HI \rightleftharpoons H_2+I_2$, the extent of dissociation depends only on the temperature and not on the volume, and could be measured by the change in intensity of a beam of light passed through the box in a direction at right angles to its motion, and received by the second observer. The consideration of the case in which the cube is at rest and the second observer in motion would naturally follow. The detailed consideration of this case would appear to involve the transformation of the statistical equations for the energy and entropy of the gas in terms of the position and momentum co-ordinates of the molecules, but I must defer detailed discussion of this matter at the moment.

In the next case we will consider a possible definition of "simultaneity" not involving the use of rays of light. A chemical reaction taking place with a measurable velocity in a given position as measured by an observer at rest is employed. A solution is divided into two equal parts. One remains with the observer at rest, the other is taken by a second observer anywhere he pleases. When an event occurs simultaneously with respect to the two observers the chemical reaction is stopped and the solutions are brought back to the original position and analysed. Let us say that if equal amounts of substance have been changed the events were simultaneous. What objection is raised to this definition? As a further case, we may consider both observers provided with equal weights of radium, and instructed to measure time by counting the number of α-particles emitted from a given instant. This change is found by experiment to be independent of external conditions. If we assume the use of rays of light as a standard method, it follows that the rate of disintegration (and the rate of a chemical reaction) will depend on the velocity. A possibility of testing this by experiment with a centrifugal machine at once suggests itself. I find by calculation, however, that according to the theory of relativity the rate of emission of α-particles would not, in the most favourable circumstances, be changed by more than about one particle per second per gram of radium (see also A. H. Compton, *Phil. Mag.*, 1920, vol. xxxix., p. 659).

Attention may perhaps be directed to the calculation of Bucherer (*Physikal. Zeitsch.*, 1920, vol. xxi., p. 451), who shows that the displacement of spectrum lines may be calculated without the assumption of a general theory of relativity from the principles of thermodynamics. The deflection of light by the sun may yet be shown to depend on the condensation of æther—a hypothesis first put forward by Newton (Boyle's "Works," ed. by Birch, 1744, vol. i.). Neither of these tests appears to be crucial.

The possibility of an upper limit of temperature, when a particle attains by thermal processes a velocity c, is complicated by the change of mass with velocity. In the case of electrons it is further complicated by the doubt as to whether they can be set in motion at all by thermal means, which follows from the values of the specific heats of metals at low temperatures.

East London College.

Variations of Eucalyptus Foliage.

THE eucalyptus tree is a common object in the gardens of Torquay, where it grows freely, though subject to having its tender branch-ends killed occasionally by frost-laden winds. In the King's Gardens here there are two of these trees of the same age which are remarkable for the contrast in the appearance and character of their foliage. One is bearing almost entirely long scimitar-shaped leaves that are petiolate and grow alternately on the branches with that pendulous habit which so characterises these plants. Its companion has a more robust appearance, and bears only the more or less elongated heart-shaped leaves that are erect, opposite, and sessile, with more of the grey-blue gummy exudation that gives them the common name of blue gum trees. It has been noticed that this plant had lost its leading shoot when very young, so that its mass is formed of branches grown from lateral buds. A few trunk shoots have appeared this season among the lower branches on the northern side of the companion tree first mentioned that bear the opposite, sessile leaves characteristic of the young plants, and a recently pollarded tree in a private garden near has developed two shoots from apparently the same lateral bud on the north side of the tree, that bear respectively the two forms of foliage, while a sheltered and uninjured tree in the Terrace Gardens of some 30 ft. in height has only the pendulous type of leaf upon it.

These observations, while bringing to notice a remarkable instance of reversion to seedling or ancestral characters, seem to indicate that with these plants light and temperature under the effects of injury influence their development relative to temporary or permanent reversion.

The Museum, Torquay.

Old Road Maps.

THE reference in NATURE of September 16, p. 90, to John Cary's old road map prompts me to send particulars of an old and rare book, "A Pocket-Guide to the English Traveller: Being a Compleat Survey and Admeasurement of all the principal Roads and most considerable cross Roads in England and Wales," by Thomas Gardner, 1719. There are one hundred copper-plate engravings showing the roads, with the bridges, woods, inns, churches, beacons, gallows, etc., passed *en route*. The scale is, for the actual roads, about one inch to the mile, and every mile is numbered. This book has been in my possession for more than forty years, and I have never met anyone who has seen another copy. It is dedicated to "His Most Serene Majesty George, King of Great Britain, France and Ireland, etc."

C. CARUS-WILSON.

September 17.

The Electrical Transmission of Pictures.

By PHILIP R. COURSEY.

THE art of the transmission of a picture or drawing by electrical means from a given place, so that it can be reproduced in another, may, speaking generally, be said to date from the perfection of Bain's early chemical telegraph about 1842. In its original form Bain's apparatus was devised for purely telegraphic purposes for the reproduction of the given message at the distant station: with this in view, the message was set up in metal type at the transmitting station, and was connected up with a battery, a number of metallic contact brushes, and a series of line wires between the two stations, so that by moving the brushes across the metallic letters a series of electrical impulses was sent out along the various wires, depending upon the form and arrangement of the letters. At the receiving station a similar series of metallic brushes was passed over the surface of a paper strip, soaked in a solution of potassium iodide in starch, with the result that whenever a brush at the transmitter rested upon a metallic part of a letter a current flowed through the corresponding line and through the wet paper strip at the receiver, decomposing the KI solution and giving a blue stain through the reaction of the free iodine with the starch. The resultant marks therefore corresponded with the form of the letters arranged at the transmitting station.

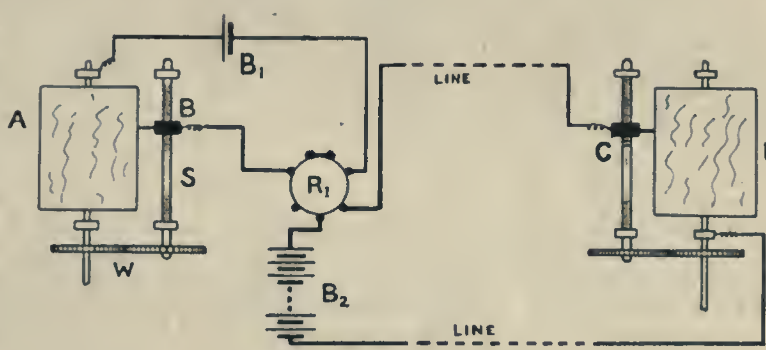

FIG. 1.

A very slight modification of this simple apparatus would enable it to be employed for the reproduction at a distant place of any sketch or line drawing, and, in fact, also of any picture or photograph not having too fine detail. In the case of a photograph, the reproduction at the receiving station would resemble a print from a block of the picture made with a rather coarse screen. This "screen" in the resultant reproduction constitutes the most serious limitation in the quality of the work produced by any of the known methods of photography, and no very obvious way of overcoming this defect is yet apparent. It may be minimised by accurate mechanical construction of the transmitting and receiving mechanism, and by enlarging the original picture photographically before transmission, so that subsequent reduction of the received reproduction will render the screen less noticeable.

The apparatus might be arranged somewhat as indicated diagrammatically in Fig. 1. A cylindrical drum A is fitted with a small contact brush B electrically insulated from, but moved by, the fine pitch screw S, geared by the wheels W to the axis of A. The brush B, therefore, traces out a spiral path on the surface of A when the drum is rotated. At the receiving station, an exactly similar drum D and contact C are provided, the two being electrically connected together through the line wires. Each cylinder is provided with a driving mechanism—of clockwork or other convenient motor—and some governing mechanism to maintain a constant speed. Exact synchronism between the two cylinders is essential if an accurate reproduction is to be obtained. Uniform driving is therefore necessary unless arrangements are made for synchronisation at the beginning of each revolution by means of a special synchronising impulse between the two stations. A phonic wheel, or some similar motor, may be employed with advantage.

For transmitting the impulses to the line wires with such an arrangement as that outlined above, the original picture may be reproduced in metal by an ordinary block-making process, and attached to the cylinder A. Contact will therefore be made with the brush B, as the cylinder revolves, at all points which would mark the paper were the same block used for ordinary printing. For the reproduction at the receiver an electrolytic arrangement similar to that of the original Bain telegraph may be employed, using potassium iodide and starch for the electrolyte, or potassium ferrocyanide with an iron electrode brush C.

This apparatus in its simple form is evidently suitable only for reproducing sketches or drawings of which ordinary line blocks can be prepared, but with an improved receiver, such, for example, as the photographic one described below, a "half-tone" block made from a photograph could evidently be used, if the screen were not too fine. For satisfactory reproduction the travel of the brush B per revolution of A should be equal to the distance between the screen lines.

The repeating relay R may be placed when required between the transmitter and the lines to enable smaller control currents to be employed. A similar relay may be placed at the receiving end, if the incoming current is too weak.

As an alternative to making a metal reproduction of the original picture for transmission by this method, a photograph of the original may be printed on to a sensitised gelatine film on the metal cylinder A, and the parts unaffected by light washed away to leave the metal exposed, so that contact may be made with the brush B.

One of the best known practical developments of photo-telegraphy was made by Dr. Korn some twelve years ago. In his apparatus the original picture was photographed on to a transparent film, which was then wrapped round the cylinder A—in this case made of glass. Instead of the contact brush B, a fine pencil of light was used, which, after passing through the film, fell on a sensitive selenium cell and thus modulated the current flowing out to the lines in accordance with the opacity of the film. At the receiver the incoming current was passed through a special form of galvanometer—practically a double-thread Einthoven galvanometer—so that a light aluminium shutter was moved aside to a greater or less extent, depending upon the strength of the current. A beam of light was thus controlled in intensity before falling upon a sensitive film attached to the receiving drum D. The path traced out by this beam followed a spiral track on the surface of D, as in the case of the brush C of the arrangement of Fig. 1, and similar governing or synchronising arrangements were of course required.

A photographic recorder of this type possesses considerable advantages over the simple electrolytic arrangement outlined at first, and enables much more accurate work to be accomplished. It is obviously not the only possible arrangement to obtain the desired result, but, although differing in detail, the other varieties that have been used operate upon similar principles.

The chief disadvantage of the selenium-cell modulator at the transmitting station is to be found in its inertia to rapid changes of illumination, with the consequent limitation of the speed of operation. In the practical apparatus a compensation arrangement was employed to increase the speed of transmission, but better results would be possible with a light sensitive material having less lag. Some of the more recently discovered sensitive materials may prove better in this respect.

An ingenious alternative transmitter has recently been put to practical test. The photographic print of the original picture at the transmitter is made in gelatine or similar material, giving a relief print when "developed." Instead of passing a metallic contact over such a print, a needle is used in such a manner that difference in relief varies the resistance of a microphonic contact, and thus controls the line current. The reproduction at the receiving station is effected with a photographic apparatus of the type described above.

From the transmission of pictures by wire, it is but a relatively small step to their transmission by radio. In the earlier stages of wireless development attempts were made in this direction with more or less success, but the irregularities of the coherer, which was at that time the only receiver capable of controlling sufficient local energy to operate the recording apparatus, prevented the practical development of the method. With the modern three-electrode valve receivers and relays this difficulty is removed, and their use at the transmitting station as continuous-wave generators is also advantageous. Considerable developments on these lines may therefore be expected in the near future. In particular the last described transmitter, with microphonic control, should be especially easily adaptable to radio work by using any one of the well-known radio-telephone modulation methods.

During the last few months some considerable interest has been aroused by a method of photograph transmission applicable to either wire, cable, or wireless signalling. Strictly speaking, however, this method is not of the same class as the above, in which the picture itself controls the actual signalling currents, as the transmission is effected by a series of code letters, words, or numbers, sent as an ordinary telegraphic message between the two stations. By this method the original picture is divided up into a number of small units, and a code letter used to designate the condition of light or shade in that unit, thus enabling a complete code message to be built up to represent the whole picture. At the receiving station the decoding may be effected in an obvious way, or a mechanical decoding machine may be employed to reproduce the picture.

The Structure of the Atom.[1]

By C. G. Darwin.

III.—*The Nucleus.*

IN the previous articles we discussed the nucleus mainly in connection with the idea of atomic number. We shall now return to the characters of the nucleus itself; but before doing so it is necessary to say something about the atom as a whole. Comparatively little is known about the electrons surrounding the nucleus—it is not even universally agreed whether they are at rest or in motion—but a successful beginning has been made by the Bohr spectrum theory, which applies mainly to the specially simple case of hydrogen. On the same lines Sommerfeld has also had some success with the X-ray spectra. It is quite certain, as in all questions of atomics, that the laws of classical dynamics do not hold, and the principal method in research at present consists in a judicious mixture of these laws with the quantum theory. This latter theory is definitely contradictory not only to the laws of mechanics, but also to almost any conceivable modification of them, and its chief justification, an entirely adequate one, is the astounding success with which it has

[1] Continued from p. 83

been extended over more and more branches of physics.

We shall not deal here with these spectroscopic questions, but it will be convenient to have a definite idea of the scale on which the atom is built. The proportions of its parts vary over so wide a range that no drawing can possibly represent them. We shall be dealing with magnitudes as small as 10^{-16} cm., and as these large negative indices convey little definite to the mind, it will be convenient in describing the atom to raise the whole scale by 10^{13}. On this scale 1 cm. would become a length about two-thirds of the distance from the earth to the sun. The outermost electrons of the atom would be about a kilometre from the nucleus, and for the heavier elements the innermost, perhaps three in number, would be roughly 10 metres from it. As to the nucleus itself, there is definite evidence that it is less than 30 cm. in radius, and, in some cases at any rate, that it is greater than 2 cm. Other physical quantities which we shall require are of a slightly more hypothetical nature. On the theory that all mass is electromagnetic, we can calculate the radius of an electron, since we know its charge and mass. This radius comes to about 2 cm. (actually $1{\cdot}88 \times 10^{-13}$ cm.). By a similar calculation the hydrogen nucleus has a radius of about one-hundredth of a millimetre. The same argument would make the radii of heavier nuclei about as small as this, but would not be justifiable, because, as we shall see, there is clear evidence that these nuclei owe their large mass to their being composite structures built up from hydrogen nuclei and electrons. From the extraordinary smallness of the quantities we have considered, it is not surprising that experiments with the nucleus should be very difficult. We now turn to these experiments.

When first describing the nucleus, in the first article, we saw that when an α-particle goes near it, it describes a calculable orbit, so that we can find a distance of closest approach between the two. As the predicted law of scattering was borne out by experiment, we can conclude that the law of force at this distance of closest approach (3×10^{-12} cm. for gold, above called 30 cm.) is still the inverse square law. Therefore the sum of the radii of the α-particle and the nucleus must be less than this. But a different case has been studied in great detail by Rutherford. Where the α-particles are passing through hydrogen, the repulsive forces between the nuclei are much weaker than for other substances, because the atomic number of hydrogen is only 1, and so the nuclei can get much closer together. But there is also another difference, for the hydrogen nucleus has mass only a quarter of that of the α-particle. Consequently, if there is a "straight on" collision the hydrogen is shot forward at a speed higher than that of the colliding α-particle, and the latter follows on behind with reduced speed. This new type of particle, the H-particle, then proceeds to traverse any matter in its path, losing speed in the same sort of way as does an α-particle, and it can be calculated that, whereas the fastest α-particles go through only 7 cm. of air, the fastest of these H-particles should go through 28 cm. (Fig. 2). Experiment bore out this prediction, but when the calculation was pushed further so as to show how many should go various distances from 28 cm. downwards, a very wide difference was found between theory and experiment. This indicates that there is something wrong with the theory—in fact, that the approach between the nuclei is so close that the ordinary law of repulsion fails. This ordinary law would give 2×10^{-13} cm. as the distance of closest approach, and we therefore conclude that the sum of the radii of the hydrogen and helium nuclei is greater than this. Now the radius of the electron is about 2×10^{-13} cm., and the coincidence of these two numbers tends to support the view that there are electrons in the nucleus of the helium atom.

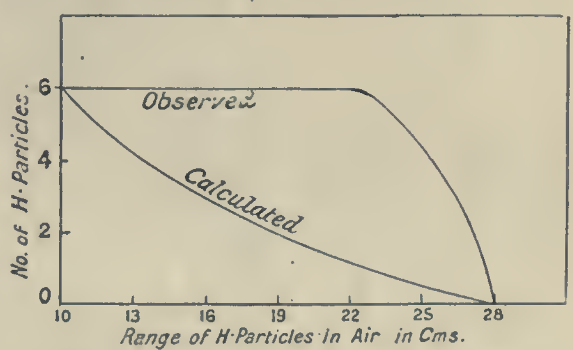

FIG. 2.—From Sir Ernest Rutherford's paper "The Collision of α-Particles with Light Atoms" (*Phil. Mag.*, xxxvii., p. 549). The wide difference between the "observed" and "calculated" curves shows that the assumed law of force between α-particle and H-nucleus is wrong; in fact, that a lower limit has been obtained to the size of the nucleus.

Turning now to the constitution of the nucleus, the first piece of information is provided by radioactivity. In successive radio-active transformations α- and β-particles are projected from the nucleus. Therefore the latter must contain both—that is, helium nuclei and electrons. Next we have the evidence from Rutherford's transmutation of elements. The experiments in which this occurred consisted in the bombardment of various elements by α-particles. When nitrogen was tried, he observed that a certain number of H-particles was obtained. As no hydrogen was present, we are compelled to conclude that these particles were knocked off the nuclei of the nitrogen atoms; so we can be confident that these nuclei contain hydrogen nuclei. In recent work Rutherford has got even further, for he has found another entirely new type of particle which is sometimes knocked off nitrogen and oxygen. These particles have atomic mass 3 and number 2, so that if they were obtained in bulk they would be helium of density 25 per cent. less than ordinary helium. It is at present unknown what happens to the remainder of the nucleus after these losses. A point of great interest in this work is that the new particles come off with greater energy than that of the bombarding α-particles. If we carry over the language of chemistry to this new domain we should say that the reaction is exothermic, and nitrogen in a metastable state.

We have so far discussed the special properties of particular elements. The next evidence is very much more general, and holds out great promise of extension. This is the recent work of Aston with the "positive rays." It was undertaken in order to detect whether ordinary elements were composed of isotopes. He found that this was true of the majority of those he examined (his numerical results are given in the table in the first article), but the important result from our present point of view is that in all his elements the atomic weight of each isotope was almost exactly an integer. This will be slightly qualified in the next paragraph. Aston has so far examined eighteen elements and found the rule true, and it is scarcely credible, therefore, that it should not be universal. But if so, it can only mean that all nuclei are constructed out of hydrogen nuclei. That would satisfy the conditions as to mass, and in order to make the atomic number correct we must then suppose that these hydrogen nuclei are cemented together by electrons. For example, chlorine has atomic number 17. Its atomic weight, determined chemically, is 35·5, and Aston finds that it is composed of two isotopes at 35 and 37. Therefore three-quarters of the chlorine atoms have nuclei composed of 35 hydrogen nuclei and 18 electrons, while for the remaining quarter the numbers are 37 and 20 respectively. This is the revived form of the famous hypothesis of Prout.

Aston's experiments have not hitherto been sufficiently accurate to detect any departures from the whole number rule, except in the case of hydrogen. In this case his work confirms the chemical result that the atomic weight is 1·008 instead of being 1. At first sight this would appear to dispose entirely of the validity of our interpretation of the whole number rule, but that is not so, and by the use of arguments based on the work of Einstein on relativity, the departure from whole numbers can be made to yield valuable information. Einstein's theory implies that all energy must have mass (and also that all mass must have weight). Thus the mass of a helium nucleus (at. no. 2 and at. wt. 4) will not be simply the sum of the masses of its four α-particles and two electrons, but will also include the mass of its energy of formation. As the helium is lighter than the sum of the weights of these particles, we conclude that this energy is negative—that is to say, an atom of helium has less energy than its separated particles. Lenz has calculated the difference and finds that it corresponds to the energy of about three of the fastest α-particles. So helium is an exceedingly stable substance, and it need create no surprise that its nuclei, when projected as α-particles, can undergo the most violent collisions without disruption. It also makes it not unnatural that in radio-active disintegration it is helium, and not hydrogen, that is emitted. Moreover, it is well known that the atomic weights of most elements are nearer whole numbers when helium is taken as standard at 4 than when hydrogen is taken as 1. This indicates that in most atoms the majority of the hydrogen nuclei are bound together in helium sub-groups.

It will thus be seen that a very promising beginning has been made in the study of the nucleus. We know that it is built up of hydrogen nuclei and electrons, and that there is a strong tendency to form helium sub-groups. We know the number of hydrogen nuclei and electrons in the nuclei of many of the elements, and may expect to know those of the majority at no distant date. Most encouraging of all, we may hope that it will not be very long before a definite theory of the structure of nuclei is made, based on exact knowledge of the energy of formation of the various elements.

Obituary.

THE RIGHT HON. SIR WILLIAM MATHER.

WE deeply regret to record the death of Sir William Mather, at his residence in the New Forest, on Saturday last, September 18. Sir William was born in Manchester in 1838, and educated at private schools, and his studies were continued under one of his English tutors at Dresden. Afterwards he entered his father's engineering firm, well known as the Salford Iron Works, and worked the usual hours of apprentices, in the evenings attending lectures at the Owens College, Manchester. In 1862, when he was twenty-four years of age, he became solely responsible for the management of the business. The firm enjoyed great repute as makers of bleaching, dyeing, finishing, and other textile machinery, exporting its products abroad, especially to Russia and the United States, in which countries Sir William travelled extensively. He took the greatest interest in the well-being of his employees, his firm being among the first to establish the eight hours' day, and providing for his young workers, more than forty years ago, the means of continued instruction in the fundamental principles of engineering science, at the hands of his chief technical officers, and with striking results, many of the students gaining Whitworth and other science scholarships.

Sir William Mather took a deep interest in local affairs and movements, was a member of the

Salford School Board for ten years, from 1872, and for a time on Salford Town Council. He also entered Parliament, where his intimate knowledge of industrial and educational matters proved of the greatest service. On the appointment of the Royal Commission of 1881 on technical education at home and abroad, the report of which did so much to direct the attention of the nation to its shortcomings in the means of education and training in science and its applications, Sir William Mather, because of his intimate experience of the conditions of industry in the United States and Russia, accepted the position of special commissioner in those countries and wrote two valuable reports which were included with that of the Royal Commission. The inquiries of this Commission undoubtedly led to the passing of the Technical Instruction Act of 1889 and to the subsequent Excise and Customs Act of 1890, by which a fund of 800,000*l*. was placed at the service of technical instruction.

Sir William Mather's intimate association with educational institutions in the United States, and his sympathy with the system of manual training prevailing there, enabled him to invite its chief exponent, Prof. Woodward, of St. Louis, to a conference in Manchester in 1882 on "Education under Healthy Conditions," with the result that there was established in the Manchester Mechanics' Institution the first manual training school in Great Britain. He gave to Chetham College (for orphan boys) in Manchester a complete manual training equipment, and likewise did the same service for the engineering department of the college at Khartoum, in the Sudan. He identified himself with all types of educational advance, founding in Manchester the Mather College for the training of kindergarten teachers, and taking a deep interest in the activities of the Union of Lancashire and Cheshire Institutes, of which he was president from 1908 until 1919, in connection with which he founded a valuable scholarship and exhibitions.

One of the chief features of the Franco-British Exhibition of 1908 was the fine display of British educational enterprise, which owed its initiation to Sir William Mather, and of which he bore the entire cost. The value of the exhibition was much enhanced by the addresses of eminent educationists whom he invited. He was a warm supporter of the British Science Guild, founded in 1905, and was its president from 1913 to 1917. He regarded it as "a body capable of development up to the rank of a powerful national institution permeating the industrial life of the Empire with the fruits of scientific research," and to it he gave the most liberal financial support. On the foundation of the Association of Technical Institutions he became its first president, and gave it effective aid in many ways. By Sir William Mather's death the causes of education and of scientific efficiency in industry suffer an almost irremediable loss. He was laid to rest on Wednesday in the grounds of Prestwich Parish Church, near Manchester.

THE death is announced, on August 19, at fifty-six years of age, of PROF. T. RIDLER DAVIES, associate professor of mathematics at McGill University, Montreal.

SIR WILLIAM BABTIE, V.C., who held many important posts in the Army Medical Service, died on September 11, in Belgium, where he was spending a holiday. Sir William was born in 1859 at Dumbarton, and was educated at Glasgow University, where he took his M.B. degree in 1880. In the same year he became L.R.C.P., L.R.C.S. of Edinburgh, and in the following year entered the Army Medical Service, of which he was made Deputy-Director-General in 1910. He retained this post until 1914, when he was appointed Director of Medical Services in India; later he filled the same office in the Mediterranean. He was created a K.C.M.G. in 1916 and a K.C.B. in 1919, and was known as an administrator rather than for his medical work.

SIR JAMES B. BALL, chief engineer of the London, Brighton, and South Coast Railway, who died suddenly on September 17, was born in 1867, and started as a railway engineer with the Great Northern Railway in 1890. He served with various companies until he became engineer-in-chief of the Great Central Railway in 1912, a post which he occupied until 1917, when he went to the London, Brighton, and South Coast Railway. During the latter part of the war, Sir James Ball was appointed Controller of Timber Supplies for the Board of Trade, and in 1918 he was knighted. He received the Telford gold medal of the Institution of Civil Engineers, and was the author of several technical papers communicated to that body. His work included the design and execution of many large-scale railway and dock enterprises.

SIR J. W. BYERS, one of the leading physicians of the North of Ireland, who died on September 20, was born in China in 1853, but was educated and spent his life in Belfast. He commenced practice in the Children's Hospital at Belfast in 1879, and in 1882 he took over the department for diseases of women in the Royal Victoria Hospital in that city. In 1896 he was elected honorary president of the International Congress of Obstetrics and Gynæcology. He was president of the Section of Obstetric Medicine and Gynæcology of the British Medical Association in 1901, and from 1902 to 1906 was a member of the council of that body. In 1907, Sir John Byers was president of the Section of Physical Education and Training in Personal Hygiene of the International Congress on School Hygiene, and in 1916 he was knighted. During his lifetime he took a prominent part in all movements concerned with public health, particularly those dealing with tuberculosis and infant mortality. He was the author of many medical works, and of some papers and a book on the folklore of Ulster.

Notes.

THE sixth International Congress of Mathematicians is being held this week at Strasbourg. It is eight years since the last congress was held at Cambridge, and it will be noted with regret that the then honorary president, Lord Rayleigh, and the president, Sir George Darwin, are no longer with us. The present meeting was fixed for this year at the Allied Conference of Scientific Societies held in Brussels in July, 1919; its organisation has been in the hands of the Comité National Français de Mathématique, of which M. Emile Picard is president, and of a local organising committee (president, M. Villat). On Wednesday, after the congress had been formally opened by M. Alapetite, Commissaire Général de la République, the members proceeded to elect their president and other officers. In the evening a reception was held by the organising committee in the Salle des Fêtes. In the course of the meeting lectures are being given by Sir Joseph Larmor (Thursday), Prof. L. E. Dickson (Friday), M. de la Vallée-Poussin (Saturday), M. Volterra (Tuesday morning next), and M. Nörlund (Tuesday afternoon). On Friday evening Gen. Taufflieb will give an address on "Science in Alsace." Conducted visits have been arranged to the cathedral and the museums, and excursions to the ports of Strasbourg and Kehl, to Saverne, and to Linge. At the end of the proceedings on Tuesday, September 28, the members will be entertained at a banquet kindly given by the organising committee. There is every prospect of a successful meeting, and it is anticipated that the members will have much of interest to communicate after being out of touch with each other for so long a period. On the eve of a new academic session English mathematicians are finding some difficulty in attending; only ten entries have so far been recorded from the United Kingdom.

SOME time ago the National Sea Fisheries Protection Association initiated a movement for the creation of a British Fisheries Society. A draft charter and by-laws have been prepared, and anyone interested in this matter can obtain a copy of the draft by-laws from Capt. G. C. L. Howell, Gadesprings, Hemel Hempstead. The proposal is to organise the society in two divisions, (1) industrial and (2) scientific, intelligence and general. Each division is organised in sections, fourteen in all, and these represent every interest in the fishery industry, producers, manufacturers, and distributors. Presumably the society as a whole will hold periodical meetings, and at these matters affecting the industry will be referred to the sections as committees. Proposals for a Journal, Transactions, and Proceedings, as well as for the institution of a library and museum, are outlined, and, in general, the objects of the society are to gather and diffuse information upon all matters relating to the fisheries and to unite all interests and affiliate the various bodies at present in existence. It is supported by a number of men very well known in the fishing industry.

WE have received notice of the forthcoming establishment in the University of Paris of an Institute of Psychology. The institute will be administered by a council composed of Profs. Delacroix, Dumas, Janet, Piéron, and Rabaud, and the Deans of the Faculty of Letters and Sciences. It will afford instruction, both theoretical and practical, in general, physiological, experimental, pathological, and comparative psychology. To it will be attached the recently established Institute of Pedagogy, forming its pedagogical section. Other sections of the institute, dealing with the general applications of psychology and with vocational selection, will be formed shortly. The institute will grant diplomas to successful students in each of these sections and to those who, after attending other courses of instruction, have passed the examinations therein. It will also be open for research work in connection with the University doctorate or higher diplomas. This union of Parisian psychologists can but strengthen the position of psychology in France. Previously Prof. Janet with his colleague, Prof. Dumas, worked in psychopathology quite independently of the late Alfred Binet, who directed the psychological laboratory. Prof. Piéron, Binet's successor, is now joining forces with the most famous representatives of French pathological psychology, and the institute thus formed is also to encourage the applications of psychology to education and to industry. The institute deserves to achieve success, and it has our best wishes.

A SUMMARY of the weather for the summer season, comprised by the thirteen weeks from May 30 to August 28, is given in the Weekly Weather Report of the Meteorological Office for the week ending August 28. The absolute highest shade temperature for the whole of the British Isles was 81° F. in Scotland E. and the Midland Counties, whilst in seven out of the twelve districts into which the country is divided the temperature failed to touch 80°, the highest temperature in England S.W. being 75° and in the English Channel 73°. Frost was registered in three of the five eastern districts. The mean temperature for the summer was below the average over the whole of the British Isles, the difference ranging from 0·5° F. in Scotland N. to 1·6° in one-half of the eastern and western districts. The essential feature of the summer was the persistent cool weather, and particularly the absence of warm days. At Greenwich the coldest of the three summer months was August, with a mean temperature of 58·7°, which is 4·2° below the average for seventy years, and there were only eleven days with the thermometer 70° or above against an average of twenty-one days. August of 1912 was slightly cooler, but this is the only exception since 1841. The mean temperature for the whole summer at Greenwich was 60°, which is 2° colder than the normal. The Meteorological Office record for the summer shows that the amount of rain was in excess of the normal except in Scotland N., England E., and Ireland. The greatest excess was 1·85 in. over the north-west of England and 1·77 in. over the south-east of England. The highest total fall was 11·77 in. for Scotland W., the least 6·25 in. for England E. July was generally the wettest summer month. The duration of bright sunshine was less than the normal except in Scotland N. and E.

THE annual exhibition of the Royal Photographic Society is being held at the society's house, 35 Russell Square, W.C.1, and will remain open until the end of October. It is divided into three sections, namely, pictorial photographs, colour transparencies, and scientific and technical exhibits. The last is exceptionally rich in radiographic and astronomical photographs. Mr. Luboshez has a room to himself in which he shows several series of X-ray negatives on "Eastman duplitized film," made to find the methods of getting the best results in normal and adverse circumstances. The Sunic Research Laboratory shows radiographs of iron and steel welds, a carbon block, and a Palmer aero tyre, besides a "radiometallograph of thumb," which shows the lines and dots of the skin with great clearness. The other radiographs include a fine series by Dr. Robert Knox. The Astronomer Royal sends series of photographs of the total eclipse of the sun in 1919, the great sun-spot of March, 1920, and the new star in Cygnus. A number of fine photographs of the moon and two of the sun is contributed by the Mount Wilson Observatory. The research laboratory of the Eastman Kodak Co. sends some very interesting experimental results. There is a large number of natural history subjects. Some of the most notable are the president's coal-plant fossils; a tree in California which is supposed to be the oldest living thing, as it was a sturdy tree when Moses was a boy, contributed by the National Geographic Society of Washington; and Mr. Hugh Main's studies of the metamorphoses of beetles and other insects which take place underground, obtained by means of his "Subterrarium." Mr. Alfred E. Tonge sends sixty photomicrographs of the ova of British butterflies, including every genus as enumerated in "The Butterflies of the British Isles," and there are other photographs of entomological, botanical, geographical, zoological, and mathematical interest, besides some excellent aeroplane photographs by Capt. F. R. Logan.

THE annual meeting of the British Mycological Society will be held at Minehead from September 27 to October 2. On Wednesday, September 29, Mr. T. Petch will deliver his presidential address on "Fungi Parasitic on Scale Insects." There will be excursions each day, and in the evenings of September 30 and October 1 the following papers will be read:—The Action of Gravity on the Fungi, Dr. Harold Wager; The Genus Ganoderma (Karst), Pat, Carleton Rea; The Mycorhiza of Orchids, J. Ramsbottom; The Audibility of the "Puffing" in the Larger Discomycetes, Prof. A. H. R. Buller; and The Sporulating Gonidia of *Evernia prunastri*, Ach., R. Paulson.

PROF. A. D. WALLER, who went by a Handley Page open aeroplane to Brussels on Friday, September 10, has sent home the following notes, which are of interest as giving details of times, etc.:—"Started 2.45 p.m., arrived Brussels 4.40. Misty over London. England very puzzling. Thames distinct. 2.55.—Sea in sight. 3.15.—Left England. 3.20.—Lovely white coast; sun and steamers. Bar. 3000 ft., 95 m.p.h. 3.23.—Marvellous view of both coasts. 3.33.—Arrive France (Calais). 3.47.—Dunkerque. 3.55.—Nieuport and scarred battlefield zone. 4.2.—Dixmude. 4.16.—Ghent. 4.24.—Approaching Brussels. 4.32.—Brussels on horizon (3000 ft.). 4.34.—Are we visible? 4.40.—Gently land."

MR. J. HORNELL produces in the September issue of *Man* new evidence to prove the common origin of the outrigger canoes of Madagascar and East Africa. From these we have evidence of a remarkable case of culture transmission. It is now clear that the dominant Madagascar form is so closely related to that of North Java that we may regard them as identical. It follows, then, that the East African forms are all varieties of the Madagascar model, that the vertical stanchion design of African outriggers is more primitive than the oblique, and that the resemblance of this oblique form of stanchion to certain widely distributed Indonesian types of oblique connecting-joints (modified stanchions) in Bali, the Celebes, and the Moluccas is an instance of convergence and of independent origin.

THE recently established Archæological Department in the dominions of his Exalted Highness the Nizam of Hyderabad is doing excellent service to the study of Indian antiquities. The report of the survey for 1917–18, recently issued, describes the progress made in the inspection of monuments. Every cave of the important Ajanta series is now in good order, and only some minor improvements remain to be made. In co-operation with Sir John Marshall, director of the Imperial Indian Survey, arrangements have been made to bring out an expert from Italy to examine the frescoes and to suggest measures to save them from further decay, while it is contemplated, under a scheme worked out by Sir John Marshall, in consultation with Sir Aurel Stein and M. Foucher, to have them reproduced by the three-colour process. Large collections of inscriptions have been made, and Mr. T. Srinivas, curator of the Hyderabad Museum, was deputed to inspect various other museums in India and to arrange for the exhibition of the Hyderabad collections. It is much to be desired that the other Native States in India, particularly those of Central India and Rajputana, should follow the example thus set by H.H. the Nizam of Hyderabad.

AN address in memory of Pasteur's residence there was delivered at Strasbourg on July 26 by M. Calmette at the Congress of the French Association for the Advancement of Science. The subject was "Ultramicroscopic Micro-organisms." After a description of the salient features connected with many of these organisms, M. Calmette referred to the difficulty of obtaining filter-candles and membranes having a constant and homogeneous texture. Besides their invisibility and filterability, these ultramicroscopic organisms present certain common features. They are all destroyed at a comparatively low temperature and by weak solutions of most disinfectants. On the other hand, they maintain their vitality for a considerable time in pure glycerin. They are infectious only by direct contact or by inoculation, and never by water, air, soil, or fomites. The pathological lesions are also similar, and characterised by cell-"inclusions" and alterations of the cell-nuclei.

A TYPICAL instance of the deplorable methods of the "oologist" is given in the September issue of *British Birds* by Mr. Thomas Lewis, who set himself the task of recording the breeding habits of a colony of lesser terns newly established last year "on the southern part of the Norfolk coast." At one period there were more than forty nests on the beach. Then, on June 19, the colony "was almost completely destroyed by an egg-collector who swept three-fourths of the eggs, most of them far gone in incubation and some actually chipping, from the beach." Instances of this kind are, unhappily, far too common, and while this state of affairs continues the "oologists" can scarcely complain when they are reminded that between "egg-collecting" and scientific ornithology there is a wide gulf. This abominable raid made a complete survey of the breeding habits of this bird impossible; but the author fortunately succeeded in making a series of very valuable observations on the courtship and incubation periods, and in taking a number of remarkably fine photographs which accompany his essay.

THE latest report of the Industrial Fatigue Research Board (No. 8), by Messrs. S. Wyatt and H. C. Weston, is concerned with a preliminary study of some of the problems connected with bobbin-winding. The authors give a description of the conditions prevailing in the bobbin-winding department of a mill where the owners are enlightened enough to appreciate the value of attention to labour-saving devices and to the welfare of the workers. It was found that the conditions of labour were generally satisfactory except for the length of one of the working periods, which was of four and a half hours; such a period is probably too long for monotonous work, and might advisably be broken up by rest-pauses. The marked individual differences in efficiency which were noticed suggest that a more careful selection of the workers would be advantageous. The liability to accidents was very slight and the labour wastage almost negligible, so neither of these could be utilised as data for fatigue. In so far as it was possible to use output as an indication of fatigue, no signs of undue fatigue were evident, although the authors are very careful to emphasise the complex nature of the processes involved, and therefore the difficulty of taking such negative results as final. Although the data obtained do not permit of generalisation, yet it is clear that before confident conclusions on the fatigue resulting from industrial conditions can be reached, very many studies of this nature extending over years must be made in this and other trades, so that an abundance of evidence may be available as a foundation for future work. Such reports are valuable as correctives to the tendency, only too noticeable at the present time, to use science unscientifically.

MR. W. H. DALL, in reviewing "Pliocene and Pleistocene Fossils from Alaska" (U.S. Geol. Surv., Prof. Paper 125-C, 1920), points out that evidence accumulates against the view of a late Cainozoic bridge whereby land animals could cross in the Bering Strait region from Asia to America. The ice of glacial times afforded the only admissible means of communication. The Pliocene fossils of England and Iceland, investigated by Mr. F. W. Harmer, indicate a more free connection than now exists between the Bering Sea and North Atlantic waters.

THE older rocks of Mysore are receiving detailed study from the State Department of Mines and Geology. In the Records of this Department, vol. xvii., p. 67 (1920), Mr. B. Jayaram shows how some of the limestones of Mysore have originated from the alteration of calciferous igneous bands, while many actually replace quartz-felspar rocks of the granite and gneiss series. In Bulletin No. 9 (1920), Mr. P. S. Iyengar treats of the acid rocks of the State in general. As in so many areas, the gneisses have proved to be younger than a schistose series (here the Dharwars), the relations being those already pointed out by Drs. Smeeth and Fermor over a wider field. Mr. Iyengar is firm, and we think thoroughly justified, in his assertion that the Peninsular gneiss is an intrusive rock that has replaced the formation invaded by it.

"THE Use of the Panoramic Camera in Topographical Surveying," by Mr. J. W. Bagley, is a useful publication of the United States Geological Survey (Bulletin 657). In comparison with other methods of survey, the panoramic camera has certain advantages. Its use reduces very considerably the time required to be spent at each station in a plane-table survey. It follows that in the case of reconnaissance surveys a larger number of stations and so greater detail are possible with the help of a panoramic camera than without it. It is also found that with this camera and the plane-table the topographer is better equipped for country of both high and low relief than with the theodolite and plate-camera. Considerations of weight owing to the use of films instead of plates, and of cost as reflected in speedier work, are claimed to show other advantages. Full details are given of the camera and the methods of using it. The largest scale of surveys in which this camera has been used is 1 : 48,000, but this is by no means the limit of its use, which is decided by the degree of accuracy necessary in determining elevations—that is, roughly, by the contour interval. The bulletin also contains some useful notes on the application of photogrammetry to aerial surveys.

MESSRS. NEGRETTI AND ZAMBRA, of Holborn Viaduct, have issued a catalogue and price-list of meteorological instruments. The publication is well illustrated, and a detailed description is given of the several instruments. Each section is prefaced by an historical sketch of the separate branch of observation, which will prove of considerable interest to an observer, and supplies an easy method of valuable information being acquired. The catalogue in our hands is not complete, and is merely a compilation of some sectional lists; the paging shows how much is missing. In the sections for barometer and thermometer the lists do not give the self-recording instruments, although in rainfall and wind the registration instruments are fully dealt with. The section for deep-sea thermometers well illustrates the advantage secured by the long association of the optician with special scientific instruments; these thermometers have been carefully watched and improved by the maker for about half a century. Sunshine instruments of two recognised forms are well described and compared: the "Campbell-Stokes" recorder burns a trace on a time-divided card by the impinging of the sun's rays focussed through a sphere of glass; this system is generally adopted by the Meteorological Office. The other form is the "Jordan" recorder, in which a photograph of the rays of the sun is obtained upon a specially sensitised chart. The catalogue will be forwarded by Messrs. Negretti and Zambra to anyone who may be interested.

According to an article by M. Jacques Boyer in *La Nature* for September 4, the aerotechnical institute of the Military Academy at Saint-Cyr has installed a pneumatic tank for experiments on the effects of reduced air-pressure and temperature on the physical powers of aviators. The tank in use up to the present time is 2 metres in diameter and nearly 4 metres long. It is of steel 5 mm. thick, and is insulated thermally by an outside layer of cork 10 cm. thick. Four glazed portholes are provided, through which the officer in charge can observe the aviator under test inside. Air-pumps and an air-refrigeration plant are provided, so that the pressure and temperature of the air in the tank can be varied at will. Oxygen tubes are also available, and the interior and exterior of the tank are in communication by telephone. By the help of this tank Dr. Garsaux has been able to study to what altitude aviators could ascend without losing their skill or injuring themselves, and at what stage of the ascent oxygen should be supplied. These altitudes differ according to the temperament of the aviator, but 6000 metres appears to be the limit for even the best men, and oxygen becomes necessary at 3500 or 4000 metres. Further observations are to be made with a larger tank.

A useful account of the "synthetic" drugs is given by Prof. J. T. Hewitt in a series of Cantor lectures recently published (Journal of the Royal Society of Arts, August 13 and 20). Strictly, the phrase "synthetic drugs," implying as it does that the substances in question are produced artificially and find a use in medicine, would include many fairly simple compounds, such as chloroform; but in practice it is restricted to more or less complex carbon compounds which are either prepared by truly synthetic methods (*e.g.* veronal, phenacetin), or obtained by modifying the structure of naturally occurring compounds through chemical treatment. Thus morphine is converted into codeine (methyl morphine) or into heroin (diacetyl morphine) by appropriate chemical reactions. The lecturer classifies the various products according to their chemical relationships as derivatives of hydrocarbons, alcohols, ketones, and so on, thus obtaining a systematic survey of the various groups. The descriptions of the drugs are supplemented by outlines of the methods of manufacture, and in many instances include notes on the history and literature.

A simple form of thermo-electric pyrometer, mainly intended for use with electric resistance furnaces, has been placed on the market by the Automatic and Electric Furnaces, Ltd. The thermo-couple is composed of wires of nickel and nickel-chrome alloy, these metals being chosen owing to their resistance to oxidation at temperatures not exceeding 1000° C. The E.M.F. developed by this couple is only about one-half that furnished by a junction of iron and constantan, but is still sufficiently high to enable a pivoted indicator to be used. In order to avoid cold-junction errors, the leads to the indicator consist of the same materials as those of the thermo-couple—a procedure now followed generally in the case of base-metal junctions. In a leaflet issued by the firm an account is given of experiments performed with the view of determining the lag caused by the use of thick wires, and also that due to the use of a protecting sheath. The results show that notable errors may arise by assuming that a sheathed junction closely follows the changing temperature of a furnace, particularly when thick wires are used; and it is concluded that the wires should be as thin as possible—consistent with sufficient strength—and, when permissible, should be used uncovered. Two types of instrument are made: one with the junction unprotected, and intended for use in a clean atmosphere; and the other provided with a silica sheath for use in salt-baths, wires of No. 20 gauge being used in each. Both forms should prove useful for the class of work for which they are intended.

Arranged by the Institution of Petroleum Technologists, an interesting lecture on petroleum refining was given on September 8 by Dr. A. E. Dunstan. Crude petroleum is a very complex mixture of substances, which are most conveniently utilised if separated into groups (petrol, "white spirit," kerosene, fuel-oil, and so on) according to their volatility. One object of refining is to effect this separation; a second is to remove impurities, colour, and odour from the products. Probably in the future physico-chemical methods rather than purely chemical treatment will be relied upon for the removal of impurities. Sulphur compounds in particular are mentioned as substances which are adsorbed by passing oil distillates through a column of bauxite or fuller's earth, or, alternatively, by passing the vapour of the oil over heated bauxite. A fact not very generally known is that "toluol" (toluene), so urgently wanted in the war period, occurs naturally in certain varieties of crude petroleum, and "innumerable tons" of it were, indeed, obtained from this source. It is much purer than the toluol extracted from coal-tar, and the lecturer predicts a "future" for the aromatic hydrocarbons yielded by petroleum. Toluol can also be manufactured by "cracking" petroleum—that is, breaking down the more complex molecules into simpler ones by means of heat. This operation, which in its modern forms the lecturer dates back to a patent issued in 1890 to the late Sir Boverton Redwood and Sir James Dewar, is considered to be the most promising way of increasing supplies of petrol from petroleum sources.

AMONG points of interest in the report (Cmd. 881) of the Government Chemist on the work of his department during the past financial year we note that radium was extracted from many thousands of luminous dials, compass-cards, gun-sights, and similar materials made for use during the war. The extraction was complicated by the overwhelming proportion of paint with which the radium was mixed, but practically all was recovered and converted into a form suitable for further use at a comparatively small cost. For the Board of Trade 532 samples of the potash material supplied by Germany to this country were analysed. The samples taken were divided into three portions; one was analysed in Germany, another here, and the third retained in a neutral country for reference in case of dispute. The report, however, does not indicate whether any dispute actually arose. Incidentally, in connection with other samples, a method was worked out for differentiating between sodium chloride and potassium chloride in solid caustic potash. A good deal of work was done on the determination of the nature and proportion of the possible toxic constituents which might be present in water receiving drainage from tarred roads. In the course of this work new and delicate methods for detecting some of the substances were devised. Carbolic acid, for instance, can now be detected and estimated when present in even smaller proportion than one part in a million parts of water. The total number of samples, 368,898, dealt with during the year showed an increase of nearly 80,000 compared with the previous year. The principal increases were due to imported goods, such as wine, sugar, tea, and cocoa; they are indicative of the revival of trade after the return to peace conditions.

WE have just received the Lincolnshire Naturalists' Union Transactions for 1919. The first portion of the volume is devoted to the annual reports of the sectional officers, recording, in most cases, the work which has been done during the past year in their own departments. The report from the botany section is somewhat different; it consists of notes selected from observations on seed-dispersal which have been made during the past fifty years by the sectional president and his colleagues. The methods adopted by birds for the transportation of seeds over long distances are mentioned, and the remainder of the report is given over to a list of the agents and methods by which the seeds of the commoner trees are dispersed. A complete list of the author's observations, which he promises to publish in a future volume, "The Flora of Lincolnshire," will be welcomed by ecologists. The volume also includes lists of marine shells of the Lincolnshire coast by Mr. A. Smith, and of non-marine mollusca of the county, contributed by Mr. J. W. Musham from data obtained from the manuscripts of the late Mr. W. J. Roebuck.

Our Astronomical Column.

ANOTHER QUICKLY MOVING DWARF STAR.—Mr. Innes's zeal in examining pairs of plates with the blink micrometer has been rewarded by the discovery of another very interesting dwarf star with a large proper motion and parallax. The former was detected from plates taken at Sydney, the latter from a series of fourteen plates taken at Johannesburg with the Franklin-Adams lens. The star is of the 12th magnitude; its position for 1920 is R.A. 11h. 12m. 52·39s., S. decl. 57° 8′ 13·1″; the proper motion in R.A. is −2·506″, in decl. +0·973″, total 2·688″ in P.A. 291·2°. The parallax from R.A. measures was found to be 0·350″, that from declination measures 0·324″.

The proper motion of α Centauri is 3·68″ in P.A. 281·4°. That of the present star is sufficiently near this to suggest that it may belong to the same system. Mr. Innes notes that if this were the case its parallax would be about 0·5″. It is not stated whether he took the radial velocity of α Centauri into account; in any case, the observed parallax is sufficiently near to render the assumption of connection tenable.

PROF. BARNARD'S OBSERVATIONS OF NOVA PERSEI.—Prof. Barnard puts the Yerkes refractor to good use in continuing to observe novæ long after they have become too faint for ordinary observers. The Monthly Notices, R.A.S., for June contains his observations of Nova Persei, 1901. Its light is still subject to fluctuations; thus it rose from 13·7 to 12·6 between 1919 November 15 and 18, declining again to 13·7 in the three following days. The mean value in 1920 is 13·48, and the progressive decline appears to have ceased. Unlike some other novæ, its aspect does not now differ from that of an ordinary star, and Prof. Barnard considers that it has returned very closely to its condition before the outburst. Micrometer measures of position appear to show a slight proper motion of the nova relatively to faint adjacent stars, the centennial displacement being 1·08″ in the direction of diminishing R.A. and 2·20″ S.

It is noted that the period required to decline to the pre-nova condition varies in different stars between eight and fifteen years, which is surprisingly short, considering the tremendous character of the outburst.

THE BERGEDORF OBSERVATORY, HAMBURG.—Vol. ii, Nos. 3–5, of the Abhandlungen of this observatory, which has just been issued, contains a useful catalogue of the positions, magnitudes, and colour-indices of the stars in the Pleiades (584 in number) down to mag. 14. The magnitudes were determined by observations with two wedge-photometers. Comparison with Hertzsprung's photographic catalogue shows that the visual magnitudes of the fainter stars are brighter in the mean by 0·7. The colour-indices increase rapidly from mags. 3 to 10, remaining fairly constant after this. Comparison is also made between the number of stars in each half-magnitude interval and the number to be expected in an average region of the same area in galactic latitude 23·7°, using the table of Van Rhijn. For stars brighter than mag. 11 the excess is more than threefold; it then gradually declines, reaching zero at mag. 13½. Another essay discusses the planetary observations made from 1909 to 1920. An interesting round dark spot on Jupiter had the abnormally large rotation period of 9h. 58·13m. from 1920, February 17 to March 18; it then split into two portions, one retaining the same rotation period, while the other had the value 9h. 53·5m., from observations between March 27 and April 1. There is also a study of the contour lines of equal luminosity in the Milky Way (north of decl. −25°). The brightest regions are between γ and β Cygni and in Sagittarius.

Physiological Effects of Insufficient Oxygen Supply.*

By J. Barcroft, C.B.E., M.A., F.R.S.

PROMINENT among the pathological conditions which claimed attention during the war was that of insufficient oxygen supply to the tissues, or anoxæmia. The statement has been made that "anoxæmia not only stops the machine, but wrecks the machinery." This phrase is so apposite that I shall commence by an inquiry as to the limits within which it is true.

Anything like complete anoxæmia stops the machine with almost incredible rapidity. Though the breath can be held for a time, it must be borne in mind that the lungs normally contain about half a litre of oxygen, and that this will suffice for the body at rest for upwards of two minutes. But get rid of the residual oxygen from the lungs even to the extent possible by the breathing of nitrogen, and you will find that only with difficulty will you endure half a minute. It seems doubtful whether complete absence of oxygen would not bring the brain to an instantaneous standstill. So convincing are the experimental facts to anyone who has tested them for himself that I will not further labour the power of anoxæmia to stop the machine. I will, however, say a word about the assumption which I have made that the machine in this connection is the brain.

It cannot be stated too clearly that anoxæmia in the last resort must affect every organ of the body directly. Stoppage of the oxygen supply is known to bring the perfused heart to a standstill, to cause a cessation of the flow of urine, to produce muscular fatigue, and at last immobility, but from our present point of view these effects seem to me to be out of the picture because the brain is so much the most sensitive to oxygen want.

To what extent does acute anoxæmia in a healthy subject wreck the machinery as well as stop the machine? By acute anoxæmia I mean complete or almost complete deprivation of oxygen which, in the matter of time, is too short to prove fatal. No doubt many data might be quoted of men who have recovered from drowning, etc. Such data are complicated by the fact that anoxæmia has only been a factor in their condition. These data, therefore, have a value in so far as they show that a very great degree of anoxæmia, if acute and of short duration, may be experienced with but little wreckage to the machine. They have but little value in showing that such wreckage is due to the anoxæmia, because the anoxæmia has not been the sole disturbance.

Cases in which the anoxæmia has been uncomplicated are to be found among those who have been exposed to low atmospheric pressures; for instance, balloonists and aviators. Of these quite a considerable number have suffered from oxygen want to the extent of being unconscious for short intervals of time.

No scientific observer has pushed a general condition of anoxæmia either on himself or on his fellows to the extent of complete unconsciousness. The most severe experiments of this nature are those carried out by Dr. Haldane and his colleagues. One experiment in particular demands attention. Dr. Haldane and Dr. Kellas[1] together spent an hour in a chamber in which the air was reduced to between 320 mm. and 205 mm. It is difficult to say how far they were conscious. Clearly each believed the other to be complete master of his own faculties, but it is evident that Dr. Haldane was not so. I gather that he has no recollection of what took place; that whenever he was consulted about the pressure he gave a stereotyped answer which was the same for all questions; and that even with a little more oxygen present he was sufficiently himself to wish to investigate the colour of his lips in the glass, but insufficiently himself to be conscious that he was looking into the back, and not the front, of the mirror. Dr. Kellas, who could make observations, never discovered Dr. Haldane's mental condition, though boxed up with him for an hour, and went on consulting him automatically. A somewhat similar experiment was performed on the other two observers, with results differing only in degree.

Yet the after-effects are summed up in the following sentence: "All four observers suffered somewhat from headache for several hours after these experiments, but there was no nausea or loss of appetite."

Of real importance in this connection are the results of carbon monoxide poisoning. Of these a large number might be cited. Those interested will find some very instructive cases described in a volume entitled "The Investigation of Mine Air," by the late Sir C. Le Neve Foster and Dr. Haldane.[2] The cases in question were those of a number of officials who went to investigate the mine disaster on Snaefell, in the Isle of Man, in May, 1897. Of the five cases cited all suffered some after-effects, by which I mean that by the time the blood was restored sufficiently to its normal condition for the tissues to get the amount of oxygen which they required, the effects of the asphyxia had not passed off, and to this extent the machine suffered.

To sum up, then, what may be said of the permanent damage caused by acute anoxæmia, it seems to me to be as follows: No degree of anoxæmia which produces a less effect than that of complete unconsciousness leaves anything more than the most transient effects; if the anoxæmia be pushed to the point at which the subject is within a measurable distance of death, the results may take days or weeks to get over, but only in the case of elderly or unsound persons is the machine wrecked beyond repair.[3]

Chronic Anoxaemia.

And now to pass to the consideration of what I may call chronic anoxæmia—that is to say, oxygen want which perhaps is not very great in amount, but is of long duration. The most obvious instances of men subject to chronic anoxæmia are the dwellers at high altitudes. In these the anoxæmia does not wreck the machine. On what I may call the average healthy man anoxæmia begins to tell at about 18,000 ft. At lower altitudes no doubt he will have some passing trouble, but it seems to me from my own experience that this altitude is a very critical one. Yet there are mining camps at such heights in South America at which the work of life is carried on. The machine is kept going by a process of compensation, in part carried out by a modification in the chemical properties of the blood, in which both the carbonic acid and the alkali diminish. The result, according to my interpretation of my own observations on the Peak of

* From the opening address of the President of Section I (Physiology) delivered at the Cardiff meeting of the British Association on August 24.

[1] Haldane, Kellas, and Kennaway. *Journal of Physiology*, vol. liii.

[2] Foster and Haldane. "The Investigation of Mine Air." (Griffin and Co., 1905.)

[3] Since the address was written Dr. Haldane has told me of a number of victims of the same accident who were brought out alive by the search party, but in whose case the machine was wrecked beyond repair. They soon died.

Teneriffe, which appeared to be confirmed by the experiments in a partially vacuous chamber in Copenhagen,[4] was this: The hydrogen-ion concentration of the blood increased slightly, the respiratory centre worked more actively, and the lung became better ventilated with oxygen, with the natural result that the blood became more oxygenated than it would otherwise have been.

The difference which this degree of acclimatisation made was very great. On Monte Rosa in one case 15 mm. of oxygen pressure were gained in the lungs. To put the matter another way, the amount of oxygen in our lungs at the summit was what it would otherwise have been 5000 ft. or 6000 ft. lower down.

The body, then, had fought the anoxæmia and reduced it very much in degree, but at the same time the anoxæmia had in a subtle way done much to stop the powers of the body, for this very acclimatisation is effected at the expense of the ultimate reserve which the body has at its disposal for the purpose of carrying out muscular or other work. The oxygen in the lungs was obtained essentially by breathing at rest as you would normally do when taking some exercise. Clearly, then, if you are partly out of breath before you commence exercise you cannot undertake so much as you otherwise would do. As a friend of mine—who has camped at 23,000 ft., a higher altitude, I believe, than any other man—put it to me: "So great was the effort that we thought twice before we turned over in bed."

One of the interesting problems with regard to chronic anoxæmia is its effect upon the mind. Sir Clement Le Neve Foster's account of himself during CO poisoning shows loss of memory, some degree of intelligence, and a tendency to repeat what is said. The whole train of his symptoms strongly suggests some form of intoxication, and is not dissimilar to that produced by alcoholic excess. Here it may be noted that, so far as isolated nerves are concerned, there is very good evidence that alcohol and want of oxygen produce exactly the same effects, *i.e.* they cause a decrement in the conducting power of the nerve. And herein lies a part of its interest, for pharmacologists of one school, at all events, tell me that the corresponding effects of alcohol are really due to an inhibition of the higher centres of the mind; you can, therefore, conceive of the mental mechanism of self-control being knocked out either because it has not oxygen enough with which to "carry on," or because it is drugged by some poison as a secondary result of the anoxæmia.

To pass now to the results of more chronic anoxæmia, if I were to try to summarise them in a sentence I should say that, just as acute anoxæmia simulates drunkenness, chronic anoxæmia simulates fatigue.

A page in my note-book written at the Alta Vista Hut, at an altitude of 12,000 ft., commences with a scrawl which is crossed out, then "6 Sept.," the word "Sept." is crossed out and "March" is inserted, "March" shares the same fate as "Sept.," and "April," the correct month, is substituted, and so on, more crossings out and corrections. All this you might say with justice is the action of a tired man. The other pages written at lower altitudes do not, however, bear out the idea that I was out of health at the time, and there was no reason for tiredness on that particular day. Another symptom frequently associated with mental fatigue is irritability. Anyone who has experience of high altitudes knows to his cost that life does not run smoothly at 10,000 ft. If the trouble is not with one's own temper, it is with those of one's colleagues; and so it was in many cases of gas poisoning and in the case of aviators. In these subjects the apparent fatigue sometimes passed into a definitely neurasthenic condition. At this point an issue appeared to arise between the partisans of two theories. One camp said that the symptoms were definitely those of anoxæmia, the other that they were due to nerve-strain. As I have indicated later on, it is not clear that these two views are mutually exclusive. It takes two substances to make an oxidation, the oxygen and the oxidised material. If the oxidation does not take place, the cause may lie in the absence of either or of both, in each case with a similar effect. The subject really is not ripe for controversy, but it is amply ripe for research—research in which both the degree of anoxæmia and the symptoms of fatigue are clearly defined.

So much, then, for the injury to the machine wrought by chronic anoxæmia.

Types of Anoxaemia.

Anoxæmia is by derivation want of oxygen in the blood. Suppose you allow your mind to pass to some much more homely substance than oxygen—such, for instance, as milk—and consider the causes which may conspire to deprive your family of milk, three obvious sources of milk deficiency will occur to you at once: (1) There is not enough milk at the dairy; (2) the milk is watered or otherwise adulterated so that the fluid on sale is not really all milk; and (3) the milkman from that particular dairy does not come down your road.

These three sources of milk deficiency are typical of the types of oxygen deficiency.

The first is insufficient oxygen dispensed to the blood by the lungs. An example of this type of anoxæmia is mountain-sickness. The characteristic of it is insufficient *pressure* of oxygen in the blood. In mountain-sickness the insufficiency of pressure in the blood is due to insufficient pressure in the air. But this type of anoxæmia may be due to other causes. In such cases, either caused by obstruction, by shallow respiration, or by the presence of fluid in the alveoli, the blood leaving the affected areas will contain considerable quantities of reduced hæmoglobin. This will mix with blood from unaffected areas which is about 95 per cent. saturated. The oxygen will then be shared round equally among the corpuscles of the mixed blood, and if the resultant is only 85–90 per cent. saturated the pressure of oxygen will only be about half the normal, and, as I said, deficiency of oxygen pressure is the characteristic of this type of anoxæmia.

The second type involves no want of oxygen pressure in the arterial blood; it is comparable to the watered milk. The deficiency is really in the quality of the blood, and not in the quantity of oxygen to which the blood has access. The most obvious example is anæmia, in which the blood contains too low a percentage of hæmoglobin, and because there is too little hæmoglobin to carry the oxygen, too little oxygen is carried. Anæmia is, however, only one example of this type of anoxæmia. The hæmoglobin may be useless for the purpose of oxygen transport; it may be turned in part into methæmoglobin, as in several diseases, *e.g.* among workers in the manufacture of some chemicals, and in some forms of dysentery contracted in tropical climates, or it may be monopolised by carbon monoxide, as in mine-air.

Thirdly, the blood may have access to sufficient oxygen and may contain sufficient functional hæmoglobin, but owing to transport trouble it may not be

[4] Hasselbach and Lindhard, quoted by Bainbridge.

circulated in sufficient quantities to the tissues. The quantity of oxygen which reaches the tissue in unit time is too small. Literally, according to the strict derivation of the word "anoxæmia," the third type should perhaps be excluded from the category of conditions covered by that word, but as the result is oxygen starvation in the tissues it will be convenient to include it.

The obvious types of anoxæmia may therefore be classified in some such scheme as the following:

ANOXÆMIA.

1. *Anoxic Type.*	2. *Anaemic Type.*	3. *Stagnant Type.*
The pressure of oxygen in the blood is too low. The hæmoglobin is not saturated to the normal extent. The blood is dark. Examples: 1. Rare atmospheres. 2. Areas of lung partially unventilated. 3. Fluid or fibrin on surface of cells.	The quantity of functional hæmoglobin is too small. The oxygen pressure is normal. The blood is normal in colour. Examples 1. Too little hæmoglobin. 2. CO hæmoglobin. 3. Methæmoglobin.	The blood is normal, but is supplied to the tissues in insufficient quantities. Examples: 1. Secondary result of histamine shock. 2. Hæmorrhage. 3. Back pressure.

Anoxic anoxæmia is essentially a general as opposed to a local condition. Not only is the pressure of oxygen in the blood too low, but the lowness of the pressure, and not the deficiency in the quantity, is the cause of the symptoms observed.

The workers on Pike's Peak, for instance, emphasised the fact that the increase of red-blood corpuscles during their residence at 14,000 ft. was due to deficient oxygen pressure. No doubt they were right, but the point was rather taken from their argument by their assertion in another part of the paper that the oxygen pressure in their arterial blood was anything up to about 100 mm. of mercury. Let me, therefore, take my own case, in which the alveolar pressures are known to be an index of the oxygen pressures in the arterial blood. I will compare my condition on two occasions, the point being that on these two occasions the quantities of oxygen united with the hæmoglobin were as nearly as may be the same, whilst the pressures were widely different.

As I sit here the hæmoglobin value of my blood is 96–97, which corresponds to an oxygen capacity of 0·178 c.c. of O_2 per c.c. of blood. In the oxygen chamber on the last day of my experiment, to which I refer later,[5] the oxygen capacity of my blood was 0·201 c.c. Assuming the blood to be 95 per cent. saturated now and 84 per cent. saturated then, the actual quantity of oxygen in the blood on the two occasions would be:

Oxygen capacity.	Percentage saturation.	Oxygen content.
0·178	95	0·169
0·201	84	0·169

Here I am in my usual health. In the chamber I vomited; my pulse was 86, it is now 56; my head ached in a most distressing fashion; it was with the utmost difficulty that I could carry out routine gas analyses, and when doing so the only objects which I saw distinctly were those on which my attention was concentrated.

In the anoxic type of anoxæmia there may then be quite a sufficient quantity of oxygen in the blood, but a sufficient quantity does not avail in the face of an insufficient pressure. Indeed, as I shall show presently, the anoxic type of anoxæmia is the most serious. We are, therefore, confronted with something of a paradox in that the most severe type of anoxæmia is one in which there is not necessarily an insufficient quantity of oxygen in the blood at all.

It is interesting and not uninstructive to try to calculate the degree to which the tissues are prejudiced by being subjected to various types of anoxæmia. Let us suppose that we have a piece of tissue—muscle, for instance—which normally is under the following conditions:

(*a*) One cubic centimetre of blood per minute runs through it.

(*b*) The total oxygen capacity of this blood is 0·188 c.c. of oxygen per c.c. of blood.

(*c*) The percentage saturation is 97.

(*d*) The oxygen pressure is 100 mm.

(*e*) The oxygen used is 0·059 c.c.

(*f*) The oxygen pressure in the tissues is half of that in the veins, in this case 19 mm.

My colleague, Mr. F. J. Roughton, has calculated the amount of oxygen which would penetrate this tissue from the blood in each type of anoxæmia, if the oxygen which reached it in the blood was reduced to 66 per cent. of the quantity stated above.

Measurement of Anoxaemia.

In the study of all physical processes there comes a point, and that very early, when it becomes necessary to compare them one with another to establish some sort of numerical standard and have some sort of quantitative measurements. The study of anoxæmia has reached that point. By what scale are we to measure oxygen want?

Let us take the anoxic type first. There are two scales which might be applied to it, both concerning the arterial blood; the one is the oxygen pressure in it, the other is the consequent percentage of the hæmoglobin which is oxyhæmoglobin. The important thing is that there should be as little reduced hæmoglobin as possible. The more reduced hæmoglobin there is present, the less saturated is the blood; or, as the American authors say, the more *un*saturated is the blood. They emphasise the fact that it is the quantity of *reduced* hæmoglobin that is the index of the anoxic condition. They speak not of the percentage saturation, but of the percentage of unsaturation. A blood which would ordinarily be called 85 per cent. saturated they speak of as 15 per cent. unsaturated.

Anoxic anoxæmia, in many cases of lung affection, should be measured by the direct method of arterial puncture introduced by Stadie,[6] for the simple reason that the relation between the alveolar air and the arterial blood is quite unknown. Such, for instance, are cases of many lung lesions of pneumonia in which the lung may be functioning only in parts, of pneumothorax, of pleural effusions, of emphysema, of multiple pulmonary embolism, in phases of which the arterial blood has been found experimentally to be unsaturated. In addition to these definite lung lesions there is another type of case on which great stress has been laid by Haldane, Meakins, and Priestley, namely, cases of shallow respiration.[7] A thorough investigation of the arterial blood is such cases is urgently necessary. Indeed, in all cases in which it is practicable, the method of arterial puncture is desirable. But in the cases of many normal persons—as, for instance, those of airmen at different altitudes—alveolar-air determinations would give a useful index.

The anæmic type of anoxæmia is gauged by the quantity of *oxy*hæmoglobin in the blood. In the case of simple anæmias this is measured by the scale in which the normal man counts as 100, and the hæmoglobin in the anæmic individual is expressed as a percentage of this. This method has been stan-

[5] Barcroft, Cooke, Hartridge, Parsons, and Parsons. *Journal of Physiology*, vol. liii., p. 451, 1920.

[6] Stadie. *Journal of Experimental Medicine*, vol. xxx., p. 215, 1919.

[7] Haldane, Meakins, and Priestley. *Journal of Physiology*, vol. lii. p. 420, 1918–19.

dardised carefully by Haldane, and we now know that the man who shows 100 on the scale has an oxygen capacity of 0·185 c.c. of oxygen for every c.c. of blood. We can, therefore, in cases of carboxyhæmoglobin or methæmoglobin poisoning, express the absolute amount of oxyhæmoglobin pressure either by stating the oxygen capacity and so getting an absolute measurement, or in relative units by dividing one hundred times the oxygen capacity by 0·185, and thus getting a figure on the ordinary hæmoglobin metre scale.

The Mechanism of Anoxaemia.

Perhaps the most difficult phase of the discussion is that of how anoxæmia produces its baneful results. Before you discuss whether a certain effect is due to cause A or cause B, be clear in your own mind that A and B are mutually exclusive.

Let me take an example and suppose

(1) That the energy of muscular contraction in the long run depends in some way on the oxidation of sugar;

(2) That in the absence of an adequate supply of oxygen the reaction $C_6H_{12}O_6+6O_2=6CO_2+6H_2O$ cannot take place in its entirety;

(3) That in such circumstances some lactic acid is formed as well as carbonic acid;

(4) That the hydrogen-ion concentration of the blood rises and the total ventilation increases. On what lines are you to discuss whether the increased ventilation is due to "acidosis," by which is meant in this connection the increased hydrogen-ion concentration of the blood, or to "anoxæmia"? Clearly not on the lines that it must be due to one or other, for in the above instance anoxæmia and acidosis are, to some extent, dependent variables.

I have chosen the above case because measurements have been made throughout which make the various assumptions fairly certain, and tell us pretty clearly in what sort of chain to string up the events, what is cause and what is effect. Clearly it would be ridiculous to start a discussion as to whether the breathlessness was due to "acidosis" or "anoxæmia." Each has its place in the chain of events, but I have heard discussions of whether other phenomena of a more obscure nature were due to oxygen want or to acidosis. Such discussions tend to no useful end.

Nor is this the only problem with regard to oxygen want concerning which my warning is needed. Oxygen want may act immediately in at least two ways:

(1) In virtue of absence of oxygen some oxidation which otherwise might take place does not do so, and therefore something which might otherwise happen may not happen. For instance, it may be conceived that the respiratory centre can go through the rhythmic changes of its activity only as the result of the oxidation of its own substance.

(2) A deficient supply of oxygen may produce, not the negation of a chemical action, but an altered chemical action which in its turn produces toxic products that have a secondary effect on such an organism as the respiratory centre.

Now these effects are not mutually exclusive. In the same category are many arguments about whether accumulations of carbonic acid act specifically as such or merely produce an effect in virtue of their effect on the hydrogen-ion concentration. Here again the two points of view are not, strictly speaking, alternatives, and, in some cases at all events, both actions seem to go on at the same time.

It will be evident that in any balanced action in which CO_2 is produced its accumulation will tend to retard the reaction; but, on the other hand, the same accumulation may very likely raise the hydrogen-ion concentration, and in that way produce an effect.

It is rather fashionable at present to say that "the whole question of acidosis and anoxæmia is in a hopeless muddle." To this I answer that if it is in a muddle, I believe the reason to be largely because schools of thought have rallied round words and have taken sides under the impression that they have no common ground. The "muddle," in so far as it exists, is not, I think, by any means hopeless; but I grant freely enough that we are rather at the commencement than at the end of the subject; that much thought and much research must be given, first, in getting accurate data, and, secondly, on relating cause and effect, before the whole subject will seem simple. No effort should be spared to replace indirect by direct measurements. My own inference with regard to changes of the reaction of the blood, based on interpretations of the dissociation curve, should be checked by actual hydrogen-ion measurements, as has been done by Hasselbach and is being done by Donegan and Parsons.[8] Meakins also is, I think, doing great work by actually testing the assumptions made by Haldane, Priestley, and himself as regards the oxygen in arterial blood.

The Compensations for Anoxaemia.

For the anoxic type of anoxæmia two forms of compensation at once suggest themselves. The one is increased hæmoglobin in the blood; the other is increased blood-flow through the tissues. Let us, along the lines of the calculations already made, endeavour to ascertain how far these two types of compensation will really help. To go back to the extreme anoxic case already cited, in which the hæmoglobin was 66 per cent. saturated, let us, first, see what can be accomplished by an increase of the hæmoglobin value of the blood. Such an increase takes place, of course, at high altitudes. Let us suppose that the increase is on the same grand scale as the anoxæmia, and that it is sufficient to restore the actual quantity of oxygen in 1 c.c. of blood to the normal. This, of course, means a rise in the hæmoglobin value of the blood from 100 to 150 on the Gowers scale. Yet even so great an increase in the hæmoglobin will increase the oxygen taken up in the capillary from each c.c. of blood only from 0·031 to 0·036 c.c., and will, therefore, leave it far short of the 0·06 c.c. which every cubic centimetre of normal blood was giving to the tissue. So much, then, for increased hæmoglobin. It gives a little, but only a little, respite. Let us turn, therefore, to increased blood-flow.

In the stagnant type of anoxæmia the principal change which is seen to take place is an increase in the quantity of hæmoglobin per cubic millimetre of blood.

This increase is secondary to a loss of water in the tissues, the result in some cases, as appears from the work of Dale, Richards, and Laidlaw,[9] of a formation of histamine in their cells. Whether this increase of hæmoglobin is to be regarded as merely an accidental occurrence or as a compensation is difficult to decide at present. Roughton's calculations rather surprised us by indicating that increased hæmoglobin acted less efficiently as a compensatory mechanism than we had expected. This conclusion may have been due to the inaccuracy of our assumptions. I must therefore remind you that much experimental evidence is required before the assump-

8 Donegan and Parsons. *Journal of Physiology*, vol. lii., p. 315, 1919.
9 Dale and Richards. *Journal of Physiology*, vol. lii., p. 110, 1919. Dale and Laidlaw. *Ibid.*, p. 355.

tions which are made above are anything but assumptions. But, so far as the evidence available at the present time can teach any lesson, that lesson is this: The only way of dealing satisfactorily with the anoxic type of anoxæmia is to abolish it by in some way supplying the blood with oxygen at a pressure sufficient to saturate it to the normal level.

It has been maintained strenuously by the Oxford school of physiologists that Nature actually did this; that when the partial pressure in the air-cells of the lung was low, the cellular covering of that organ could clutch at the oxygen and force it into the blood at an unnatural pressure, creating a sort of forced draught. This theory, as a theory, has much to recommend it. I am sorry to say, however, that I cannot agree with it on the present evidence. I will only make a passing allusion to the experiment which I performed in order to test the theory, living for six days in a glass respiration-chamber in which the partial pressure of oxygen was gradually reduced until it was at its lowest—about 45 mm. Such a pressure, if the lung was incapable of creating what I have termed a forced draught, would mean an oxygen pressure of 38–40 mm. of mercury in the blood, a change sufficient to make the arterial blood quite dark in colour, whereas, did any considerable forced draught exist, the blood in the arteries would be quite bright in colour. Could we but see the blood in the arteries, its appearance alone would almost give the answer as to whether or no oxygen was forced, or, in technical language, secreted, through the lung-wall. And, of course, we could see the blood in the arteries by the simple process of cutting one of them open and shedding a little into a closed glass tube. To the surgeon this is not a difficult matter, and it was, of course, done. The event showed that the blood was dark, and the most careful analyses failed to discover any evidence that the body can force oxygen into the blood in order to compensate for a deficiency of that gas in the air.

Yet the body is not quite powerless. It can, by breathing more deeply, by increasing the ventilation of the lungs, bring the pressure of oxygen in the air-cells closer to that in the atmosphere breathed than would otherwise be the case. I said just now that the oxygen in my lungs dropped to a minimal pressure of 48 mm.; but it did not remain at that level. When I bestirred myself a little it rose, as the result of increased ventilation of the lung, to 56 mm., and at one time, when I was breathing through valves, it reached 68 mm. Nature will do something, but what Nature does not do should be done by artifice. Exploration of the condition of the arterial blood is only in its infancy, yet many cases have been recorded in which in illness the arterial blood has lacked oxygen as much as, or more than, my own did in the respiration-chamber when I was lying on the last day, with occasional vomiting, racked with headache, and at times able to see clearly only as an effort of concentration. A sick man, if his blood is as anoxic as mine was, cannot be expected to fare better as the result, and so he may be expected to have all my troubles in addition to the graver ones which are, perhaps, attributable to some toxic cause. Can he be spared the anoxæmia? The result of our calculations so far points to the fact that the efficient way of combating the anoxic condition is to give oxygen. During the war it was given with success in the field in cases of gas poisoning, and also special wards were formed on a small scale in this country in which the level of oxygen in the atmosphere was kept up to about 40 per cent., with great benefit to a large percentage of the cases. The practice then inaugurated is being tested at Guy's Hospital by Dr. Hunt, who administered the treatment during the war.

Nor are the advantages of oxygen respiration confined to pathological cases. One of the most direct victims of anoxic anoxæmia is the airman who flies at great heights. Everything in this paper tends to show that to counteract the loss of oxygen which he sustains at high altitudes there is but one policy, namely, to provide him with an oxygen equipment which is at once as light and as efficient as possible—a consummation for which Dr. Haldane has striven unremittingly. And here I come to the personal note on which I should like to conclude. In the pages which I have read views have been expressed which differ from those which he holds in matters of detail—perhaps in matters of important detail. But Dr. Haldane's teaching transcends mere detail. He has always taught that the physiology of to-day is the medicine of to-morrow. The more gladly, therefore, do I take this opportunity of saying how much I owe, and how much I think medicine owes and will owe, to the inspiration of Dr. Haldane's teaching.

The University Problem in London.

A REUNION of the Old Students' Association of the Royal College of Science was held on Tuesday evening, September 14, at the Imperial College Union, South Kensington. The president (Sir Richard Gregory) was in the chair, and the principal feature was an address by Prof. H. E. Armstrong entitled "Pre-Kensington History of the Royal College of Science and the University Problem in London." The address was devoted largely to an autobiographical sketch of Prof. Armstrong's early experiences at the Royal College of Science, dating back to the summer term of 1865, when he became a student of its forerunner, the Royal College of Chemistry, then situate in Oxford Street. Prof. Armstrong's reminiscences of Hofmann, McLeod, Tyndall, Huxley, Frankland, and others were all delightful to listen to, but especially of the first-named did he evidently cherish an affectionate memory. A discussion followed, in which the chairman, Dr. M. O. Forster, Prof. Whitehead, Prof. Morgan, Prof. E. W. Skeats, Dr. G. T. Moody, and Mr. S. W. Hunt took part. Some remarks of the lecturer referring to examinations seemed to be regarded as a polemic against this feature of university life, and called forth a certain amount of timid apology and some vigorous defence. Prof. Armstrong, briefly replying, explained that he did not object to examinations, but to the London system; what he was anxious to see was a series of institutions established in London which would make education effective. It was for each one to consider what was the best system, but so long as each school attempted to do everything there could not be success. The part of the address referring to this subject is subjoined.

I have now fifty years' direct experience of the London University system. Throughout this period the talk has ever been of examinations, never of learning—London has been without educational ideals. Under the system methods of teaching have been hopelessly stereotyped; the teachers have neither been free to teach nor the students to learn. At no time has the character of the training been under discussion; the one concern has been to maintain the "standard" of the examinations—as if there could be a fixed standard when examiners are always being changed and knowledge grows from day to day. No two individuals are mentally comparable. In the degree examinations no allowance has been made for the student's proclivities and choice of profession; for example, whether chemist or physicist, the candidate has been forced to reach the same standard in both chemistry and physics. There may have been a well-meant intention to lay a broad foundation, but there has been no understanding of student-nature.

Philosophers insist that the main office of education is to develop and foster the altruistic spirit—a belief in truth, in goodness, in beauty, in each for its own sake; so we should believe in education primarily for its own sake, as the source of our happiness, not mainly because it brings pecuniary advantage or preferment. From this point of view the present university examination system is one of the most selfish, the most corrupting, ever created; it encourages love of show and advertisement, the spirit of competition and commercialism. Unfortunately, the vested interests which its practice has created are numerous and powerful; the underground influence these will exert in deprecation of change cannot fail to be great. Teachers themselves will be loth to abandon it, for, being paid starvation wages, the pittance they gain from examinations is of consequence.

The Germans alone have grasped the problem of university education. At the degree examination they have only required proof of competent knowledge of the student's chosen subject, together with general knowledge of a couple of cognate subjects which he has been allowed to select from a list. Whatever stones we may throw at German morals, we cannot but admit that their system has given results in practice, whilst ours has not. The time is coming when we shall be forced to allow "self-determination" in higher education as well as in the case of small nations.

Intellectuals are not only a peculiar people, but a mixture of peculiar classes of definitely peculiar people.

We have long ceased to believe in the disciplinary value of this or that subject, and are gradually, but all too slowly, coming to admit that allowance must be made for the extraordinary variation in the ability and intellectual proclivities of individual students. I have given particulars of my own case, but I know of many similar experiences among friends and students whom I have had under constant observation. I know several men who have greatly distinguished themselves as students in subjects which they have thrown entirely to the winds in later life, the study of which has been without the least influence on their mental development. Being acquisitive and conscientious workers, they set themselves to an allotted task and succeeded in it, but the time spent in the study was wasted. Many able students have the advocate's faculty of getting up a case for the time being and as quickly forgetting it when over.

I am satisfied, from long study of the two classes, that the average engineering student and the average chemical or physical student are of two quite different types of mind. The engineering student shies at chemistry and physics, and rarely acquires sympathy with either subject, not because he does not want to learn them, but because their method makes no appeal to his intelligence—the habit of mind of the engineer being constructive, whilst that of the chemist and physicist is analytical and introspective. The engineer usually does work at the request of others; when he realises what is wanted, as a rule he can meet requirements. He is prepared to learn how to use electrical machinery, but he does not want to know much about electricity.

Chemical engineers are being much asked for. We may raise a few by striving to teach engineers to be chemists; a larger proportion, perhaps, by teaching chemists engineering, because many chemists are constructive in their outlook as well as analytical, but in neither case will the hybrid be really competent in both subjects. If we are wise we shall follow the German example and manacle chemist with engineer and attune the two to work in sympathetic vibration. The engineer has been spoilt in this country, and needs to be put in his place. He has far too much assurance, and is believed in just because he does things which make a public show; really, he is not anything like so big as he would have us believe, and is largely dependent on chemists and others who do the work he but plans. All this is by way of emphasising my point that special kinds of university education must be provided to meet the wants of specific classes—that there is no one royal road to effective knowledge. The man who masters a subject he has feeling for does so intuitively—it is in him to understand. When we complain, too often unjustly, of the failure of students in examinations and that they have learnt little or nothing, assuming that it is because they have been inattentive or not applied themselves, we do not realise how difficult it is for most to learn.

To be specific, I am of the opinion that the Imperial College must be autonomous. To be efficient its courses must be most carefully adjusted to suit the special peculiarities of its students, and their ability must be rated by those who can follow and appreciate their work. Only their teachers can do this. As Sir W. H. Bragg and Prof. Starling stated in their striking letter to the *Times* of December 22 last: "The whole development of university education in London is impeded at every step by the subjection of the colleges to an examining body which is incompetent by constitution to deal with academic affairs. Academic freedom is essential to progress." The teachers must always be in advance of the examiners, who necessarily work to a published programme; if they be made subservient, all sense of initiative disappears, and their efforts to improve and advance are stultified and sterilised; moreover, but few students have the desire to work at subjects which do not pay in the examinations, nor can they be blamed in view of the intensity of the struggle for existence. True ideals are only possible under a free system.

But I would not merely free the Imperial College and continue it as it is; I would limit its functions, because I am sure that it does not, and cannot in the future, do all that it now attempts, and apparently desires, to do. It attempts to provide both for physical and biological science, but the requirements of these two branches of knowledge are totally distinct, to be met only by distinct staffs. Devotion to physical science involves and requires a mathematical habit of mind; biological science is definitely non-mathematical in its tendencies; the two habits are very rarely conjoined. Past discussions on heredity afford a striking illustration of this duality. Though a chemist, I happen always to have had marked biological leanings. In studying my colleagues in science, nothing has struck me more than the slight appeal biology makes to those on the physical side. Naturalists there are, not a few; but these, as a rule, are not developed scientific workers. The professed devotee to physical science is rarely a naturalist; even mineralogists are not often found among them. Biochemistry has been to the fore of late years, but the so-called biochemists are mostly just ordinary chemists in disguise, working with materials derived from animal or vegetable substance. The number who have distinct biological feeling is very small—probably to be counted on the hand.

To meet the entirely special requirements of biology, I would constitute University College an Imperial College of Biological Science and Technology. I would interchange the biological staff of the college at South Kensington and that on the physical side of the college in Gower Street. The Rockefeller gift has rendered this change one that is now easier to make and more desirable than it ever was. If effected, it would at least be a great step towards the solution of the pressing problem of preliminary medical education in London.

To deal with the third of the London colleges, King's, its science may well be handed over to the two colleges I have suggested. Let it, then, become a great independent Imperial College of Arts and Economics.

The three colleges should be federated in one Imperial University of London. The objective of the tripartite organisation would be to make education in each of the three departments effective, which it never will be so long as three conflicting colleges exist in which the same subjects are taught without any provision for the mental dissimilarities to which I have insistently referred.

London and the provincial universities suffer from the disability that they afford no opportunity for social training. Cambridge and Oxford necessarily rank before them in this respect, and the attractiveness of the two ancient Universities cannot be countered, as it largely depends on time and tradition. But social training is of the utmost importance, and the attempt must be made to provide it in London.

> The man of men who knowe h men, the Man of men is he!
> His army is the human race and every foe must flee.

If the Arts College were established on a country site, such as that at Kenwood, space might be found for attractive residential quarters as well as playing fields, and on these latter students from the three colleges might well unite their forces; but it is clear that hostels will be required both at Kensington and in Gower Street. If these had gymnasia and debating halls, students would be much brought together. But even if such provision be made, Cambridge and Oxford, on account of their social advantages, will always tend to attract the intelligence of the nation, and the teaching centres in London and the provinces will suffer accordingly. The only way of competing open to the latter is that each should become so prominent in some special subject that, of necessity, those who wish to be proficient in the subject will be attracted.

Each of the three colleges would award its own degrees. Sir Philip Magnus, who is a conservative advocate of the present system, would have the colleges grant a diploma, leaving the degree to be awarded by the University. In a letter to the *Times* of June 11 last he remarks: "In the interests of university education it is surely wiser to maintain the distinction between a college diploma and a university degree. They do not, and should not, connote the same qualifications, and for that reason, if for no other, they should remain distinct."

As a matter of fact, in London the diploma has connoted the same qualification as the degree; the course of training at the Imperial College is the same, whether or no the student take the university degree; at most he is compelled to "cram" some subject or special section of a subject not in the diploma course. Such learning, we know, is almost always forgotten after the examination is over.

The degree-hunger is upon us; students demand degrees, and will have them at any cost. The question is: Shall it be at the cost of their moral outlook and of much wasted time, or in recognition of honest, thorough work? Scientific workers desire to be designated by some distinct title; even the American puts aside his Republican feeling and is pleased to be called "doctor."

Diploma is not an English word; it is suggestive of exhibitions and a framed illuminated certificate rather than of the university. You cannot call a man "Diplomat so and so"—the more so as diplomacy now ranks as a doubtful profession. When Sir Philip Magnus says that diploma and degree do not connote the same qualifications, he has unconsciously in his mind the idea that the University course includes "arts" training, and counts for culture; but the diploma-holder is not required to pass in any literary subject when a candidate for the degree.

Sir Philip Magnus, I know, fears the neglect of literary study in a college such as the Imperial College, though he has nothing to say against the neglect of science in an arts course. Those who live in houses built of the thinnest of glass should not speak too loudly. This view is based on a fallacy, on the assumption that scientific workers in general are weak on the literary side, especially in expressing themselves. They are no weaker than their literary brethren; as a rule, both come to the University with the same literary preparation; neither has been taught the art of writing. The art of reading is acquired during youth; literary foundations should be laid during the school-years, and, if well and truly laid, will be built upon afterwards. The love of books can come only as a free gift, through quiet suggestion and opportunity and leisure to read. The university is the place for special study and self-development—the place where chances sacrificed at school are often recovered; but as the future student of science in an efficient college will be required to record the work he does in accurate and logical terms and to be concise in his statements, he will, in fact, receive definite literary training, maybe in advance of his literary contemporary.

Under a federal scheme such as I have outlined a student would be free to attend courses at a college not his own, and would have credit for such outside attendance. He would be as broad as his heredity would permit.

My proposals may seem to be revolutionary, but we need a revolution in education to make it effective. Merely to mend and patch the old machine will not help us; new ideals should prevail. We must determine to go forward, putting self in the background and thinking only of national interests. Somewhere a leader must be found: "to see and dare and decide; to be a fixed pillar in the welter of uncertainty." It is our imperative duty to "shut together the clasps of resolve."

> Dreading retreat, dreading advance to make,
> Round we revolve, like to the wounded snake.

At this critical hour there can be no better call to all than that of the single line in the biting, short poem "To England," in a recent issue (August 26) of the *Times*:

> Show what you are, *of high and generous race.*

The Exmoor Earthquake of September 10.

EARLY in the morning of Friday, September 10, three slight earthquakes were felt in North Devon in the district between Morte Bay and Exmoor Forest. The first occurred at about 12.15 a.m., and this was followed about an hour later by two slighter shocks separated by an interval of ten minutes. Though it is reported that part of a chimney was dislodged at East Down, and that the light at Bull Point lighthouse was extinguished, it is doubtful if the intensity of the shock at any place exceeded the degree 4 of the Rossi-Forel scale.

The chief interest of the earthquake lies in its connection with a similar, but slightly stronger, shock which occurred on January 23, 1894 (*Geol. Mag.*, vol. iii., 1896, pp. 553–56). This earthquake disturbed an area 30 miles long, extending from Ilfracombe to about 2 miles east of Dulverton, and 16½ miles wide, the whole area containing about 389 square miles. The centre of the inner isoseismal (intensity 4) was half a mile south-west of Simonsbath. From the dimensions and relative positions of the isoseismal lines it was inferred that the earthquake was due to a fault passing close to Simonsbath, running in the direction E. 22° S., and hading to the south—a position which agrees almost exactly with that of the northern boundary fault of the Morte Slates. The length of the fault-displacement was probably about 10 miles.

From the accounts so far received it appears that the disturbed area of the recent earthquake is shifted to the west. It is about 22 miles long, 13½ miles wide, and contains about 230 square miles. The centre lies half a mile north of East Down and a mile south of the northern boundary fault of the Morte Slates—that is, on its downthrow side. The length of the seismic focus was about 8 miles, with its centre 10 miles west of that of the earthquake of 1894. The points of interest are (1) that, as is so often the case in British earthquakes, the epicentre migrated to the west, and (2) that the lengths of the two foci and the distance between their centres were roughly equal to that which separates the epicentres of British twin earthquakes. C. DAVISON.

Aids to Forecasting.[1]

A LONG-FELT want of the weather forecaster has been a methodical classification of weather types associated with the various weather conditions which present themselves. The weather-chart commonly offers a picture familiar enough to the forecaster, but there is much connected with the movement and development which depends upon the bounding conditions. A low-pressure system or depression when appearing off our south-west coasts may have a clear path to the north-eastward, the high-pressure system in its front giving way to its progress. On the other hand, the high-pressure system or anticyclone may be well established and may maintain its ground, thus compelling the advancing disturbance to adapt its track to the situation—a feature of no uncommon occurrence, but one offering considerable difficulty to the work of the forecaster.

Lt.-Col. Gold has made a good attempt to classify the different types of weather which present themselves, and it seems an advance on any previous effort in this direction. The memoir is not hampered by mathematics, and is the outcome of a classification and analysis made by the Meteorological Section, R.E., in France during the late war. It is an effort to supply the forecaster when in doubt with reference to some previous situations of a similar character, so that he may see what developments occurred.

Forecasting is admitted to be a matter of experience which is not always very lengthy. Fifteen types and sub-types have been selected, and are graphically shown in the diagrams. The controlling feature in the type is the distribution of atmospheric pressure, and especially the position of the anticyclone. The Daily Weather Charts for fourteen years, 1905–18, have been analysed according to these types and are classified by months. The results are given in tables, and the forecaster, having drawn his chart, can see to which type it most nearly corresponds, and then look up the dates in the corresponding month on which the type previously occurred. On reference to the Daily Weather Charts for these days he will be able to trace the later developments.

The type-frequency is given in a table for the several months on the totals for fourteen years, which shows clearly the preference of different types for the separate seasons. The essential weather features associated with each type are clearly set out, and relate primarily to the winds and weather of North-East France and Flanders, although applying also to the conditions over the British Isles. C. H.

[1] "Types of Pressure Distribution, with Notes and Tables for the Fourteen Years 1905–18." By E. Gold. Meteorological Office. Geophysical Memoirs, No. 16. (Published by the Air Ministry.) Price 2s. 6d.

American Work in Genetics.

THE increasing intricacy of genetic problems and the volume of contributions from American investigators are notable features of present-day biology. Selection of a few recent papers will indicate the way in which genetic experiment is permeating many fields of biological research.

Dr. F. B. Sumner is continuing his studies of the Californian races of the deer-mouse, *Peromyscus maniculatus*, and in a paper on geographic variation and Mendelian inheritance (*Journ. Exptl. Zool.*, vol. xxx., No. 3) reaches conclusions which, if substantiated by further work, will be of great interest. The subspecies studied are *rubidus*, which occurs near the coast northwards from San Francisco Bay; *Gambeli*, a coast-form south of the bay; and *sonoriensis*, a desert form from the interior of Southern California. Wild mice were trapped from eight stations within these areas, and caged mice are also being extensively bred. Significant racial differences are found in respect to mean length of skull, ear, foot, pelvis, femur, and tail, width of the dorsal tail stripe, colour of pelage, pigmentation of feet, and number of tail vertebræ. Local differences also occur within the range of the same sub-species. Mutations have been described which show Mendelian inheritance, but in hybrids between geographic races it is claimed that the result is a blend, with very little evidence of later segregation.

Among the numerous genetic studies of extra bristles in Drosophila, that of MacDowell has been most extensive. In two of his latest papers (*Journ. Exptl. Zool.*, vol. xxiii., No. 1, and vol. xxx., No. 4) he has further analysed the effects of selection on the number of bristles. After selection for a high number through several generations, reverse selection was found to be impossible, except after crossing with the normal type, which has four bristles. One main factor determines a monohybrid ratio in crosses with normal flies, but there is no dominance in the ordinary sense, and there are additional genetic differences between flies having extra bristles. Studies by Payne indicate the presence of one bristle factor in the sex chromosome and another in the third group, but the exact relation of these to the increase in number of bristles has not been determined. The environment also influences the number of bristles which appear. In MacDowell's experiments forty-nine generations were bred, and it was found that in a uniform environment selection had no effect after the thirteenth generation; statistical methods show that selection failed to shift the modal condition, and no mutations occurred during the experiments.

In a study of the effects of alcohol on white rats, the same author (Proc. Nat. Acad. Sci., vol. iii., p. 577) finds that alcoholised rats showed a considerable falling off in the weight of their offspring, and a still greater loss in fecundity. Twenty-nine pairs of normal rats produced three hundred young in the same time that thirty alcoholised pairs produced one hundred and eight young. He also (Proc. Soc. Exptl. Biol. and Med., vol. xvi., p. 125) finds that the children and grandchildren of parents which had been treated with alcohol for two months before the birth of their young were less apt than the controls in learning to run a maze or to make a multiple choice.

The Leguminosæ are well known to have usually compound leaves, but several genera have unifoliolate varieties, or even species. Blakeslee (*Journal of Heredity*, April, 1919) describes such a form arising as a mutation in the Adzuki bean (*Phaseolus angularis*). His studies of Datura (Blakeslee and Avery, *Journal of Heredity*, March, 1919) have disclosed a number of new forms differing from the type in shape of capsule, foliage, and other characters. They transmit their characters as a complex, chiefly through the female, and in one instance a distinct new species seems to have arisen which breeds true, but appears to be sterile in crosses with the parent species.

R. R. G.

Increase of Population—a Warning.

PROF. E. M. EAST has much that is important in his address as retiring president of the American Society of Naturalists, meeting at Princeton (*Scientific Monthly*, vol. x., 1920, pp. 603–24). At present there are about 1700 million people, with an annual increase of between 14 and 16 millions. The white race is increasing much more rapidly than the yellow or the black. China's 300 million population is practically stationary. With the exception of France, few white peoples are increasing at a less rate than 10 per thousand. It is true that in most of the civilised countries of the world the birth-rate is slowly but steadily decreasing, but the result is not what many would have us believe. Where the birth-rate is low, the death-rate is low, except in France. Prof. East predicts that, owing to the steadily increasing development of preventive medicine, the decrease in the birth-rate will have no great effect on the natural increase in the world for many years to come. If the rate of increase actually existent during the nineteenth century in the United States should continue, within the span of life of the grandchildren of persons now living the States will contain more than a billion inhabitants. "Long before this eventuality the struggle for existence in those portions of the world at present more densely populated will be something beyond the imagination of those of us who have lived in a time of plenty." The law of diminishing returns is even now in operation in a comparatively new country like America, thought to be supplied with inexhaustible riches. Prof. East considers in detail what may be done by improved utilisation of energies, improved agriculture, improved breeding, and so on; but he is not sanguine. To the criticism that he has not allowed for the "immense possibilities in the way of utilising sea food," he responds with vigour. The cloud grows denser when it is noticed that the birth-rate of the foreign population of the United States, coming largely now from eastern and southern Europe, is so much greater than that of the Anglo-Saxon stock (to which, it is claimed, most of the superior types belong) that within a century the latter will be but a fraction of the whole. Prof. East looks forward to severe restriction of immigration; the spread of education; equitable readjustment in many economic customs; rational marriage selection which will tend to an increase of the birth-rate in families of high civic value; and among the rank and file a restriction of births commensurate with the family resources and the mother's strength.

Glass Technology.

WE have received from the Department of Glass Technology, University of Sheffield, a copy of vol. ii. of "Experimental Researches and Reports" published by that department. The papers included have already appeared in the Journal of the Society of Glass Technology. They range over a somewhat wide field of the glass industry, and include papers dealing with bottle-glass and glass-bottle manufacture, chemical glassware, glass for lamp-working purposes, besides accounts of such relevant investigations as the accurate calibration of burette tubes, a simple apparatus for the detection of strain in glass, and the annealing temperatures of lime-soda and magnesia-soda glasses. There are also a paper descriptive of the glass industry of North America and an account of the year's progress in glass research under the auspices of the Glass Research Delegacy. The condition of the glass industry in this country undoubtedly calls for sustained and systematic research, and this contribution of the Department of Glass Technology of the University of Sheffield must be of considerable assistance to what should be a great and national industry. The newly founded Glass Research Association has also an extensive programme of research in the field of what may be called industrial and laboratory glass, and the British Scientific Instrument Research Association is also more particularly concerned with investigations into optical glass. With such a measure of co-operation and co-ordination as the development of the researches shows to be necessary between these various bodies, there is hope that the users of all types of glass in this country may be able to find a home supply equal, if not superior, to the foreign sources to which, before the war, they perforce had to go for much of the glass they needed.

Rate of Evolution.

PROF. E. G. CONKLIN discusses (*Scientific Monthly*, 1920, vol. x., pp. 589–602) the difficult question of the rate of evolution, including under evolution (*a*) diversification of species, (*b*) more perfect adaptation to the conditions of life, and (*c*) increasing differentiation and integration, or, more briefly, progress. If the rate of diversification ("divergent evolution") depends upon the number of mutations that appear, Prof. Conklin argues that it should be proportional, other things being equal, to the rate of reproduction. But this does not seem to be the case. If the rate of improvement in adaptation ("adaptative evolution") depends upon the rate of mutation and the severity of elimination, it also should be proportional to the rate of reproduction; but the finely adapted birds and mammals have a relatively low rate of reproduction. If the rate of "progressive evolution" depends upon the rate of mutation and the severity of selection, it again should be proportional to the rate of reproduction; but the most complex and most highly differentiated of all animals have the lowest rate of reproduction. In face of the difficulty of accounting for the differences in the rate of evolution, Prof. Conklin doubts whether current theories as to the causes of evolution are wholly satisfactory. It may be doubted, however, whether we are able to state the problems of diversity of rate with sufficient precision to allow of their being used as tests of the validity of the ætiological formulæ in the field. It is likely enough that there are factors of organic evolution still to be discovered, but we do not think that Prof. Conklin exhausts the potency of those that are already known. Thus, after writing: "It seems highly probable that the rate of mutation is influenced by environmental conditions, as Plough has shown in the case of the pomace-fly, and it is probable that environment has played a large part in the rate of evolution," he adds: "On the other hand, the evidences against the inheritance of the effects of use and disuse are so strong that one hesitates to invoke their aid." We submit, however, that the *rôle* of a changeful environment in affording mutational stimulus has very little to do with its *rôle* in imprinting modifications. We agree, all the same, with Prof. Conklin that there is no reason for supposing that the formulation of the factors in evolution is approaching exhaustiveness. Ætiology is still a young science.

University and Educational Intelligence.

THE Air Ministry announces that Dr. O. S. Sinnatt, lecturer in mechanical engineering at King's College, University of London, has been appointed professor of aeronautical science at the R.A.F. Cadet College, Cranwell.

WE learn from *Science* for August 27 that the family of the late Sir John Darling, of Adelaide, South Australia, has contributed the sum of 15,000*l.* towards the cost of erecting a new building for the medical school of the University of Adelaide. This building will be designed to accommodate the departments of physiology, biochemistry, and histology, and the medical library. The building will be erected and equipped at a cost of 25,000*l.*

A FULL account of the courses of instruction in the various departments of Bradford Technical College will be found in the calendar which has just been issued. Full-time day courses in technical sciences are provided which extend over three or four years; they lead to the college diploma. Part-time courses, mainly evening work, are also given. The latter are intended to meet the needs of those who are engaged in industry during the greater part of their time. Special facilities are also given to students who may wish to undertake advanced study or research work. The college is well provided with laboratories, among which may be mentioned the engineering and testing shops, a complete plant for the production of textiles, and a power-house which has been arranged for demonstration purposes.

THE calendar of Birkbeck College has been issued, and contains useful information for students intending to take degrees at London University. The courses provided by the college are set out in detail; they consist of day and evening courses in the faculties of arts and science, and evening courses in the faculties of laws and economics. Facilities are also provided for post-graduate and research work. During the autumn and spring terms special courses of lectures on the history of London will be given, and there will also be four lectures, commencing October 11, on "The Thomson Effect" by Mr. H. R. Nettleton for the physics side. Particulars of university and other courses can be obtained from the office of the college or by letter to the secretary.

THE calendar of the London School of Economics and Political Science has been issued, and contains a detailed syllabus of all the courses available for students. Classes are open to those who intend to proceed to degrees in economics and commerce, and also to such as wish to pursue specialised or advanced study on topics on which they may be engaged. All the courses necessary for the degrees of B.Sc.(Econ.) and B.Com. are given at hours which make it possible for both day and evening students to take them. The school provides courses for a number of university diplomas and school certificates; among these are the university diploma for journalism, the academic diploma in sociology and social science and the certificate in social science, the academic diploma in geography, and the commercial and geography certificates granted by the School itself. Facilities are also provided for students desirous of proceeding to the degrees of Master and Doctor of Science, Philosophy, Laws, and Literature.

IN the calendar of the Merchant Venturers' Technical College, Bristol, attention may be directed to some novel features which are mentioned. The first is the Bristol "sandwich" scheme of training for engineers. This course takes five years to complete, about half of which are spent in a works and the other half in the university. A number of engineering firms co-operate with the college for this instruction, and others have expressed their willingness to accept students who have completed the course, in some cases at reduced premiums. Another feature of the college is a two years' course for apprentices. The curriculum extends over two years, and the classes take up one day each week. Students who pass the two examinations given will receive the Engineer Apprentice's Testamur. A series of popular lectures will also be given during the autumn and spring, two of which should be of scientific interest, namely, "Lightning and Thunder," by Prof. J. T. Macgregor-Morris, and "Devices which Won the War," by Mr. J. R. Raphael.

Societies and Academies.

PARIS.

Academy of Sciences, August 23.—M. Henri Deslandres in the chair.—**A. Lacroix**: The existence in Madagascar of a silicate of scandium and yttrium, thortveitite. This mineral, the richest known in scandium, was discovered in 1911 by J. Schetelig in Norway, and since that time has not been found in any other locality. Amongst specimens collected from the pegmatite of Befanamo, Madagascar, was one which agreed in its physical properties with the mineral described by Schetelig. The presence of scandium, ytterbium, and neoytterbium was confirmed by the spectrograph, and there were also indications of zirconium, aluminium, and titanium. In view of the importance of obtaining a sufficient supply of scandium for a more complete study of this element, other minerals from this region have been examined spectroscopically, and scandium has been detected in cymophane, a mineral not hitherto reported as containing this metal.—E. **Bourquelot**: Remarks on the biochemical method of examining hydrolysable glucosides by emulsin, with reference to the note by M. P. Delauney. Historical account of the results obtained since 1901 by the application of this method. Glucosides have been discovered and isolated in fifty-six species of plants.—E. **Cosserat**: Stars the annual proper motion of which exceeds 0·5″. An addition of two stars to the list published on September 1 in the *Comptes rendus*.—I. **Fredholm**: The reduction of a problem of rational mechanics to a linear integral equation.—P. **Humbert**: The function

$$W_{k, \mu_1, \mu_2 \ldots \mu_n}(x_1, x_2, x_3, \ldots x_n).$$

—W. **Swyngedauw**: The supertensions created by the three harmonics of saturation in triphase transformers.—P. **Bary**: Colloidal sulphur.—P. **Delauney**: The extraction of glucosides from two indigenous orchids: the identification of these glucosides with loroglossin. Details of the extraction of the glucosides from *Orchis simia* and *Ophrys aranifera* are given; the melting points, rotatory power, colour reaction with sulphuric acid, and products of hydrolysis proved the identity in each case with loroglossin.—A. **Krempf**: A new planariform Ctenophore, *Coeloplana gonoctena*.—J. **Feytaud**: The destruction of ants by chloropicrin. Chloropicrin has a destructive effect on the wood-mining ant, *Leucotermes lucifugus*, and particulars are given of the best method of applying this substance for the disinfection of houses.—A. **Paillot**: *Coccobacillus insectorum*. Remarks on a recent note on the same subject by MM. Hollande and Vernier.

SYDNEY.

Linnean Society of New South Wales, July 28.—Mr. J. J. Fletcher, president, in the chair.—A. A. **Hamilton**: Notes from the Botanic Gardens, Sydney. Species of Lepidosperma and Prostanthera and varieties of *Grevillea punicea, Hakea saligna,* and *Prostanthera saxicola* are described as new. New locality records are made for several other species.—J. **Mitchell** and W. S. **Dun**: The Atrypidæ of New South Wales, with references to those recorded from other States of Australia. In addition to the three species of Atrypa already known from New South Wales, three species are described as new. Specimens from Molong, Yass, and Bowning, which externally resemble Meristina, but the internal structure of which shows them to belong to the Atrypidæ, are referred to a proposed new genus. The records of Atrypa from Queensland, Victoria, and Western Australia are revised.—Marjorie I. **Collins**: Note on certain variations of the sporocyst in a species of Saprolegnia. In the species of Saprolegnia examined, Leptolegnia, Pythiopsis, and Achlya conditions of the sporocyst occurred rarely, while the Dictyuchus and Aplanes conditions were frequent; the variations occurred in both club-shaped and cylindrical sporocysts, but were not observed arising from resting sporocysts. Composite sporocysts were observed combining the features of Dictyuchus and Aplanes. Evidence is given in favour of the suggestion that the Aplanes condition has arisen from the Dictyuchus by failure of the protoplast to escape from the germ-tube during its early growth.—Prof. W. N. **Benson**, W. S. **Dun**, and W. R. **Browne**: The geology and petrology of the Great Serpentine Belt of New South Wales, part ix. The geology, palæontology, and petrography of the Currabubula district, with notes on adjacent regions. The relationship structurally and stratigraphically between this region and that formerly described by the writer in the Burindi and Horton River districts is indicated. In the Currabubula district the oldest formation is the Burindi mudstone with tuffs, followed by the Middle Carboniferous Kuttung series, largely composed of keratophyre-tuff and conglomerates, but containing two or three horizons of contorted, seasonally banded "varve-rock" of fluvioglacial origin, accompanied by tillite containing striated, and occasionally faceted, erratics. This series is 9500 ft. in thickness, and contains Rhacopteris and other fossil plants. It is followed by the Werrie series of basalt-flows, which are invaded by a very varied series of sills and dykes radiating from Warragundi Mountain, related to which is an extensive series of keratophyric, andesitic, doleritic, and basaltic sills and dykes which invade the Burindi, and especially the Kuttung rocks.

WASHINGTON, D.C.

National Academy of Sciences (Proceedings, vol. vi., No. 2, February).—Messrs. **Harkins** and **Ewing**: An apparent high pressure due to adsorption, the heat of adsorption, and the density of gas-mask charcoals. In addition to the volume of the pores and density of the active charcoal, the effect of the compressibility, viscosity, and surface tension of the liquid are discussed.—H. J. **Spinden**: Central American calendars and the Gregorian day. Rules are set up for turning Mayan and Mexican dates into the Gregorian calendar so that American history is made more exact than that of Egypt, Greece, or Rome.—C. **Barus**: The torsional magnetic energy absorption of an iron conductor.—Y. **Henderson**: The adjustment to the barometer of the hæmatorespiratory functions in man. It appears that the blood-alkali is controlled by the dissolved CO_2, the amount of CO_2 by preliminary ventilation, and the ventilation by the oxygen partial pressure of the air.—A. S. **King**: A study of absorption spectra with the electric furnace. The tube-resistance furnace hitherto used for the study of emission spectra offers interesting possibilities also in the field of absorption spectra.—A. S. **King**: A study of the effect of a magnetic field on electric-furnace spectra. Lines common to furnace and to spark spectra show no difference in number of components nor in separation; the furnace may thus be used to supplement the spark.—D. F. **Jones**: Selective fertilisation in pollen mixtures. Experiments on maize show that there is a definite receptiveness of the plant to its own kind of pollen, and that in proportion as the cross-fertilisation benefits the progeny the less effective are the germ-cells in accomplishing fertilisation. The writer believes that the assumption that heterogeneity in protoplasmic structure is favourable to developmental efficiency is founded on fallacious reasoning and not supported by the facts.—G. A. **Miller**: Groups generated by two operators, S_1, S_2, which satisfy the conditions $S_1^m = S_2^n$, $(S_1S_2)^k = 1$, and $S_1S_2 = S_2S_1$. Results useful in the study of the generalised groups of the regular polyhedra.—W. E. **Castle**: Model of the linkage system of eleven second-chromosome genes of Drosophila. Continuation of the discussion of the spatial *versus* linear arrangement of the genes with the conclusion that in this case the arrangement appears linear.—G. A. **Baitsell**: The development of connective tissue in the amphibian embryo. The origin of connective tissue lies in an intercellular secretion of the embryonic cells which constitutes the ground substance of the connective secretions from the cells. Under various chemical and mechanical factors this substance forms connective tissue-fibres by consolidation of its minute elements.—F. P. **Underhill**, J. A. **Honeij**, and L. J. **Bogert**: Calcium and magnesium metabolism in certain diseases. Clinically, in leprosy there is loss of bone-salts;

experimentally, the leprous organism tends to retain bone-salts, especially calcium. Clinically, in multiple exostosis bone-salts are inferred to be added to the body; experimentally, the organism tries to rid itself of bone-salts, particularly calcium, and in the stabilised stage throws out excessive quantities of magnesium.—C. G. **Abbot**: The larger opportunities for research on the relations of solar and terrestrial radiation. A general research survey communicated by the National Research Council.—S. R. **Detwiler**: The hyperplasia of nerve-centres resulting from excessive peripheral loading. The experiments proving these results consisted in transplanting the right anterior limb rudiment of *Amblystoma punctatum* a given number of body segments posterior to the normal position.

A "Tour de Force."

THERE are three fundamental subjects in education—the history of our race, the world around us, and the conditions of health, happiness, and effective work. They correspond to Le Play's "famille, lieu, travail"; to the biologist's "Organism, Environment, Function." Fundamental they certainly are, but it is generally admitted that most men know little about any of them and understand less. We are perhaps deplorably slow to learn, but we are also very badly taught. Especially in regard to the history of mankind it is difficult to forgive our teachers, for we spent so long over it (the other fundamentals were for the "modern" side) and we know that we were not unappetised. Yet for bread we got stones. We find the same disappointment among most of our fellows, the disappointment of half-educated men who know their deficiencies. There are well-known ways of making the study of history grip—the use of graphs and charts, the biographical approach, with its calendar of great men, the emotional and dramatic methods so vividly illustrated by Dr. Hayward, and so on; but they seem rarely to be tested in schools or colleges, and widespread ignorance of a supreme subject prevails. We except, of course, those who are by birth historically minded, who learn in spite of bad methods or the absence of any; though even those who know many historical facts seem often like students who are familiar with fossils, but unaware of the æonic pulse and progress of life.

These bitter reflections are prompted, of course, by Mr. Wells's "Outline of History,"[1] which convinces us of sin. For here we find what, in spite of its imperfections, is of the nature of a revelation—a sketch of the continuous movement from the nebula that became the earth to the League of Nations, a suggestion of the sweep and surge of civilisation, not in one corner, but all the world over, an attempt to focus attention on the things that have counted in the past and are living on, around us and in us, to-day. We use such words as "sketch," "suggestion," and "attempt," not in any disparaging way, but because no single man could offer anything else. The book is called "The Outline." There are probably big omissions, unconscious misinterpretations, mistaken accentuations, and so forth, but the point is that Mr. Wells has shown his day and generation the sort of history of the world that every educated man should have as a possession in his mind. It is a fine thing to have achieved what has hitherto been called impossible. We recall two books of many years ago—Haeckel's "Natural History of Creation" and Krause's "Werden und Vergehen"—which traced the cosmic genesis from nebula to consolidated earth, and the organic evolution from Protists to Man, and did this in a vividly picturesque way. They may not have been quite so fine as we thought they were, but, errors and omissions excepted, they were fine books.

Mr. Wells's "Outline" is another such big gift to education. Perhaps it will be a still bigger gift when someone writes another like it from a different point of view. For out of the mouth of two or more witnesses there is some chance of the truth being stated. But, as the author says, the book is an "experimental contribution to a great and urgently necessary educational reformation, which must ultimately restore universal history, revised, corrected, and brought up to date, to its proper place and use as the backbone of a general education. We say 'restore,' because all the great cultures of the world hitherto, Judaism and Christianity in the Bible, Islam in the Koran, have used some sort of cosmogony and world-history as a basis. It may indeed be argued that without such a basis any really binding culture of men is inconceivable. Without it we are a chaos." We would also quote the striking sentence which expresses Mr. Wells's appreciation of what a

1 "The Outline of History: Being a Plain History of Life and Mankind." By H. G. Wells. Revised and corrected edition. Pp. xx+658. (London: Cassell and Co., Ltd., 1920.) Price 21s. net.

living conception of world-history may mean: "A sense of history as the common adventure of all mankind is as necessary for peace within as it is for peace between the nations." Yet we go on fumbling with educational methods, if such they may be called, which we know do not grip.

As is noted in the Introduction, it is usual to say that the time-table of instruction is full up, and that the idea of learning world-history is preposterous.

"If an Englishman, for example, has found the history of England quite enough for his powers of assimilation, then it seems hopeless to expect his sons and daughters to master universal history, if that is to consist of the history of England, *plus* the history of France, *plus* the history of Russia, and so on. To which the only possible answer is that universal history is at once something more and something less than the aggregate of the national histories to which we are accustomed, that it must be approached in a different spirit and dealt with in a different manner. This book seeks to justify that answer. It has been written primarily to show that *history as one whole* is amenable to a more broad and comprehensive handling than is the history of special nations and periods, a broader handling that will bring it within the normal limitations of time and energy set to the reading and education of an ordinary citizen. . . . History is no exception amongst the sciences; as the gaps fill in, the outline simplifies; as the outlook broadens, the clustering multitude of details dissolves into general laws."

We are forced to add that there would be no difficulty about the time for instruction if the methods employed were psychologically sound, if the suggestions of "historical associations" and clear-headed enthusiasts were put into practice. It is certain, for instance, that the purely intellectual presentation usually slips off the child's mind like water off a duck's back, and that it ought to. Moreover, in higher classes what is wanted is not history *plus* history, but a discipline in the way of reading history of such a kind that it will be natural to continue learning. What we so often do not get are centres of crystallisation—a less static metaphor than it used to seem.

There are nine books in "The Outline of History"—The Making of our World; The Making of Man; The Dawn of History; Judea, Greece, and India; The Rise and Collapse of the Roman Empire; Christianity and Islam; The Great Mongol Empires of the Land Ways and the New Empires of the Sea Ways; The Age of the Great Powers; and then a prospect—The Next Stage in History. It was said of Buffon that he took all Nature for his province and was not embarrassed; but Mr. Wells has an even wider reach. It seems almost superhuman—to be so well done; but the author tells us frankly: "There is not a chapter that has not been examined by some more competent person than himself and very carefully revised. He has particularly to thank his friends Sir E. Ray Lankester, Sir H. H. Johnston, Prof. Gilbert Murray, and Mr. Ernest Barker for much counsel." There is a long list of authorities who have helped in various ways to keep the book true to the facts (their footnotes are illuminating); and he has been fortunate in securing in Mr. J. F. Horrabin a skilful illustrator who has put brains into his drawings.

It need scarcely be said that "The Outline" is a *personal* document—materials had to be selected, much had to be left out; prominence is given to some figures, others are in the background; the relative significance of various movements had to be judged, and all this has been obviously influenced by the author's philosophy. The difference here between Mr. Wells and other historians is that he is so clearly aware of the relativity of his work. There is another way, of course, in which the book is personal: it is written in good style—clear, picturesque, and incisive—and it expresses throughout the serious purpose of improving things by understanding them. Another personal characteristic, familiar to readers of Mr. Wells's books, is the courage of his convictions.

The First Book gives in very brief compass an account of the genesis of the earth and the evolution of organisms. There are a few points that puzzle us, such as an indication that the breastbone of Pterodactyls had no keel, but the sketch is masterly. The Second Book deals with the ascent of man, his Primate ancestry, the extinct Neanderthal offshoot, the first true men and their thoughts, the differentiation into races, with their various languages. The Third Book pictures the dawn of history, the primitive Aryan life, the first civilisations, the early traders and travellers, the beginning of writing, the emergence of priests, and the establishment of classes and castes. The treatment is a fine illustration of the art of leaving out what obscures the main issues and of the reward that comes to a man of science who has insisted on seeing things clearly. It is of great educational value to have this vivid and accurate picture of the rock whence we were hewn and the pit whence we were digged.

What dominates the Fourth Book is the idea that by the beginning of the third century B.C. there had already arisen in the Western civilisation of the Old World the great structural ideas (1) of communicable and verifiable knowledge, as contrasted with priest-guarded mysteries; (2) of one universal God of Righteousness, whose temple is the whole world; and (3) of a world polity of which Alexander the Great became the symbol. "The rest of the history of mankind is very largely the history of these three ideas of science, of a universal righteousness, and of a human commonweal." The Fifth Book gives an account of the rise and collapse of the Roman Empire—an account which seems to us to betray bias. It was a very unsound political system. "The clue to all its failure lies in the absence of any free mental activity and any organisation for the increase, development, and application of knowledge." It was "a colossally ignorant and unimaginative Empire." When the smash came "there was one thing that did not perish, but grew, and that was the tradition of the world-empire of Rome and of the supremacy of the Cæsars." The Great War "mowed down no fewer than four Cæsars" who insisted on keeping up the evil tradition. We do not hear much of Roman Law from Mr. Wells, but he frankly confesses that he "contemplates the law and lawyers of to-day with a temperamental lack of appreciation."

The Sixth Book is chiefly concerned with Christianity and its idea of the Kingdom of God, and with Islam with its broad idea of human brotherhood under God. It is admitted that the founder of Islam "had to tack on to his assertion of the supremacy of God an assertion that Muhammad was in especial his prophet, a queer little lapse into proprietorship, a touchingly baseless claim for the copyright of an idea which, as a matter of fact, he had picked up from the Jews and Christians about him." Regarding Christianity, the author quotes with approval a sentence from Dean Inge's "Outspoken Essays": "St. Paul understood what most Christians never realise, namely, that the Gospel of Christ is not *a* religion, but religion itself in its most universal and deepest significance." Thereafter follows a passage which will interest many, in which Mr. Wells declares that there is no antagonism between science and religion. What he says seems to us to suggest rather that there is no antagonism between science and *morals*. "The psychologist can now stand beside the preacher and assure us that there is no reasoned peace of heart, no balance and no safety in the soul, until a man in losing his life has found it, and has schooled and disciplined his interests and will beyond greeds, rivalries, fears, instincts, and narrow affections." And then he goes on to say, all too elliptically: "The history of our race and personal religious experience run so closely parallel as to seem to a modern observer almost the same thing; both tell of a being at first scattered and blind and utterly confused, feeling its way slowly to the serenity and salvation of an ordered and coherent purpose. That in the simplest is the outline of history; whether one have a religious purpose or disavow a religious purpose altogether, the lines of the outline remain the same."

In the Seventh Book the Age of the Land Ways is illustrated by the great empire of Jengis Khan and his successors, very sympathetically sketched ("the blood in our veins was brewed on the steppes as well as on the ploughlands"). Land ways give place to sea ways and Western civilisation has its renascence ("Europe begins to Think for Itself," "Paper Liberated the Human Mind," "the expansion of human horizons," "intimations of a new and profounder social justice"). The Eighth Book is devoted to the Age of the Great Powers.

"Tremendously as these phantoms, the Powers, rule our minds and lives to-day, they are, as this history shows clearly, things only of the last few centuries, a mere hour, an incidental phase, in the vast, deliberate history of our kind. They mark a phase of relapse, a backwater, as the rise of Machiavellian monarchy marks a backwater; they are part of the same eddy of faltering faith, in a process altogether greater and altogether different in general character, the process of the moral and intellectual reunion of mankind. For a time men have relapsed upon these national or imperial gods of theirs; it is but for a time. The idea of the world state, the universal kingdom of righteousness, of which every living soul shall be a citizen, was already in the world two thousand years ago, never more to leave it. Men know that it is present, even when they refuse to recognise it."

Glimpses of this same vision we find throughout the book; it is so dominant in Mr. Wells's mind that he has seen all history in the light of it. Whether it makes for good history we do not know; it has made for a fascinating book which it does one good to read. Its influence will be far-reaching.

To what prospect does his study of universal history lead Mr. Wells? The trend of human evolution points in the direction of internationalism —but beyond. "Our true nationality is mankind." Religion and education, closely interwoven influences, have been the chief synthetic forces throughout the great story of enlarging human co-operations: of the former we may look for a revival, of the latter a re-adjustment informed with science. As a necessary basis for world co-operation, as a preparation for a world league of men, there must be "*a new telling and interpretation, a common interpretation, of history.*" And that this book will further. "There can be little question that the attainment of a federation of all humanity, together with a sufficient measure of social justice, to ensure health, education, and a rough equality of opportunity to most of the children born into the world, would mean such a release and increase of human energy as to open a new phase in human history." Mr. Wells looks forward to "the final achievement of world-wide political and social unity," which will be reached by and based on righteousness as well as science, "perhaps with long interludes of setback and disaster," but "it will mean no resting stage, nor even a breathing stage, before the development of a new struggle and of new and vaster efforts. Men will unify only to intensify the search for knowledge and power and live as ever for new occasions." Almost the ending of what we cannot but regard as a great book is a key sentence: "Life begins perpetually."

The Dioptrics of Huygens.

Œuvres Complètes de Christiaan Huygens. Tome Treizième. Dioptrique 1653; 1666; 1685–1692. Fascicule i., 1653; 1666. Pp. clxvii+432. Fascicule ii., 1685–1692. Pp. 434–905. (La Haye: Martinus Nijhoff, 1916.)

NEARLY ten years have elapsed since we reviewed the twelfth volume of this great work (NATURE, vol. lxxxiv., p. 491), of which vol. xiii., consisting of two parts of altogether nearly 1100 pages, only lately reached us, though dated 1916. It contains everything written by Huygens on geometrical optics, both what was incorporated in the "Dioptrica" published in his "Opuscula Posthuma" in 1703 and 1728, and various extracts from his manuscripts now printed for the first time.

Already in 1652 and 1653 Huygens had written a treatise on refraction and telescopes, divided into three books, and by the present editors called part i. In the next twelve years he occupied himself with the subject from time to time, as appears from his correspondence. In 1665 he resumed more systematically his researches on spherical aberration, and found results which seemed to him so important that he wrote an essay (part ii.) on them. This was soon interrupted by his settling at Paris as a member of the Academy and a pensioner of Louis XIV., but within a year he had a copy made of all he had yet written on the subject, and this is still in existence. In 1668 Huygens tried to verify by experiments his theory of spherical aberration, by which he thought he would be able to compensate the aberration of the object glass by that of the eyepiece; but this led only to disappointment, and he perceived that it was colour-effects which prevented the realisation of his ideas. He next got the idea of forming the object-glass of two lenses, situated close to each other, an idea which was never incorporated in his MS.; and it was probably the uncertainty he felt about the value of his latest results which still made him put off the publication of his work. In 1672 he heard of Newton's discovery of the composition of white light, and after some hesitation he realised its fundamental importance for the problems of dioptrics, so that the results he had himself found had not the value he had supposed them to have, and they were therefore removed from his MS.

In the meantime the undulatory theory of light had arisen in the mind of Huygens, and he proposed to write a larger work dealing with the new theory and its applications, in which his MS. on dioptrics might find a place. But in 1677 he discovered the explanation of double refraction in Iceland spar, which he considered the finest confirmation of his new theory, and beside which all his earlier work on dioptrics appeared to be of secondary importance. He therefore decided to let this work be preceded by a treatise on the undulatory theory of light and its principal applications, without dealing with the theory of lenses and telescopes. This was the origin of the celebrated little book, "Traité de la lumière," which, though not published till 1690, had been practically completed in 1678. Finally, in 1684, Huygens resumed his researches on the magnifying power of telescopes and questions related thereto, and it was probably in the following year that he wrote nearly all that which in the present edition has been put together in part iii., on telescopes. In 1692 he wrote to Leibniz that he seemed to have finished with the subject, though everything was not yet written down. He then numbered the pages of his MS. in the order which he proposed to follow in the final redaction. This pagination was generally followed in the posthumous edition of 1703, but in this way parts written at very different epochs are mixed up together. The present editors therefore preferred to follow the chronological order, so that the gradual development of Huygens's ideas could be clearly seen. A synoptic table at the end of the introduction shows where each section of the two old editions is to be found in the new one, and also what is now printed for the first time.

As already mentioned, the first part is the treatise of 1653 on refraction and telescopes. Of this, Book I. deals with refraction due to plane and spherical surfaces and lenses. Huygens describes various methods of determining the refractive index of liquids or glass, but thinks it unnecessary to attain great accuracy in this, as the value of the index varies slightly for different liquids and different sorts of glass. He then investigates the two principal problems of this book: the determination of the foci of lenses, and of the places where the images of objects in known positions are formed. If this book had been published in 1653, Huygens would have had undoubted priority for most of his results, though he had (without knowing it) been anticipated by Cavalieri as regards foci. But the important propositions on the places of images were quite new. In September, 1669, when Huygens sent to the Royal Society a series of anagrams to secure priority, Barrow's "Lectiones Opticæ" were in the press. In this work there is a determination of the foci of a spherical lens, and of the position of the image of a luminous point situated on the axis of the lens. And when the "Dioptrica" of Huygens was at last published, in 1703, the "Dioptrica Nova" of Molyneux (1692) and a paper by Halley in the Phil. Trans., 1693, had also much diminished the importance of Huygens's discoveries.

Book II. is "On the Apparent Size of Objects seen by Refraction." Among the contents is an elegant theorem of far-reaching applicability. When an object is seen through a number of lenses, and the positions of the eye and the object are interchanged, while the lenses are undisturbed, the apparent size of the object will be unaltered, and the image will have the same position, upright or inverted. A striking application of this was made by Huygens in Book III., where he shows that the magnifying power of a telescope is the ratio of the diameter of the object-glass to the diameter of the pencil of parallel rays emerging from the eye-lens.

Book III. deals with telescopes and contains, among other things, a description of the Huygenian eye-piece.

As described above, part ii. of Huygens's works treats of spherical aberration, and part iii. of telescopes and microscopes, representing the outcome of his lifelong studies and experiments, made in order to improve the theory and construction of refracting telescopes.

These two beautiful volumes reflect as much credit as did the previous ones on both the editors and the printers. The lengthy introduction and the footnotes are most valuable contributions to the history of optics. The numerous figures in the text are facsimile reproductions of Huygens's own rough diagrams.

J. L. E. D.

Analysis of Foods.

Food Inspection and Analysis: For the Use of Public Analysts, Health Officers, Sanitary Chemists, and Food Economists. By Albert E. Leach. Revised and enlarged by Dr. Andrew L. Winton. Fourth edition. Pp. xix + 1090 + xli plates. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1920.) Price 45*s*. net.

IT is now some sixteen years since this work was first issued, and in the interval it has become favourably known in this country to analysts and others concerned with securing the purity of foodstuffs. In its general plan the book remains much as it was when the first edition was reviewed in these columns (NATURE, vol. lxxi., p. 50, November 17, 1904), though naturally there have been many additions and amendments. The author and reviser have brought between two covers some essential information upon almost every subject with which, in the exercise of his profession, the food analyst is likely to be concerned—from the "cutting up" of beef and mutton to the equipment of a laboratory, and from the taking of a photomicrograph to the use of a hydrogen electrode. The more he employs the book, the more the reader will be confirmed in the impression that the literature of the subject has been well searched and judiciously abstracted for him.

No doubt this quality of comprehensiveness largely accounts for the success which the work has achieved. Still, the quality has its inherent defect. So many things are dealt with that, even in this bulky volume of more than a thousand pages, little space is left for discussion of the difficulties which arise either in making the various analyses or in correctly interpreting the results. It is here that the personal judgment and experience of the individual analyst must come in. The book gives him valuable help, but of a generalised kind. It puts up analytical signposts to indicate the high roads for him, but when off the beaten track he must find his own by-ways.

In preparing the present edition Dr. Winton has had expert assistance for the revision of various sections—as, for example, those on dairy products, meat, cereals, spices, oils, sugars, colouring matters, and flavouring extracts. A special chapter upon the determination of acidity (hydrogen-ion concentration) by the electrical method is contributed by Dr. G. L. Wendt; this contains a lucid explanation of the theory and practice of the process, with details of the apparatus employed. Very few errors have been noticed, but in the section on alcoholic beverages there are some slight inaccuracies respecting English proof spirit. This contains 49·28 per cent. of alcohol by weight, and 57·10 by volume, instead of the values given in the text (49·24 and 57·06); whilst the correct factor for calculating proof spirit from volume percentage is 1·7535, not 1·7525 as stated. Analysts in this country should be on their guard against using the table on p. 754 for determining the original specific gravity of beer. This table was superseded several years ago, so far as statutory purposes are concerned, and it is now mainly of historic interest. The last remark applies also in some degree to the methods described for detecting and estimating methyl alcohol.

As a whole, however, the new edition well maintains the reputation of the work. It contains so much trustworthy information that chemists concerned with foodstuffs will find it invaluable.

C. S.

Adventitious Plants of Tweedside.

The Adventive Flora of Tweedside. By Ida M. Hayward and Dr. George Claridge Druce. Pp. xxxii+296. (Arbroath: T. Buncle and Co., 1919.)

THIS is an interesting book. The usual lists and records of alien plants are not particularly inviting to the botanist generally, and there is no doubt a tendency to look with a tolerant eye upon the labour which is devoted by many workers to the botanical treasures of waste grounds and rubbish heaps. But the present book, like its prototype in Southern France, treats the whole subject on a high plane, and brings out many important general conclusions. The record is founded mainly on the careful fieldwork of Miss Ida Hayward continued for several years. The main share of the identification and classification of the plants has fallen to Dr. G. Claridge Druce. Dr. Druce is so well known for his intensive studies on the flora of Great Britain that one need only say that this part of the work is in keeping with his high reputation. Not the least interesting section of the book is the introductory part, where a summary of the origin of this adventive flora is given along with a short history of the development of the town of Galashiels and its woollen industry. There follows a review of the sources from which Galashiels derives the wool it manufactures into tweeds. Some little space is given to the remarkable survival of the seeds after the very drastic treatment they are subjected to when the wool is passed through some of the preliminary processes. The results obtained of the temperature-resisting power of certain seeds are certainly very remarkable.

In these days of printing difficulties one must refer specially to the excellent way in which the book has been printed. The general list has not been spoiled by paring down the text from pressure of space. Quite ample summaries of the orders and of the genera concerned are included in the text. With the limitations now imposed on the publications of scientific matter by the greatly enhanced cost of printing, one looks with a certain amount of envy on the appearance presented by the book under review, which is quite up to prewar standard. The correctness of the records and the proof-reading leave little scope for criticism. On p. 235, Fig. 71 is subscribed "Polygonum" instead of "Polypogon." On p. 122 *Cotula coronopifolia* is mentioned as recorded for the first time in Scotland by Miss Hayward for August, 1908. It was previously recorded in the Trans. Bot. Soc. Edin., vol. xi., 1873, p. 256, by Mr. William Evans, near Aberdour, Fife. But these are minor points.

The authors need have no care for what Dr. Druce terms the "scoffs of some suburban botanists at the inexhaustible rubbish heaps of Tweedside." The book is worthy of its place beside "La Flore Adventice de Montpellier." Those interested in the flora of Great Britain, especially from the point of view of the influence of cultivation and industry upon the native flora, would do well to have this book upon their shelf. It raises much wider issues than the mere record of accidental aliens.

Meteorological Constants.

Smithsonian Meteorological Tables. Fourth, revised, edition. (Smithsonian Miscellaneous Collections, vol. lix., No. 1.) Pp. lxxii+261. (Washington: Smithsonian Institution, 1918.)

THE first edition of the "Smithsonian Meteorological Tables" was issued in 1893. It is now fourteen years since the last edition came out, and the opportunity has been taken in the present edition to make a number of changes, some of which call for brief comment.

The tables dealing with the relative accelerations due to gravity at different latitudes have been recomputed on the basis of the recent work of the U.S. Coast and Geodetic Survey. New water-vapour pressure tables have been recalculated from the latest Reichsanstalt investigations, a modification of Van der Waal's formula being employed for the purpose of interpolation.

These alterations have involved extensive revision of a number of associated barometric tables, together with those dealing with the ventilated hygrometer, the treatment of which is very satisfactory. The most important advance in the matter of the wet- and dry-bulb hygrometer was the discovery (known to Belli so far back as 1830) that it may be made a trustworthy instrument if the wet bulb is exposed to moving instead of to still air. Even then different instruments were found to give different readings to an extent depending on the shape and dimensions of the thermometer bulb and stem.

But all such idiosyncrasies were swept away by the later discovery that if an air-velocity of not less than 3 metres per second is employed, agreement results in the readings afforded by various instruments. In practice the velocity of the air need not be known so long as it is above that which gives sensibly the greatest depression of the wet-bulb thermometer.

Among other new tables are those for converting barometric inches or millimetres of mercury into the millibars which now receive international acceptance.

The various logarithmic and simpler trigonometrical tables which appeared in former editions have now been omitted—a retrograde step, we think, from the point of view of the convenience of the reader.

It may not be known to all readers of NATURE that the Smithsonian tables are not obtainable in the ordinary way by purchase through a bookseller.

Our Bookshelf.

Elements of Radiotelegraphy. By Lieut. Ellery W. Stone, U.S.N.R.F. Pp. vii + 267 + xxxiii plates. (London: Crosby Lockwood and Son, 1920.) Price 16*s.* 6*d.* net.

THIS is a work written with the primary object of forming a manual of instruction for those in the wireless branch of the U.S. Navy, but on account of the clear sketch of the subject it gives, it will probably appeal to a wider circle. The way in which the elementary principles are set forth should be appreciated on both sides of the Atlantic. Details are given of several systems better known in America than here, but French and German methods, as well as some originating from this country, are also dealt with. The book has a breadth of outlook which is refreshing after some works which tend towards making one think that all wireless progress is due to one group of investigators. The author does not favour any one system unduly, although naturally he has to base a certain proportion of his remarks upon the various systems employed in the American Fleet. This includes a good deal of interest regarding the recent developments of the Poulsen arc system, and apparatus up to 1000 kw. is illustrated. We only regret that considerations of space have rather curtailed the treatment of the thermo-ionic valve, or "electron tube," and that wireless telephony, as distinct from telegraphy, receives only a passing reference, for it is well known that the American Navy made early advances in this direction. The treatment throughout is non-mathematical; the range covered embraces elementary principles as well as up-to-date methods, and the illustrations are excellent.

Exercises from Elementary Algebra. By C. Godfrey and A. W. Siddons. Vols. i. and ii., complete. (With Answers). Pp. x + 395 + c. (Cambridge: At the University Press, 1920.) Price 7*s.* 6*d.* net.

THE exercises in this book are identical with those in the first edition of "Elementary Algebra" by the same authors, with the exception that some new revision papers have been inserted. The first fourteen chapters deal with elementary algebra up to quadratic equations, graphs, and the graphical solution of equations of degree higher than the second. Then follow thirteen chapters which take in logarithms, surds, progressions, rate of change and simple differentiation and integration. An appendix of eight chapters on various forms of linear and quadratic equations, on factors, etc., has been added.

Catalysis and its Industrial Applications. By E. Jobling. Second edition. (Text-books of Chemical Research and Engineering.) Pp. viii + 144. (London: J. and A. Churchill, 1920.) Price 7*s.* 6*d.* net.

THE first edition of this useful little book was reviewed in NATURE for February 17, 1916. Since that time, the subject of catalysis has undergone extensive developments, and the present edition aims at bringing the book up to date. Besides necessary alterations, two chapters have been added, one on the synthesis of acetic acid, alcohol, and allied compounds, and the other on enzymes, electro-chemistry, and vulcanisation accelerators. A number of references, both to text-books and to patents, are given at the end of each chapter for the assistance of readers desirous of obtaining fuller details of the processes discussed.

William Smith: His Maps and Memoirs. By T. Sheppard. Pp. iii+75-253+plates. (Hull: A. Brown and Sons, Ltd., 1920.) Price 7s. 6d.

MR. SHEPPARD has spared no pains in making bibliography attractive. He has reproduced by photography original title-pages and maps; he has added portraits, and views of William Smith's homes at Midford and at Harkness—the latter from a good oil-painting. By quoting characteristic passages, including "The Geology of England: Mr. Wm. Smith's Claims," published in 1817, he has given a very interesting and effective picture of the man. The rarity of Smith's original works—only 250 copies seem to have been printed of the four parts of "Strata identified by Organized Fossils"—has rendered Mr. Sheppard's collation of various copies a labour of time as well as of pious erudition. The result is a book that will be welcomed in every scientific library. Smith's sections across various English districts are here given in a reduced form, and we are grateful to the Yorkshire Geological Society for undertaking this liberality of illustration when Mr. Sheppard's memoir first appeared in its Proceedings. As the author points out, Messrs. Cruchley of London, in quite recent years, sold road-maps of English counties reproduced from John Cary's plates (though of course with the addition of railways), and on some at least of these William Smith's geological data still appeared. If the original plates exist, it might be possible to reconstruct for libraries Smith's "Geological Atlas," much as it was issued between 1819 and 1824.

G. A. J. C.

Practical Histology. By Prof. J. N. Langley. Third edition. Pp. viii+320. (Cambridge: W. Heffer and Sons, Ltd., 1920.) Price 10s. 6d. net.

PROF. J. N. LANGLEY'S work is a laboratory manual containing full directions for students undergoing a course of practical histology. Though primarily a book of histological methods, a description is given of the appearances which should be found after the instructions regarding each preparation have been carried out, but the volume does not aim at being a descriptive histology, and contains no illustrations beyond those of apparatus. Provision is made for the instruction of both junior and senior students, the large type in general representing the course of practical histology for elementary students in Cambridge. Histological methods vary somewhat in different schools, but whatever the general procedure may be, this volume is full of useful information, and may be turned to in confidence for assistance in the preparation of any histological specimen.

Prof. Langley, in his preface, comments on the desirability of histology being taught by the physiologist, seeing that minute structure and function are so bound together. The plea is a good one, but the point of view of the pathologist must not be neglected, for the medical student rarely arrives at a full appreciation of the value of histology until he has studied the pathological alterations which occur in the normal tissues.

Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

The Separation of the Isotopes of Mercury.

WE have been successful in achieving a partial separation of the isotopes of mercury by evaporating mercury at low pressure and condensing the evaporated atoms on a cooled surface. The rate of evaporation of the isotopes being inversely proportional to the square root of their atomic weight, and practically every atom leaving the liquid being condensed on the highly cooled surface, a partial separation of the isotopes of mercury was to be expected.

By using the pyknometer method the following numbers have been obtained in one set of experiments for the density of the condensed, and in another set for that of the residual, mercury, when taking the density of ordinary mercury as unity:

Condensed mercury ...	0·999980
Residual mercury ...	1·000031

The apparatus contained 40 c.c. of mercury. In the first set of experiments about one-seventh of the mercury was evaporated and the density of the condensed part determined; in the second set about three-fourths of the mercury was evaporated and the residual portion examined. After the separation every portion was distilled again several times in the ordinary way and the density measured after each distillation. No difference was found between these measurements, the error of measurement of density being less than one in a million.

J. N. BRÖNSTED.
G. HEVESY.

Physico-Chemical Laboratory of the Polytechnic High School, Copenhagen, September 23.

The British Association.

THE leading article in NATURE of September 16 directs attention to a matter which must have exercised the thought of most men of science. There is certainly a widespread feeling that the British Association might be better occupied than in listening to papers on special subjects, often given before very small groups of people. Speaking of my own section, that of Physiology, it has become more and more difficult to get promises of communications of this kind, and discussions on questions of interest at the time have been arranged. I am inclined to think, however, that the addresses of presidents of sections are useful when they present general aspects of the science which would be inappropriate in papers published in the proceedings of learned societies or in journals and describing original discoveries. The discussions would undoubtedly be of more value if the practice of joint meetings of several sections were more extensively made use of than is the case at present, since it is becoming less and less possible for a worker in any one branch of science to acquaint himself with advances in other branches, although these may have a very material bearing on his own work. There can be no doubt that the more he knows of other sciences the better equipped is the worker in any particular branch. If the Association were able to remove some of the dangers of the excessive specialisation into which modern science seems to be drifting, it would be a function useful to men of science themselves. I am inclined to think that the reading of original papers, and probably also discussions on subjects of interest, to one section only might well be given up.

But, however this may be, I thoroughly agree that the chief function of the British Association is to arouse interest in science amongst the general public. How this is to be done is not an easy problem. One thing that might certainly be done is to adopt the suggestion of the *Electrician*, and arrange that the latest discoveries in science should be described in simple language. It seems to me that this should be done by several individual workers rather than by one lecturer alone, even in the case of a subject of comparatively narrow field. It is not always possible to know where a hearer may find difficulty of apprehension, and different ways of putting things aid in clearness of grasp. In fact, something more in the nature of a public discussion might be more stimulating and instructive. I am somewhat ignorant as to how far the popular lectures as at present given can be considered to be successful. Personally, I find a set lecture of a length approaching an hour somewhat tiresome; but opinions differ as to this. The presentation of a new discovery by more than one person might tend to overcome the difficulty referred to in the article in NATURE, namely, the fact that genius for discovery is not always associated with facility of popular exposition or with an attractive manner of bringing out its importance. At the same time it should not be forgotten that there is a natural interest in hearing an account of a new discovery from the lips of the man who made it, even though he may not be able to make it as clear as may another speaker whose gifts are of a different kind. Men of science themselves are not devoid of this interest or curiosity. If the practice of formal lectures is followed, I feel sure, from remarks that I have heard, that the method adopted at the Royal Institution is the best—I mean the absence of any introduction or votes of thanks. At the end of an hour's lecture the audience is more or less fatigued and apt to be impatient of the kind of remarks usually made.

If the Association were known to be made up of members from all kinds of callings and positions in life, its pronouncements on such national problems as the teaching of science in schools, the relation of science to the public services, and so on, would have a greater influence. It has already done good work in this way, and could do more.

There is another way in which I venture to think the Association might be useful. Sensational, exaggerated, and inaccurate statements with regard to supposed new discoveries appear from time to time in the daily Press. Those unfamiliar with the facts find it difficult or impossible to learn the truth about them, and when the statements are found at a later date to have no basis scientific credit is likely to suffer. Such assertions as the overthrow of Newton, and even of the foundations of science, by Einstein's work, and the wild statements about the transplantation of glands of internal secretion and about Besredka's work on immunity, require authoritative correction. Possibly committees of a more or less permanent character might meet throughout the year, but it is not easy to see how it could best be done.

The mention of committees suggests an appreciative reference to the Special Reports issued from time to time by the Association. These are frequently of great value as showing the wide bearing of facts in one branch of science upon other branches. The reports on "Colloid Chemistry" may illustrate my meaning. These various reports are by no means so widely known as they should be, and this part of the activity of the Association might well be continued.

I feel some doubt as to whether the research committees repay their cost, and whether their work would not be better transferred to the Department of Scientific and Industrial Research or to the Medical Research Council, as the case may be.

This letter contains little, it is to be feared, in the way of suggestion for constructive advance, but I should like to add my testimony in support of the position taken up in the article in NATURE.

W. M. BAYLISS.

University College, London, September 21.

THE leading article in NATURE of September 16 brings out very clearly what many of us feel to be an increasing difficulty at the meetings, not only of the British Association, but also of most other scientific societies. In fact, it is scarcely an exaggeration to say that members sit through the bulk of meetings and listen to the majority of papers out of mere courtesy. Only in rare instances, when the paper read happens to touch the listener's special line of work, can one take an intelligent interest in the proceedings. Even then it is wise to wait until a paper is in print before forming an opinion. Some good-natured person, however, often sacrifices himself and offers a few trite, and usually irrelevant, remarks which pass muster for a discussion. Under these conditions one is tempted to ask oneself what real good is achieved by such meetings and in what way they can help the progress of research. I admit this state of things is far worse in some subjects than in others; in mathematics it exists in an aggravated form. On the other hand, I have rarely attended a meeting of the Royal Astronomical Society without being stimulated and interested. But this defect is found, in varying degrees, at every scientific meeting, and it grows steadily worse as years go by.

Much of the trouble seems to be due to the increasing subdivision of the departments of science and the tendency of each subdivision to create a nomenclature of its own, so that science is being rapidly threatened with the curse which fell upon the builders of the Tower of Babel. Often a mere name, which if explained in terms known to all scientific workers would be at once mastered, proves a decisive stumbling-block. Thus it is not infrequent to hear the engineer complain of the general unintelligibility of the ordinary mathematician or physicist, but he seems entirely unaware that he himself uses what seems to the others an equally unintelligible jargon.

Another contributory cause, to which your leading article alludes, is that the rapid growth of many borderline sciences is now overshadowing the old recognised domains. In much of the new physical chemistry, for instance, both the physicist and the chemist brought up on classical lines feel themselves equally at sea. The thing has grown up unnoticed, as it were; they have had a glimpse here and a glimpse there, but they have no clear understanding of the new foundations or of how their own work is affected by the new developments. Many would like to obtain this understanding, but find that in order to do so they must first read up hundreds of scattered original papers containing 90 per cent. of matter of no interest to them, and they may have neither the time nor the inclination for the task. The fact is that research in such border-line sciences has outstripped the text-book writer; and although text-books are often bad, they nevertheless have a useful, even an essential, function to fulfil.

If such are the difficulties confronting the trained scientific worker, what are we to say of the intelligent amateur in a provincial town, such as the British Association regularly visits? To him, indeed, much must be Greek, even of the presidential addresses; and the papers, many of quite special and trivial interest, which make up the bulk of the business of the sections, can make no appeal whatever. Indeed, the only surprising thing to me is that any such persons attend the meetings at all; it speaks volumes for their keenness and devotion that some do.

But if the British Association is really to take for one of its tasks the bringing of science home, so to speak, to the British public, if it is to give its energies to what the French call "vulgarisation," and if in addition it is to promote co-operation and understanding between workers in different branches, then it must modify not only the procedure at its meetings, but also the character of its printed reports. These are often scrappy and confusing in the extreme. More attention ought to be paid to systematic expositions of recent scientific developments set forth in such a manner that they can be read and understood by everyone with a fair all-round scientific education, and supplemented by exhaustive references for those who wish to go into the subject. Such "Reports on the State of Science" will not be a new departure in the history of the Association. A good recent example of a difficult mathematical subject so treated is to be found in H. Bateman's report "On the History and Present State of the Theory of Integral Equations," printed in the 1910 Report. On the other hand, much of the material now published under the heading "Reports on the State of Science" seems to me far too special, and could with advantage be published elsewhere.

As to the meetings, I agree entirely with the view expressed in the leading article that the function of a section "should not be technical discussion by specialists for specialists, but the enlightenment of an extensive group of workers as to main lines of advances in fields not specifically their own." To obtain this result what is needed is not a succession of papers by individual specialists, but rather one or two stimulating addresses by a carefully selected lecturer who can be trusted to avoid the faults referred to in your article.

At the same time I suggest there should also be social and entirely informal meetings for semi-private discussion. These should be for real, effective comparing of notes by workers on the same lines, each set chatting round its own table; a member, during the course of one meeting, might talk and listen at several tables in succession.

About organisation, the arbitrary division of science into watertight sections is inevitably bound to lead to trouble as subjects grow. (Incidentally, there is much to be said against the present classification.) The main trouble, however, is that with the sections as at present it is nobody's business to arrange joint meetings to deal with border-line subjects. A possible solution would be to have standing joint committees of groups of sections, the sole duty of which should be that of co-ordination. If need be, the same section could appear in more than one group; thus chemistry might take its place both in a physical and in a physiological group.

L. N. G. Filon.

University of London, University College, September 21.

The problem of the best use that we can make of the annual meetings of the British Association is one that presents many difficulties. There is so much to be accomplished and so little time available—less than ever since 1914, though in this respect I understand the former conditions are to be restored next year.

At present the most important functions of the Association are to stimulate and maintain the interest and activities of local workers, and to enable men of science who are engaged on problems which require the co-operation of a number of observers scattered about the country to obtain new recruits. At the same time the meetings give them the opportunity of addressing a wider audience than that afforded by the scientific societies—an audience which includes a large number of university workers who are resident in the provinces during the university terms and a certain proportion of the men and women, all too few in number, who take an intelligent interest in science, though they have not adopted it as a career.

But, as you have indicated, the Association has almost wholly failed to appeal to the man of at least ordinary intelligence and education who has never seriously considered the purpose and achievements of science. This is, I believe, largely the fault of the methods of our schools. If science has been taught at all, the aim has been to drill the pupil in the use of correct technical language and in the exact mathematical expression of natural laws, instead of to implant a living interest in the subject—a far more important matter in the early stages of mental development.

However that may be, the task with which we are now faced is to attract to the meetings those who are at present quite apathetic about all that concerns the progress of science. We already have a few popular lectures on Royal Institution lines, and no doubt it would be desirable to increase their number; but they should be comparatively brief—forty minutes at most—and arrangements should always be made for the discussion of debatable points by competent speakers. Nothing is so calculated to increase the interest and facilitate the understanding of a subject as its presentation from different aspects. Perhaps the greatest successes of recent meetings have been the inter-sectional discussions, which have on one hand aroused popular interest, and on the other done much to develop co-operation between different branches of science.

I am not in agreement with the idea that a meeting of the British Association should not be made an occasion for the announcement of new discoveries or for the description of new developments in research. Provided they are not of too abstruse a character, they are of great value in increasing the prestige of the Association among its members.

If, however, we wish to attract larger audiences of the general public and secure a wider membership, we must do more to advertise the meetings. Something in the nature of a *catalogue raisonné* of the more interesting features should be circulated some weeks beforehand, especially in the neighbourhood to be visited. Short illustrated articles should be contributed to the local papers indicating the topics that are to be considered and the problems that present themselves for solution—sufficient to whet, but not to satiate, the curiosity of the man in the street, so that he may understand that he will not be compelled to listen to dissertations on abstract subjects in unintelligible phraseology, but will have the opportunity of hearing important and interesting questions discussed in a simple, straightforward fashion that any intelligent man will be able to follow.

John W. Evans.

Imperial College, September 22.

I have been greatly interested in the leading article in Nature of September 16 on the position of the British Association. Anyone is interested in an expression of his own views in better language than he can himself command.

While it is the function of the several scientific societies to do their utmost for the advancement of science, each within its own narrow limits, the Royal Society affording common ground for discussion for the *élite* only, the British Association has primarily a double duty to the nation and to the world. On one hand, it should encourage the "cross-fertilisation of the sciences," as no other body can, by bringing together the members of its various Sections so that each may help the others. This co-operation is valuable, not simply on the border-land where the sciences appear to come in contact, but also because it may penetrate the whole area of a science. Perhaps the time is not far distant when we shall cease to speak of "a science," and the unity of *science*, already begun to be recognised in the elementary schools, will be universally acknowledged. It has been stated that when two Sections meet in common the attendance is greater than the sum of the attendances at the separate meetings of the same Sections. This indicates the need, and the direction in which to look for improvement. On the other hand, the Association is mainly responsible for making known to the public the recent advances in science and their bearing on social life—in other words, their possible practical applications. To this end representatives of each Section should be annually appointed for the task of reporting to the next meeting, in terms which will appeal to the man in the street, the progress which has been made in the advancement of science and its applications. It has even been suggested that two sets of reports should be prepared in this way, one as described and the other for experts, and that these reports should form the chief material for the meeting, not much encouragement being offered to original papers suitable for their respective societies. In the preparation of these reports there should be much intercourse between the representatives of the several Sections, and many of them should be the result of joint work. In some cases distinguished investigators should be invited to describe their results in popular language, irrespective of previous publication in the transactions of learned societies. The advancement of science depends not only on the skill and genius of the expert, but also on the appreciation of the people.

September 24. WM. GARNETT.

As one who regularly attends the meetings of the British Association, and in particular those of Section A, may I be allowed to state that I cannot recall in the last twenty years any meeting of the Association when the attendances at Section A were more numerous than at Cardiff. On several occasions it was almost impossible to obtain a seat in the large lecture hall assigned for our meetings unless one came in good time. This was particularly the case when the discussion took place on the constitution of the atom, so admirably exposed by Dr. Aston and by Sir E. Rutherford. A very large audience also assembled to hear Sir Oliver Lodge's controversial note on popular relativity, and the room was full for the discussion on the origin of spectra. And, too, the majority of those who attended, or at least a very large proportion, were not professional physicists, but members of the Association who take an interest in science in general, and who came to hear about the latest advances in physical science. It is for these members that the Association caters, and it would seem that, so far as Section A is concerned, it is fulfilling its functions quite admirably.

This testimony as to the efficiency of the Association may serve as an antidote to some of the jeremiads as to the decadence of the Association which have appeared in the columns of NATURE. The only drawback to the complete success of Section A was that some of the speakers did not seem to realise the very indifferent acoustical properties of the hall in which our meetings were held.

The relatively meagre attendance at the two evening discourses was accounted for by the local strike of tramwaymen. This made it difficult to get to distant parts of the city when the discourses were finished. A. L. CORTIE.

Stonyhurst College Observatory, September 25.

IN your leading article in NATURE of September 16 you have expressed what many of us have long felt: that the British Association is losing its interest for the people of the locality in which it meets. This is mainly on account of the highly technical character of most of the papers, which are suitable only for meetings of the special societies. The Association should not be regarded as a means of publishing new observations unless these are of fundamental importance. Its object is rather to give an opportunity for the local worker to exchange ideas with those who are more favourably placed. Again, the laboratory worker may come in contact with the practical man in many subjects to the benefit of both. Another useful function it may perform is in the discussion of border-land subjects in which more than one Section may be interested, and which do not lie definitely within the limits of any one of the special societies. In these functions, the extension of scientific interest to wider classes of the community and the removal of the barriers between different sets of scientific observers, the Association may meet a crying need of the time. ARTHUR R. CUSHNY.

University of Edinburgh, September 27.

Uses for Aircraft.

WHEN in the year 1912 I gave the first of the James Forrest lectures on aerial flight, I said that the chief uses of aircraft would probably be for the purposes of war or for sport. As a member of the Advisory Committee for Aeronautics I have been in a position to follow the various developments which have been made since that date, but I see no reason to alter my opinion. While the cost of carriage by air is as high as it necessarily must be at present, the commercial use of aircraft on any considerable scale seems impossible. There is no difficulty in carrying goods; the difficulty is to find any class of goods which, for the sake of halving the time of transit, will bear the increased cost of carriage. A certain small amount of postal work, with a few passengers, so long as the novelty is an attraction, or in special cases, seems to be the only opening. If the ton-mile cost could be reduced to as many farthings as it now is shillings, commercial uses on a much enlarged scale would be found.

For sport and private use (*i.e.* for air-yachts) the existing patterns of machines would have to be altered to allow of a greater range of speed and a greater facility in getting off and landing. Both these objects could be attained by the introduction of wings of variable area. It would be a great advantage also, both for storage and in other ways, if the wings could be properly folded (not merely unshipped and turned back) by the pilot from his seat. I have shown in another place how this might be done for monoplanes, and for these the necessary mechanism is simple. For biplanes it would be more difficult to design, but not impossible.

Among the more special uses of aircraft may be mentioned those of map-making and exploration in difficult countries, and of obtaining information regarding winds and other meteorological matters at various altitudes.

For exploring purposes the machine should be amphibian. In New Guinea, for instance, it is only at a few places on the coast that it would be possible to come down and get off on land not previously cleared, but many of the rivers reach far inland, and (judging from photographs) places could be found even near the mountains where there is a water-surface sufficient for the purpose, provided that the machine has great climbing capacity and a wide range of speed.

An expedition which had aeroplanes at command would have the advantage of photographic maps of the whole district it proposed to explore, and could therefore choose the best routes. Supplies also, which would take days to carry by canoes and porters, might be brought from the coast by air in a few hours; and one has only to read the accounts of previous expeditions to realise what a difference it would have made in the results had the geography of the country been known in advance and had there been no fear of scarcity of provisions.

Among the many ways in which aircraft could help in meteorology, not the least useful would be an examination of the trade winds, especially as regards their variations in altitude and their vertical components in different latitudes. At the present time not much more is known about these winds than their velocities and distribution on the earth's surface.

Exploration and meteorology are scarcely, or only indirectly, commercial matters, and comparatively few aircraft would be required for the purposes suggested, but results of great value might be obtained by their use.

A. MALLOCK.

September 21.

Minerals Hitherto Unknown in Derbyshire.

DURING the past three years I have been conducting investigations relating to the mineralogy of Derbyshire, checking and confirming (or contradicting) asserted occurrences, surveying mineral deposits, and also prospecting, with the result that several minerals —chiefly of scientific interest only—hitherto unknown in Derbyshire have been discovered. The work is not quite completed, and I have not yet issued any paper or other publication upon it, but the following observations may be worth putting on record now:

Zaratite, Nickel-ore.—Samples of this mineral, of a pale emerald-green colour, and usually containing a large quantity of hydrozincite, were recently found in old dumps of decomposed dolerite raised during the early working of a local mine driven in search of lead-ore. When following up the search for further nickel, some nickeliferous hydrozincite (or zinciferous zaratite) was found which was of a blue colour instead of the pure green of zaratite. On analysis this was found to contain *cobalt*, which probably existed as *remingtonite*, the accompanying zinc and nickel existing as their hydrous carbonates. The "mineral" is, therefore, probably a mixture of the three mineral species, hydrozincite, zaratite, and remingtonite.

Considerable difficulty attaches to the following up of such finds with the view of ascertaining the quantity available, as many of these mines are of considerable antiquity and dilapidation, having been driven in search of lead-ore when little or nothing was known of the rarer metals.

Nephrite, Jade.—Near the margin of a basalt quarry at Bonsall a somewhat lenticular nodule-shaped lump of white nephrite was found.

Diabantite.—Beautiful specimens of this uncommon member of the chlorite group of complex silicates were found at Mill Close Mine, Darley Dale, having been raised during the early working of the mine. It occurs in the much decomposed dolerite as radiated spherical aggregates (up to 2 cm. diameter) and of a dark green colour. It is usually associated with calcite in amygdaloidal cavities, has a specific gravity of 2·79, a hardness of 2·3, and is strongly pleochroic.

Cimolite.—A hydrous aluminium silicate. A thin bed of this mineral occurs near Hopton. It is quite white, amorphous, and chalk-like.

Allophane.—A hydrous aluminium silicate. Many of the numerous rake-veins in the mountain limestone of the Middle Peak region are rich in forms of limonite, but chiefly the earthy variety—ochre. In one of these veins which is cut in the Coal Hills Quarry, near Wirksworth, allophane is to be found in more than one form. The commonest form is that of a light amorphous powder; it also occurs as an opaque, white encrustation, and as a translucent, sub-crystalline encrustation of the faintest green tinge due to the presence of a minute trace of malachite.

Utahite (?).—The limestone-shale in the vicinity of Wensley contains a quantity of an insoluble basic ferric sulphate as dull, yellowish-brown films in the shale. Its mode of occurrence renders its accurate analysis difficult, but it seems to be a variety of utahite.

Native Sulphur.—"Native sulphur is said to have been found" is recorded by ancient writers, but no confirmation in recent years seems to have been made. A good specimen was recently found near Eyam. It is a greyish-yellow powder, burning readily when ignited.

Manganese-ore.—Manganese is not a new discovery; the indefinite hydrous oxide—wad—has long been known to exist in certain districts in the county. It has also been previously worked, but the present scarcity (recently mentioned in the House of Commons) led to the work of prospecting for a deposit to be mined on as large a scale as possible. This work has been successful, and arrangements are being made, by the company for which the work was undertaken, for the mining of the ore.

Riber View, Oak Road, Matlock,
September 16.

Wheat-bulb Disease.

IN view of their economic bearing and of the nearness of the wheat-sowing season, the data given below should be widely known, all the more that in the latest notice I have seen regarding the life-history of the insect pest concerned (*Rev. Applied Entom.*, June, 1920, abstract of papers by R. Kleine in *Zeitschr. f. angew. Entom.*, Berlin, 1915–16) the practical conclusions given appear to be entirely misleading. These conclusions are that "wheat should be preceded by root crops" and "it is apparently useless to attempt to grow wheat or rye on ground which has not been under cultivation for some time." Now it is chiefly among root crops, especially potatoes, and on fallow ground that the insect elects to lay its eggs. This month, for example, in one infected area I find that the number of potential "wheat-bulb" larvæ in a particular potato-field ranges from six to twenty per square foot of surface, while the next field (pasture) has very few, and the neighbouring wheat-field, which was the sufferer last spring, has still fewer. Obviously to sow wheat on infected ground means laying up progressive trouble for the future. The disease has done much damage this year in the East of Scotland and elsewhere, and is evidently spreading, in this locality at any rate. Larvæ obtained from infected wheat were allowed to pupate in the laboratory here, and the flies which hatched out (*Hylemyia coarctata*, *vide* Theobald's "Agricultural Zoology," 1913, p. 242) were kept until they laid their eggs. (Two of them still survive, though the field Hylemyias are all apparently dead.) The distribution of the eggs in nature was then studied (so far as time allowed) by a method permitting accurate enumeration.

The Iridescent Colours of Insects.

By H. ONSLOW.

I.—THE COLOURS OF "THIN FILMS."

IT is strange that the cause of the iridescent hues of insects and other animals should to a great extent still remain one of the unexplained problems of optics: theories have been advanced without end, but so far not one that is completely satisfactory. It is very significant that Prof. R. W. Wood, in speaking of certain metallic films the bright colours of which may be due to an exceedingly fine state of division, remarks: "There appears to be a large number of cases in which brilliant colours are shown which cannot be explained by any of the common laws of optics with which we are familiar. As far as I am aware, no very satisfactory explanation has ever been given of the colours of certain feathers and butterflies, and I strongly suspect there is some action of absorbing matter, in a state of very fine division, upon light waves, which is not yet completely understood."

This opinion is given in spite of the fact that no less an authority than Michelson declares that all the colours in question are surface colours; that is to say, they are due to selective metallic reflection, like the coloured surfaces of aniline dyes and metals. Nothing further is required to show how chaotic and contradictory is the present state of knowledge on this subject.

A discussion of the merits of the rival theories would not here be in place.[1] There will not, however, be much danger in venturing to predict that the almost infinite variety of iridescent colours depends upon every possible factor which can produce such colours. Neglecting the metallic films of Prof. Wood, just mentioned, and analogous cases, it is clear that the colours of insects must be caused in one of the following ways:—

(1) Pigmentation.

(2) Interference of light by "thin films" (as in the case of soap-bubbles).

(3) Diffraction of light by "gratings."

(4) Dispersion of light by prisms.

(5) The scattering of light by small particles (as in the blue of the sky).

(6) Selective metallic reflection (as in metals and aniline dyes).

In dealing with iridescent colours, the first possibility may be neglected, though pigments, such as yellow, are often found combined with structural colours, to form green and so forth.

The Interference of Light by "Thin Films."

This is well known to be the cause of the colour of soap-bubbles and oil films, and it certainly seems to offer one of the best explanations of the iridescence of insects. The late Lord Rayleigh has shown how the objections of Michelson may be met by postulating films of a peculiar structure. Also Biédermann has shown that when iridescent scales are placed in a highly refractive fluid, all colours disappear. This could not possibly occur if the colour were due to a substance resembling aniline dyes, for in these circumstances its body-colour would inevitably be seen by transmitted light. If, however, the colour were due to thin films of air separated by layers of chitin, this loss of colour is exactly what would be expected when the air-spaces were filled by a liquid; for the periodic structure would become a continuous medium. Moreover, Mallock has described how, by applying gentle pressure to scales, the colour fades, sometimes tending to return when the pressure is released. Naturally, if there are plates of chitin separated by air-films, such pressure would alter the spacing between the plates, and thus cause the colour to fade.

Since the minute structure of iridescent scales, etc., had never been examined, the present writer

FIG. 1.—*Ornithoptera poseidon* ♂. Body yellow, wings emerald-green and black. (½ natural size.)

has carried out an extensive microscopical investigation in order to discover whether any light could be thrown on the question by this means. The varied types of the different structures found fully justified the expectation that a number of factors were involved, but though the colours of many scales could be accounted for by well-known laws, in other cases no explanation appeared adequate. A few instances will therefore be selected to illustrate the main types of iridescent colours found in insects.

Morpho menelaus.—The brilliant blue-green of this wonderful insect is well known. It is given by two layers of scales—section *1a*, Fig. 2, the pale blue upper layer, which shows the anomaly of appearing blue both by transmitted and by reflected light (NATURE, vol. ciii., p. 84, April, 1919), and section *1b*, Fig. 2, the deep blue lower layer of scales, which bears a very curious periodic structure. This structure, best seen in transverse sections of the scales, is shown in Fig. 2, *1b*. The films of transparent chitin, *a*, here appear as pillars, and between them there are films of air, *af*. Seen in longitudinal section, these pillars become long,

[1] "On a Periodic Structure in Certain Insect Scales, and the Cause of their Iridescent Colours." By H. Onslow. Read before the Royal Society on January 29, 1920.

narrow strips of chitin, a, Fig. 2, $1c$. The chief peculiarity of these films is that they are placed at right angles, and not parallel, to the surface of the scale or wing, as may clearly be seen from the sections. This results in an obvious consequence, which goes far to prove that the plates are the true cause of colour. It has always been said that the colour of iridescent insects changes towards the violet end of the spectrum, like a flat soap film, when the wing is turned from the normal to grazing incidence. This should be true if the colour were produced by films parallel to the wing surface, but if they were at right angles to it, the reverse should be the case; that is to say, the colour should approach the red end of the spectrum as the angle reaches the grazing incidence.

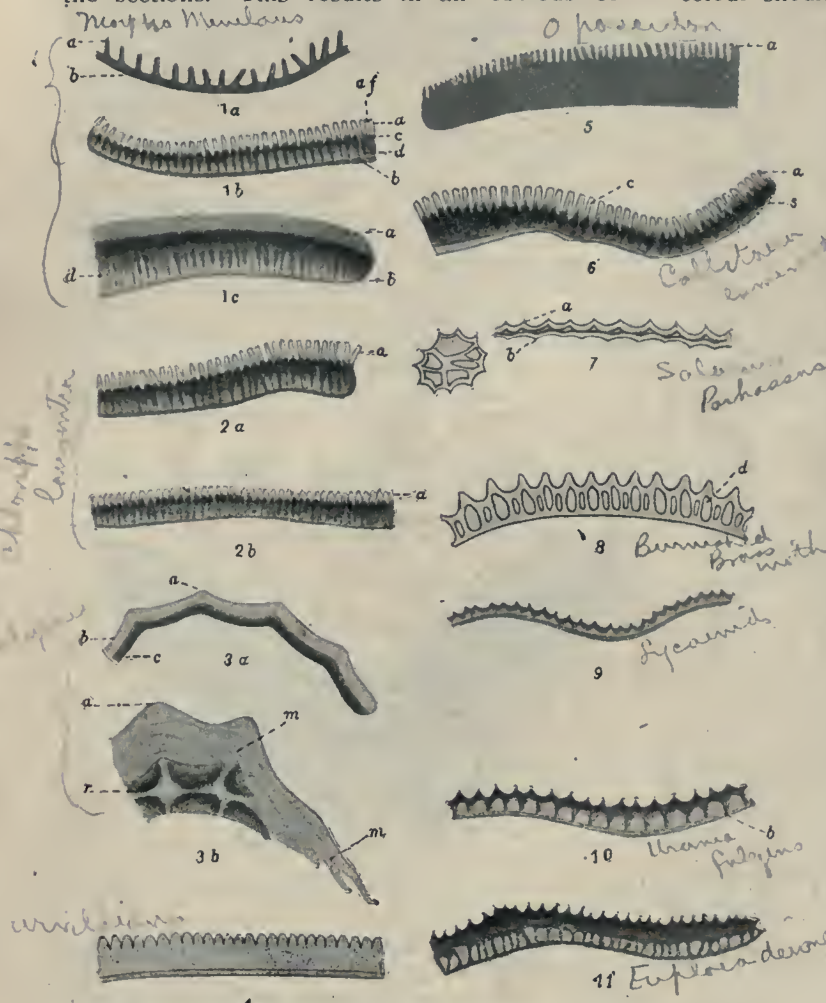

Fig. 2.

1a, Upper scale of *Morpho menelaus*. *a*, striæ; *b*, lower membrane.
1b, Lower scale of *M. menelaus*. *af*, air-film; *a*, chitin film; *c*, pigmented striæ; *d*, bands of chitin joining upper and lower membranes; *b*, lower membrane.
1c, Longitudinal section of the last. *a*, chitin film seen from the side.
2a, Central spot of *Chlorippe laurentia*. *a*, tall films of chitin.
2b, Periphery of the above, showing *a*, bosses of chitin.
3a, Scale of *Papilio ulysses* showing *a*, wave-like striæ; *b*, transparent layer of chitin; *c*, pigmented layer of chitin.
3b, Diagonal section of the same. *a*, striæ; *r*, pigmented portion of striæ; *mm*, films of chitin.
4, Blue scale of *Ornithoptera urvilliana*. The chitin is colourless.
5, Green scale of *O. poseidon*. The whole scale, including the chitin films *a*, contains a yellow pigment.
6, Magenta scale of *Callitaera esmeralda*, showing granular pigment *s*; and a cleft, or division *c*, in the films of chitin *a*.
7, Section through scale, and tip of scale of *Salamis parhassus*. *a*, upper membrane; *b*, lower membrane.
8, Metallic golden scale of *Dione juno*. *d*, large air-space.
9. Iridescent scale of *Lycaena icarus* stained with carbol-fuchsin.
10, Black under-scale of *Urania fulgens*. *b*, transparent, iridescent membrane.
11, Partially depigmented scale of *Euploea deione*.
All these sections were drawn to the scale $\mu = 1{\cdot}5$ mm. with Zeiss 2 mm. apochromat, N.A. 1·4, and Comp. Oc.

The variation of colour in a number of insects was measured in wave-lengths, and most of them were found to fall into two groups—(a) those with the periodic structure just described, which at grazing incidence reflected the longest waves, and (b) those without this structure, which reflected the shortest waves when in the same position. Further, it was possible to show that the distance between two consecutive plates of chitin was from $0{\cdot}6\mu$ to $1{\cdot}0\mu$,[2] and since the chitin plates often show a line of cleavage, c, Fig. 2, section 6, so that they appear double, this space may contain two films of chitin and one of air. Thus the plates may be of the most efficient thickness for producing colour (*i.e.* one-half wave-length), which for chitin is $0{\cdot}17\mu$, and for air $0{\cdot}25\mu$, or $0{\cdot}6\mu$ for the three plates.

Chlorippe laurentia.—The edges of the dull green patches on this insect's wings are brown at normal incidence, but the whole area becomes a brilliant green at grazing incidence. This illustrates the effect of the height of the chitin plates on the quality and saturation of the colour. The central area, which is always green, is shown in section $2a$, Fig. 2, where the chitin plates are the usual height. In the area which is brown at normal incidence, section $2b$, Fig. 2, the chitin plates, a, have become merely bosses. If a ray must traverse three or four films to give a certain depth of colour, it is obvious that, in the case of section $2b$, it will do this only at very oblique incidence; whereas, in section $2a$, this will happen with rays more nearly normal to the surface.

Ornithoptera poseidon (Fig. 1).—The males of this gorgeous species, and of the even more remarkable *O. paradisea* (Fig. 3), are emerald-green, and they illustrate the effect of combining structural and pigmentary colours. The narrow plates of chitin, a, seen in section 5 of Fig. 2, produce a blue colour, but the body of the scale is dyed by a bright yellow pigment, the colour of picric acid. This pigment extends into the chitin

[2] $1\mu = \frac{1}{1000}$ mm. The sections in Fig. 2 were all drawn to the scale $\mu = 1{\cdot}5$ mm., so that the relative distances may be seen at a glance.

plates themselves, so that they also are yellow. The addition of this pigment converts the blue into a green, and the effect of suppressing it is seen in *O. urvilliana*, a powdery blue insect, a section of which, *4*, is shown in Fig. 2. It is pale blue on the upper surface, probably because the chitin plates are broad, but underneath, where the plates are like those in section 5, and contain a little yellow pigment, it is pale green. In some other insects

FIG. 3.—*Ornithoptera paradisea* ♂. Body and hind-wings gold fore-wings green and black. (½ natural size.)

the pigment is granular, as at *s*, in section 6, being situated in the body of the scale, but not in the chitin plates. This is the case with those Pierids which have magenta tips to their fore-wings, as well as with the beautiful purple-eyed *Callitaera esmeralda*, which has scaleless but iridescent fore-wings (Fig. 5).

FIG. 4.—*Nomiades arion* (the Large Blue) Male and female, and under sides of same. (Natural size.)

Black is naturally a very important pigment, for it often serves the purpose of absorbing white light, which otherwise, being reflected, would greatly desaturate the colour. Thus the white spots in many insects, such as *Morpho cypris*, have exactly the same structure as the deep blue parts, except for the absence of the absorbent backing of black pigment in the lower layers of the scale.

Papilio ulysses.—The insects the colour of which changes towards the violet at grazing incidence do not have a periodic structure such as that described; but they invariably exhibit a somewhat thick superficial layer of clear chitin. The scales of many iridescent Papilios belong to this group, as, for example, the satin-blue scales of *P. ulysses*, section *3a*, Fig. 2. The layer of chitin, *b*, is clearly too thick to cause colour, and no finer structure could be made out, even with an objective capable

FIG. 5.—*Callitaera esmeralda*. The wings are scaleless and faintly iridescent. The eyes of the hind-wings are magenta. (Natural size.)

of separating the rulings of a grating 0·21μ apart. This is less than one-half the mean wave-length in air, which seems to preclude the existence of air-films. Nevertheless, the surface layer might contain three or four half-wave-length plates of chitin, placed exceedingly close together, though not actually in optical contact. It is, however, doubtful whether in this case pressure experiments and immersion in highly refractive fluids would produce the effects observed.

Very strong confirmation of the existence of a periodic structure, of some description, parallel to the surface, can be obtained by cutting oblique sections of *P. ulysses*. These sections, *3b* (Fig. 2), show the ragged edges of three or four layers of chitin, *mm*, which come into focus successively on lowering the objective.

Salamis parhassus.—There are some insects, like the pale pink *Salamis parhassus*, which have scales that might owe their colour to the thin double membranes of which they are composed, *a* and *b*, section 7 (Fig. 2). If these single films of chitin really cause the colour, it is difficult to account for the uniformity of shade, which ought to vary with the inevitable differences of thickness inherent in an organic film. Such variegated colours are actually found in the lower membrane of many black scales, such as those of *Urania fulgens*, *b*, section 10 (Fig. 2).

There are, however, other insects, such as many Lycænids (Figs. 4 and 6), the iridescent scales of which have membranes too thick to produce colour, though no finer structure can anywhere be made out, section 9 (Fig. 2).

Euploea deione.—There is one large group of

FIG. 6 *Lycaena corydon* (the Chalk Hill Blue). Male, female, under-side of female and larva. (Natural size.)

insects of considerable interest, the colour of which cannot be accounted for in any way. This group includes the dark purples and deep, glossy blues and greens of all the most sombre iridescent insects, such as the Purple Emperor (*Apatura iris*), the Scarlet Tiger (*Callimorpha dominula*), the Purple Hairstreak (*Zephyrus quercus*), and many exotic species. Any one of these, such as the section of *Euploea deione*, *11* (Fig. 2), shows no difference from the black, non-iridescent scales immediately beneath them. They are all so densely pigmented that nothing can be made out until they are bleached, and even then a thin cuticle only sometimes appears. Were it not for the fact that the colours disappear under pressure and in refractive fluids, it might be thought that the iridescence was due to selective metallic reflection, as will be shown to be probably the case in most scaleless beetles.

Dione juno.—Scarcely less puzzling are the metallic greenish-gold and silver scales of many Plusia, such as the Burnished Brass Moth (*Plusia chrysitis*). Section 8, Fig. 2, shows the golden scale of the tropical insect *Dione juno,* which has no structure that can adequately account for the colour, since it is identical with the scales in the adjoining brown areas, except for the absence of the pigment. To produce anything approaching metallic reflection a highly polished surface would be necessary, as well as a large number of air-spaces not more than the diameter of a few air-molecules in thickness. The effect of a highly polished surface is seen in the scales of the Coppers, as, for instance, the Small Copper (*Chrysophanus phlaeas*), which has ordinary scales containing a granular orange pigment, yet appearing almost iridescent. The only trustworthy evidence of true iridescence is, of course, the change of colour seen on altering the angle of the incident light.

(*To be continued.*)

Ballistic Calculations.

By D. R. HARTREE.

THE purpose of the present article is to give an outline of the more important methods of numerical solution of the various problems of external ballistics—that is to say, problems connected with the resisted motion of a shell after leaving a gun. Most of the methods to be mentioned were developed during the war, either for working out range tables or other information to be used in the field, or for analysing a trial shoot.

The problems that arise may conveniently be divided into two groups, comprising what are sometimes known as primary and secondary problems, the theoretical and practical treatments of which proceed on rather different lines. The primary problems are those which involve the calculation of the performance of a gun, or rather its shell, under ideal conditions, such as still air, a standard muzzle velocity, and so on. The secondary problems are those in which we are concerned with the calculation of the corrections to be applied to the solutions of the primary problems to allow for the departure of actual conditions from the ideal.

A very important simplification is introduced by assuming that the forces due to the motion of the shell through the air consist only of a resistance in a direction opposite to the direction of the motion of the shell relative to the air. Lack of trustworthy information until recently about the other forces made this the only possible course. Some account of these forces and their effects is given in a recent issue of NATURE.[1]

Making this assumption, and neglecting the effect of earth rotation (which may be considered as a secondary problem), it appears that the trajectories concerned in any primary problem lie entirely in the vertical plane containing the initial direction of motion. For this reason they are known as "plane trajectories."

The retardation due to air resistance R acting

[1] See NATURE, June 10, "The Dynamics of Shell Flight," by R. H. Fowler.

on a shell of mass m is usually expressed by the formula :—

$$\frac{R}{m}=\frac{F(v)}{Cf(y)},$$

where v is the velocity of the shell relative to the air, $f(y)$ is the reciprocal of the density of the air at height y, $F(v)$ is an experimentally determined function of the velocity, and C depends on the size and shape of the shell.

Standard functions $F(v)$ and $f(y)$ are used in all ordinary calculations; the quantity C is determined for any particular shell by comparing the results of firing trials with trajectories calculated for the same muzzle velocity and elevations as used in the trial, and two or three values of C.

Primary Ballistic Problems.

Before the advent of the anti-aircraft gun the point of fall was the only point of a trajectory of any great practical importance, and this could be found to a certain degree of accuracy by means of approximate integrals of the equations of motion, for high-velocity guns at small elevations, and for low-velocity howitzers at high elevations, which were the two cases of importance before the war.

But when guns began to be used at higher elevations, and the muzzle velocities of howitzers were increased, these approximate solutions became unsatisfactory; also, with the development of the anti-aircraft gun, came the necessity for calculating whole trajectories, instead of merely a point on each trajectory. Later, it was found necessary to know the whole trajectory, even for guns only intended for use against targets on the ground, in order to solve certain secondary problems, such, for example, as the wind correction to be applied when the wind varied with the height.

The equations of motion, even of the plane trajectory, are formally insoluble, which is not surprising, considering that the air resistance which enters into them contains two functions, $F(v)$ and $f(y)$, of an empirical nature. The only really satisfactory way of obtaining numerical solutions is to carry out a numerical integration of the equations of motion.

To perform this integration a step-by-step method is employed. That is to say, the trajectory is divided up into a series of fairly short intervals, and the integration through each interval in turn performed by means of suitable approximate formulæ, the size of the interval being chosen to make the errors negligible. The complicated way in which the different variables are connected makes it impossible to use directly any of the ordinary integration formulæ, such as Simpson's rule.

Methods of step-by-step integration have, of course, long been known in astronomy; they seem, however, to have been regarded until recently as too laborious for ballistic work except in special cases. However, during the war those concerned with ballistic calculation were forced to use them, for reasons already mentioned, and gradually with experience methods were evolved which were both simple to carry out and not too lengthy. The use of a series of intervals of the same length, and of the finite differences of various quantities at the ends of successive intervals, both simplifies the integration and makes possible a complete check on the numerical work.

When two or more trajectories of the same gun with different elevations have been calculated by these methods, it is obviously possible to determine intermediate trajectories by interpolation. Theoretically, interpolation methods are of a subsidiary nature; in practice, if simple and accurate, they are often very useful.

For a range table, or for the graduation of sighting apparatus, either for flat or high-angle fire, interpolation from the data furnished by the calculation of trajectories is necessary.

Thus in a flat range table the elevation necessary to reach a given range is tabulated as a function of the range, but in calculating a trajectory an exact value of the elevation is taken, and the range is found. The interpolation in this case is usually done graphically.

For a high-angle range table the question is more complicated, for this table is one of double entry, giving the elevation required to reach various points in a two-dimensional region. A table obtained by graphical interpolation usually needs some smoothing. This process, though fairly simple for a single entry table, is almost prohibitive for a table of double entry. A scheme of accurate numerical interpolation was therefore evolved; this scheme as a whole is rather elaborate, but the individual calculations are very simple.

In England the greater part of the numerical work of ballistics is carried out by means of calculating machines.

Secondary Ballistic Problems.

The development of the methods of solution of the secondary problems in general arose in the first place from the necessity of finding the effect of a wind, or change of atmospheric density from standard, which varied along the trajectory. These are the most important secondary problems in practice, but the methods can be extended to others with little difficulty.

To make the problem more manageable, only "first order" effects of applied variations are considered. That is to say, it is assumed that the effects of such variations are additive, so that, for example, the effect of a given wind and a given change of atmospheric density acting together is the sum of the effects of each separately. In cases of practical importance the error is probably very small.

The problem of calculating the effect of a wind variable along the trajectory is generally divided into two parts, the determination of the effect of unit constant wind, and the determination of the "equivalent constant wind"—*i.e.* the constant wind which produces the same effect at the same time. The latter is obtained by means of a set of "weighting factors" which express the relative importance of the wind at different parts of the trajectory.

Considering the wind effect at any given point, the weighting factor for any section of a trajectory is the ratio of the effect at that point of unit wind blowing in that section only to the effect at the same point of unit wind blowing throughout the trajectory. If W is the actual wind in any section, and k is the weighting factor for that section, then the equivalent constant wind is given by the sum of the values of kW for all sections up to the point where the effect of the wind is being considered.

The same arguments apply to variations of atmospheric density from standard. An account of the application of weighting factors has appeared in a recent number of NATURE[2]; we are concerned here with the calculation of them.

The values of the weighting factors for given sections depend on the point at which the effect of a wind (or change of density) is being calculated, and on the precise effect which is being considered. For example, a wind in the plane of the trajectory produces changes in both horizontal and vertical co-ordinates of the point reached in a given time, and if the wind varies along the trajectory the constant wind which will produce the same horizontal displacement will not generally produce the same vertical displacement.

The four equations of motion of the plane trajectory express the relations between the components of velocity, the co-ordinates, and the time. From them can be obtained, by a process analogous to differentiation, four "equations of variation" expressing the relations between the changes in these quantities, for a given time, for any change in conditions which causes first order variations in the plane of the trajectory. (A cross-wind produces only second order effects in this plane, and its treatment is entirely separate.)

The equations of variation have no formal solution, and step-by-step integration is necessary for numerical work. To find wind weighting factors, the obvious method is to integrate the equations for winds blowing in the sections for which weighting factors are required; but this is not necessary, for if the integration is performed for three suitable changes of conditions, the results may be combined to give weighting factors, not only for wind, but for density changes as well.

The numerical work of the process of combining the three solutions is rather heavy and not altogether simple, and a more direct way of calculating weighting factors has been worked out. The equations of variation form a system of linear differential equations of the first order, and by using a certain property of such a system another set of equations (the "adjoint" system) can be obtained, the solutions of which give directly the effect at a given time of a constant wind (or density changes) which begins at a previous variable time. Weighting factors are obtained at once by dividing by the effect of a constant wind which begins at the origin, and differencing the results.

The equations of variation may be applied to any problem in first order variations. The subject of second order variations has not been developed, as its practical importance appears small.

[2] NATURE, June 17. "The Importance of Meteorology in Gunnery," by Dr. E. M. Wedderburn.

Obituary.

THE study of earthquakes in New Zealand and Australia has suffered a serious loss through the death of MR. GEORGE HOGBEN on April 20 last. For many years Mr. Hogben acted as secretary of the seismological committee of the Australasian Association for the Advancement of Science, and we are indebted to him for reports of this committee, and for many studies of individual earthquakes published in the Transactions of the New Zealand Institute and other journals. It was owing to his efforts that the Milne seismograph was erected at Wellington, N.Z., and that, shortly before his death, an order was given for the improved Milne-Shaw seismograph. In addition to his contributions to our knowledge of earthquakes, Mr. Hogben was interested in education generally, and was for two years president of the Wellington Philosophical Society. According to a notice issued with the Hector Observatory Bulletin (No. 28, 1920), he also issued a valuable report on proportional representation, and at the time of his death had an improved set of mathematical tables in the press.

THE *Atti dei Lincei* (vol. xxix. (1), parts 9–10) contains an obituary notice by R. Versari on the late PROF. FRANCESCO TODARO. Born at Tripi (Messina) on February 14, 1839, Todaro entered the University of Messina in 1860, but on the entry of Garibaldi he took up arms as a volunteer in the Chasseurs of Etna. On the conclusion of hostilities and of service to the wounded, he returned to the University, and was attracted by the German biologists to anatomical and physiological studies. He went for some time to study at Florence under Schiff and others, and in 1865 published his first paper on the muscular system of the human heart and the Eustachian valve. He returned to Messina as professor of human anatomy, and in 1869 gave an address on the renewal of the human body. Todaro was among the earliest to study the anatomy of the lower marine animals, and to realise, in accordance with the doctrine of evolution, the importance of comparative anatomy as throwing light on the anatomy of man. In 1870 he read a paper on the sense-tubes of Plagiostomata, and the following year was invited by Brioschi to the chair of human anatomy at Rome. Shortly afterwards he concentrated his attention on the development and anatomy of the Salpidæ, discovering many new organs. His first paper on this group appeared in 1875, and his last is in proof. Todaro also published papers on the fertilisation and segmentation of *Seps chalcides*. Being the first to advocate the introduction of gymnastics in Italian schools, he was elected president of the Italian Gymnastic Federation, in which capacity he delivered several inaugural discourses at meetings and reunions.

AMONG the many skippers and hunters of northern Norway who have taken part in Arctic exploration one of the best known was HANS CHRISTIAN JOHANNESSEN, whose death at Tromsö at the age of seventy-four is announced by the *Times*. During his sealing and walrus-hunting in the Barents Sea Capt. Johannessen many years ago visited the little-known Wiche Islands to the east of Spitsbergen and the coasts of North-east Land. At a later date he hunted off Novaya Zemlya and Franz Josef Land, penetrating westward to White Island and Spitsbergen. But Capt. Johannessen's principal work was in the navigation of the Kara Sea and the opening of a sea route between Europe and Siberia. When Baron Nordenskjöld sailed in the *Vega* in 1878 to do the North-East passage he was accompanied by the small steamer *Lena* under the command of Capt. Johannessen. Without the help of a pilot Johannessen took the *Lena* safely through the difficulties of the Lena delta, and ascended the river for more than 1700 miles to Nyuiskaya, eventually returning to Yakutsk. This was the first steamer to reach Siberia by this route. Johannessen returned overland, and the *Lena* is still in service on the river. Capt. Johannessen piloted many other vessels through the Kara Sea to the Yenisei River. In 1883, in the *Nordenskjöld*, he rescued the crew of the Dutch expedition in the *Varna*, crushed in the Kara Sea. In the *Gjoa*, which he afterwards sold to Amundsen for his North-West passage expedition, Johannessen made many successful hunting expeditions to the Far North.

DR. DUCKWORTH gives in the September issue of *Man* an account, with a full catalogue of his writings, of the eminent Italian anthropologist, MAJOR-GEN. RIDOLFO LIVI, whose death on April 12 last was a serious loss to science. Gen. Livi is best known by his great work, "Anthropometria Militare," published in 1896–98, which deals mainly with the question of physical development in relation to fitness for military service. He was also author of a manual of anthropometry of wide scope and originality, and of a treatise on domestic slavery in Italy in medieval times. Gen. Livi died at the age of sixty-three, his degrees in medicine and surgery being taken in 1878, when he entered the Army. He served in the African campaign of 1887–88 as well as in the recent war, holding at the time of his death the rank of major-general, to which he was promoted in 1917.

WE much regret to announce the death on September 27, at fifty-seven years of age, of MR. D. H. NAGEL, Vice-President and Senior Tutor of Trinity College, Oxford.

Notes.

A SPECIAL conference has been called together by the Royal Society to consider the future of the International Catalogue of Scientific Literature. The conference held its first meeting at Burlington House on September 28, Sir Joseph Thomson in the chair. The following is the list of delegates:—Sir David Prain, Sir Arthur Schuster, Mr. J. H. Jeans, Prof. H. E. Armstrong, Dr. F. A. Bather, and Dr. P. C. Mitchell, representing the Royal Society; Prof. M. Knudsen, Denmark; M. A. Lacroix, France; Dr. G. van Rijnberk, Holland; Prof. R. Nasini and Comm.-Ing. E. Mancini, Italy; Dr. H. Nagaoka, Japan; Mr. R. Laache, Norway; Baron Alströmer, Sweden; Dr. H. Escher, Dr. M. Godet, and Dr. H. Field, Switzerland; Dr. R. M. Yerkes, Dr. L. E. Dickson, Mr. L. C. Gunnell, and Dr. S. I. Franz, U.S.A.; Sir Henry Hayden and Dr. S. W. Kemp, India; Sir Thomas Muir, South Africa; Sir Edward Parrott, Queensland; Prof. E. W. Skeats, Victoria; Mr. C. B. Rushton, Western Australia; and Prof. A. Dendy, New Zealand. The delegates were the guests of H.M. Government at a dinner at the Carlton Hotel on September 29.

WE understand that Mr. Reid Moir, during his investigations of the north-east coast of Norfolk, has made an important discovery in the neighbourhood of Cromer. It appears that a flint-workshop site, apparently of Early Chellian Palæolithic age, occurs at this place at an horizon referable to one of the lower members of the Cromer Forest Bed series. The site, though limited in extent, is very rich in humanly fashioned flints, and Mr. Moir hopes in the near future to exhibit and describe the large number of specimens he has collected.

THE MINISTER OF HEALTH has appointed a Committee to investigate and report on the causes of blindness, including defective vision sufficient to impair economic efficiency, and to suggest measures which might be taken for the prevention of blindness. The members of the Committee are:—Mr. G. H. Roberts, M.P. (chairman), Mr. Stephen Walsh, M.P., Mr. N. Bishop Harman, Dr. J. B. Lawford, Mr. G. F. Mowatt, Mrs. Wilton Phipps, Mr. J. H. Parsons (representing the Royal College of Surgeons), Dr. J. Taylor (representing the Royal College of Physicians), Mr. J. C. Bridge (representing the Home Office), Dr. A. Eicholz (representing the Board of Education), Mr. J. S. Nicholson (representing the Ministry of Labour), Mr. W. M. Stone (representing the Scottish Office), Mr. E. D. Macgregor (representing the Ministry of Health), and a representative of the Medical Research

Council (to be appointed later). Dr. R. A. Farrar and Mr. P. N. R. Butcher will act as joint secretaries to the Committee, and any communications should be addressed to them at the Ministry of Health, Whitehall, London, S.W.1.

SIR FREDERICK ANDREWES, professor of pathology in the University of London, will deliver the Harveian oration of the Royal College of Physicians on Monday, October 18, at 4 p.m.

MR. J. D. FRY, lecturer on physics at the University of Bristol, and Mr. A. Hessell Tiltman have been appointed to the scientific staff of the Research Association of British Rubber and Tyre Manufacturers.

THE third annual Streatfeild memorial lecture will be delivered by Mr. J. H. Coste at the City and Guilds Technical College, Leonard Street, E.C.2, on Thursday, October 14, at 4 p.m. The subject will be "The Gases Dissolved in Water." Admission will be free.

Science for September 10 announces that it is proposed to establish in Panama an international institute for research on tropical diseases as a memorial to the late Major-Gen. W. C. Gorgas. Panama has been chosen in view of the fact that Gen. Gorgas's most noteworthy work was accomplished there.

WE learn from the *British Medical Journal* that the Hughlings Jackson lecture of the Section of Neurology will be delivered at the Royal Society of Medicine by Dr. H. Head on October 7 at 8.45 p.m. Dr. Head has chosen as his subject "A New Conception of Aphasia."

THE British Cutlery Research Association has been approved by the Department of Scientific and Industrial Research as complying with the conditions laid down in the Government scheme for the encouragement of industrial research. The secretary of this association is Mr. J. M. Denton, P.O. Box 49, Sheffield.

CERTAIN friends of Mr. W. F. Denning and admirers of his lifelong devotion to astronomy have contributed a sum of about 300*l.* to a fund which has just been established for him. Mr. Denning has been sent 50*l.* to meet his immediate necessities, and the balance remaining in hand has been paid over to Sir Frank Dyson and Col. E. H. Hills in trust for Mr. Denning, with directions to pay him the sum of 50*l.* annually. Should it be necessary, further subscriptions will be raised in order that a payment of this amount may be secured to Mr. Denning as an annuity for life.

THE Cryptogamic Society of Scotland held its first annual gathering since the war on September 21–23 at Perth. Under the leadership of the secretary, the Very Rev. Dr. D. Paul, of Edinburgh, and Mr. Jas. Menzies, of Perth, the society made excursions to Murthly on the first day and to Invermay on the second, where the dominant species found was *Tricholoma saponaceus*; here the dog-stink horn, *Mutinus caninus*, turned up again, having been recorded many years ago, since when it had not been seen; also in the woods, below a fir-tree, the curator of the Perth Museum, Mr. J. Ritchie, was fortunate in finding *Collybia ludius*, Fr., this being a new species recorded for Britain. The last day's excursion was to Methven, where the outstanding species numerically were *Lactareus vellereus* and *Craterellus cornucopoides*.

THE forthcoming general discussion on "The Physics and Chemistry of Colloids and their Bearing on Industrial Questions," which is being arranged jointly by the Faraday Society and the Physical Society of London, has been fixed for Monday, October 25, at the Institution of Mechanical Engineers, Storey's Gate, London, S.W.1. The discussion will be presided over by Sir W. H. Bragg, and it will be introduced by Prof. The Svedberg, of the University of Upsala, who will give a general survey of the subject before discussion is opened in its various branches. Non-members of the above societies desirous of attending the discussion may obtain tickets of admission from Mr. F. S. Spiers, 10 Essex Street, London, W.C.2. The Faraday Society, the Institution of Mechanical Engineers, the Institute of Metals, and probably also the Iron and Steel Institute contemplate holding early in 1921 a joint general discussion on "The Failure of Metals under Internal or Prolonged Stress."

IT is announced that the British Antarctic Expedition, which Mr. John L. Cope has been organising for some time, has left England for its base at Port Stanley, in the Falkland Islands. Other members of the expedition are Capt. Wilkins, Mr. W. T. Bagshawe (geologist), and Mr. M. C. Lester (navigator and surveyor). The *Times* states that from the Falkland Islands the expedition will be taken by a whaling vessel to the Weddell Sea, and there landed on the ice during January. The party hopes to survey hitherto unexplored regions, but no attempt will be made to reach the Pole, the aims of the expedition being purely geographical and biological. At the end of eighteen months or so the party will return to England, by which time a specially built ship and a large aeroplane will be ready for a further expedition, which is expected to be of five years' duration.

A SMALL but interesting exhibition of books, manuscripts, and relics illustrative of the life and work of Gilbert White was held on September 24–25 at the Art Workers' Guildhall, Queen Square, W.C.1. The exhibition concluded the bicentennial celebration of the birth of the Selborne naturalist organised by the Gilbert White Fellowship. A fine series of modern water-colours of Selborne and of Ringmer adorned the walls of the hall. Upon the tables there were laid out for inspection a large number of editions of "The Natural History and Antiquities of Selborne," together with somewhat rare contemporary works upon subjects discussed by Gilbert White. Microscopy also received attention, while living specimens illustrative of the life of the mosquito aroused considerable interest. In an address delivered by Dr. Gilbert White, Bishop of Willochra, North Australia, and great-grandnephew of Gilbert White, reference was made to the life and work of the naturalist as emphasising the value of a study of Nature—a study which opened out a realm of interest and knowledge untouched by changes in human life and environment.

Nature-study for its own sake was comparatively modern; the earliest writers, such as Pliny the Elder and St. Basil, looked towards the marvellous and the utilitarian, while passages by St. Gregory depicting scenery and the beauty of the country were exceptional. Gilbert White inculcated a love of Nature which might be regarded as a revelation of Divine intelligence. With reference to the "Natural History," Dr. White spoke of its many editions, exceeding in number, so it was said, that of any other book excepting the Bible and "The Pilgrim's Progress." Its popularity was continuous and progressive; it illustrated the steady and quiet devotion still being given to the study of Nature.

At the meeting of the Association of Economic Biologists held at Kew on September 24 the subject discussed was that of immunity to fungus diseases in plants. The president, Sir David Prain, was in the chair. Mr. E. S. S. Salmon dealt with the relation of climatic factors, and directed attention to those cases where immunity broke down under certain weather conditions. His observations showed that the wild hop comprises numerous physiological forms with distinctive "constitutional" characters with regard to mildew, ranging from extreme susceptibility to immunity. The immune forms when grown in the greenhouse remained immune; when grown in the open, with warm, sunny weather, immunity is retained; with low temperatures and lack of sunshine there is a temporary loss of immunity. Climatic factors would appear to influence also the degree of immunity of certain wheats to "rust." Mr. F. T. Brooks spoke on the question of inheritance of disease resistance, and dealt chiefly with the work of Biffen and Armstrong on *Puccinia glumarum*. Although susceptibility and immunity behave as a pair of allelomorphic characters segregating in Mendelian fashion, it was pointed out that the "genetic constitution" of "immune" plants is liable to modification within narrow limits by environmental conditions, so that a family rust-free one year may be slightly affected by rust another season. Rust-resistance in wheat behaves as a simple Mendelian recessive, but there is evidence that resistance to mildew, on the other hand, acts as a dominant character. A brief analysis of the meanings attached to the use of the word "immunity" in plant pathology was made. A *résumé* of a paper by Mr. A. Howard on the importance of soil factors in bringing about epidemics was read. In the discussion Dr. N. L. Britten and Dr. E. J. Butler spoke of conditions in America and India respectively. Members were entertained to tea by the president, and afterwards visited the Botanic Gardens.

Among the Turkana tribe in the Sudan, according to a writer in *Sudan Notes and Records* (vol. iii., No. 3), a curious system of recording prowess in war is in force. When a man has killed an enemy a number of incisions are made on the victor's body to record the fact, those on the right side indicating that the victim was a man, those on the left a woman. A hook is inserted in the skin, a portion of which is raised, in which a cut about half an inch long is made. Fat and clay are then rubbed in until the man can endure no further pain. The endurance of this people may be measured by the fact that many of them are covered from waist to shoulder with such marks. It is only on the first occasion when an enemy has been slain that these marks are made, later deeds of valour being left unrecorded.

The question of the origins of the Babylonian and Assyrian scripts has been again raised by M. G. C. Teloni in an article entitled "L'écriture babylonienne et assyrienne" in *Scientia* (vol. xxviii.) for 1920. After a full review of various speculations, M. Teloni thus summarises his conclusions: "Les théories exposées dans les pages précédentes, et qui sont celles qui prévalent aujourd'hui au sujet de l'origine de l'écriture babylonienne-assyrienne, se rapportent principalement aux monuments d'épigraphie sumériens et sémitiques du bassin de l'Euphrate et du Tigre. Il n'a été, jusqu'à aujourd'hui, examiné au service de cette question que bien peu d'autres inscriptions appartenant au système cunéiforme. On peut attendre beaucoup d'un examen approfondi des signes élamites (anciens et modernes), vannico-assyriens et persans; en particulier, le syllabaire élamite, rival du babylonien au point de vue d'antiquité, et le syllabaire persan cunéiforme, dont la dérivation de Babylone apparaît de jour en jour plus contestable, promettant de faire la lumière sur l'histoire générale de l'écriture cunéiforme."

An account of a remarkable sculpture recently found on a capstone of a dolmen at Déhus, in the parish of the Vale, Guernsey, is given in the September issue of *Man* by Lt.-Col. T. W. M. de Guérin. The figures consist of a face and two hands, with the outlines of a portion of both arms. Below these is a mark possibly representing the girdle so often found on French statue-menhirs. Anthropomorphic figures very similar to that of Déhus are found in France sculptured on the props of the Late Neolithic dolmens of the valleys of the Seine and Oise, and also of Collorgues, in the Department of Gard, while very similar figures have been noticed in the grottoes of Le Petit Morin, Marne, which are believed to date from the Æneolithic period. It is now certain that the cult of the divinity represented by the figures on the Déhus dolmen and the statue-menhir of the Castel lasted from early times in Guernsey, for the second statue-menhir, now standing as a gate-post at the Church of St. Martin, is of much later date than that of Castel. It is one of the largest and best-preserved statue-menhirs in existence, far surpassing in style and execution those of south-eastern France.

Sir James Frazer in a letter to the *Times* of September 22 gives a further report of the progress of the Mackie Expedition to East Africa conducted by the Rev. John Roscoe. The expedition has been at work among the Banyoro of Lake Albert in the Uganda Protectorate. This tribe or nation is composed of two ethnical strata, the Bahuma, a ruling caste of herdsmen of Hamitic stock, and the Bairu, a subject agricultural peasantry of Bantu stock. The whole life of the Bahuma king is devoted to ceremonial observances of a priestly or magical character for the good of the people, their cattle, and their land. Consequently he is seldom, or never, able to quit the enclosure in which he resides. An interesting custom once was the annual raising of an agricultural peasant to the kingly rank, representing the real king's dead father. After a period of about a week, during which he lived at the tomb of the dead king, treating the royal widows as his own wives and blessing the real king and the country in the name of the dead man, he was taken to the back of the tomb and strangled.

THE report of the director of the New York Aquarium, reprinted from the twenty-fourth Annual Report of the New York Zoological Society, is chiefly concerned with the unsatisfactory condition of the building. Mr. Townsend has our sympathy, but he arouses our interest more by two brief paragraphs. One of these states that the large crayfish of the Columbia River was safely transported alive from California to New York in wrappings of damp paper. The other ascribes the total disappearance of the sea-horse (*Hippocampus hudsonius*) from local waters to the unusually severe winter of 1918. The report describes and illustrates ingenious gravity filters and strainers and air-compressors used when sending fishes by train or ship.

THE Davidson collection of recent Brachiopoda in the British Museum has hitherto been regarded as taking the lead, but, at all events in point of numbers, it is now outclassed by the collection in the United States National Museum, of which Dr. W. H. Dall has lately published an "Annotated List" (Proc. U.S. Nat. Mus., vol. lvii., pp. 261–377). The latter contains more than six thousand specimens, representing 181 different forms, of which thirty-three are here introduced as new. These fall into some fifty genera. The ordinary zoologist will regret to see some apparently inevitable changes in well-known names: thus *Lingula anatina* becomes *L. unguis*, Linn.; *Terebratulina caput-serpentis* having been based on a fossil of different structure, the name *T. retusa*, Linn., must be adopted for the recent species; and Liothyrina gives place to Gryphus. Among interesting facts of distribution are noted the discovery off the Californian coast of two Japanese species, *Terebratulina crossei* and *T. kiiensis*.

AN interesting discussion arises in Dr. N. Annandale's "Observations on 'Physa Prinsepii,' Sowerby" (Rec. Geol. Surv. India, vol. li., p. 50, 1920), as to the cause of extinction of this giant planorbid some time after the intertrappean (late Cretaceous) epoch in India. The genus Bullinus (formerly Bulinus, Adanson), to which this shell is now transferred, survives in Africa, the Malay Archipelago, and Australia, in conditions apparently less favourable than those surrounding the fossil forms in India. Dr. Annandale suggests that exceedingly congenial surroundings led to an overgrowth of the mollusc (which attains 76 mm. in height), and that it was unable to survive any reduction of the luxury that it had long enjoyed.

IN connection with blood-transfusion experiments during the war it was found that severe reactions sometimes followed the intermingling of the blood of certain individuals. Previous work, in which human sera were classified into four groups according to their iso-agglutinating actions, was therefore very useful in determining between which individuals transfusion could safely take place. In a short paper by Mr. J. R. Learmonth (*Journ. Genetics*, vol. v., No. 2) the author has studied the blood reactions of a number of families, and concludes that the iso-agglutinins are inherited, two pairs of Mendelian factors being concerned. But it appears from observations by Bond that iso-agglutinins which are absent from the serum of a given individual may appear after the patient has reacted to a systemic infection. It has been suggested that these serum reactions might be used as a legal proof of illegitimacy.

IN two papers in the *Journal of Genetics* (vol. x., No. 2) Mr. F. L. Engledow deals with the inheritance of the various forms of lateral florets and rachilla in barley and length of glume and grain in a hybrid wheat. A bristly rachilla is dominant to smooth, and it is suggested that the same factor governs the type of hair in other parts of the flower, and may also be concerned with the development of the root-hairs, which would affect the yield. The barleys differ in the form of their lateral florets, six-row and two-row barley differing by a single factor, the heterozygotes being intermediate with some fluctuations in expression. These fluctuations are found to be environmental in origin, and not a case of mosaic inheritance. In a cross between Polish and Kubanka wheat long and short glumes behave as a pair of characters, the F_1 being intermediate. But the interesting result is obtained that in the extracted "longs" the length of glume is reduced by nearly 25 per cent. in comparison with the long-glumed parent, and this shift or modification remains true in the F_3. Similar results were obtained with grain-length, the long grain being reduced by 12·5 per cent. in the extracted F_2's. These two pairs of characters are inseparable in inheritance, length of grain unexpectedly behaving as a maternal character, although it must be partly determined by the character of the endosperm. Possible explanations of these results are discussed.

SOME very fine views of glaciers in Canada occur in Dr. C. D. Walcott's "Geological Exploration of the Canadian Rockies: Field Season of 1919," extracted as a pamphlet from "Explorations and Field-Work of the Smithsonian Institution in 1919." The photograph of the environs of the Mount Lyell Glacier makes a folding plate nearly 3 ft. long, and includes the superb stratigraphical sections of the Mount Forbes and Mons Peak region, where Carboniferous rocks appear on the crests, succeeded downwards by Devonian, Ordovician, and Upper Cambrian strata.

DR. C. D. WALCOTT, in the Middle Cambrian Burgess Shale of British Columbia, has secured a field of remarkable palæontological richness. He remarks (Smithsonian Miscell. Coll., vol. lxvii., No. 6, 1920) that the sponges from this series comprise nearly all the siliceous sponges known to him from the Cambrian strata of America. He mentions the few other known examples described by Matthew, Bornemann, and others, and now adds several new genera and species of monactinellid, hexactinellid, octactinellid, and heteractinellid types. Chancelloria, of which the general form is preserved in spite of the absence of a strong spicular skeleton, upholds Hinde's Heteractinellida as a distinct sub-order. The form of the spicules, with four to seven horizontal rays and one vertical axial ray, is not tetractinellid, while their grouping is not that of the hexactinellid mesh. The previously known imperfect specimens of this sub-order are of Carboniferous age. The spicules in the Burgess Shale are usually preserved as pyrite, like those of the British Protospongia, the glories of which are now much diminished by its rivals.

TEMPERATURES and humidities in the upper-air conditions favourable for thunderstorm development and temperatures over land and sea have been discussed by Capt. C. K. M. Douglas. The results are published as Professional Notes No. 8 by the Meteorological Office. The flight observations were made in the north of France during 1918 in the preparation of reports and forecasts for military purposes. The most marked feature of the observations was the number of instances of an unstable condition above 8000 ft. Every thunderstorm is said to have been associated with a shallow depression or secondary, and many with the arrival of cooler surface-air. Up to a level of 10,000 ft., and possibly above, the higher the humidity the greater the chance of thunderstorms, which are not likely to develop unless there is at least one fairly damp layer as low as 6000 ft. Thunderstorms in our latitudes are not usually severe if the base of the thunder-clouds is above 8000 ft.; the cloud-base is stated to be, as a rule, at about 5000 ft. or 6000 ft. in hot weather, and lower in cool weather. The height of thunder-clouds is said to be very great, the rounded tops attaining 20,000 ft. and the false cirrus 30,000 ft. in hot weather, and 15,000 ft. and 20,000 ft. respectively in cool weather. Thunderstorms are divided into three classes: (A) those due mainly to heated surface-air in fine, sunny weather; (B) those associated with powerful upper currents from south-west, the surface-wind being light and variable or southeasterly; and (C) those associated with very low upper-air temperatures in the south-westerly or north-westerly currents of cyclonic depressions. Detailed observations and weather-maps are given of each class. The whole discussion is full of valuable suggestions which will aid alike the weather forecaster and the aeronaut.

IN the *Bulletin de la Société d'Encouragement pour l'Industrie Nationale* (May–June, 1920) will be found the second part of the experimental study of the quenching of carbon steels by MM. Portevin and Garvin. This study is mainly concerned with the conditions of formation of troostite and martensite. By means of cooling curves the authors claim to have established that the formation of troostite corresponds to a rapid transformation at about 650° C., while that of martensite is due to a relatively slow transformation at a temperature which is generally below about 300° C. The former is rendered evident by a clear break in the curve, the latter merely by a gradual change in direction. It was found possible by choosing a certain rate of cooling to prepare specimens in which both these changes occurred and where the curves showed both types of change. The authors confirm the generally held view that troostite represents the chemically stable mixture of iron carbide and α-iron in a fine state of division, but their results do not throw any fresh light on the constitution of martensite.

A VERY convenient new showroom is being opened by the Cambridge and Paul Instrument Co., Ltd., at the commodious head office into which the firm has just moved at 45 Grosvenor Place, S.W.1. As a nucleus of the fine assemblage of scientific apparatus which is being brought together there, the collection of instruments shown by the company at the Engineering Exhibition at Olympia has been provided with a permanent home. This relates more particularly to industrial apparatus, and one of the most interesting items is the firm's new CO_2 recorder, which is entirely electrical in its principle. It depends for its action on resistance measurements revealing the difference in the rates of cooling of two platinum helices, one exposed to air saturated with water-vapour, and the other to the flue-gases to be tested. The indicating instrument is arranged so as to read direct in percentage of CO_2, and can be at a considerable distance from the gas-chambers. Continuously recording apparatus can be used, or one indicator can be arranged to be plugged on to any one of a number of CO_2 meters. A variety of patterns of both resistance and thermo-electric thermometers and pyrometers are included in the collection, as well as temperature measuring apparatus on other principles, pressure-gauges, measuring microscopes, fuel calorimeters, and electrical testing apparatus.

AN interesting report of tests on a 1500-kilowatt Ljungström steam turbine conducted by Capt. H. Riall Sankey appears in *Engineering* for September 10. The turbine had been in regular service for fifteen months at the date of the test in the works of Messrs. Marshall, Sons, and Co., Ltd., Gainsborough, and was constructed by the Brush Electrical Engineering Co., Ltd., at Loughborough. No overhaul of the turbine or any special preparation was made for the trials. The principal result, corrected to the guarantee figures of 190 lb. per sq. in. stop-valve pressure, 634° F. stop-valve temperature, and 28·75 in. vacuum at the turbine exhaust, was 11·95 to 12·00 lb. of steam per kilowatt-hour, as measured at the switchboard. The result is slightly below the original guarantee, and indicates that there can have been no serious wear of the blading during the period of service of the turbine. The heat supplied per minute per kilowatt ranged from 258·0 to 257·0 thermal units, and the overall efficiency ratio varied from 68·0 to 68·4 per cent.

THE steaming trials of the armoured cruiser H.M.S. *Raleigh* have just been completed on the Clyde, and form the subject of an article in

Engineering for September 24. The cruiser was built by Messrs. William Beardmore and Co., Ltd., from designs prepared in 1915. The leading consideration was suitability for ocean work in any part of the world, so that a large radius of action was necessary. Her overall length is 605 ft., beam 65 ft., and draught 17 ft. 3 in., with a displacement of 9700 tons. The speed of 30 knots at load draught required a shaft-h.p. of 60,000; she carries 1600 tons of oil-fuel and 800 tons of coal. During construction it was decided to increase the power to 70,000 shaft-h.p. Actual trials have been carried out at powers ranging from 3000 to 71,350 shaft-h.p., and at full power a speed of 31 knots was attained. A remarkable feature of the machinery performance (geared turbines) was the fact that at 35,000 shaft-h.p. a speed of 28 knots was measured. The machinery ran remarkably well and the noise of the gearing was not obtrusive.

WE have received from the firm of Mr. Charles Baker, of High Holborn, a classified list of his second-hand scientific instruments. The catalogue is divided into twelve sections, ten of which are devoted to physical and other appliances and instruments, *e.g.* the first contains particulars of apparatus and materials for microscopic work; the third, instruments used by astronomers; and the tenth is devoted to photographic apparatus. Section xi. contains a list of second-hand scientific works, including a number of bound volumes of periodicals which are for sale; while section xii. is a list of instruments which the firm is desirous of purchasing.

SIR J. A. EWING and Sir Joseph Larmor are editing, for publication by the Cambridge University Press in the spring of next year, the scientific papers of the late Prof. Bertram Hopkinson, of whom the volume will contain a memoir. The Cambridge University Press promise for the end of the present year "The Origin of Man and of His Superstitions," by Carveth Read. Portions of the work have appeared in the *British Journal of Psychology*, but they have been extended and largely rewritten for this first appearance in book form.

THE UNIVERSITY OF LONDON PRESS, LTD., announce a book by Dr. E. E. Slosson entitled "Creative Chemistry," the aim of which is to show how indigo and other coal-tar colours are made, and to arouse the interest of its readers in the practical application of modern science and so induce them to give further attention to the subject. Another book to be issued by the same publishers is "The Psychology of the Six Great Periods of Human Life," by Benchara Branford. It will be published in The New Humanist Series.

MR. F. EDWARDS, 83 High Street, Marylebone, has just circulated a finely illustrated Catalogue (No. 405) of Rare and Beautiful Books which is worthy of perusal. Among the six hundred odd works offered for sale we notice a first edition of Gerarde's "Herball," two black-letter editions of Hakluyt's "Principal Navigations, etc.," and a number of scarce gardening books.

Our Astronomical Column.

EPHEMERIS OF PALLAS.—Now that the Nautical Almanac no longer gives the places of the four bright asteroids, an ephemeris of Pallas may be of use. It is from Marseilles Circular No. 389, and is for Greenwich midnight. Perturbations were not allowed for, but the places are corrected approximately by observations during August. Opposition takes place on October 25, when the magnitude is 7·8, but the beginning of October is more favourable for observation owing to the rapid motion southward.

	R.A. h. m. s.	S. Decl. ° ′		R.A. h. m. s.	S. Decl. ° ′
Sept. 29	2 16 24	13 51	Oct. 19	2 3 18	19 33
Oct. 9	2 10 42	16 49	29	1 55 18	21 45

TEMPEL'S PERIODIC COMET.—The Japanese *Astronomical Herald* for June confirms the conjecture that the R.A. of the above comet when detected by Mr. Kudara on May 25 was 22h. 55m. 7s., not 20h. as telegraphed. This is implied in its statement that the time of perihelion passage deduced from the observation was 1920 June 10. It is seldom that an error in a single digit of a message has such serious consequences, which were the loss of two months' observation of the comet in Europe and America. Many observers searched for it, but the error of 30° in the place prevented them from finding it.

ECLIPSE OBSERVATIONS AT MONTE VIDEO.—The National Meteorological Institute of Uruguay has published an attractive volume, illustrated with numerous photographs, dealing with the observations made during the eclipses of December 3, 1918, and May 29, 1919, which were respectively annular and partial there. The co-ordinates of the Central Observatory are 3h. 44m. 51s. W. Greenwich, 34° 54′ 33″ S. The observed contacts, and comparison with those calculated from "Conn. des Temps" data, are as follows:

G.M.T. d. h. m. s.	Phase	Earlier than calculated time s.	Notes
Dec. 3 1 27 3·07	First contact	11·58	
3 12 24·34	Second ,,	16·78	
3 15 29·95	Third ,,	40·33	Uncertain, very cloudy
May 28 22 57 8·21	First ,,	10·00	
29 0 38 30·05	Second ,,	8·05	

On December 3 clouds prevented observation of Baily's Beads, stars, shadow-bands, etc. The thermometer fell from 20·4° C. before first contact to a minimum of 17·9° C. twenty minutes after mid-eclipse. The other meteorological and magnetic data are carefully recorded, but show no obvious variation due to the eclipses. But on each occasion there was a very distinct improvement in the clearness with which wireless signals from distant stations were received during eclipse—a phenomenon which has been abundantly verified elsewhere.

On December 3 an interesting record of the variation in the general illumination was obtained by exposing slips of sensitised paper to the sky for 1½ minutes at uniform intervals. The result shows a fairly smooth curve, the irregularities being due to clouds. In view of the fact that there will be an annular eclipse of the sun in Scotland next April, many useful hints for observation of the accompanying phenomena may be derived from this volume.

Fossils and Life.*

By F. A. BATHER, M.A., D.Sc., F.R.S.

I PROPOSE to consider the relations of palæontology to the other natural sciences, especially the biological; to discuss its particular contribution to biological thought; and to inquire whether its facts justify certain hypotheses frequently put forward in its name. If I subject those attractive speculations to cold analysis, it is from no want of admiration, or even sympathy, for in younger days I too have sported with Vitalism in the shade and been caught in the tangles of Transcendental hair.

The Differentia of Palaeontology.

Palæontology is often regarded as nothing more than the botany and zoology of the past. True, the general absence of any soft tissues and the obscured or fragmentary condition of those harder parts which alone are preserved make the studies of the palæontologist more difficult, and drive him to special methods. But the result is less complete; in short, an inferior and unattractive branch of biology. Let us relegate it to Section C!

Certainly the relation of palæontology to geology is obvious. It is a part of that general history of the earth which is geology. To the scientific interpreter of earth-history the importance of fossils lies, first, in their value as date-markers, and, secondly, in the light which they cast on barriers and currents, on seasonal and climatic variation. Conversely, the history of life has itself been influenced by geologic change. But all this is just as true of the present inhabitants of the globe as it is of their predecessors. It does not give the *differentia* of palæontology.

That which above all distinguishes palæontology, the study of ancient creatures, from neontology, the study of creatures now living, that which raises it above the mere description of extinct assemblages of life-forms, is the concept of Time. The bearing of this obvious statement will appear from one or two simple illustrations.

Effect of the Time-concept on Principles of Classification.

Adopting the well-tried metaphor, let us imagine the tree of life buried except for its topmost twigs beneath a sand-dune. The neontologist sees only the unburied twigs. He recognises certain rough groupings, and constructs a classification accordingly. From various hints he may shrewdly infer that some twigs come from one branch, some from another, but the relations of the branches to the main stem are matters of speculation, and when branches have become so interlaced that their twigs have long been subjected to the same external influences he will probably be led to incorrect conclusions. The palæontologist then comes, shovels away the sand, and by degrees exposes the true relations of branches and twigs. His work is not yet accomplished, and probably he never will reveal the root and lower part of the tree, but already he has corrected many natural, if not inevitable, errors of the neontologist.

* * *

Effect of the Time-concept on Ideas of Relationship.

Etienne Geoffroy-Saint Hilaire was the first to compare the embryonic stages of certain animals with the adult stages of animals considered inferior. The idea grew until it was crystallised by the poetic imagination of Haeckel in his fundamental law of the reproduction of life, namely, that every creature tends in the course of its individual development to pass through stages similar to those passed through in the history of its race. This principle is of value if applied with the necessary safeguards. If it was ever brought into disrepute, it was owing to the reckless enthusiasm of some embryologists who unwarrantably extended the statement to all shapes and structures observed in the developing animal, such as those evoked by special conditions of larval existence, sometimes forgetting that every conceivable ancestor must at least have been capable of earning its own livelihood. Or, again, they compared the early stages of an individual with the adult structure of its contemporaries instead of with that of its predecessors in time.

Such errors were beautifully illustrated in those phylogenetic trees which, in the 'eighties, every dissector of a new or striking animal thought it his duty to plant at the end of his paper. The trees have withered because they were not rooted in the past.

A similar mistake was made by the palæontologist who, happening on a new fossil, blazoned it forth as a link between groups previously unconnected—and in too many cases unconnected still. This action, natural and even justifiable under the old purely descriptive system, became fallacious when descent was taken as the basis.

The so-called "generalised types," combining the features of two or three classes, and the "annectant types," supposed to unite lines of descent which had diverged many ages before, are conceptions still with us. But they are hopelessly inconsistent with any genealogy either proved or probable.

As bold suggestions calling for subsequent proof these speculations had their value, and they may be forgiven in the neontologist, if not in the palæontologist, if we regard them as erratic pioneer tracks blazed through a tangled forest. As our acquaintance with fossils enlarged, the general direction became clearer and certain paths were seen to be impossible. In 1881, addressing this Association at York, Huxley could say: "Fifty years hence, whoever undertakes to record the progress of palæontology will note the present time as the epoch in which the law of succession of the forms of the higher animals was determined by the observation of palæontological facts. He will point out that, just as Steno and as Cuvier were enabled from their knowledge of the empirical laws of co-existence of the parts of animals to conclude from a part to a whole, so the knowledge of the law of succession of forms empowered their successors to conclude, from one or two terms of such a succession, to the whole series, and thus to divine the existence of forms of life, of which, perhaps, no trace remains, at epochs of inconceivable remoteness in the past."

Descent not a Corollary of Succession.

Note that Huxley spoke of succession, not of descent. Succession undoubtedly was recognised, but the relation between the terms of the succession was little understood, and there was no proof of descent. Let us suppose all written records to be swept away and an attempt made to reconstruct English history from coins. We could set out our monarchs in true order, and we might suspect that the throne was hereditary; but if on that assumption we were to

* Opening address of the President of Section C (Geology), delivered at the Cardiff Meeting of the British Association on August 24. Greatly abridged. Only the larger excisions are indicated by asterisks.

make James I. the son of Elizabeth—— Well, but that's just what palæontologists are constantly doing. The famous diagram of the evolution of the horse which Huxley used has had to be corrected in the light of fuller evidence. Palæotherium, which Huxley regarded as a direct ancestor of the horse, is now held to be only a collateral, as the last of the Tudors were collateral ancestors of the Stuarts. The later Anchitherium must be eliminated from the true line as a side-branch—a Young Pretender. Sometimes an apparent succession is due to immigration of a distant relative from some other region—"the glorious House of Hanover and Protestant Succession." It was, you will remember, by such migrations that Cuvier explained the renewal of life when a previous fauna had become extinct. He admitted succession, but not descent. If he rejected special creation, he did not accept evolution.

Descent, then, is not a corollary of succession; or, to broaden the statement, history is not the same as evolution. History is a succession of events. Evolution means that each event has sprung from the preceding one. Not that the preceding event was the active cause of its successor, but that it was a necessary condition of it. For the evolutionary biologist a species contains in itself and its environment the possibility of producing its successor. The words "its environment" are necessary, because a living organism cannot be conceived apart from its environment. They are important because they exclude from the idea of organic evolution the hypothesis that all subsequent forms were implicit in the primordial protoplast alone, and were manifested either through a series of degradations, as when thorium by successive disintegrations transmutes itself to lead, or through fresh developments due to the successive loss of inhibiting factors. I say "a species contains the possibility" rather than "the potentiality," because we cannot start by assuming any kind of innate power.

Huxley, then, forty years ago, claimed that palæontologists had proved an orderly succession. To-day we claim to have proved evolution by descent. But how do we prove it? The neontologist, for all his experimental breeding, has scarcely demonstrated the transmutation of a species. The palæontologist cannot assist at even a single birth. The evidence remains circumstantial.

Recapitulation as Proof of Descent.

Circumstantial evidence is convincing only if inexplicable on any other admissible theory. Such evidence is, I believe, afforded by palæontological instances of Haeckel's law, *i.e.* the recapitulation by an individual during its growth of stages attained by adults in the previous history of the race. You all know how this has been applied to the Ammonites; but any creature with a shell or skeleton that grows by successive additions and retains the earlier stages unaltered can be studied by this method. If we take a chronological series of apparently related species or mutations, a^1, a^2, a^3, a^4, and if in a^4 we find that the growth-stage immediately preceding the adult resembles the adult a^3, and that the next preceding stage resembles a^2, and so on; if this applies *mutatis mutandis* to the other species of the series; and if, further, the old age of each species foreshadows the adult character of its successor, then we are entitled to infer that the relation between the species is one of descent. Mistakes are liable to occur for various reasons, which we are learning to guard against. For example, the perennial desire of youth to attain a semblance of maturity leads often to the omission of some steps in the orderly process. But this and other eccentricities affect the earlier rather than the later stages, so that it is always possible to identify the immediate ancestor, if it can be found. An admirable example of the successful search for a father is provided by R. G. Carruthers in his paper on the evolution of *Zaphrentis delanouei*. Surely when we get a clear case of this kind we are entitled to use the word "proof," and to say that we have not merely observed the succession, but have proved the filiation.

* * *

The "Line-upon-Line" Method of Palaeontology.

You will have observed that the precise methods of the modern palæontologist, on which this proof is based, are very different from the slap-dash conclusions of forty years ago. The discovery of Archæopteryx, for instance, was thought to prove the evolution of birds from reptiles. No doubt it rendered that conclusion extremely probable, especially if the major premise—that evolution *was* the method of Nature—were assumed. But the fact of evolution is precisely what men were then trying to prove. These jumpings from class to class or from era to era by aid of a few isolated stepping-stones were what Bacon calls anticipations, "hasty and premature," but "very effective, because as they are collected from a few instances, and mostly from those which are of familiar occurrence, they immediately dazzle the intellect and fill the imagination" ("Novum Organon," i., 28). No secure step was taken until the modern palæontologist began to affiliate mutation with mutation and species with species, working his way back, literally inch by inch, through a single small group of strata. Only thus could he base on the laboriously collected facts a single true interpretation; and to those who preferred the broad path of generality his interpretations seemed, as Bacon says they always "must seem, harsh and discordant—almost like mysteries of faith."

I have long believed that the only safe mode of advance in palæontology is that which Bacon counselled, namely, "uniformly and step by step." Was this not, indeed, the principle that guided Linnæus himself? Not until we have linked species into lineages can we group them into genera; not until we have unravelled the strands by which genus is connected with genus can we draw the limits of families; nor until that has been accomplished can we see how the lines of descent diverge or converge, so as to warrant the establishment of orders. Thus by degrees we reject the old slippery stepping-stones that so often toppled us into the stream, and foot by foot we build a secure bridge over the waters of ignorance.

The work is slow, for the material is not always to hand, but as we build we learn fresh principles and test our current hypotheses. To some of these I would now direct your attention.

Continuity in Development.

Let us look first at this question of continuity. Does an evolving line change by discontinuous steps (saltations), as when a man mounts a ladder; or does it change continuously, as when a wheel rolls uphill? The mere question of fact is extraordinarily difficult to determine. Considering the gaps in the geological record, one would have expected palæontologists to be the promulgators of the hypothesis of discontinuity. They are its chief opponents.

Again I must leave the facts and their interpretation, merely reminding you of such cases as the heart-urchins or Micrasters of the Chalk. Here, where we have a fairly continuous succession of many hundred feet of similar rock, we do find a slow and gradual change, such that no clean line can be drawn between one form and its successor.

Whatever may be the explanation, the facts do seem to warrant the statement that evolutionary change can be, and often is, continuous. I propose to speak of it as "transition."

* * *

The Direction of Change.

Those who attempt to classify species now living frequently find that they may be arranged in a continuous series, in which each species differs from its neighbours by a little less or a little more; they find that the series corresponds with the geographical distribution of the species; and they find sometimes that the change affects particular genera or families or orders, and not similar assemblages subjected, apparently, to the same conditions. They infer from this that the series represents a genetic relation, that each successive species is the descendant of its preceding neighbour; and in some cases this inference is warranted by the evidence of recapitulation—a fact which further indicates that the change arises by addition or subtraction at the end of the individual life-cycle. For this appearance of successive differences we may here use the brief and non-committal term "seriation."

The comparison of the seriation of living species and genera to the seriation of a succession of extinct forms as revealed by fossils was first made by Cope, who in 1866 held the zoological regions of to-day to be related to one another "as the different subdivisions of a geologic period in time." This comparison is of great importance. Had we the seriations of living forms alone, we might often be in doubt as to the meaning of the phenomenon. In the first place, we might ascribe it purely to climatic and similar environmental influence, and we should be unable to prove genetic filiation between the species. Even if descent were assumed, we should not know which end of the series was ancestral, or even whether the starting-point might not be near the middle. But when the palæontologist can show the same, or even analogous, seriation in a time-succession, he indicates to the neontologist the solution of his problem.

Restricting ourselves to series in which descent may be considered as proved or highly probable, we find then a definite seriation—not merely transition, but transition in orderly sequence such as can be represented by a graphic curve of simple form. If there are gaps in the series as known to us, we can safely predict their discovery; and we can prolong the curve backwards or forwards so as to reveal the nature of ancestors or descendants.

Orthogenesis: Determinate Variation.

The regular, straightforward character of such seriation led Eimer to coin the term "orthogenesis" for the phenomenon as a whole. If this term be taken as purely descriptive, it serves well enough to denote certain facts. But orthogenesis, in the minds of most people, connotes the idea of necessity, of determinate variation, and of predetermined course. Now, just as you may have succession without evolution, so you may have seriation without determination or predetermination. Let us be clear as to the meaning of these terms. Variation is said to be determinate or "definite" when all the offspring vary in the same direction. All the changes are of the same kind, though they may differ in degree. For instance, all may consist in some addition, as a thickening of skeletal structures, an outgrowth of spines or horns; or all may consist in some loss, as the smaller size of outer digits, the diminution of tubercles, or the disappearance of feathers. A succession of such determinate variations for several generations produces seriation; and when the seriation is in a *plus* direction it is called progressive, when in a *minus* direction retrogressive. Now, it is clear that if a single individual or generation produces offspring with, say, *plus* variations differing in degree, then the new generation will display seriation. Instances of this are well known. You may draw from them what inferences you please, but you cannot actually prove that there is progression. Breeding experiments under natural conditions for a long series of years would be required for such proof. Here again the palæontologist can point to the records of the process throughout centuries or millennia, and can show that there have been undoubted progression and retrogression. I do not mean to assert that the examples of progressive and retrogressive series found among fossils are necessarily due to the seriation of determinate variations, but the instances of determinate variation known among the creatures now living show the palæontologist a method that may have helped to produce his series. Once more the observations of neontologist and palæontologist are mutually complementary.

Predetermination.

So much for determination; now for predetermination. This is a far more difficult problem, discussed when the fallen angels

> reasoned high
> Of providence, foreknowledge, will, and fate,
> Fixed fate, free will, foreknowledge absolute,
> And found no end in wandering mazes lost,

and it is likely to be discussed so long as a reasoning mind persists. For all that, it is a problem on which many palæontologists seem to have made up their minds. They agree (perhaps unwittingly) with Aristotle that "Nature produces those things which, being continuously moved by a certain principle inherent in themselves, arrive at a certain end." In other words, a race once started on a certain course will persist in that course, no matter how conditions may change, no matter how hurtful to the individual its own changes may be, progressive or retrogressive, uphill and downhill, straight as a Roman road, it will go on to that appointed end. Nor is it only palæontologists who think thus. Prof. Duerden has recently written: "The Nägelian idea that evolutionary changes have taken place as a result of some internal vitalistic force, acting altogether independently of external influences, and proceeding along definite lines, irrespective of adaptive considerations, seems to be gaining ground at the present time among biologists."

The idea is a taking one, but is it really warranted by the facts at our disposal? We have seen, I repeat, that succession does not imply evolution, and (granting evolution) I have claimed that seriation can occur without determinate variation and without predetermination. It is easy to see this in the case of inanimate objects subjected to a controlling force. The fossil-collector who passes his material through a series of sieves, picking out first the larger shells, then the smaller, and finally the microscopic Foraminifera, induces a seriation in size by an action which may be compared to the selective action of successive environments. There is, in this case, predetermination imposed by an external mind, but there is no determinate variation. You may see in the museum at Leicester a series beginning with the *via strata* of the Roman occupants of Britain, and passing through all stages of the tramway up to the engineered modern railroad. The unity and apparent inevitability of the series conjure up the vision of a world-mind consciously working to a foreseen end.

An occasional experiment along some other line has not been enough to obscure the general trend; indeed, the speedy scrapping of such failures only emphasises the idea of a determined plan. But closer consideration shows that the course of the development was guided simply by the laws of mechanics and economics and by the history of discovery in other branches of science. That alone was the nature of the determination, and predetermination there was none. From these instances we see that selection can, indeed must, produce just that evolution along definite lines which is the supposed feature of orthogenesis.

The arguments for orthogenesis are reduced to two: first, the difficulty of accounting for the incipient stages of new structures before they achieve selective value; and, secondly, the supposed cases of non-adaptive, or even—as one may term it—counter-adaptive, growth.

The earliest discernible stage of an entirely new character in an adaptive direction is called by H. F. Osborn a "rectigradation" (1907), and the term implies that the character will proceed to develop in a definite direction. Osborn gives as instances the first folding of the enamel in the teeth of the ancestral horses and the first slight elevation on the skull of the older Titanotheres, foreshadowing the large nose-horns of those strange Tertiary mammals. He contrasts rectigradations with the changes in shape and proportion of some pre-existing structure, and calls the latter "allometrons." Further, he claims that some predetermining law or similarity of potential governs the appearance of rectigradations, because they arise independently on the same part of the skull in different lineages at different periods of geological time.

Osborn maintains, then, that rectigradations are a result of the principle of determination, but this does not seem necessary. In the first place, the precise distinction between an allometron and a rectigradation fades away on closer scrutiny. When the rudiment of a cusp or a horn changes its form, the change is an allometron; the first swelling is a rectigradation. But both of these are changes in the form of a pre-existing structure; there is no fundamental difference between a bone with an equable curve and one with a slight irregularity of surface. Why may not the original modification be due to the same cause as the succeeding ones? The development of a horn in mammalia is probably a response to some rubbing or butting action which produces changes first in the hair and epidermis. One requires stronger evidence than has yet been adduced to suppose that in this case form precedes function. As Jaekel has insisted, skeletal formation follows the changes in the softer tissues as they respond to strains and stresses. In the evolution of the Echinoid skeleton any new structures that appear, such as auricles for the attachment of jaw-muscles and notches for the reception of external gills, have at their inception all the character of rectigradations, but it can scarcely be doubted that they followed the growth of their correlated soft parts, and that these latter were already subject to natural selection. But we may go further; in vertebrates, as in Echinoderms, the bony substance is interpenetrated with living matter, which renders it directly responsive to every mechanical force, and modifies it as required by deposition or resorption, so that the skeleton tends continually to a correlation of all its parts and an adaptation to outer needs.

The fact that similar structures are developed in the same positions in different stocks at different periods of time is paralleled in probably all classes of animals; Ammonites, Brachiopods, Polyzoa, Crinoids, and Sea-urchins present familiar instances. But do we want to make any mystery of it? The words "predisposition," "predetermining law," "similarity of potential," "inhibited potentiality," and "periodicity" all tend to obscure the simple statement that like causes acting on like material produce like effects. When other causes operate the result is different. Certainly such facts afford no evidence of predetermination in the sense that the development must take place willy-nilly. Quite the contrary; they suggest that it takes place only under the influence of the necessary causes.

The resemblance of the cuttle-fish eye to that of a vertebrate has been explained by the assumption that both creatures are descended, *longo intervallo* no doubt, from a common stock, and that the flesh or the germ of that stock had the internal impulse to produce this kind of eye some day when conditions should be favourable. It is not explained why many other eyed animals, which must also have descended from this remote stock, have developed eyes of a different kind. Nevertheless, I commend this hypothesis of Prof. Bergson to the advocates of predisposition. To my mind, it only shows that a philosopher may achieve distinction by a theory of evolution without a secure knowledge of biology.

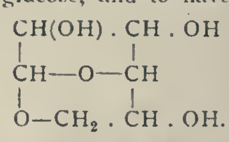
When the same stock follows two quite different paths to the same goal it is impossible to speak of a predetermined course. [An instance of this was given.]

(*To be continued.*)

The Constitution of Cellulose.

IN an illuminating lecture delivered before the French Chemical Society on May 21, Prof. A. Pictet, of Geneva, described the results obtained by his pupils and himself on distilling cellulose at a low pressure, and showed how these can be interpreted so as to throw much new light on the constitution of this complicated substance.

When cotton cellulose is heated gradually in a distilling apparatus under a pressure of 10–15 mm. decomposition begins at 210° and an oil distils over equal in weight to 45 per cent. of the original cellulose, which soon solidifies, and consists of lævoglucosan. This is considered to be an anhydride derived from β-glucose, and to have the constitution



Previous work has shown that cellulose furnishes on acetolysis a disaccharide, cellobiose, which probably contains an α-glucose and a β-glucose group. Also, with hydrobromic acid, cellulose gives bromomethylfurfurol. The origin of the latter, a hydrofuran nucleus containing two side-chains, the author terms the chitose grouping. Prof. Pictet therefore regards cellulose as containing two β-glucose groups, one chitose grouping, and probably an α-glucose group, represented thus:

β	Ch
β	α?

By acetolysis the α-glucose group and a β-glucose group together form cellobiose (50 per cent.), and in the decomposition with hydrobromic acid the chitose grouping furnishes bromomethylfurfurol (25 per cent.), the other three groups being converted into the black mass which is always formed in the reaction. Finally, on dry distillation under reduced pressure the β-glucose groupings split off to give lævoglucosan (50 per cent.), and the others, which are not volatile without decomposition, furnish water, furfurol, carbon, etc.

In the molecule of cellulose the various groups are probably united together in consequence of the opening of the ring at an oxygen atom which does not form the furan ring, and in this way the cellulose molecule, forming a vast cyclic network, may bear some analogy to those of the albuminoids, in which the linking agents are nitrogen atoms.

Joseph Black and Belfast.

UNDER the title of "Joseph Black: His Belfast Friends and Family Connections" Mr. Henry Riddell has recently published in the Proceedings of the Belfast Natural History and Philosophical Society (vol. iii., 1919–20, p. 49) an interesting account of Joseph Black's connection with Belfast. As is well known, the famous chemist was born at Bordeaux, where his father, John Black, was a factor and wine merchant, but his ancestors for many generations back were Ulstermen, and he himself received his school education either in the old Latin School in Belfast, endowed by Earl Donegall in 1666, or at the hands of a Mr. Sprott, a schoolmaster of repute in that city. Up to the age of twelve Black was educated by his mother, Margaret Gordon, who is described as a woman of great force of character and many accomplishments. She was the daughter of Robert Gordon, a merchant of Aberdeen, and was married to John Black in 1716, by whom she had issue eight sons and five daughters, Joseph Black, who was born in 1728, being the fourth son.

The Blacks were of Scottish extraction, and were said to be descended from a member of the Clan Lamont who was known as Gillie-dhu on account of his remarkably black hair. Some of his sons, on the invitation of James I., passed over to Ulster, which had been laid waste and depopulated by the wars among the Irish chiefs and their clans. Their descendants, or some of them, settled in Belfast and anglicised their name to Black. One of them, John Black, the great-grandfather of the chemist, fought as a trooper against Cromwell. His son, also John Black, born in 1682, was a burgess of Belfast, and had a family of five sons, all engaged in "merchandysinge" in various parts of the Continent. The various members married into some of the leading Ulster families—the Eccles, Wilsons, Banks, Legges, Clarkes, and others. Jane Eccles, the grandmother of the chemist, was the daughter of John Eccles of Cranmore, who entertained William III. on his way from Carrick to Drogheda. The chemist's eldest brother, John, married Jane Banks, a member of one of the best-known families in Belfast. One of their granddaughters, Maria, became the wife of Lord Downs, and from them sprang two girls, Ann and Charlotte, who married respectively Lord Clonmel and Lord Seaton. Isobel Black, the sister of the chemist, married James Burnett, of Aberdeen; their daughter became the wife of Adam Ferguson, the moral philosopher and colleague, intimate friend, and cousin of Joseph Black. A descendant of one of his other sisters, Katherine, became the wife of Prince Waldeck and Pyrmont.

Two of Joseph's brothers, Samuel and George, returned to Belfast and took a prominent part in the municipal life of the town, holding the office of "Sovereign" (mayor) between them no fewer than seven times between 1772 and 1789.

Joseph Black, after a good grounding in classics and mathematics, left Belfast for Glasgow in his eighteenth year, entering the University, therefore, considerably older than the usual run of matriculants at that period. He came almost immediately under the influence of two remarkable men, Dick, professor of natural philosophy, and Cullen, professor of medicine and lecturer on chemistry. The fact that Black was considerably senior to the majority of his fellow-students may have induced Cullen to offer him the position of lecture-assistant, and it was probably this fortunate circumstance that determined his career.

The great chemist, who died in 1799, was never married, and left no immediate descendants. It is evident from this short statement that he belonged to a family of noteworthy mental peculiarities, many members of which were characterised by remarkable powers and capacity. Joseph Black, so far as is known, is the only one who showed any striking predilection towards scientific pursuits, and there are special circumstances in his case which may serve to explain the direction of his inclinations. If, as the late Sir Francis Galton contended, high reputation is a pretty accurate test of high ability, Joseph Black certainly ennobled his ancestry. But an examination of their individual history seems to show that he is no less a debtor to those who went before him, and that his eminence is in no small degree due to qualities implanted in him by his Ulster upbringing and associations.

T. E. THORPE.

The Sakura-jima Eruption of 1914.

PROF. OMORI has recently made two additions to his valuable series of memoirs on the eruption of the Sakura-jima (South Japan) on January 12, 1914. The fourth memoir deals with the continued changes of elevation in the neighbourhood of the volcano, and the fifth with the numerous earthquakes which preceded and followed the eruption (Bull. Imp. Earthq. Inves. Com., vol. viii., 1920, pp. 323–51 and 353–466). Until 1914 the Sakura-jima was an island in the Bay of Kagoshima, the inner bay to the north of it being a basin 12½ miles long from east to west and 7½ miles wide. A comparison of two series of levels made a few years before the eruption and in April and May, 1915, revealed a depression of not less than 20 in. in the northern part of the bay, and of from 1 ft. to 5½ ft. round the coast of the former island, the centre of which was elevated in two places by as much as 30 ft. and 41 ft. In the winter of 1918–19 a new series of levels was made along the west and north coasts of the bay, from which it is seen that the depression of the inner bay gave place to an elevation, the mean rise from February, 1915, to December, 1918, being about 4 in. In 1917 a series of soundings was also made in the bay, and these show that there are three depressions (of maximum depth 85, 113, and 79 fathoms), the first being separated from the others by a submarine ridge running north from the volcano, and apparently due to the eruptions of A.D. 764, 1468–76, and 1779. Comparing the new soundings with those made in 1906, there are seen to be three areas of fresh depression (from 3 to 4 fathoms) coinciding with the three depressions, and two areas of new elevation, the more important one (of 3 fathoms) being near the submarine ridge. Prof. Omori estimates that the total resultant depression of the district amounts to about one-quarter of a cubic mile, and the volume of lava and ashes ejected to slightly more than one-half of a cubic mile, and he suggests that this difference may account for the defect of gravity sometimes observed in the neighbourhood of a volcano.

The records of the Sakura-jima earthquakes at Kagoshima (6½ miles from the volcano), Nagasaki

(92 miles), and Osaka (348 miles) leads to the following conclusions:—(1) The frequent occurrence of earthquakes, both unfelt and strong, terminated at or immediately before the opening of the eruption; (2) the principal centre of the after-shocks coincides roughly with the centre of elevation of the sea-bed to the north of the Sakura-jima, which is 8·9 miles from Kagoshima; (3) the mean duration of the preliminary tremor at this place was 1·94 seconds, corresponding to a focal distance of 8·9 miles, from which it follows that the focal depth was very small; and (4) in the after-shocks the first distinct displacement was usually directed towards or from the source of disturbance, while the mean directions of the maximum vibrations were parallel and perpendicular to the line joining the craterlets on the two flanks of the volcano. C. D.

University and Educational Intelligence.

AN introductory public lecture to a series of seven courses of lectures on the history of science will be given by Sir W. H. Bragg at University College (University of London) on Thursday, October 7, at 5 p.m. The courses arranged are as follows:—The General History and Development of Science, Dr. A. Wolf; The More Important Developments in Physical Science during the Nineteenth Century, Sir W. H. Bragg, Prof. E. J. Garwood, Mr. D. Orson Wood, and others; Egyptian Science, Prof. Flinders Petrie; The History of the Biological and Medical Sciences from Early Times to the Eighteenth Century, Dr. Charles Singer; The History of the Biological Sciences since the Eighteenth Century, Prof. J. P. Hill; Elementary Astronomy, treated Historically, Prof. L. N. G. Filon; and The History of Mathematics up to the Eighteenth Century, Mr. T. L. Wren.

IN the annual report for 1919–20 of the Coventry Public Libraries several points are worthy of notice. Figures are given showing the number of issues which have been made during the past and the previous year. Of the total of 380,170 issues of books in 1919–20, 167,758 were of technical and literary books, while 144,296 were works of fiction. The figures are significant of the use to which the library is put by the inhabitants. As compared with the previous year, the number of issues of technical works has increased by 26,976, while the increase for fiction was only 2087. These figures indicate the revival of study which was to be expected with the return of students to peaceful occupations. In the issues of the home-reading libraries similar figures were observed, the increase in the demand for works on the arts and sciences being 6449. On the other hand, research work, by which is meant the study of the accumulated data of a subject before proceeding with investigations, has declined since the armistice. Only one-twelfth of the 82,245 volumes in stock are classed as fiction. The libraries are intended chiefly for the use of students, and their continued popularity shows that they are appreciated as such.

THE President of the Board of Education has addressed a letter to the Vice-Chancellor of the University of London (Dr. Russell Wells), under date September 24, with reference to the Government offer of a site for the University behind the British Museum, explaining that, with the consent of the vendor (the Duke of Bedford), it is possible for the offer to remain open until the Senate's meeting on October 20, but no longer. Mr. Fisher expresses general approval of the proposed conditions to be attached to acceptance of the offer which were discussed by the Senate in July, save that respecting freedom from debt as regards the new buildings before the old buildings are vacated. He suggests a revision of the wording of this condition, but admits that the Government fully shares the view as to the undesirability of the University and King's College entering upon the occupation of their new buildings under an embarrassing load of debt. Mr. Fisher further explains that the Government offer is not available for any alternative site, since on a review of all the circumstances the Government has come to the definite conclusion "that the site behind the British Museum is the most suitable and the only one which they would feel justified in acquiring for offer to the University." In conclusion, Mr. Fisher expresses his earnest hope that the Senate will decide to accept the offer which the Government has made.

THE educational system of Japan (Bulletin No. 57, 1919, of the United States Bureau of Education) is the result of a fusion of the traditional training in national humanistic studies with that in modern science. Progress is possible on the latter side only. Technical education of an elementary type is given in the vocational schools, to which students who have passed through the elementary schools are admitted. In 1915–16 the number of technical schools attached to such vocational institutes was 9001, an increase of 533 over the preceding year; while that of the private technical schools was 366, an increase of 20. Approximately 95,000 pupils were enrolled in all schools of this kind, exclusive of continuation schools. The technical continuation schools admit students who have passed the standard of the elementary schools, though the individual school authorities have power to admit or refuse any candidate. In the year 1915–16 407,600 male pupils and 89,601 females were enrolled in these schools, an increase of nearly 50,000 over the numbers joining during the previous year. Within the next six years it is proposed to spend some four and a half million pounds on higher education. The technical and high schools already in existence will accommodate 14,000 students only, while during the year 1917–18 about 56,000 applied for admission. This money will therefore be devoted to the building of ten new high schools and eighteen new technical and commercial institutes. Great prominence is given to the rapid but efficient training of teachers of all grades.

Societies and Academies.

PARIS.

Academy of Sciences, August 30.—M. Henri Deslandres in the chair.—G. **Humbert**: An arithmetical link between the real ternary quadratic forms and the indefinite forms of Hermite.—H. **Deslandres**: The recognition in stars of the successive layers of their atmosphere and the periodic variations of these stars. From the study of the calcium lines in the solar spectrum the existence of three layers in the solar atmosphere has been deduced. The same method can be applied to the fixed stars, and an account is given of the results obtained up to the present by various observers.—E. **Ariès**: The specific heat of saturated vapours at low temperatures. Reply to a communication by G. Bruhat.—J. **Andrade**: The regulating organs of chronometers.—E. **Jouguet**: Waves of shock in solid bodies.—M. **Galbrun**: The deformation of a helical spring.—M. **d'Azambuja**: The spectrum of the new star in Cygnus. On August 25 and 28 the spectrum of the new star presented the appearance usual with novæ in the course of the first stage of their evolution.—M. **Burson**: The spectrum of Nova Cygni.

—C. **Raveau**: The thermodynamical properties of fluids in the neighbourhood of the critical state.—MM. **Orékboff** and **Tiffeneau**: The hydrobenzoin transposition. The influence of the paramethoxy-substitution on the dehydration of the triarylglycols.—G. **Zeil**: The ascending movements of the earth's crust and the recurrences of subterranean erosion.—E. **Aubel**: The influence of the nature of the carbon compounds present on the utilisation of nitrogen by *Bacillus subtilis*.

September 6.—M. Léon Guignard in the chair.—A. **Lacroix**: The regular grouping of two different minerals constituting certain ores of iron and titanium.—M. **Laubeuf**: A small submarine for oceanogcaphic work. Details of design and equipment of a small submarine, 18·8 metres in length and of 50 tons displacement, for use in oceanography. It would sustain the pressure of water at depths of 80 to 100 metres, and, it is estimated, would now cost 600,000 francs to build, although in 1907, when the plans were first drawn up, it could have been built for less than a third of that sum. The work suggested for this submarine includes collecting samples from the ocean-floor, water at various depths, plankton, and observations on temperature and transparency of water and the direction and velocity of the currents.—P. **Humbert**: Hypercylindrical functions.—C. **Nordmann**: Observations of the new star in Cygnus, made at the Paris Observatory with a heterochrome photometer. In this apparatus the ratio of the intensities of the star studied and a known star is compared in various regions of the spectrum by equalising by means of Nicol prisms the brightness of the star under examination and that of an artificial star observed simultaneously through a coloured screen. It was found that the magnitude of the new star changed from 3·43 on August 27 to 4·01 on August 29. The brightness of the new star is, therefore, rapidly decreasing. On the first date the star had an effective temperature of 6100° C., which on the later date had increased to 7800°. Attention is directed to the fact that the increase of effective temperature is accompanied by a diminution in the brightness, contrary to what would have been expected.—H. **Groullier**: First observations of Denning's nova made at the Lyons Observatory. Measurements of the magnitude of the star on August 23, 24, 25, 26, and 27. The brightness passed through a maximum on August 24 and then rapidly decreased.—J. **Guillaume**: Observations of the sun made at the Lyons Observatory during the first quarter of 1920. Observations were possible on sixty-eight days, and the results are summarised in three tables showing the number of sunspots, their distribution in latitude, and the distribution of the faculæ in latitude.—J. **Rouch**: Inversions of temperature in the lower atmospheric layers in the Antarctic.

WASHINGTON, D.C.

National Academy of Sciences (Proceedings, vol. vi., No. 3, March).—S. **Flexner**: Encephalitis and poliomyelitis. A short sketch of the present state of knowledge relative to these two diseases.—A. F. **Kovarik**: A statistical method for studying the radiations from radio-active substances and the X-rays, and its application to some X-ray problems. A continuation of the work of Kovarik and McKeehan. The author finds 7×10^{10} γ-rays from radium B and C per second per gram of sodium instead of 3×10^{10} formed by Lawson and Hess.—L. B. **Loeb**: The nature of the heat production in a system of platinum black, alcohol, and air. Of the two theories that the heat is due (1) to the adsorption of alcohol and (2) to the oxidation of the alcohol at the platinum surface, the latter is substantiated.—H. **Noguchi**: *Leptospira icteroides* and yellow fever. A special organism, *Leptospira icteroides*, has been detected in certain cases of yellow fever. Guinea-pigs have been inoculated with it by Stegomyias, but until further studies have been made its standing as the inciting agent of yellow fever cannot be regarded as certain.—S. **Hecht**: Human retinal adaptation. A binocular reaction is involved; in all essentials the mechanism underlying the initial phase of retinal sensitivity in dim light is the same as involved in the initial process of photoreception in Mya and Ciona.—L. **Page**: A kinematical interpretation of electromagnetism. The equations of electrodynamics are shown to be simple kinematical relations between the moving elements which constitute lines of force.—A. A. **Michelson**: The laws of elastico-viscous flow, ii. A criticism of the formula which combines the laws of Larmor and Maxwell; an elaboration with many data of a previous paper of the same title.—H. **Shapley**: A note on a simple device for increasing the photographic power of large telescopes. A short-focus lens is placed in the converging beam at an appropriate distance in front of the photographic plate, giving high speed and reducing the scale on the photograph.—L. R. **Sullivan**: Anthropometry of the Siouan tribes. Of interest (1) because accurately describing and defining the Siouan type and showing its relationship to American Indian tribes already described, and (2) because of the intermixture of two widely separated races represented by this series of individuals.—F. M. **Guyer** and E. A. **Smith**: Transmission of eye-defects induced in rabbits by means of lens-sensitised fowl-serum. The defects have been transmitted to the sixth generation.—H. G. **Barbour** and J. B. **Hermann**: The mechanism of fever reduction by drugs. Antipyritic drugs increase the blood-content of dextrose. In fevered animals this is accompanied by dilution of the blood, with resulting fall in temperature.—E. H. **Hall**: Inferences from the hypothesis of dual electric conduction: The Thomson effect. A tabulation of a great variety of data correlated with theory under either of two hypotheses of electron equilibrium in metals unequally heated.—C. L. E. **Moore** and H. B. **Phillips**: Note on geometrical products. Development of a series of geometrical products, independent of the dimensions of space, intermediate between the progressive and the inner product.

The Metric System and International Trade.

IN the year 1917, when the nation was in the throes of war, a committee of the Conjoint Board of Scientific Societies arrived at certain conclusions on the question of the compulsory adoption of the metric system in Great Britain, but, unfortunately for the committee, the publication of its findings has been delayed until the present time.[1] During the intervening three years our attention has been transferred from warlike to peaceful occupations, and the nation at large is now much more alive to the necessity of improving our commercial equipment for the impending vital struggle to recover and expand our overseas trade in order that we may "pay for the war." The committee apparently appreciates this change in the general atmosphere, and has accordingly published an apologetic prefatory note, from which it incidentally appears that the chief source of its evidence was the "Report on Commercial and Industrial Policy after the War." It may be recalled that Lord Balfour of Burleigh, the chairman of that committee, naïvely admitted afterwards, during a House of Lords debate on decimal coinage, that his committee had been so overloaded with other problems that the subject of decimalisation had possibly not received the attention it really deserved.

Unfortunately, this preface will probably escape general attention, because so many readers will skip it, glance through the report, and really note only the final "Recommendations," which are published on p. 35 of the committee's report, and are about as unsatisfactory as they could well be. Hence we have the lay Press to-day stating that British men of science have denounced the metric system, whereas actually the report has not been adopted by the Conjoint Board, and is issued solely on the authority of the committee. Moreover, in par. 88 of the report the committee recognises "the intrinsic superiority of the metric system in scientific and technical work."

One looks in vain for a note in these recommendations to the effect that the metric system is (*a*) already universally employed in science; (*b*) the practical basis of industry in many countries the trade of which we seek; (*c*) already legally recognised throughout the civilised world; and that accordingly, in the interests of the scientific permeation of industry, as well as of the expansion of our overseas trade, everything possible should be done to encourage its use. Instead of this, we find the committee recommending "that the British system of units of weights and measures be retained in general use in the United Kingdom," which is tantamount to suggesting that British manufacturers engaged in world-wide trade must continue indefinitely to employ two systems—the British for home trade and the metric for overseas trade—involving an increasing volume of misunderstandings and unnecessarily wasted time spent in conversions from one system to the other. If the British manufacturer can, as he already does, sell a portion of his output under metric description, he can obviously sell the whole of it on that basis, and he should clearly be encouraged to conduct all his business in one language of quantity instead of two.

In par. 82 of the report the following constructive sentence occurs: "In the opinion of the committee it would be to the advantage of British industry if the manufacture of all machinery and apparatus of new types were to be established as a matter of course in the metric system; and that this practice should be directed and encouraged by specification in this system for Government and official work"; and yet no reference is made to this in their final "recommendations," which, instead, include a plea for the continued use of British units by Departments of State.

[1] "Report on Compulsory Adoption of the Metric System in the United Kingdom." Submitted by the Metric Committee appointed by the Conjoint Board of Scientific Societies, and published on the authority of the Committee. Pp. 70. (London: Board of Scientific Societies, Royal Society, n.d.) Price 1*s*.

According to the second recommendation, the committee apparently views with equanimity the perpetuation of our use of two systems where one would suffice for all purposes. In the third recommendation the committee suggests the decimalisation of the British units of weight and measure, thus supporting a proposal roundly condemned by a select committee of the House of Commons which, in 1862, reported that "It would involve almost as much difficulty to create a special decimal system of our own as simply to adopt the metric system in common with other nations. And if we did so create a national system we would, in all likelihood, have to change it again in a few years, as the commerce and intercourse between nations increased, into an international one."

Our choice to-day rests between (1) the continued use of a dual system (because we must employ the metric system in an increasing proportion of our business, whether we like it or not), and (2) the establishment of the metric system as the universal language of quantity (involving the gradual abandonment of the Imperial system which, by reason of its manifest defects, is so obviously unsuitable for universal adoption).

It is sheer insularity which makes us cling to the first course and, regarding the alternative, the committee of the Conjoint Board states in par. 50 of its report (but omits from the "recommendations") that "It will be sufficient for the purpose of this inquiry to admit unreservedly that the metric system of weights and measures is the only system which has considerable claims to be truly international, and that it is the only system to which a change could reasonably be made should any country propose to abolish its existing national system."

Some further Government action is clearly required beyond the Act of 1897, but it does not necessarily follow that the next step need be the adoption of legislation of a compulsory character. The Government could do very much to *encourage* the more widespread use of the system by its employment in Government specifications and by a declaration that ultimately at some future date (not necessarily fixed at present) the metric system would become the sole legal system in this country. Many manufacturers would be thereby stimulated to establish all their new standards and their revisions of old standards in terms of the metric system, and there would be nothing to prevent them from continuing to manufacture their existing standards in the British system and describing them for sale in terms of the metric system, as they already have done for so many years. We should thus progress beyond the present passive permission, through a period of intensive encouragement, to the final stage in which the metric system would become the sole legal system of weights and measures, when "compulsion" need be applied only to the stragglers who had failed to adopt it voluntarily.

It is satisfactory to note that with regard to decimal coinage the committee "sees no serious objection in principle" to the proposals for decimalising the £ sterling, and it may be interested to know that the revision of Lord Southwark's Bill is now under consideration with a view to the removal of some of the practical difficulties to which the committee refers. In the meantime we may perhaps be permitted to remark that it is futile to talk about "preserving the credit of the penny" at a time like the present, when the failure of the penny to meet modern conditions is so very obvious.

Harry Allcock.

The Study of Live Embryos.

Contributions to Embryology. Vol. ix., Nos. 27 to 46. A Memorial to Franklin Paine Mall. (Publication No. 272.) Pp. v+554+plates. (Washington: The Carnegie Institution of Washington, 1920.)

Long before the war it was being realised in England that the centre of embryological research, at least so far as concerns inquiries into the developmental stages of the human body, was shifting from the laboratories of Germany to those of the United States. The transference was the work of one man—the late Prof. F. P. Mall, who died in 1917 at the age of fifty-five. Prof. Mall stocked the new and highly equipped anatomical laboratories of the United States with young men and women who had served their apprenticeship with him in the anatomical department of Johns Hopkins Hospital, Baltimore. In 1918 he would have reached the twenty-fifth anniversary of his appointment at Baltimore, and his pupils, "in recognition of his inspiring leadership, and in response to the strong feeling of affection with which they had come to regard him," intended to mark the occasion by dedicating to him a volume of their most recent investigations. These essays, owing to his untimely death, have now to appear as a memorial volume, and the sense of regret that Prof. Mall did not live to study it will be felt as acutely on this side of the Atlantic as on the other, for many of its contributors have made highly important additions to our knowledge of the growing embryo. The volume is issued by the Carnegie Institution of Washington, under the ægis of which Prof. Mall had established a department of embryology two years before his death.

In these essays we see employed the exact technique which Prof. Mall learned when working under the late Prof. His, of Leipzig, but in addition there is evidence of a clear realisation that embryology is a series of vital processes, and that to understand them the living as well as the dead embryo must be studied. The developing chick lends itself particularly well for vitalistic observation, but we have every reason to suppose that the earlier stages of mammalian development—including the early stages in the growth of the human ovum—can be investigated in a similar manner. In this respect a return has been made to the earlier methods of Harvey and of Hunter.

As examples of the vitalistic method of observation, we may cite papers by Prof. Florence Sabin on "The Origin of Blood-vessels and of Red Blood Corpuscles," by Dr. Eliot R. Clark and Eleanor L. Clark on "The Origin and Early Development of the Lymphatic System," and by Dr. Margaret R. Lewis on "Muscular Contraction in Tissue Cultures." Prof. Sabin shows that blood-vessels arise from islets, or groups, of angioblastic cells, which by canaliculisation and inosculation unite to form a capillary network. The angioblastic cells give rise to the endothelial lining of blood-vessels, and both the angioblasts and endothelial cells can, and do, produce nucleated red blood corpuscles. The lymphatic system of vessels, however, as one is led to infer from the experiments of the two Clarks, arises from the endothelium of the veins in certain embryonic regions, and from these regions, or centres, the endothelial outgrowths invade certain neighbouring areas of the body and thus provide it with a lymphatic system. If one centre of outgrowth is destroyed, neighbouring centres will supply the deficiency.

Another series of papers records observations on the vital reactions of certain cells in the body of adult animals. Capt. Charles Essick found that when a solution containing fine particles was placed in the sub-arachnoid spaces of the brain of a living animal the endothelial cells of these spaces were transformed into phagocytes, which consumed the foreign matter thus introduced. Capt. Essick's investigation was occasioned, apparently, by observations made by Capt. Lewis H. Weed during a research on "The Experimental Production of Hydrocephalus"—an important inquiry which also appears in this memorial volume. To this series also belongs the paper contributed by Dr. Charles C. Macklin on "The Development and Function of Macrophages in the Repair of Experimental Bone-wounds Vitally Stained with Typan-blue." We infer from Dr. Macklin's experiments that the phagocytes which appear at the sites of repair and of rapid growth have, as their chief business, the consumption of tissue-débris and the rendering of that débris fit for return to the general circulation of the body. Dr. George Corner's observations on "The Widespread Occurrence of Reticular Fibrils produced by Capillary Endothelium" serve to enhance the functional importance of the cells which line blood and lymphatic vessels.

Besides these papers on the living behaviour of the tissues of the body, this volume contains important contributions to orthodox or morphological embryology—particularly a most valuable summary of the present state of our knowledge of the youngest known human embryos, given by Prof. George L. Streeter, who succeeded Prof. Mall as director of the department of embryology in the Carnegie Institution of Washington. Dr. Warren H. Lewis's description of the skull of a human fœtus towards the end of the second month of development is also a very welcome addition to our knowledge of the human body. Other papers, like those of Prof. C. R. Bardeen on "The Post-natal Development of the Human Body," Prof. Robert Bean's on "The Post-natal Growth of the Heart, Kidneys, Liver, and Spleen of Man," and Dr. Schultz's "Development of the External Nose of Whites and Negroes," represent contributions to anthropology as well as to embryology. Altogether, this volume represents a worthy memorial to a really great man.

Two Books for the Country.

(1) *Springtime and Other Essays.* By Sir Francis Darwin. Pp. vii + 242 + viii plates. (London: John Murray, 1920.) Price 7s. 6d. net.

(2) *Memories of the Months.* Sixth series. By the Right Hon. Sir Herbert Maxwell, Bart. Pp. xi + 314. (London: Edward Arnold, 1919.) Price 7s. 6d. net.

(1) SIR FRANCIS DARWIN'S essays have a peculiar charm; the reader is caught in the current of the author's enjoyment. Uninfluenced by artifice, we find ourselves sharing in his pleasures, and, to begin with, in the delight of the spring renascence. "The spring is the happiest season for those who love plants, who delight to watch and record the advent of old friends as

the great procession of green leaves and beautiful flowers unwinds itself with a glory which no familiarity can tarnish." To a representative list in the order of their flowering, Sir Francis adds the remark: "To a lover of plants, this commonplace list will, I hope, be what a score is to a musician, and will recall to him some of the charm of the orchestra of living beauty that springtime awakens."

The book begins with "Springtime" and ends with "A Procession of Flowers," behind both essays lying the problem of "the elements in the struggle for life which fix the dates on which plants habitually flower." "It looks, to put the thing fancifully, as if a parliament of plants had met and decided that some arrangement must be made, since the world would be inconveniently full if they all flowered at once; or they may have believed that there were not enough insects to fertilise the whole flora, if all their services were needed in one glorious month of crowded life. Therefore it was ruled that the months should be portioned among the aspirants, some choosing May, others June or July. But it must have been difficult to manage, and must have needed an accurate knowledge of their own natural history." Similar touches of wise humour are not rare. "It has been said that Thoreau, the American recluse and naturalist, knew the look of the countryside so intimately that had he been miraculously transferred to an unknown time of year he would have recognised the season 'within a day or two, from the flowers at his feet.' If this is true, either American plants are much more business-like than ours (which is as it should be), or else Thoreau did not test his opinions too severely, and this seems even more probable." For, as a matter of fact, the dates of flowering vary considerably with the temperature and some other environmental variables—a fact which gives subtle value to old-fashioned phenological maxims: "When the sloe tree is as white as a sheet, You must sow your barley be it dry or wet"; "When we hears the wryneck, we very soon thinks about rining (barking) the oaks." "There is," Sir Francis says, "something delightfully picturesque in the thought of man thus helped and guided on some of his most vital operations by the proceedings of the world of plants and animals, to whom that hard taskmaster, Natural Selection, has taught so much."

Another delightful essay discusses the traditional names of English plants. "The fact that language is handed on from one generation to the next may remind us of heredity, and the way in which words change is a case of variation. But we cannot understand what determines the extinction of old words or the birth of new ones. We cannot, in fact, understand how the principle of natural selection is applicable to language: yet there must be a survival of the fittest in words, as in living creatures." The author proceeds to show how "the wonderful romance inherent in the great subject of evolution also illumines that cycle of birth and death to which existing plant-names are due."

This is scarcely the place for an appreciation of the essays on "Some Names of Characters in Fiction" or "Old Instruments of Music," or for those on Sydney Smith and Charles Dickens, but they are not less interesting than those on Sir Joseph Dalton Hooker and Sir George Biddell Airy. In connection with the last, we looked for some remark on the astronomer's paper on phyllotaxis, which seemed to us particularly luminous many years ago, but we were disappointed. Very delightful are the author's personal recollections, especially of his early years. We have not the courage to write in Nature of the way in which Francis Darwin expressed in the church at Down his innate fondness for musical instruments; but we are within safe natural history lines in quoting the next two sentences: "The only other diverting circumstance was the occurrence of book-fish [Lepisma?] in the prayer-books or among the baize cushions. I have not seen one for fifty years, and I may be wrong in believing that they were like minute sardines running on invisible wheels." One more quotation from a fascinating book, and we have done: "I continued to work with my father at Down, and in spite of the advantages I gained by seeing and sharing in the work of German laboratories, I now regret that so many months were spent away from him."

(2) Sir Herbert Maxwell has given us a sixth volume of his "Memories of the Months," and it will be as much appreciated as its predecessors. It consists, for the most part, of evening recollections of the natural history experiences of the day. The breezes play with the pages. For while the author is often erudite he never wears his learning but lightly. The year begins with winter flowers and winter visitors, with the humble leek which Nero is said to have loved, and with good-going problems like the significance of the white disc on the roe-deer's rump or the rabbit's cotton-tail. The temperature rises, and we have daffodils and birds' nests and the puzzles of the cuckoo and the corncrake. In speaking of the frog-hopper, the author slips in calling it a diminutive member of the grasshopper family, and his story of the

foam-making is not quite accurate. But this is merely a crumpled rose-leaf: Summer's memories deal with butterflies, British orchids, the behaviour of a hunter-wasp, the ways of char, and the insurgence of climbing plants. Here also is included an unashamed confession of faith in the powers of the divining rod. In the fall of the year Sir Herbert discourses on gossamer and migration; in midwinter he brings us up against such problems as the otter's survival in the hard months and the general question of animal intelligence. In connection with animal behaviour, the author inclines, if we understand him rightly, to a somewhat remarkable transcendental conclusion, that conscious intelligence is "the consequence of an external and superior mandate or suggestion, acting upon a suitable physical receptacle." "Assuming a First Cause, instinctive activities in the lower animals may be regarded as the comparatively simple and intelligible results of forces initiated by him, acting unerringly in prescribed directions by means of co-ordinate organs modified by evolution." In short, this lifelong student of the ways of living creatures is frankly dualistic. But he does not seek to ram his philosophy down the reader's throat.

We notice a few slips in the pages; thus Fabre's volumes are referred to as "Etudes Entomologiques," and again as "Mémoires Entomologiques," whereas the title was surely neither. But such slips are trivial in a book of great attractiveness. It is full of interesting observations; it expresses and arouses the inquiring spirit. Its happy style suggests that the writing of it must have been a pleasure, and that is certainly true of the reading. We wish there had been an index, for the topics touched on are numerous.

Principles of Aeronautics.

Aeronautics: A Class Text. By Prof. E. B. Wilson. Pp. vii+265. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1920.) Price 22*s*. net.

THE work under notice differs considerably in conception and treatment from that usually associated with the title "aeronautics." It is very clearly written, and will be particularly valuable to advanced students of the subject for many reasons. On the other hand, it will not appeal strongly to the less advanced worker who delights to regard himself as "practical," for he will find only a "skeleton airplane" of the simplest type as a basis for all the calculations made. The more usual curves by which laboratory results are expressed are subordinated to analytical expressions. The peculiar advantages of this point of view are obvious in many places, notably in the treatment of the fall of bodies through air. Without containing such original matter as that of Bryan in "Stability in Aviation," the new volume expresses ideas more nearly those of Bryan than of any other writer on the subject.

The introduction to the book includes the ideas underlying simple flight and the aerodynamics of aerofoils, and the chapters of this section are probably of little importance. It is with the chapter on "Motion in Two Dimensions" that the serious student of aeroplane motion will begin to appreciate the book, for here are collected with concise proofs the fundamental theorems in dynamics which are otherwise only to be found by perseverance in the reading of such volumes as Routh's "Rigid Dynamics." The principles are carried step by step to the consideration of stability, and are then illustrated by example. The study of motion in three dimensions is committed to a following chapter, and starts from the apparently simpler problems relative to fixed axes and uses these as a basis for developing the theorems for moving axes. The reasons for the ultimate simplicity of the latter in relation to complex motions are given, and the treatment is direct and helpful. The last chapter in the section devoted to rigid dynamics applies the equations developed to the stability of the aeroplane. The stage reached is not further than that of English workers, and is obviously dependent on the latter for much of its inspiration; but the chapters are more complete and self-contained than any others available at the moment.

The rest of the book is devoted to "Fluid Mechanics," and here are interposed chapters on the simpler theories generally known as "hydraulics" and the more complex and unfortunately less applicable theorems of velocity potential, etc., of hydrodynamics. The ninth chapter introduces the fundamental laws of laminar motion, and develops the formula for an adiabatic atmosphere. Then follow the important Bernoulli's theorem and the Rayleigh expansion, which indicates the velocity at which air must be considered as a compressible fluid so far as the effect on the resistance of bodies moving through it is concerned. From Bernoulli's equation the laws for Pitot and Venturi tubes are developed on standard lines. Viscous fluids are dealt with in steady motion up to the calculations relating to Poisseuille's famous experiments, and a table of coefficients of viscosity is given.

The fundamental principles of dynamical similarity, which have been applied so fruitfully in aeronautics, receive attention in chap. xi., and cover the ground rendered familiar to us by the reports of the Advisory Committee for Aeronautics.

The remainder of the book is conventional hydrodynamics, and is a further reminder of the lack of success which has attended the efforts of mathematicians and others to solve the problems of the motion of fluids under conditions resembling those of normal occurrence. As a summary of formulæ the chapters have a value to advanced students.

Taken as a whole, the book is one to be recommended to those students on whom the future developments of aviation will depend, for it contains the fundamental theorems on which the science of the subject rests and must continue to rest for such period as we can now visualise.

Text-books on Chemistry.

(1) *Treatise on General and Industrial Inorganic Chemistry.* By Prof. Ettore Molinari. Second edition. Translated from the fourth revised and amplified Italian edition by Thomas H. Pope. Pp. xix+876+2 plates. (London: J. and A. Churchill, 1920.) Price 42*s.* net.

(2) *Trattato di Chimica Generale ed Applicata all' Industria.* Vol. ii. *Chimica Organica.* By Prof. Ettore Molinari. Parte Prima. Terza edizione riveduta ed ampliata. Pp. xix+624. (Milano: Ulrico Hoepli, 1920.) Price 28 lire.

(3) *A Text-book of Inorganic Chemistry.* Edited by Dr. J. Newton Friend. Vol. ix. Part 1. *Cobalt, Nickel, and the Elements of the Platinum Group.* By Dr. J. Newton Friend. (Griffin's Scientific Text-books.) Pp. xvii+367. (London: Charles Griffin and Co., Ltd., 1920.) Price 18s.

(1 and 2) DR. ETTORE MOLINARI is professor of industrial chemistry at the Royal Milan Polytechnic and at the Luigi Bocconi Commercial University in the same city, and his treatises on inorganic and organic chemistry are, apparently, mainly directed to the special character of his teaching in those institutions. Here chemical theory, in effect, is wholly subordinated to practical application, and the books are simply descriptive manuals of chemical technology, adapted to the needs of polytechnic students and suitable for general reading. They may be said to occupy a position intermediate between the general treatise on chemical theory and the specialised handbooks on chemical technology. Prof. Molinari goes so far as to say that his books reflect the change which has come over the teaching of modern chemistry. In his opinion the methods and spirit of the teaching of Liebig, Hofmann, and Kekulé no longer correspond with present-day requirements. The "beneficent impulse" which these great teachers gave to chemical studies was, we gather, too exclusively "scientific" and "theoretical." The author, however, is a little unfortunate in his argument. He could scarcely have selected three names more alive to the utilitarian aspects of chemical science, however mindful they might be of the primary purpose of their calling and profession. The whole development of certain great branches of applied organic chemistry may be said to have sprung directly from the teaching and example of Liebig, Hofmann, and Kekulé. Liebig's genius ranged over practically the whole field of the industrial chemistry of his day; Hofmann early threw himself, with characteristic zeal and energy, into the newly created synthetic colour industry, the enormous extension of which is fundamentally based upon Kekulé's fruitful conception.

Prof. Molinari insists that "general chemistry can no longer be a simple and arid exposition of fundamental laws and of the properties of the innumerable known substances, but should possess a soul which brings it into contact with the vital activities around which it clings." "The chemical text-books which have been used up to the present time do not correspond sufficiently with these requirements." "The present treatise took its rise from these considerations, and has no other pretensions than to be an attempt to initiate a work of reform in the teaching of chemistry."

These excerpts are taken from the preface to the first edition of the former of Prof. Molinari's two works cited above, in which the author sketches the general plan of his work and makes his *apologia* for its special character. In the preface to the fourth Italian edition, on which the present English edition is based, he enforces his point of view. The Great War, he contends, "has emphasised the necessity of developing chemical teaching more and more along the lines of its practical applications." Hence he has been led "to treat the material still more from the industrial standpoint." Various chapters have been considerably enlarged, "certain improvements—presumed or real—being indicated only by the numbers of the patents in question, so that the further details may be ascertained from the journals of applied chemistry." Considering the class of person to whom the work is ostensibly addressed, a list of patents restricted to their numbers, with a general reference to technical journals in which further particulars may possibly be discovered, is of no great educational value. The extension of his principles has, in fact, led the author into an *impasse*, and by carrying it still further on similar lines his volumes threaten to become unwieldy and their material ill-digested.

Although we have no great sympathy with the spirit which has actuated the author in the compilation of these treatises, and, indeed, may be said to pervade them, in bare justice it must be admitted that they contain a great mass of useful facts, and the reader who will steadily work through their 1500 pages will acquire a considerable stock of information on general industrial chemistry. But we question whether this is quite the *pabulum* on which to feed the young chemist, even if intended for technology. Prof. Molinari thinks that the slow progress, and even the ruin, of many Italian chemical industries are to be attributed to the erroneous direction of chemical training in the universities. Nevertheless, this training was presumably modelled on that of French and German schools of chemistry, and similar evil results have not followed in France or Germany. There must be other causes—social, economic, temperamental—to account for the general lack of success of which the author complains. We seriously doubt if it will be remedied in the manner he indicates. The experience of every other country in Europe which has acquired a commanding position in chemical industry is against him. It is only in America that a similar sentiment has been seen, and, until comparatively recently, America has shown no great aptitude in creating chemical industry. Now, thanks to the enormous development of chemical teaching of a university type in the United States, a great impetus has been given to the higher branches of chemical technology, especially since the war, and largely owing to the collapse of Germany. But the system of chemical training in the best American institutions is not markedly different from that which prevails in the leading European schools. Japan affords a like example. Practically all her leading teachers and technologists have been trained in Continental laboratories, and have introduced their systems into the Japanese universities and technical institutes. It would be interesting to know the views of such eminent Italian chemists as Paternò, Ciamician, and Nasini concerning Prof. Molinari's surmise as to the cause of Italy's backward condition in chemical industry. We should be surprised to learn that they would attribute it to faulty methods of teaching the science and theory of chemistry. It may turn out to be due to a superficial system of instruction in chemical technology, in which chemical theory is insufficiently considered and the methods and practice of chemical manufacture are imperfectly expounded.

(3) Vol. ix. of the "Text-book of Inorganic Chemistry" edited by Dr. Newton Friend is concerned with the elements of Group viii. of the Periodic Table, on which system of classification the entire work is based. The volume is divided into two parts, of which this instalment is the first. It deals with cobalt, nickel, and the metals of the platinum group, six in number. Strictly speaking, this is a departure from the plan uniformly followed in the preceding volumes, in which the element of lowest atomic weight in the several groups is treated of first; in this case it should be iron. It is proposed, however, to deal with iron and its compounds in a separate section forming part ii. of this particular volume. There are, no doubt, good reasons for this course. Iron occupies an exceptional position, and the space needed for its consideration may well necessitate a special section. But this fact does not necessarily require any alteration in the established plan of sequence—viz. that the element of lowest atomic weight should take precedence of its fellow-members in the group. We surmise that the only reason for the change in treatment was that on account of "the enormous amount of research" that has been carried out in connection with the properties of iron and of its compounds, delay has occurred in putting together the material. It is, of course, a small matter, and leads to no practical inconvenience. But in the interests of uniformity it is worth rectifying, which can easily be done in a later edition of the entire work.

The present volume well maintains the reputation which its predecessors have conferred upon the work as a whole. In general plan and arrangement and method of treatment it is similar to these. It opens with a chapter on the general characteristics of the elements of the group with which it is concerned. The anomaly in the position of cobalt in the Periodic Table is duly pointed out. In the table cobalt is placed between iron and nickel, although the bulk of experimental evidence goes to show that the atomic weight of cobalt is distinctly greater than that of nickel. No sufficient explanation of this anomaly has been given. It is one of those apparent exceptions to the universality and comprehensiveness of the doctrine which await solution. Similar difficulties have occurred before, and subsequent research has removed them. A case in point was met with in other members of the same group. When Mendeléeff enunciated his generalisation the accepted atomic weights of osmium, iridium, and platinum were found to be not in accordance with the previsions of the law, and Seubert showed that Mendeléeff's surmise that the numbers were inaccurate was correct. The proper sequence of the elements has now been established, although we concur with Dr. Friend that, with the exception of that of platinum, which, thanks to the careful experiments of Archibald, published in the Proceedings of the Royal Society of Edinburgh, is now well determined, the values of the other members, especially of osmium and iridium, fall very far short of the standard demanded by modern atomic weight work.

It may be hoped that we shall not have long to wait for new and more accurate determinations. These elements, it is true, present special difficulties, accentuated, no doubt, by the present scarcity of material. Indeed, the term "rare elements," originally applied to some of those of Group iii., is in these strenuous and evil days more appropriate to the members of the platinum group.

We presume that part ii., devoted to iron and its compounds, will complete the entire work of ten volumes, when we hope to be able to congratulate Dr. Friend and his coadjutors on the termination of their task. The complete treatise will form an admirable contribution to the chemical literature of this country, philosophical in plan, comprehensive in treatment, and accurate in detail, not the least of its merits being its excellent bibliography.

Our Bookshelf.

Practical Plant Biochemistry. By Muriel Wheldale Onslow. Pp. vii + 178. (Cambridge: At the University Press, 1920.) Price 15*s.* net.

THE author indicates that her book is primarily intended for students of botany, and that it should be a guide to practical work. It is stated that the volume is planned to supplement the knowledge of plant products which students obtain in their study of organic chemistry and of plant physiology. The introduction is followed by eight chapters, each giving a brief survey of some portion of the chemistry of plant life—*e.g.* the colloidal state (chap. ii.), carbon assimilation (chap. iv.), glucosides and glucoside-splitting enzymes (chap. ix.). The general matter of the chapters is followed by, or interspersed with, data upon which experimental work can be carried out to illustrate the points dealt with in the respective chapters. A list of references to original literature is given at the end of each chapter, and cross-references are frequently employed. As to errors, it is rather surprising that those in the structural formulæ for α- and β-glucose on p. 48 (where the formulæ are used to illustrate a statement concerning the two forms) should have been overlooked.

The chapter on plant bases (chap. x.) consists rather too largely of a list of names, to which are attached complex structural formulæ that are more likely to confuse the students who have "an elementary knowledge of organic chemistry" than to be of assistance to them. But for the somewhat disjointed effect resulting from the method of introducing the experimental instructions, the matter is presented in an interesting form, and on the whole there is a pleasing freedom from dogmatic assertions concerning unknown or uninvestigated chemical changes, which so frequently detract from the value of works of this type. The general survey of the problems involved in the chemistry of plant life, and the instructions for experimental work which this volume contains, should prove both useful and interesting to the class of student for whom it was written, and to many others who are interested in the chemistry of the plant world.

A. E. E.

Vergleichende Anatomie des Nervensystems. Erster Teil., Die Leitungsbahnen im Nervensystem der Wirbellosen Tiere. Von Æ. B. Droogleever Fortuyn. Pp. viii + 370. (Haarlem: De Erven F. Bohn, 1920.) 12.50 guilders.

THE author is to be congratulated on this excellent digest of the known facts regarding the paths of conduction in the nervous system of invertebrates—a work which has entailed careful reading of the extensive and complicated literature of the subject and skilful collation of the results. He gives an account of the principal issues of the researches—treated for the most part in historical sequence—on the arrangement of the sensory cells and ganglion cells and the course of their processes, so far as this has been ascertained, in each phylum of invertebrates. The internal structure of the cell and the intracellular neurofibrillæ are not discussed. After dealing with the Porifera in less than a page, there being no evidence of the presence of nervous elements in sponges, the author examines in turn the Cœlentera, Vermes, Mollusca, Echinoderma, Arthropoda, Bryozoa, Tunicata, and Amphioxus, the last-named being included because its nervous system presents a number of features in common with that of invertebrates. In some cases—*e.g.* Echinoderma, Bryozoa, Tunicata—our knowledge of the paths of conduction is extremely slight, but in others—*e.g.* Annelida and Decapod Crustacea—there is an extensive literature which has received full consideration. The digest, illustrated by 116 diagrams, shows clearly what has been done, and renders obvious how much still remains to be done to elucidate the detailed structure of the nervous system of invertebrates, for, as the author remarks, we have as yet only an imperfect conception of the various conduction paths in the ganglia of the earthworm's nerve-cord, although these ganglia have been investigated more than any other part of the nervous system of any invertebrate. A Guide to the Old Observatories at Delhi; Jaipur; Ujjain; Benares. By G. R. Kaye. Pp. vii + 108 + xv plates. (Calcutta: Superintendent Government Printing, India, 1920.) Price 3*s*. 6*d*.

THIS little book is an abstract of the larger publication on the same subject which was reviewed in NATURE, vol. ciii., p. 166. It is evidently intended for travellers who have seen one or more of these curious and gigantic instruments and wish to know something about their origin. All the tabular matter and similar details have been omitted, while the clear descriptions and some of the excellent pictures have been retained. We could have wished that the author had omitted from this guide-book his remarks about the supposed scientific knowledge of Jai Singh. It cannot be denied that this man, living in the eighteenth century, not only was quite unaware of what had been done in Europe during the previous two hundred years to improve the construction of instruments, but also did not even make the slightest advance on the work of the Greek and Arabian astronomers. All he did was to copy some instrumental monstrosities erected at Samarkand three hundred years before his time, and it is no wonder that little or no use was ever made of them.

(1) *Reports on Hides and Skins.* Pp. ix + 123. (2) *Reports on Oil-seeds.* Pp. ix + 149. (Imperial Institute. Indian Trade Inquiry.) (London: John Murray, 1920.) Price 6*s*. net each vol.

IN 1916 the Imperial Institute Committee for India was invited to inquire into the possibility of the increased use of Indian raw materials within the Empire. Various committees were set up to deal with the principal groups of materials selected for the inquiry, and the present volumes are the reports of those dealing with hides and skins and with oil-seeds. In the report on the former materials (1) it is shown that the pre-war trade in "kips" was almost entirely with Germany and Austria. During the war the Government was able to utilise most of the material produced, and proposals are made for preventing the return of the trade to the countries of Central Europe. For this purpose a preferential export duty is proposed; also the leading tanners of the Empire have been approached, and they have agreed that they can utilise all the hides produced by India. Suggestions are also made for improving the quality of the hides. Statistics showing the export trade between 1910 and 1918 in raw cow-hides, buffalo hides, and goat and sheep skins have been inserted. The report of the committee dealing with oil-seeds (2) discusses the position of the trade in that commodity with England, Germany, and France at some length. It is pointed out that there is likely to be a serious shortage of fats in the world, and a system of rationing is recommended in order to secure adequate supplies to Great Britain and her Allies. It is further suggested that a preferential import tax on vegetable oils should be levied at our ports, and that there should be co-operation between the seed-crushers, the banks, the Government, and the transport companies with the view of facilitating the transit or re-export trade and of reducing the cost of production. Statistics for 1895 onwards of the trade in ten different kinds of oil-seeds produced in India are given.

Immunity in Health: The Function of the Tonsils and other Subepithelial Lymphatic Glands in the Bodily Economy. By Prof. K. H. Digby. Pp. viii + 130. (London: Henry Frowde, and Hodder and Stoughton, 1919.) Price 8*s*. 6*d*. net.

IN this book Prof. Kenelm Digby discusses the functions which may be performed by such structures as the tonsils, the intestinal lymphoid follicles, and the vermiform appendix, all of which are essentially lymphoid organs grouped by the author under the term "subepithelial lymphatic glands." The disadvantage of these structures in the body is their proneness to bacterial invasion and infection. The tonsils and appendix are, moreover, frequently removed by operation without any apparent effect due to their loss. The utility of these glands has, therefore, been doubted, and the appendix is commonly regarded as a vestigial organ in process of reduction. It is noteworthy that all these structures are located in situations—mouth, throat, and intestine—where large masses of bacteria are present, that they freely ingest bacteria, and that they occur only in birds and mammals, the highest and most differentiated of animals.

The hypothesis put forward by the author of the use of the subepithelial collections of lymphoid tissue is that they play an important function in immunising the body against pathogenic bacteria in proximity to the tissues—they are immunising stations, so to speak. The several tonsils form a protective circum-pharyngeal ring, and the Peyer's patches, appendix, and solitary follicles are distributed over the intestine—localities which are most in need of protection from bacterial invasion. In the stomach, on the other hand, lymphoid structures are almost absent, but here the acid nature of the secretion is sufficiently protective without their aid. The argument is sustained by a number of anatomical, microscopical, and clinical observations and data, and we think the author has made out a good case. The book is illustrated with several original drawings and diagrams. R. T. H.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The British Association.

THE discussion about the future of the British Association has turned mainly upon what may be called the "scale effect" consequent upon the vast increase in the activities connoted by the advancement of science. The effect is real enough; the decimal point has been moved on by one or more places in the course of the three-quarters of a century of the life of the Association.

And it is not only science of which this is true. We see the same kind of problem in such common affairs as university education, Parliamentary government, and Treasury control of expenditure Formulæ which were worked out fifty years ago or more for a certain scale are still being used, but they are not applicable now that the scale is increased tenfold or a hundredfold. Each case has, no doubt, an appropriate solution if we have the courage to face the facts and deal with them instead of ignoring them.

But as regards the British Association there is a social side of the question which has not received much attention. The Association does not select a town out of all England, Wales, Scotland, and Ireland at which to hold a summer meeting. It is invited to honour a town with its assemblies. The first magistrate and other leading citizens attend a meeting of the Association and offer the hospitality of their city.

If we go back some years beyond the beginning of the present century, the invitation meant an offer of the personal hospitality of the citizens to the active members of the Association. In those days the prosperous householders of the larger towns and their neighbourhood had spare rooms which were intended to be used, and were used, for the purpose of entertaining friends. The devotees of science were interesting people with whom to spend a week was a pleasure worth seeking. To offer hospitality for an astronomer from Ireland, a mathematician from Cambridge, an economist from Oxford, a geographer from London, a geologist from Wales, or a chemist from Scotland was not altogether a one-sided bargain. What these guests did with the time devoted to the discussion of recondite matters of their own science in the Sections was not the *quid pro quo*. Their hosts would become members or associates as part of the invitation, and possibly attend the Sections in order to be able to show their guests the way; but their insight into science and its methods was obtained by having one or more successful exponents of science staying in the house. They would probably learn more of what went on in the Sections from their guests' account of it over breakfast than by hours of personal attendance in a room where the difference between drivel and discovery is not always signalled. A party of half a dozen guests at one of the larger houses was brilliant company well worth entertaining.

The president's address dealt with the moving scientific topics of the day, the evening lectures were the last word in scientific exposition. The evening parties gave guests and hosts an opportunity of widening the circle of acquaintance, and the excursions often developed acquaintance into friendship. The guests left with a feeling of personal obligation which was not without opportunity of requital. If that feature of the British Association is lost in the effort to make the world better for somebody else, the loss of the grace of domestic hospitality is profound.

At the time it was not only a simple and natural grace, but also an essential preliminary to an invitation. To house a thousand visitors in the early days of the Association otherwise than by private hospitality would have puzzled the most energetic of local secretaries.

Very little money beyond the cost of the ticket came into the question. On the joint invitation of the authorities of a town, halls were available for meetings and other facilities provided. There remained to be paid for an abundant supply of stationery —which members appreciated, but not always with due respect—the printing of the journal and other incidental expenses, and one or more evening parties.

As time went on personal service became merged in or supplemented by a guarantee fund. The actual expenses of a meeting of the British Association do not appear in its accounts. In later years it was a shock to learn that people who had spare rooms actually absented themselves from home at the time when the Association was known to be coming; when it was our turn to act as hosts we thought the plea of an inexorable summer holiday rather a shabby excuse. But from the occasion of the meeting of a certain jubilee year hotel accommodation became the rule for the most active members of all the Sections, and members may now go through a meeting of the Association without making a single acquaintance in the town. There is no small danger of the meetings being changed from occasions for the exercise of graceful hospitality into the periodical lumbering of a rather ineffective machine.

I have no particular wish to be simply *laudator temporis acti*. If we have definitely turned our backs on the past and the pleasure of company has vanished, with all that that must have meant for a town in the dissemination over the table or round the hearth of information about science and education, where to go, and what to see or to read and all the rest, are we now instead to deliver within a week, in return for a guarantee fund, something which will be recognised as its equivalent in scientific exposition? If so, we shall want a strength of organisation that is at least quite uncommon in the scientific world, and I do not envy the organising secretary who has the duty in hand. The existing machinery is certainly not sufficient. The equivalent of twelve men enlightening a great town on the mysteries of all the sciences by talking for twelve hours each in a single week gives me the same impression as "seven maids with seven mops sweeping for half a year."

> "Do you suppose," the Walrus said,
> "That they would make it clear?"
> "I doubt it," said the Carpenter.

What I am quite clear about is that if you would allow a company of meteorologists, magneticians, seismologists, and other students of the earth and the sky to meet together for a week and discuss matters of common interest, the community that entertained us should not complain for lack of interest; but if you tell me that I have to expound modern meteorology to the man in the street in a paper or discussion of an hour and a half, and that ninety-five other people will do the like for their respective subjects within the week, I give it up. I know it cannot be done, even if I am allowed unlimited use of technical language, which appears, somewhat irrationally, to annoy some of your correspondents. I wonder why? Would they wish us always to paraphrase electricity as that which is produced when amber is rubbed with cat-skin? Science without technical language is very much like "French without accents."

We might do better if we concentrated our attention on the successful execution of what ostensibly we attempt. Let us give up arranging meetings at a time when we know, from the circumstances of the case, people cannot and will not attend, and give up also the formality of voting on questions which have been neither read nor circulated. If the popular evening lecture has ceased to be attractive, let us devise some other form of after-dinner appeal with scientific accessories; the Red Lions ought not to lag behind the kinema. If we wish to address an audience, let us address the audience; if we have something to say, let us say it; if we wish to make ourselves heard, let us make ourselves heard or know the reason why; and, finally, if the proceedings are reported, let the Sections make skilled reporting a part of their business. The word recorder seems to have got adrift from its moorings lately. Machinery in motion always has an irresistible attraction; if the meetings of the British Association presented examples of scientific purpose, perfectly managed and scientifically executed, they would be acceptable in many large towns, although the subject-matter might not all of it appeal to the man in the street. It ought not to be forgotten at this particular time that in 1903 Sir Norman Lockyer endeavoured to strengthen the hold of the British Association by keeping its organisation in operation throughout the year, and when the Association declined the suggestion, sought other means of giving expression to his views.

October 3. NAPIER SHAW.

IF you do not consider the subject of the British Association, which has been so fully discussed in recent issues of NATURE, to be now exhausted, I should like to state briefly how it appears to me.

The Association had at first six "Committees of Sciences." They were in 1835 converted into Sections. The following year another Section was added for Mechanical Science. The Sections continued to be seven only for the next fifty years, when H (or Anthropology) became a separate Section. Botany, Physiology, Educational Science, and Agriculture have since been added, making up the twelve existing Sections.

The Association was not in a hurry, for it was well aware of the practical difficulties arising from a multiplicity of Sections, but these added Sections have certainly not detracted from its popularity. The Conference of Delegates is another modern development of the work, and keeps interest in that work alive in many parts of the country.

A still more recent extension of the activities of the Association is the Citizens' Lectures, which were very successful at Cardiff. The meeting there was a good one, and would have been much larger but for the exorbitant railway fares. The address of the president, Prof. Herdman, was both brilliant and practical, and will, I hope, be fruitful in the near future. EDWARD BRABROOK.

October 1.

The Examination System.

PROF. H. E. ARMSTRONG's address on the university problem in London, published in NATURE of September 23, induces me to make the following remarks with special reference to the examination system in England.

The chief defects are:

(1) Expecting a candidate to remember details necessary for giving a complete answer to an essay question.

(2) Expecting him to answer a lot of questions in three hours.

This has been improved on recently by giving highest honours for five questions out of ten. But, in my opinion, at most four essay questions in three hours are all that should be expected; and in the case of difficult mathematical or similar questions not more than three.

It is notorious that the best men do not always come out at the top, partly because some hate to be hustled, others think slowly, and others still are not walking encyclopædias even in their own subject.

I know of an institution where the examinations are quite as well managed as in other educational institutions, though I admit the syllabus is so large for the time allowed that there is a good deal of "cram" necessary. As a rule, a student who is good at any subject seldom comes out very high up, whereas others who often have no taste or gift for a subject are placed at the top Also, there is a student who can come out top of nearly every examination because he is good at examinations.

I suggest the following improvements:

(1) That students be continuously examined throughout the period of their instruction by weekly or monthly papers and practical work.

(2) That there be fewer questions set in essay or problem papers. Details I have already suggested.

(3) That manuscript note-books of any kind be used by students in all theoretical as well as practical examinations, particularly in scientific subjects.

OXFORD M.A.

An Awkward Unit.

THERE has lately been introduced on the Daily Weather Report a small map showing barometric tendency. The barometric change from 4h. to 7h. is given as "a multiple of the half-millibar, that unit having been found convenient for reading the barograms and adopted for telegraphic reporting" (*Meteor. Mag.*, August, 1920, p. 150).

It is to be regretted that European meteorologists appear to be unaware of the fact that the megadyne or megabar atmosphere was correctly defined by Prof. Theodore Richards in his classic paper on "New Methods of Compressibility," published by the Carnegie Institution in 1903, and in later papers. The bar is a pressure unit expressed in terms of force, and is equal to one dyne per square centimetre. This is the bar of American chemists and physicists, and has been in use at Blue Hill Observatory since 1914. The term "millibar" which meteorologists hastily adopted in 1913 appears to us to be a misnomer for "kilobar."

There are many solid arguments in favour of the use of a megabar atmosphere. These will not be repeated here, but it may be pointed out that the expression "*multiple of a half-millibar*" is awkward. It is so much easier to use the proper definition "500 bar."

Isallobars can then be drawn for any desired value, while it would be rather troublesome to express the same values in fractional parts, such as "*one-fifth millibar*," meaning a 200-bar change.

ALEXANDER MCADIE.

Harvard University, Blue Hill Observatory, Readville, Mass., September 23.

Absorption Spectrum of Hydrogen Chloride.

THE unexpected satellites which Imes (*Astrophysical Journal*, November, 1919) found beside each line in the HCl absorption band at $1{\cdot}76\mu$, and which measurements of his curves show to have an average wave-length $16 \pm 4 \cdot$ Å. longer than the lines which they accompany, are readily accounted for as due to the heavier of the two isotopes, atomic weights 35 and 37, of which Aston (*Phil. Mag.*, vol. xxxix., p. 611, 1920) has shown ordinary chlorine to consist. An approximate theory shows the wave-length of the band centre to vary as the square root of the effective mass, $m = \frac{m_1 m_2}{m_1 + m_2}$, where m_1 is the mass of the hydrogen nucleus and m_2 that of the chlorine atom. Taking $m = 35/36$ for the lighter and $37/38$ for the heavier isotope, the calculated difference between the wave-lengths of corresponding lines for the two isotopes comes out 13 Å. This is much larger than the differences of about 0·004 Å. which have been found between lines of the isotopes of lead (Aronberg, *Astrophysical Journal*, vol. xlvii., p. 96, 1918, and Merton, Roy. Soc. Proc., A, vol. xcvi., p. 388, 1920).

I hope soon to publish a more detailed account of the theory and measurements of these lines, probably in the *Astrophysical Journal*. F. W. LOOMIS.

New York University, University Heights, New York City, U.S.A.

A New Visual Illusion.

A VISUAL illusion which I have never seen referred to may be of interest. If the gaze is steadily fixed for a few minutes on a spot in the descent of a waterfall which has a fairly long unbroken fall, and afterwards quickly transferred to the adjacent hillside, the hill itself appears to rise slowly as a whole, somewhat as though it were an elevator. The same result may be obtained by looking fixedly at the broken surface of a rapid and fairly wide stream; on directing the eyes suddenly to the opposite bank this appears to move slowly up-stream.

The illusion seems to me to be due to the rapidly moving water tending to carry the vision along in its own direction, as occurs when any moving object is unreflectively observed. But while the eyes are kept fixed on the selected point, this tendency becomes counteracted by a series of slight and rapid but unconscious muscular efforts which prevent the eyes from following the motion. After the gaze is removed to the adjacent stationary ground, these muscular efforts automatically persist for a short time, thus causing the ground to appear to move in the opposite direction to that of the water. But possibly a more accurate explanation can be advanced.

J. E. TURNER.

55 Allerton Road, Mossley Hill, Liverpool.

Plant-life in the Cheddar Caves.

SINCE reading the letter relating to plant-growths in the Cheddar caves by Mr. L. Pendred which appeared in NATURE of August 5, I have been able, by the courtesy of Messrs. Gough, to examine the plants *in situ*, and to secure a quantity of material for fuller investigation.

The green patches on the cave-walls were found to consist of a small green unicellular alga. The loose cave-earth on the sides of the cave-paths yielded a few specimens of fern prothallia. The plant patches in the neighbourhood of the electric lights were found to consist of the following species of mosses: *Plagiothecium denticulatum, Amblystegium serpens*, and *Fissidends bryoides*, all of which are fairly common. My determinations of these species have been confirmed by Mr. A. Gepp, of the botanical department of the British Museum (Natural History).

I think Mr. Pendred's suggestion that the spores were carried into the caves by the spades or on the clothes of the workmen is highly probable, or that the excellent ventilation maintained in the caves may have resulted in the spores being carried in by air-currents. In any event, the dampness and the air-currents would be factors assisting in the subsequent germination of the spores.

EDITH BOLTON.

Armstrong College, Newcastle-upon-Tyne.

Old Maps.

REFERRING to the kind notice of my presidential address to the Conference of Delegates at the Cardiff meeting of the British Association in NATURE of September 16, p. 90, time did not permit details to be given of the evolution of Scottish maps, or those of Faden, etc., would certainly have been referred to. The large map of Cary's which I mentioned was not the one you surmise, "with the coach roads coloured in blue, which is on the scale of five miles to an inch," but the map on the scale of *two* miles to an inch. The typist or printer, quite pardonably, has apparently mistaken my "two" for "ten." With regard to Griffith's map of Ireland, I still contend that the date of the map "to be included as a classic" is that of 1853. I know there was a slightly improved edition in 1855; there is one in the library of the Geological Society of London, but that was the *third* edition, and not the second, as stated in your columns. T. SHEPPARD.

The Museum, Hull.

I CONFESS that I was not aware of a large map by J. Cary on the scale of one inch to two miles. The one that I mentioned, with mail-coach routes in blue, is of constant service to me. Great confusion has been caused in regard to Griffith's geological maps of Ireland by references to them as successive editions, as if all were published and on the same plan and scale. Maxwell H. Close (Journ. R. Geol. Soc. Ireland, vol. v., p. 136, 1879) is, I think, responsible for calling a geological map exhibited in 1815 "the first edition," but he carefully added that it was never printed, and he evidently meant only "the first form." He emphasised the fact, by underlining the word, that W. Smith's map of England was *published* in the same year. Griffith's map of 1835 was, according to John Phillips (*op. cit.* above, p. 138), large, but also unpublished. Phillips utilised its details in 1838. In 1838 a coloured geological map by Griffith was issued in connection with the Report of the Railway Commissioners, scale one inch to ten miles. A few months later in the same year his large map (one inch to four miles) appeared under the same auspices, and was, as Close tells us, sold to the public from March 28, 1839. These two maps of 1838 can scarcely be called two editions of the same groundwork, since they were both simultaneously in preparation. The large map of 1838 (published, with date, in 1839) was completely revised and re-engraved, with the addition of mineral localities, and issued in six sheets in April, 1855, the date being engraved on it against Griffith's signature. The map of 1853 was a small one (one inch to sixteen miles), and was issued in a guide to land-valuers.

The plates of the "classic" map of 1855 are preserved in the Ordnance Survey Office, Dublin. From inquiries that I have recently made of this office and of the original publishers, no coloured copies seem now to be available.

It is rarely that one has a chance of correcting Mr. Sheppard. THE WRITER OF THE NOTE.

The Iridescent Colours of Insects.[1]

By H. ONSLOW.

II.—DIFFRACTION COLOURS.

THE structure of the scales of a number of iridescent butterflies was described and illustrated in the first article. The colours of many of these insects are undoubtedly produced by thin plates, either of chitin or of chitin and air. In a few instances, however, the structure gave no indication whatever as to how the colours were evoked.

Some definite modification of the structure gives rise to the principal colour, but all the minor details, such as the exact shade and the quality of the surface, which are so characteristic of any particular species or variety, are determined by

FIG. 1.—The Green Hairstreak (*Thecla rubi*). Showing the iridescent green under-wings, which are the same colour as the leaves. (Natural size.)

the shape and position of the scales, the amount and form of the surface modelling, and the colour and localisation of any accompanying pigment. Consider, for instance, the shimmering appearance of the familiar Green Hairstreak (*Thecla rubi*), Fig. 1, which makes this insect so difficult to find, when it sits with its wings folded high overhead, looking like a green leaf dancing in the breeze. The appearance of the green scales is well known, *1* (Fig. 2), and a discussion on their colour, and on the cause of their characteristic reticulation, was carried on in the *Entomologist's Record*, vol. vi., p. 35, 1895.

When observed by reflected light under the microscope, this shimmer is seen to be due to the spangled appearance of the scale, which is divided into many small, irregular areas, *o*, which reflect a green glitter of varying intensity, like so many sequins. These areas are divided from one another by pale lines, which form a reticulation. By transmitted light the reticulation shows as a transparent line, and, moreover, the brown colour of the polygonal areas is seen to vary considerably, some being dark brown and very opaque, and others pale yellow and transparent. Now the intensity of the green light varies in exactly the same way as this brown colour, the darkest and most opaque areas reflecting the brightest green. The iridescent colour is probably caused by a periodic structure not unlike that described in *Papilio ulysses*, the normal brown

FIG. 2.

1, Green under-scale of *Thecla rubi*, showing reticulation. *o*, dark polygonal areas.

2, Section through scale of *Hypomeces squamosus*, var. *durulentus*, showing stratification. *c*, surface cuticle.

3, Scale of the same weevil, *in situ*. *r*, root.

4, Plan of scale from the same weevil.

5, Cross-section of green scale of *T. rubi*, showing places *b*, where the scale is looped up, corresponding to the reticulation in *1*. *s*, striæ.

6, Tangential section through the wing-case of *Heterorrhina elegans*, made through the plane *ab* of section 7, showing the tops of the doubly refractive rods.

7, Cross-section through the same wing-case, showing layer of rods r_1 and a deep layer r_2. *c*, the surface cuticle.

All these sections, with the exception of *5*, were drawn to the scale μ=1 mm. with Zeiss 2 mm. apochromat, N.A. 1·4, and Comp. Oc. The scale *1* has a magnification of about 100 diams.

colour of the scale concealing any trace of this structure that might otherwise have been visible. The explanation of the reticulation and the spangled appearance it produces becomes at once evident on cutting a transverse section, *5* (Fig. 2), through the scale. It can be seen that the network corresponds to the thin places on the scale, *b*,

[1] Continued from p. 152.

where it appears, as it were, to have been looped up. The bright green areas then correspond to the thickest portions of the scale. This is evidently only another example of the intensification of the colour produced by an underlying screen of dark pigment, which absorbs the excess of white light that would otherwise be reflected to the eye, causing the colour to become much desaturated.

Diffraction of Light by "Gratings."

Colours due to barred structures, or "gratings," which diffract light in the usual way, cannot be said, in Lepidoptera at least, to be of very great importance. They do, however, often produce effects which, though of secondary value, contribute a good deal to the final result. The fact that most scales appear to be marked with striæ, which form gratings of suitable dimensions, has sometimes given rise to the idea that most insect colours are produced in this way. This is evidently not the case, for iridescent scales are sometimes smooth, and, moreover, plain black and white ones are often striated. Impressions or replicas were therefore taken of many scales in a special preparation of collodion, in order to isolate the effect of the surface structure from any other colour-producing factors. Good "gratings," showing normal lateral spectra, were obtained from most insects, such as the Large White (*Pieris brassicae*), but if the film was dyed, the colours became feeble or disappeared. This indicates that diffraction colours are, as might be expected, discernible only on very pale or colourless scales. The existence of diffraction colours can be clearly demonstrated by the following experiment. An impression was made from the pale blue surface scales of *Morpho achilles*, in such a way that at least one patch adhered to the collodion film. On tipping the grooved film so as to cause the spectrum colours to pass across the patch of scales, it could be seen that their normal blue colour became intensified in the violet region of the spectrum, changed to mauve or pink in the red region, and returned to its original shade on passing into the infra-red. When this effect has once been seen, a very similar play of pale mauve and pink diffraction colours can be discerned on examining the wings of *M. achilles* itself, and of certain similar insects.

Very brilliant colours are shown by scale-bearing beetles or weevils, like the Brazilian Diamond Beetle (*Entimus imperialis*) (Fig. 3). Michelson admits these colours to be an exception to the general rule, by which he attributes all insect colours to selective metallic reflection, or surface colour. He believes the colours of these beetles to be due to gratings within the scale itself, since as soon as a fluid can enter the scales through a rent or tear the colour vanishes. Moreover, since the light is concentrated in a single spectrum, he is obliged to assume that the grating has bars, which are asymmetric or prism-shaped, so that they refract the incident rays in the same direction as the diffracted rays of the lateral spectra. For several reasons it is difficult to believe that such saw-tooth-shaped gratings are responsible for the total colour effect. For instance, the very saturated complementary colours seen by transmitted light, and the monochromatic character of the reflected colours at different angles, demand a form of grating structure even more complicated than that described by Michelson, such, for instance, as that named by Prof. R. W. Wood the "échelette grating." Moreover, though as a rule no structures are seen, a very well-defined stratification, 2 (Fig. 2), sometimes appears in cutting sections of certain scales, as in the pink weevil, *Hypomeces squamosus*, var. *durulentus*. This stratification can be seen in plan, 4 (Fig. 2), and appears to exist throughout the scale, giving it in section the crossed appearance of the strings of a tennis racquet. It seems probable that such a structure would contribute a large share to the total colour effect. Further, a suitable irregularity in the periodicity or thickness of the plates

FIG. 3.—The Brazilian Diamond Beetle (*Entimus imperialis*), a large, iridescent weevil. The black pits on the wing-cases are lined with gem-like scales. (Natural size.)

would account for the existence of the very saturated colours of some weevils, and of the very pale and desaturated colours of others.

Dispersion of Light by Prisms.

If Michelson's hypothetical prism- or saw-tooth-shaped gratings are omitted, no case of prismatic structure has been met with. It is true that Dr. H. Gadow has explained how the colours of certain feathers might be the result of the roughly prism-shaped structure of the barbules. He supposed that these were placed in such a way, in respect to each other, that each barbule obscured part of the spectrum formed by the preceding one, so that partially monochromatic colours would result. Numerous theoretical and practical considerations, however, make this suggestion highly improbable.

The Scattering of Blue Light due to Small Particles.

The investigations of the late Lord Rayleigh, and others, have shown that the blue of the sea, sky, snow and even tobacco smoke is caused by particles which, being very small compared with the wave-length of light, scatter the blue waves to a much greater extent than the longer red waves. Several colours can be produced in this way, as, for instance, the blue, green, and purple of certain feathers, which are matt, and do not change colour with the angle of incidence.

Such feathers show a faint yellow colour by transmitted light, and any pressure which destroys the structure also destroys all colour. The small bodies which scatter the light are in this case said to be exceedingly minute air-canals, which, on being filled with fluid, lose this property. In the case of feathers, as well as of certain animals, such as green frogs and many reptiles, the green is said to be due to the additional effect of a yellow pigment which is superimposed on the blue colour, as in the case of *Ornithoptera poseidon*, already described. There are also some exceedingly brilliant marine copepods which owe their colours to a prismatic layer of minute rods, said to be small enough to scatter coloured light.

In most beetles the metallic colours are seen to come from the surface, and the slightest scratch on the elytron removes all the colour. In the case, however, of certain emerald-green and blue Cetoniids, the colour appears to come from underneath the surface, which gives the wing-case a curious enamelled appearance. This peculiarity can be instantly recognised, and, moreover, the colour, though matt, is seen to persist, even when the surface layer has been removed with a scalpel. This layer has been called the "*Emailschicht*," and when sections are cut from it tangentially to the surface, *6* (Fig. 2), they give a bright green colour by reflected light, even when mounted in fluid media. A transverse section, 7 (Fig. 2), was cut from this layer of a beetle called *Heterorrhina elegans*; it is seen to be made up of very fine rods of chitin, r_1, about 1μ apart, and arranged at right angles to the surface; r_2 represents a second layer of rods at a lower depth. The section, *6* (Fig. 2), made through the line *ab* of section 7, reveals the cut ends of the rods. Thus the light, on striking the wing-case, is reflected from the tips or ends of a large number of these rods or pillars, and it seems possible that they may scatter the light in the same way as the air-canals do in the case of birds' feathers. It must, however, be pointed out that the above theory demands that the rods, or other bodies which scatter the light, should be appreciably smaller than the wave-length of light; that is to say, not much larger than a complex molecule. It is, however, uncertain whether bodies of the same order of magnitude as light waves (*i.e.* $0{\cdot}5$–$1{\cdot}0\mu$) can produce analogous colours. A very remarkable point about these rods of chitin is that under crossed Nicols they appear to be doubly refractive. This suggests that there may be some analogy with doubly refractive striated crystals like the tourmaline.

(To be continued.)

Physical Anthropology of Ancient and Modern Greeks.

By L. H. DUDLEY BUXTON.

IN classical times a clear distinction was drawn between Greek and Barbarian; Aristotle, indeed, claimed that they differed physically. To a certain extent it may be shown that in detail Aristotle had right on his side, but it can also be shown that Greek differs physically from Greek, so that his general thesis is untenable. It is true that most of our evidence rests on measurements made on modern Greeks, but there are data to prove that the latter possess physical characteristics not differing essentially from those of the former.

Among recent writers it has been generally admitted that at least two races are represented in Greek lands—the "Mediterranean" and the "Alpine." The former are short in stature, dark in colouring, and long-headed, typically represented by the Spaniards; the latter are fairer, and often, but not invariably, have auburn hair and hazel eyes, and vary very much in stature. The Eastern branch of the Alpines are usually known as "Armenoids." They are distinguished by their short, high heads, which are extremely flattened in the occipital region. It has also been suggested that long-headed, blond giants—Nordic—have contributed to the population of Greek lands.

Of the aboriginal population there is little evidence at present. Von Luschan believes that, at any rate in Anatolia, the earliest people were Armenoids, and in the Morea Prof. Myres considers that the Alpine strain is certainly ancient and may even be primitive. Early material is, however, so rare that it is easier, in stating the problem before us, to reverse the time process and to study the ancient people after the modern, about whom we are better informed.

The mean cephalic index in Greek lands to-day varies from 79 in Crete to 84 in the island of Leukas. None of the Greeks are as long-headed as the pure Mediterranean type, such as we find in a comparatively pure form in Corsica or Spain and in a less pure form in Egypt; nor, again, are they as broad-headed as the Lycian gipsies, who certainly represent pure Armenoids. If we group such cephalic indices on the living as are available, we obtain three classes: (1) Under 81, Cretans, Peloponnesians, Lycians (Greeks and Turks); (2) intermediate, Messenians and Cypriots; (3) more than 84, Leukadians, Albanians, Lycian gipsies. It would appear unlikely that this grouping is of any significance, if we turn from these figures to the variation, conveniently measured by taking the square root of the average square deviation from the mean (standard deviation). The Lycian Greeks and Turks have a very high standard deviation, suggesting considerable mixture, and the standard deviation of the cephalic indices of all the Greeks is sufficient to suggest a greater or less degree of intermixture. The condition of intermixture in Cyprus can be seen in Fig. 1—a photograph of a Cypriot woman and her three children. The elder boy might easily have been taken for an almost pure Armenoid; the younger had many characters usually associated with the Mediterranean people. The inadequacy of grouping by cephalic index alone is confirmed by the very great local differences to be found between groups of villages in Cyprus, to take one example only. The villages on the north coast have a cephalic index of 81·9, those round the Bay of Salamis, just the other side of the hills, an index of 83·4. There are similar local differences in Crete.

FIG. 1.—A Greek family, showing the two extreme types. The father (not shown in the photograph) had fair hair and blue eyes. The contrasted contours of the backs of the head should be noticed.

If we compare ancient crania with modern heads it would appear that the modern Greeks are slightly more round-headed than the ancient inhabitants of the same places. But this difference is not of any great significance, and there is a greater resemblance between the modern inhabitants of any one place and their predecessors than between the modern inhabitants of two neighbouring areas; in other words, the variation of types at any stage is horizontal, and not vertical, in the strata. First, the cranial indices, then, of the Greeks exhibit great variety, sufficient to suggest ethnic admixture. Secondly, this admixture has not been evenly distributed, and local and distinct sub-races have been formed, the mean of which forms a series of types, one of which is illustrated in Fig. 2—a type which has neither the breadth of head of the Armenoid, nor the length of head of the Mediterranean. So distinct are these sub-races that where crania over a long period have been obtained the cephalic index of one modern village more closely resembles that of their Bronze-age predecessors than that of a neighbouring area. Thirdly, there is archæological material which suggests that the mixture of race is early, possibly Neolithic in Leukas, certainly Bronze-age (or before) in Cyprus and Crete.

So few complete ancient skeletons have been collected that we cannot estimate the stature of the ancient Greeks. Among the modern, we find that

FIG. 2.—An intermediate type, with hazel eyes and brown hair.

the Cypriots and Cretans are the tallest, averaging about 5 ft. 6½ in., and the Leukadians and Peloponnesians the shortest, being about an inch shorter. So few measurements are, however, at present available that the stature must remain uncertain.

Data for hair and eye colour are rather scanty. The number of blue-eyed individuals is not, however, so few as might be expected. In Cyprus they form about 10 per cent. of the population, and most authorities are in agreement that blue eyes are not rare in Greek lands. It is this occurrence of light eyes that has made some writers postulate the presence of Nordics among the Greeks. Speaking from personal experience, the author was struck by the continual association of blue eyes with a very Armenoid type of skull in Cyprus and elsewhere—the taller boy in Fig. 1 is a good instance of this type—and though, historically, no doubt Nordics have filtered into the

Eastern Mediterranean at various times, the evidence of blue eyes is certainly insufficient to establish their presence as a recognisable element in the population.

The distribution of other characters, such as the form of the nose and of the orbits, cannot at present be plotted, as the evidence is scanty. Such measurements as have been made on the face suggest that, among the Greeks at any rate, broad faces accompany broad heads, and *vice versa*.

If we sum up the evidence afforded by all the physical characters which have been measured, we find that the Greeks probably represent a very old hybrid, older than the beginnings of the Bronze age. In Cyprus the earliest skulls examined were found associated with red polished and white painted ware, and were clear examples of this hybrid. We cannot at present say whether these early Greeks formed this physical type in the island or before they reached it. Elsewhere, so far as our scanty data go, the same tale seems probable. In each little district there is a mixture; sometimes the population of widely distant spots is similar; sometimes villages close to one another differ. It must be remembered that the geography of Greek lands favours the development of local strains, communication being often very difficult. There does seem to be a physical background to the differences between village and village in classical times, and to the struggles between Athens and Sparta. Most of the inhabitants of the Eastern Mediterranean, however, are also of this hybrid stock, and so Aristotle's dictum seems unjustified. There is no physical background for Hellas as a whole. Our present evidence suggests that the degree of mixture is fairly uniform throughout, though the results of the mixing may be different. Lycia, however, presents a far greater degree of heterogeneity; this heterogeneity did not escape the notice of Herodotus, who says that the Lycians were Cretan immigrants into a country with a previous Minyan population, with a third element from Attica.

There is little reason to doubt the generally accepted statement that the two stocks which have formed this hybrid are Mediterranean and Armenoid. The former is found in a comparatively pure state to the west and south of the Greek world, the latter sporadically in a pure state among the Greeks of Anatolia, and may even occur, though we have no evidence at present, in the Balkan Peninsula itself.

Obituary.

Alfred E. Fletcher.

By the death of Alfred E. Fletcher, at the great age of ninety-four, the country has lost a scientific worker who, in his particular sphere, exercised on chemical manufacture a powerful and healthful influence. Born in 1826, Fletcher completed his school education in Berlin, and was employed for a time on railway surveying. He relinquished his career as an engineer in order to attend the science classes at University College, London (being debarred as a Nonconformist from attending the older universities), where he studied mathematics and chemistry, for which he received the gold medal in 1851. In the following year he was elected a fellow of the Chemical Society, and afterwards began a series of researches on artificial colouring matters, a field of inquiry which had been developed by Perkin's discovery of mauve in 1856, and greatly stimulated by the work of Hofmann and his pupils at the Royal College of Chemistry. Discouraged by prolonged litigation on the subject of a patent for a new colour process in which he was interested, Fletcher accepted in 1863 the post of assistant to Dr. Angus Smith, the first Chief Alkali Inspector. The origin of this department, which played so large a part in Fletcher's subsequent career, was the numerous complaints from farmers owing to the fumes from alkali and other chemical works. These fumes arose mainly from the discharge of hydrochloric acid in the manufacture of salt-cake. These and other acid vapours destroyed vegetation over large areas.

Under the Alkali Act of 1863 trained chemists were appointed to control this industry. The result of such inspection was soon apparent. The acid, which has since become a staple and profitable product of the process, was absorbed in towers by passing the gases through a descending stream of water. This is not by any means the only example whereby the alkali inspectors have helped the chemical manufacturer to utilise his noxious by-products to his own advantage and to that of the public.

As assistant, Fletcher devised an ingenious aspirator for extracting flue gases for analysis, and also invented an anemometer for determining their rate of flow. In 1884, on the death of Dr. Smith, he succeeded him as Chief Inspector, and continued in that office until his retirement in 1895.

Fletcher's activities were not confined to clearing the atmosphere from noxious fumes. He entered upon a campaign against the smoke nuisance, which he continued for thirty years, embodying his views in a series of articles, addresses, and pamphlets. He was, so far as the writer remembers, a strong advocate of a centralised inspectorate of all factory chimneys on the lines of the Alkali Act, and set an example of domestic heating without smoke by installing a central warm air system in his own house, details of which he published in the Press and technical journals. He also assisted the Scottish Office in the administration of the Rivers Pollution Act.

Fletcher married in 1858 Sarah Elizabeth, eldest daughter of Richard Morley, of Leeds, and is survived by his wife, six sons, and three daughters.

J. B. C.

D. H. Nagel.

By the death of D. H. Nagel, of Trinity College, Oxford, science has lost an advocate who did much to remove the prejudice keenly felt in Oxford thirty years ago, and the University has lost a teacher remarkable for the thoroughness, the understanding, and the sympathy which endeared him to many generations of undergraduates.

In the examination for the open Millard Scholarship in Natural Science in 1882 Nagel was the only candidate who gained distinction both in the science subjects and in the optional classical paper. Elected Millard scholar, he worked under the writer (then Millard lecturer at Trinity) in the newly equipped laboratory in Balliol, between which and Trinity a doorway had been opened in 1879—a novelty in inter-college communications which was guarded with some anxiety by the college deans on each side, and usually referred to as "the scientific frontier."

As an undergraduate Nagel was distinguished by the width of his scientific interests; he was one of the few who attended professorial lectures outside their own subjects, and his enthusiasm may be said to have resuscitated and kept alive some of the courses in geology and mineralogy which did not form part of the usual honours schools. In addition to science he studied languages and gained a University exhibition in German.

Nagel took a first class in chemistry in 1886, and in the following Michaelmas term became demonstrator in the laboratory, and succeeded the writer as Millard lecturer in 1888.

The Balliol laboratory was soon extended into adjacent cellars to meet the needs of the two colleges, and in 1904 a considerable addition was made on the Trinity side of the "frontier," when the two colleges undertook to give practical training in physical chemistry as part of a general scheme for honours men in the University. In planning and supervising this course Nagel's knowledge and judgment found full scope.

At the opening of his Oxford career Nagel was one of the founders of the Junior Scientific Club, an institution which has been particularly successful in bringing together men engaged on different lines of scientific work, and of its members none were better equipped than Nagel by study and sympathy to understand and elucidate the relations of one branch of science to another. It was this faculty that gave him his unique position in Oxford when he settled down as fellow and tutor of his college.

It has been said of Nagel that he was too busy to do original work. This is partly true, but not the whole truth; on one side there were diffidence, some lack of the fighting spirit, and, perhaps, a fear lest the road he chose to pursue might lead nowhere; on the other, there were his keen delight in and critical appreciation of many lines of work, and the consciousness that his life would be more complete in unselfish devotion to others than in seeking fame for himself. Such being his nature, he was inevitably drawn into administrative work, and perhaps he found himself most completely as chairman of the board of the Faculty of Natural Science. In this position his wide knowledge, sound judgment, and kindly tact were invaluable, and it was largely under his guidance that the Department of Forestry was successfully instituted in the University.

As a delegate for local examinations and for the inspection and examination of schools Nagel exerted great influence on the study of science in schools, and his judgment and experience of school work have been largely utilised by the Board of Education.

To old Trinity men Nagel had become almost an institution; his pupils scarcely regarded him as a "don," for there was a wonderful *camaraderie* between them and their tutor. But they all came to him for help and counsel. His friends and colleagues did likewise, and we are all the poorer for his loss. H. B. Dixon.

Dr. Adolf Berberich, who was on the staff of the *Berliner Jahrbuch* for thirty-five years, and for some time its director, died at Berlin last April after a long illness. Berberich was born in Baden in 1861; his family was for many years in serious financial difficulties; nevertheless, he secured a good education, first at the Gymnasium at Rastatt, then at Strassburg University, where he studied astronomy under Winnecke and Schur. He suffered from extreme short-sight, which made astronomical observing difficult, so he turned his energies to the computational side of the science, in which he showed such energy and skill that his name was already known as an orbit computer in 1884, in which year he obtained a post on the staff of the Rechen-Institut. Berberich was soon led to take a special interest in reducing the computation of orbits and ephemerides of the minor planets to an orderly system, his work being invaluable in identifying and following the immense number of new planets that were discovered by photography. He was on terms of intimate friendship with Prof. Max Wolf and Dr. Johann Palisa, who were indefatigable on the observational side; he frequently received the observed places of a new planet at breakfast, and sent back its orbit and ephemeris before lunch. He had a marvellous memory, enabling him to keep the elements of many planets in his head, thus greatly facilitating their identification. The task of keeping the immense array of planets under sufficient observation is a Herculean one, only to be accomplished by systematic division of labour. International arrangements had been made in this direction before the war, largely under the initiative of the Rechen-Institut. Unfortunately, unnecessary duplication of work now prevails again. Berberich was much esteemed by a wide circle of friends as an earnest, religious, and benevolent man. He married not long before his death, and his wife survives him. An appreciation of his work by Prof. F. Cohn is contained in *Astronomische Nachrichten*, No. 5053.

The death is announced, at the age of fifty-eight, of Prof. Samuel Sheldon, professor of physics and electrical engineering at the Polytechnic Institute of Brooklyn since 1889. Prof. Sheldon was at one time assistant to Kohlrausch, with whom he was associated in the former's determination of the ohm. In 1906 he was elected president of the American Institute of Electrical Engineers.

The death of Sir Lindsay Wood, Bt., on September 22, at eighty-six years of age, is announced in the Journal of the Royal Society of Arts. Sir Lindsay was born in 1834, and educated at the Royal Kepier Grammar School, Houghton-le-Spring, and King's College, London. He served as a mining engineer apprentice at Hetton Collieries, of which in 1866 he became managing director. He was also on the boards of several other coal companies and allied undertakings. From 1875–78 he was president of the Northern Institute of Mining and Mechanical Engineers, and in 1879 he served on the Royal Commission on Accidents in Mines. His chief work was a series of elaborate and exhaustive experiments on the pressure of gas in coal. Sir Lindsay was created a baronet in 1897, and served as Deputy-Lieutenant and High Sheriff of the County of Durham.

Dr. Harmon Northrup Morse, professor of inorganic and analytical chemistry and director of the chemical laboratory at Johns Hopkins University, died recently in his seventy-second year. Having graduated at Amherst in 1873, Dr. Morse returned to that college as an assistant in chemistry in 1875, after a period of study at Göttingen. In the following year he was appointed associate professor at Johns Hopkins, and in 1891 was promoted to a full professorship. He carried out many original researches on osmotic pressure and related subjects.

Notes.

At the concluding meeting of the International Congress of Physiologists, which was held in Paris on July 16–20, it was unanimously resolved, on the invitation of Sir E. Sharpey Schafer, to hold the next meeting in Edinburgh in 1923.

The annual oration of the Medical Society of London is to be delivered in May next by Lord Dawson of Penn. The Lettsomian lectures of the same society are to be given in February and March next by Mr. George E. Gask.

The British Electrical and Allied Industries Research Association has been approved by the Department of Scientific and Industrial Research as complying with the conditions laid down in the Government scheme for the encouragement of industrial research. The association may be approached through Mr. E. B. Wedmore, Electrical Research Committee, c/o Electrical Development Association, Hampden House, 64 Kingsway, W.C.2.

The following arrangements have been made by the Royal College of Physicians of London:—The Horace Dobell lecture will be delivered by Sir William B. Leishman, at 5 o'clock on November 2, on "An Experimental Investigation of the Parasite of Tick Fever, *Spirochaeta Duttoni*"; the Bradshaw lecture by Dr. C. Wall, at 5 o'clock on November 4, on "Chorea"; and the FitzPatrick lectures by Dr. E. G. Browne, at 5 o'clock on November 9 and 11, on "Arabian Medicine after Avicenna."

The council of the Chemical Society has arranged for the following lectures to be held during the coming session:—October 28, Emil Fischer memorial lecture, Dr. M. O. Forster; December 16, Some Properties of Explosives,' Sir Robert Robertson; April 7, 1921, Mass Spectra and Atomic Weights, Dr. F. W. Aston; and June 16, 1921, The Natural Photosynthetic Processes on Land and in Sea and Air, and their Relation to the Origin and Preservation of Life upon the Earth, Prof. Benjamin Moore. By the courtesy of the council of the Institution of Mechanical Engineers, the first two lectures will be held in the lecture hall of that institution (Storey's Gate, Westminster, S.W.1). Informal meetings, at which fellows are invited to show experiments and apparatus, will be held at Burlington House on November 18 next and on February 3 and May 19, 1921.

Prof. F. Soddy's review of the activities of the Department of Scientific and Industrial Research published in the *Observer* of September 26 has been followed up in the same newspaper by letters from Dr. J. W. Evans and Mr. J. W. McConnell. Prof. Soddy remarked: "To-day a new kind of science—Government science—is being step by step built up, not for humanity, but its masters; not for the community, but big business"; emphasised the fundamental change of policy which accompanied the creation of the new department for the administration of funds for industrial research; and contrasted the generous treatment and comparative freedom from Government control accorded to industrial associations with the arbitrary methods of dealing with individual research workers. Dr. Evans suggests that the mistakes of the Department are attributable to the "fundamentally wrong-headed attitude adopted by the nation generally with regard to our scientific societies and the science faculties of our universities," and instances the disabilities under which these bodies suffer in carrying on their work. He deplores also the decision of some university authorities to raise their fees at a critical time in the nation's history. Mr. McConnell, who acted as chairman of the provisional committee for forming the Cotton Research Association, although in general sympathy with the views expressed by Prof. Soddy, is of the opinion, which is not shared, however, by scientific workers generally, that "the rewards of the research of whatever kind should have been primarily secured to those who found the money to pay for it."

The wonderful achievements of Rolf, the thinking Airedale terrier, bid fair to be eclipsed by the marvel of his daughter Lola. Lola passed at the age of two years into the keeping of Miss Kindermann when she could only say "yes" and "no," but after a few days of schooling the dog could read and count. In one day's lesson she could tell the hour by the clock. In the same way she acquired a knowledge of days, months, measurements, and musical notes, could forecast the weather, and gave evidence of "filosofia morale." Dr. W. Mackenzie, from whose "Gli Animali 'Pensanti'" (*Quaderni di Psichiatria*, 1920) these particulars are taken, vouches for Miss Kindermann's ability, veracity, love of animals, and ignorance of psychology. He does not attribute all the intelligence to Lola, but believes that there is a *rapporto medianico* between the supra-liminal consciousness of mistress and the sub-liminal unconsciousness of pupil. Seeing, however, that Dr. Neumann's experiments (duly discussed in the pamphlet) place Rolf's achievements in a new light, it may be well to await further observations on Lola before passing judgment on Dr. Mackenzie's conclusions. The trouble is that negative results may be explained as due to lack of the said *rapporto*.

The study of place-names, of great importance in American geography, has been much advanced by a monograph entitled "Yurok Geography," by Mr. T. T. Waterman, published in the series of publications of the University of California, vol. xvi., No. 5. This summarises a great mass of material collected by Dr. A. L. Kroeber and the writer among the Yurok Indians along the Klamath River and in the adjacent region of north-western California. Many of these primitive Indian names are now used by white settlers, and appear in the ordinary maps of this region in anglicised form. Their identification and interpretation naturally present much difficulty, but the present monograph, with its careful lists and maps, will be of interest to both the geographer and the philologist.

The system of geomancy or divination known as Raml, "sand," is common among the Arabs. At a propitious hour, noon, or one-third of the day before or after noon, the Khattāt, or "writer," prepares a smooth patch of sand, while his client places the tip of the middle finger of his right hand on the ground and states mentally the object of his quest. Then the diviner makes finger-prints at random in the sand and counts off the prints of each line in pairs to see if it contains an odd or an even number. There are, on the whole, sixteen possible figures in the diagrams which he makes, each of which has its special name and meaning. The nomad Arab in the Sudan, says Mr. R. Davies, who gives a full account of the system (*Sudan Notes and Records*, vol. iii., No. 2), spends much of his time in search of lost or stolen animals, and this system of divination has thus arisen. It seems to be successful, for Mr. Davies writes: "On the only occasions, three in number, when serious trial of the Khatt has been made in the presence of the writer, the forecast of the Khattāt has each time been justified by the result."

In an elaborate monograph (University of California Publications in American Archæology and Ethnology, vol. xvii., No. 1) Mr. Paul Radin discusses the sources and authenticity of the history of the ancient Mexicans. These sources, which are of great extent, fall into two types: the actual old Indian codices, of which there are but a few extant, and the works of Christianised Indians and Spaniards. The vast majority of the old manuscripts have disappeared, as well as the copies made of them. As late, however, as 1746 Boturini was able to make a large collection dealing with all the aspects of the ancient culture. Mr. Radin in this monograph has made a critical study of a large number of ancient documents, and provides English translations of the most important passages. The value of some of these materials is doubtful, but the Nahua peoples had a complex calendar system and a rude system of writing, and as they were deeply interested in the traditions of their migrations, it seems clear that these records contain information of much value to ethnologists. Mr. Radin has done good service to science in his careful account of these manuscripts and by his translations of the most important records.

During the Mahdist occupation of the Sudan (1885–98) coins were struck by the Mahdi at Khartum, and later by the Khalifa at Omdurman. Many of these coins have now become scarce, and Mr. H. S. Job, in *Sudan Notes and Records* (vol. iii., No. 3), has done good service to numismatics by giving a full account of this example of the debasement of currency in the hands of a despotic ruler, and by providing a full catalogue, with illustrations, of the various types of mintage. After the fall of Khartum in 1885 considerable treasure of Egyptian and English gold coins, the Mejidi and Maria Theresa dollars, with smaller Egyptian coins, fell into the hands of the Mahdi, who determined to have the bullion melted down and recoined. It was decided that two coins should be struck, a gold pound and a silver dollar, to which later a half-dollar was added. For the first the Egyptian gold piece of 100 piastres of Sultan Abd-al-Mejid was taken as the model, the name of the Sultan being replaced by the words "By Order of the Mahdi." Though these coins were of good quality they were regarded with mistrust, and circulated at less than their par value, while many foreign coins, though much worn, remained in circulation. It may be hoped that a full series of these interesting coins has been provided in our museums.

In a detailed analysis of the inheritance of hoariness in stocks, Miss Saunders (*Journ. Genetics*, vol. x., No. 2) shows that a graded series from the fully hoary form *incana* to the completely glabrous form can be obtained. Historical records indicate that the extreme glabrous form was probably the first to arise from *incana*, being mentioned as early as

1588, while Linnæus mentions the rare half-hoary *semi-incana* in 1762. Crosses of these forms produce a series of intermediate factorial combinations, including a type with a single hair on the tip of each leaf. It is concluded that the "factor" for a particular degree of hairiness represents a particular condition of physiological equilibrium subject to environmentally produced fluctuations.

In the Journal of the Royal Microscopical Society (1920, part 2) Mr. T. E. Wallis describes a method of quantitative microscopy by use of Lycopodium spores. By a sufficiently thorough mixing of the materials to be tested with the spores and by the use of a suitable suspending medium, the author finds it possible, by making a number of counts of the spores in different fields of view, to obtain results of an order of accuracy equal to many of those obtained by chemical operations both qualitative and quantitative. As examples are cited the determination of the proportion of maize-starch that had been added to some ordinary wheat-flour, and the determination of the number both of starch grains per milligram of maize-starch and of pollen-grains per milligram of insect-powder; the last-mentioned supplies an index of the value of the powder.

Dr. W. Mackie has shown that monazite is widely distributed in the granites of the North of Scotland, and it has now been found by Dr. A. Gilligan in almost all the beds of the Millstone Grit of Yorkshire, doubtless derived from this northern source ("The Petrography of the Millstone Grit of Yorkshire," Quart. Journ. Geol. Soc., vol. lxxv., p. 271, 1920).

The "Final Report of the Work of the Commission on Munition Resources, Canada" (Toronto, 1920), besides useful notes on recent prospecting, contains (pp. 58–88) an account of trenches made for the investigation of bog-manganese ore, which may be of service to those interested in such deposits in Ireland. There seems not much hope of competition between the bog material and the hard ores of the ordinary mines. We have yet to learn how far selective action by bacteria is responsible for the precipitation of manganese oxides in swamps. Mr. Uglow's practical report naturally leaves the matter open.

Dr. R. S. Lull describes in the *American Journal of Science* (vol. l., p. 83, 1920) two "new Tertiary Artiodactyls" from remains discovered in Nebraska in 1914 by an expedition from Yale under his guidance. The deposits are of Late Miocene or Early Pliocene age. A very pleasing restoration is given of a new antelope, *Aletomeryx gracilis*, of which abundant material has been obtained, including nineteen skulls, both male and female. The name, meaning "wandering ruminant," is chosen on account of the migratory powers indicated by the delicacy of the limbs. The limb-bones are, indeed, generally broken.

From the General Report of the Survey of India for 1918–19 we learn that the curtailment of work owing to war conditions continued, several survey parties being engaged in Mesopotamia, East Africa, and elsewhere out of India. Of the topographical map on the one-inch scale 57 sheets were published during the year in place of the pre-war figure of 150 to 200. About 1500 one-inch sheets have now been published out of a total of 6218. Thirty half-inch and 11 quarter-inch, or "degree," sheets were published. The half-inch map is now the tactical map of India, and 177 of the 630 sheets are available. The "degree" sheets are making slower progress, and their total is now only 52 out of 450. No further sheets of La Carte Internationale (1 : 1,000,000) appeared during the year, but two sheets of the India and Adjacent Countries Series (1 : 1,000,000) were published. The report includes complete indices of all sheets published by the Survey of India.

The Mines Branch of the Department of Mines of Canada has just issued a valuable monograph on graphite, written by Mr. Hugh S. Spence. It describes in detail the important Canadian occurrences of this mineral, and also reviews all other known sources of supply throughout the world. It is interesting to note that in 1913 Germany and Austria together produced practically one-half of the world's total supply, but that since then the American output has been nearly trebled. An interesting account is given of the various methods used for the concentration of graphite, for which purpose the flotation process appears now to be the most favoured, and the manufacture of artificial graphite is also described. An important section is devoted to the industrial applications of graphite; it is stated that the world's production of natural graphite is utilised in approximately the following proportions: For crucibles, 75 per cent.; for lubricants, 10 per cent.; for pencils, 7 per cent.; for foundry facing and stove-polish, 5 per cent.; and for paints, 3 per cent. The method of manufacture of all these articles is described, as well as that of others not included in the above list, such as graphite brushes for dynamos and motors, graphite electrodes, graphite for dry batteries, for electrotyping, and for various less important purposes. The monograph should prove valuable to all interested in the mining of graphite or the manufacture of graphite articles.

The United States Geological Survey has just issued an elaborate monograph on the economic geology of Gilpin County and adjacent parts of Clear Creek and Boulder Counties, Colorado, by Mr. E. S. Bastin and Mr. J. M. Hill. This district includes most of the mining camps of Colorado that are producing minerals of economic importance, including the well-known auriferous pyritic ores of Gilpin County, the gold and silver veins of Clear Creek County, the lead ores of Leadville, the telluric gold ores of Telluride, and many others. In addition to gold, silver and lead ores, the district here described produces also ores of zinc, copper, uranium and tungsten, the gold production being, however, economically by far the most important. The monograph describes the general topography of the area, spoken of here as the Central City quadrangle; the geology is described in detail, particular attention being devoted to the igneous rocks, amongst which the monzonites are the most important. Chapters are devoted to the economic geology and to the general features and origin of the various ore deposits, each of the more important ores being discussed separately. An interesting chapter is devoted to the methods of ore-treatment, the history of the development of the so-called Colorado or Gilpin County method of gold-milling being clearly traced, as also its displacement by the more recent processes of cyanidation and flotation. Justice is also done to the development of the smelting process, under Mr. R. Pearce, from its small beginnings at Blackhawk, removed afterwards to Argo, close to Denver. Statistical tables of the output are given, showing the economic importance of this district. The remainder of the book is taken up with a detailed description of all the mines of importance, the geological relationships of the ore-bodies being worked out in much detail.

THE Journal of the College of Science of the Imperial University of Tokyo for May 10 last contains an important paper, of interest to the students of the genesis of mineral deposits, under the title of "A Contribution to the Knowledge of the Cassiterite Veins of Pneumato-Hydatogenetic or Hydrothermal Origin: A Study of the Copper-Tin Veins of the Akénobé District in the Province of Tajima, Japan," by Takeo Katō. The district in question contains a system of practically parallel veins worked at first for copper, but afterwards found to contain important proportions of tinstone and wolframite. The author holds that "the veins of the Akénobé district are all consanguineous, and all gradations exist between the copper veins containing little or no cassiterite and the copper-tin veins containing much of the same mineral." The veins occur chiefly in Palæozoic slates. The abnormal feature of the occurrence is the fact that the district shows important exposures of intrusive dioritic rocks, forming either large masses or offshoots from these. There are, it is true, dykes of andesites and porphyrites, but these cut the veins "and are clearly later in generation than the latter." "No granitic or allied acid plutonic rocks have been observed," and the author concludes definitely that the veins are related genetically to the dioritic rocks—an occurrence which, though common enough so far as copper-bearing veins are concerned, is probably unique in respect of tin veins. The author's summary of the genesis of these veins is as follows: "The copper-tin veins of the Akénobé district were deposited from hydrothermal solutions, still containing fair quantities of mineralisers, at gradually decreasing temperatures, chiefly considerably below 360° C. The solutions had naturally a temperature far above the critical point of water (364° C.), and were gaseous in character, after emanation from the consolidating diorite magma. As they ascended through the surrounding slate complex the rate of fall of the temperature was very rapid, and they soon changed to superheated hydrothermal solutions."

THE chief periods of seismic activity of the well-known Comrie centre are from 1788 to 1801 and from 1839 to 1844. Since the latter year very few shocks have been felt. Some are recorded from time to time in Perrey's annual catalogues. During the last thirty years five have been felt, all of them slight and disturbing an area of at most a few square miles. Three of these occurred towards the close of last century —on July 12, 1894, July 12, 1895, and August 22, 1898. In the present year a slight increase of activity is shown by the occurrence of a shock of intensity 3 (Rossi-Forel scale) on July 21, and of a slightly stronger shock (intensity 4) on September 14.

CANADA is keeping well abreast of the times in meteorology, and its Monthly Record of meteorological observations, which includes data from the Colonies of Bermuda and Newfoundland, will add much of value to the general knowledge of the world's weather. Results for the early months of the present year are to hand. Tables and maps are given showing the monthly average temperature and precipitation, together with differences from the normal over the whole Dominion. The observations are classified for province and district. For many places temperature, atmospheric pressure, and humidity are given for each hour, and the mean monthly averages and totals are well set out, also the mean proportion of bright sunshine for each hour that the sun is above the horizon. Observations of wind direction and velocity and of cloudiness are also obtainable. The detailed observations of wind both from the first- and second-class stations will prove of much value to the aeronaut. No observations are made at present of the form of cloud, or of the direction and speed of either lower or upper clouds. Such observations would be useful in the elucidation of upper-air problems.

AN analysis of the rate of ascent of pilot-balloons has been made by Lieut. R. P. Batty, and is published by the Meteorological Office as Professional Notes No. 12. The observations were taken at Butler's Cross, Salisbury Plain, from June to December, 1919. The ascents were not made at fixed hours of the day, but when required by the School of Artillery; 75 per cent. of the ascents were between 9h. and 13h. G.M.T., and mostly during July, August, and September. Average rates of ascent are given for each of the first thirteen minutes. From 225 ascents 1464 minute readings were obtained, and the mean rate of all ascents is 530 ft. per minute. Ascents have been grouped for specified hours of the day, and the mean rate is shown to be greatest at about mid-day. Ascents are also classified according to the amount of cloud in the sky, and it is seen that more cloud gives an increased rate of ascent. Moderate and strong winds give a higher rate of ascent than light winds, and the rate of ascent for different wind directions is also classified. It is noticed that immediately prior to entering cloud the rate of ascent almost invariably increases, mostly to 600–700 ft. per minute. Rain is said to decrease the rate of ascent by about 20 per cent. The size of the pilot-balloons used was 70 in. or 90 in., and their weight varied from 20 to 30 grams. Tables and diagrams are given showing the variations under the different classifications.

FATHER FROC has added yet another contribution to his already valuable researches on the typhoons of the Far East, in the "Zi-Ka-Wei Observatory Atlas of the Tracks of 620 Typhoons, 1893–1918." The atlas contains a series of charts showing the actual tracks of the centres of 620 typhoons which have been reported in the Far East during the twenty-six years, 1893–1918. The original purpose of the author was to issue these charts as an appendix to a more general study of the subject, but since the publication of this more comprehensive report has been considerably delayed, it was decided that the appendix should appear at once. Consequently, the atlas contains little more than the charts themselves, with brief explanatory notes on each. It lays no claim to be a theoretical treatise on the structure and origin of these revolving storms. No attempt at classification is made, since the charts are intended solely for the nautical guidance of sailors. The cases are enumerated month by month as they occur, and to avoid confusion and overlapping of the tracks, three charts are allotted to each of the months of maximum frequency (July to October inclusive). The maps cover a wide geographical area, from Cochin China and the Philippines in the south, to Manchuria and the Kurile Islands in the north, while embracing a vast stretch of the Pacific eastwards from the Asiatic mainland to 150° E. longitude. The irregular west-south-westerly motion of occasional storms in this region—chiefly in the China Sea—is clearly shown in the charts, and the author lays stress on the point that navigators should be familiar with the possibility of this unusual movement, even though the vast majority of the storms follow a general north-westerly track, such as is customary in the northern hemisphere. In conclusion, twelve summary maps are given, showing the dangerous zones and the successive changes which take place throughout the year. The atlas is of additional value in that it gives a trustworthy and up-to-date measure of typhoon frequency.

WE have received a copy of Catalogue No. 23 of second-hand books in science just issued by Mr. R. S. Frampton, 37 Fonthill Road, Finsbury Park, N.4. The works listed (some 1100 odd) range over most of the sciences, and the prices asked are very reasonable. The catalogue will be sent free upon application.

DR. WALTER KIDD is publishing through Messrs. H. F. and G. Witherby a work entitled "Initiative in Evolution," which will contribute to the evidence in favour of Neo-Lamarckism, and give especial consideration to the arrangement of the hair in mammals. Messrs. Witherby also give notice of "A Naturalist in Himalaya," by Capt. R. W. G. Hingston, in which attention is given, among other subjects, to geometrical spiders and their work, various species of ants and their organisations, and the nesting instincts of birds.

THE reviewer of "Smithsonian Meteorological Tables" in NATURE of September 30, p. 142, stated that the Tables are not obtainable in the ordinary way. Messrs. W. Wesley and Son, 28 Essex Street, Strand, W.C.2, remind us, however, that they are the agents for the Smithsonian Institution in London, and that the Tables can be purchased from them. The Tables form vol. lxix. of the Smithsonian Miscellaneous Collections, and not vol. lix., as given at the head of the review.

Our Astronomical Column.

PROF. PICKERING'S LUNAR OBSERVATIONS.—Prof. W. H. Pickering has for many years been making a careful study of certain lunar formations under all angles of illumination, finding striking changes of relative luminosity of adjacent markings in the course of the lunar day, which he ascribes to the presence of snow or hoar-frost, or in some cases to vegetation. There can be only one opinion as to the interest and value of the observations, whether Prof. Pickering's conclusions are accepted or not. His latest study (*Popular Astronomy*, August and September) is of the region round the crater Conon in the Apennines and the neighbouring formation of Bradley. He asserts that this region contains snowfields, clouds, and tracts covered with vegetation. He distinguishes the clouds from the snowfields as being more yellowish, less brilliant, and more subject to change. One note that he makes about them would seem to throw some doubt on their assumed nature. "No clear evidence of motion due to wind has ever been seen in the lunar clouds, which apparently merely form and dissolve *in situ*." The white snow-patches, on the other hand, which appear hazy at sunrise, are stated to show some drift; the "vegetation" regions darken conspicuously as the sun rises higher upon them. The author asserts that volcanic activity is by no means extinct on the moon, the floor of Plato being stated to be an active region emitting many steam-jets.

There cannot be much doubt about the relative change of brightness of the different markings, but it does not appear that the author has given enough consideration to the possibility that it may arise from differences in the composition of the rocks or of their degree of slope and of smoothness. While the occurrence of snow, cloud, and vegetation cannot be ruled out as impossible, it is at least somewhat difficult to reconcile with the tenuity of atmosphere that is demonstrated by the practical absence of refraction in occultations and eclipses.

THE SUN'S MAGNETIC FIELD.—The *Observatory* for September contains an article by Dr. F. H. Seares, written at Prof. Hale's request, giving an account of the researches made at Mount Wilson since 1908 on the sun's magnetic field. The investigation was suggested by the discovery of the Zeeman effect in the spectra of sun-spots, which were surrounded by hydrogen vortices. In the case of the general field the spectral shifts are extremely minute, less than one-thousandth of an angstrom, and it is only the remarkable accordance in the results that gives confidence that the effect is a real one, the shifts being of the same order as accidental errors in the measures. The precaution was taken that the measurer should not know in which direction the shift on any plate was likely to be, so that all bias was eliminated. Comparatively few of the spectral lines were found to be suitable for the research, and the results depend chiefly on iron and chromium lines. A first solution showed that the northern hemisphere had negative polarity, and that the magnetic axis was close to the rotational one. It was afterwards found that the inclination of axes is about 6°, and that the magnetic axis revolves about the other in 31·44 days. The investigation indicates that the field strength diminishes rapidly with increasing elevation, falling from 50 to 10 gausses in 200 km. It will be noted that the shifts in this investigation are much smaller than in the Einstein spectral test; but differential measures suffice here, while in the other case absolute ones are required.

Fossils and Life.*

By F. A. BATHER, M.A., D.Sc., F.R.S.

II.

THE argument for orthogenesis based on a race-history that marches to inevitable destruction, heedless of environmental factors, has always seemed to me incontrovertible, and so long as my knowledge of palæontology was derived mainly from books I accepted this premise as well-founded. But more intensive study generally shows that characters at first regarded as indifferent or detrimental may have been adapted to some factor in the environment or some peculiar mode of life.

Prof. Duerden's studies of the ostrich lead him to the opinion that retrogressive changes in that bird are destined to continue, and "we may look forward," he says, "to the sad spectacle of a wingless, legless, and featherless ostrich if extinction does not supervene." Were this so, we might at least console ourselves with the thought that the process is a very slow one, for Dr. Andrews tells me that the feet and other known bones of a Pliocene ostrich are scarcely distinguishable from those of the present species. But, after careful examination of Prof. Duerden's arguments, I see no ground for supposing that the changes are other than adaptive. Similar changes occur in other birds of other stocks when subjected to the requisite conditions, as the flightless birds of diverse origin found on ocean islands, the flightless and running rails, geese, and other races of New Zealand, and the Pleistocene Genyornis of the dried Lake Callabonna, which, as desert conditions came on, began to show a reduction of the inner toe. Among mammals the legs and feet have been modified in the same way in at least three distinct orders or sub-orders during different periods and in widely separated regions. [The instances were given.]

In all these cases the correlation of foot-structure with mode of life (as also indicated by the teeth) is such that adaptation by selection has always been regarded as the sole effective cause.

My colleague, Dr. W. D. Lang, has recently published a most thoughtful paper on this subject. His profound studies on certain lineages of Cretaceous Polyzoa have led him to believe that the habit of secreting calcium carbonate, when once adopted, persists in an increasing degree. Thus in lineage after lineage the habit "has led to a brilliant, but comparatively brief, career of skeleton-building, and has doomed the organism finally to evolve but the architecture of its tomb." These creatures, like all others which secrete calcium carbonate, are simply suffering from a gouty diathesis, to which each race will eventually succumb. Meanwhile, the organism does its best to dispose of the secretion; if usefully, so much the better, but, at any rate, where it will be least in the way. Some primitive Polyzoa, we are told, often sealed themselves up; others escaped this self-immurement by turning the excess into spines, which in yet other forms fused into a front wall. But the most successful architects were overwhelmed at last by superabundance of building material.

While sympathetic to Dr. Lang's diagnosis of the disease, still I think he goes too far in postulating an "insistent tendency." He speaks of living matter as if it were the over-pumped inner tube of a bicycle tyre, "tense with potentiality, curbed by inhibitions" [of the cover], and "periodically breaking out as inhibitions are removed" [by broken glass]. A race acquires the lime habit or the drink habit, and, casting off all restraint, rushes with accelerated velocity down the easy slope to perdition.

A melancholy picture! But is it true? The facts in the case of the Cretaceous Polyzoa are not disputed, but they can be interpreted as a reaction of the organism to the continued abundance of lime-salts in the sea-water. If a race became choked off with lime, this perhaps was because it could not keep pace with its environment. Instead of "irresistible momentum" from within we may speak of irresistible pressure from without. Dr. Lang has told us "that in their evolution the individual characters in a lineage are largely independent of one another." It is this independence, manifested in differing trends and differing rates of change, that originates genera and species. Did the evolution follow some inner impulse, along lines "predetermined and limited by innate causes," one would expect greater similarity, if not identity, of pattern and of *tempo*.

Many are the races which, seeking only ornament, have (say our historians) perished like Tarpeia beneath the weight of a less welcome gift: oysters, ammonites, hippurites, crinoids, and corals. But I see no reason to suppose that these creatures were ill-adapted to their environment—until the situation changed. This is but a special case of increase in size. In creatures of the land probably, and in creatures of the water certainly, size depends on the amount of food, including all body- and skeleton-building constituents. When food is plentiful larger animals have an advantage over smaller. Thus by natural selection the race increases in size until a balance is reached. Then a fall in the food-supply handicaps the larger creatures, which may become extinct. So simple an explanation renders it quite unnecessary to regard size as in itself indicating the old age of the race.

Among the structures that have been most frequently assigned to some blind growth-force are spines or horns, and when they assume a grotesque form or disproportionate size they are dismissed as evidences of senility. Let us take the case of certain spiny trilobites. Strange though these little monsters may be, I cannot, in view of their considerable abundance, believe that their specialisation was of no use. Such spines have their first origin in the tubercles which form so common an ornament in Crustacea and other Arthropods, and which serve to stiffen the carapace. A very slight projection of any of these tubercles further acts as a protection against such soft-bodied enemies as jelly-fish. Longer outgrowths enlarge the body of the tribolite in such a way as to prevent it being easily swallowed. When, as is often the case, the spines stretch over such organs as the eyes, their protective function is obvious. This becomes still more clear when we consider the relation of these spines to the body when rolled up, for then they are seen to form an encircling or enveloping *chevaux-de-frise*. But, besides this, the spines in many cases serve as balancers; they throw the centre of gravity back from the weighty head, and thus enable the creature to rise into a swimming posture. Further, by their friction they help to keep the animal suspended in still water with a comparatively slight motion of its numerous oar-like limbs. Regarded in

* Opening address of the President of Section C (Geology), delivered at the Cardiff Meeting of the British Association on August 24. Greatly abridged. Only the larger excisions are indicated by asterisks. Continued from p. 164.

this light, even the most extravagant spines lose their mystery and appear as consequences of natural selection.

The fact that many extreme developments are followed by the extinction of the race is due to the difficulty that any specialised organism or machine finds in adapting itself to new conditions. A highly specialised creature is one adapted to quite peculiar circumstances; very slight external change may put it out of harmony, especially if the change be sudden. It is not necessary to imagine any decline of vital force or exhaustion of potentiality.

What, then, is the meaning of "momentum" in evolution? Simply this: that change, whatever its cause, must be a change of something that already exists. The changes in evolving lineages are, as a rule, orderly and continuous. Environment changes slowly and the response of the organism always lags behind it, taking small heed of ephemeral variations. Suppose a change from shallow to deep water—either by sinking of the sea-floor or by migration of the organism. Creatures already capable of becoming acclimatised will be the majority of survivors, and among them those which change most rapidly will soon dominate. Place your successive forms in order, and you will get the appearance of momentum; but the reality is inertia yielding with more or less rapidity to an outer force.

* * *

But in all these apparent instances we should do well to realise that we are still incompletely informed about the daily life of these creatures and of their ancestors in all stages of growth, and we may remember that structures once adaptive often persist after the need has passed or has been replaced by one acting in a different direction.

The Study of Adaptive Form.

This leads us on to consider the influence of the mode of life on the shape of the creature, or, briefly, of function on form; and, conversely, the indications that form can give as to habits and habitat. For many a long year the relatively simple mechanics of the vertebrate skeleton have been studied by palæontologists and anatomists generally, and have been brought into discussions on the effect of use. These studies, however, have usually considered the structure of an animal as an isolated machine. We have to realise that an organism should be studied in relation to the whole of its environment, and here form comes in as distinct from structure. Similar adaptive forms are found in organisms of diverse structure, and produce those similarities which we know as "convergence." To take but one simple instance from the relations of organisms to gravity. A stalked Echinoderm naturally grows upright, like a flower, with radiate symmetry. But in the late Ordovician and in Silurian rocks are many in which the body has a curiously flattened leaf-like shape, in which the two faces are distinct but the two sides alike, and in which this effect is often enhanced by paired outgrowths corresponding in shape if not in structure. Expansion of this kind implies a position parallel to the earth's surface, *i.e.* at right angles to gravity. The leaf-like form and the balancers are adaptations to this unusual position. Recognition of this enables us to interpret the peculiar features of each genus, to separate the adaptive form from the modified structure, and to perceive that many genera outwardly similar are really of quite different origin.

Until we understand the principles governing these and other adaptations—irrespective of the systematic position of the creatures in which they appear—we cannot make adequate reconstructions of our fossils, we cannot draw correct inferences as to their mode of life, and we cannot distinguish the adaptive from the fundamental characters. No doubt many of us have long recognised the truth in a general way, and have attempted to describe our material—whether in stone or in alcohol—as living creatures; and not as isolated specimens, but as integral portions of a mobile world. It is, however, chiefly to Louis Dollo that we owe the suggestion and the example of approaching animals primarily from the side of the environment, and of studying adaptations as such. The analysis of adaptations in those cases where the stimulus can be recognised and correlated with its reaction (as in progression through different media or over different surfaces) affords sure ground for inferences concerning similar forms the life-conditions of which we are ignorant. But from such analyses there have been drawn wider conclusions pointing to further extension of the study. It was soon seen that adaptations did not come to perfection all at once, but that harmonisation was gradual, and that some species had progressed further than others. But it by no means follows that these represent chains of descent. The adaptations of all the organs must be considered and one seriation checked by another.

In applying these principles we are greatly helped by Dollo's thesis of the Irreversibility of Evolution. This is a simple statement of the facts as hitherto observed, and may be expressed thus:

(1) In the course of race-history an organism never returns exactly to its former state, even if placed in conditions of existence identical with those through which it has previously passed. Thus, if through adaptation to a new mode of life (as from walking to climbing) a race loses organs which were highly useful to it in the former state, then, if it ever reverts to that former mode of life (as from climbing to walking) those organs never return, but other organs are modified to take their place.

(2) But (continues the law), by virtue of the indestructibility of the past, the organism always preserves some trace of the intermediate stages. Thus, when a race reverts to its former state there remain the traces of those modifications which its organs underwent while it was pursuing another mode of existence.

The first statement imposes a veto on any speculations as to descent that involve the reappearance of a vanished structure. The second statement furnishes a guide to the mode of life of the immediate ancestors, and is applicable to living as well as to fossil forms. It is from such persistent adaptive characters that some have inferred the arboreal nature of our own ancestors, or even of the ancestors of all mammals.

The Study of Habitat.

The natural history of marine invertebrata is of particular interest to the geologist, but its study presents peculiar difficulties. The marine zoologist has long recognised that his early efforts with trawl and dredge threw little light on the depth in the sea frequented by his captures. The surface floaters, the swimmers of the middle and lower depths, and the crawlers on the bottom were confused in a single haul, and he has therefore devised means for exploring each region separately. The geologist, however, finds all these faunas mixed in a single deposit. He may even find with them the winged creatures of the air, as in the insect beds of Gurnet Bay, or the remains of estuarine and land animals.

The Upper Ordovician starfish bed of Girvan contains not only the crawling and wriggling creatures from which it takes its name, but also stalked echinoderms adapted to most varied modes of life, swimming and creeping trilobites, and, indeed, representatives of almost all marine levels.

In the study of such assemblages we have to distinguish between the places of birth, of life, of death, and of burial, since, though these may be all the same, they may also all be different. The echinoderms of the starfish bed further suggest that closer discrimination is needed between the diverse habitats of bottom forms. Some of these were, I believe, attached to seaweed; others grew up on stalks above the bottom; others clung to shells or stones; others lay on the top of the sea-floor; others were partly buried beneath its muddy sand; others may have grovelled beneath it, connected with the overlying water by passages. Here we shall be greatly helped by the investigations of C. G. J. Petersen and his fellow-workers of the Danish Biological Station. They have set an example of intensive study which needs to be followed elsewhere. By bringing up slabs of the actual bottom they have shown that, even in a small area, many diverse habitats, each with its peculiar fauna, may be found, one superimposed on the other. Thanks to Petersen and similar investigators, exact comparison can now take the place of ingenious speculation. And that this research is not merely fascinating in itself, but illuminatory of wider questions, follows from the consideration that analysis of faunas and their modes of life must be a necessary preliminary to the study of migrations and geographical distribution.

The Tempo of Evolution.

We have not yet done with the results that may flow from an analysis of adaptations. Among the many facts which, when considered from the side of animal structure alone, lead to transcendental theories with Greek names, there is the observation that the relative rate of evolution is very different in races living at the same time. Since their remains are found often side by side, it is assumed that they were subject to the same conditions, and that the differences of speed must be due to a difference of internal motive force. After what has just been said, you will at once detect the fallacy in this assumption. Prof. Abel has recently maintained that the varying *tempo* of evolution depends on the changes in outer conditions. He compares the evolution of whales, sirenians, and horses during the Tertiary epoch, and correlates it with the nature of the food.

* * *

Whether such changes of food or of other habits of life are, in a sense, spontaneous, or whether they are forced on the creatures by changes of climate and other conditions, makes no difference to the facts that the changes of form are a reaction to the stimuli of the outer world, and that the rate of evolution depends on those outer changes.

Whether we have to deal with similar changes of form taking place at different times or in different places, or with diverse changes affecting the same or similar stocks at the same time and place, we can see the possibility that all are adaptations to a changing environment. There is, then, reason for thinking that ignorance alone leads us to assume some inexplicable force urging the races this way or that, to so-called advance or to apparent degeneration, to life or to death.

The Rhythm of Life.

The comparison of the life of a lineage to that of an individual is, up to a point, true and illuminating; but when a lineage first starts on its independent course (which really means that some individuals of a pre-existing stock enter a new field), then I see no reason to predict that it will necessarily pass through periods of youth, maturity, and old age, that it will increase to an acme of numbers, of variety, or of specialisation, and then decline through a second childhood to ultimate extinction. Still less can we say that, as the individuals of a species have their allotted span of time, long or short, so the species or the lineage has its predestined term. The exceptions to those assertions are indeed recognised by the supporters of such views, and they are explained in terms of rejuvenescence, rhythmic cycles, or a grand despairing outburst before death. This phraseology is delightful as metaphor, and the conceptions have had their value in promoting search for confirmatory or contradictory evidence. But do they lead to any broad and fructifying principle? When one analyses them one is perpetually brought up against some transcendental assumption, some unknown entelechy that starts and controls the machine, but must for ever evade the methods of our science.

The facts of recurrence, of rhythm, of rise and fall, of marvellous efflorescences, of gradual decline, or of sudden disappearances, all are incontestable. But if we accept the intimate relation of organism and environment, we shall surmise that on a planet with such a geological history as ours, with its recurrence of similar physical changes, the phenomena of life must reflect the great rhythmic waves that have uplifted the mountains and lowered the deeps, no less than every smaller wave and ripple that has from age to age diversified and enlivened the face of our restless mother.

To correlate the succession of living forms with all these changes is the task of the palæontologist. To attempt it he will need the aid of every kind of biologist, every kind of geologist. But this attempt is not in its nature impossible, and each advance to the ultimate goal will, in the future as in the past, provide both geologist and biologist with new light on their particular problems. When the correlation shall have been completed, our geological systems and epochs will no longer be defined by gaps in our knowledge, but will be the true expression of the actual rhythm of evolution. Lyell's great postulate of the uniform action of Nature is still our guide, but we have ceased to confound uniformity with monotony. We return, though with a difference, to the conceptions of Cuvier, to those numerous and relatively sudden revolutions of the surface of the globe which have produced the corresponding dynasties in its succession of inhabitants.

The Future.

The work of a systematic palæontologist, especially of one dealing with rare and obscure fossils, often seems remote from the thought and practice of modern science. I have tried to show that it is not really so. But still it may appear to some to have no contact with the urgent problems of the world outside. That also is an error. Whether the views I have criticised or those I have supported are the correct ones is a matter of practical importance. If we are to accept the principle of predetermination or of blind growth-force, we must accept also a check on our efforts to improve breeds, including those of man, by any other means than crossings and elimination of unfit strains. In spite of all that we may do in this way, there remain those decadent races, whether of ostriches or human beings, which "await alike the inevitable hour." If, on the other hand, we adopt the view that the life-history of races is a response to their environment, then it follows, no doubt, that the past history of living creatures will have been determined by conditions outside their control, it follows that the idea of human progress as a biological law ceases to be tenable; but since man has the power of altering his environment and of adapting racial characters through conscious selection, it also follows that progress will not of necessity be followed by decadence; rather that, by aiming at a high mark, by deepening our knowledge of ourselves and of our world, and by controlling our energy and guiding our efforts in the light of that knowledge, we may prolong and hasten our ascent to ages and to heights as yet beyond prophetic vision.

International Catalogue of Scientific Literature.

An international conference of delegates from scientific academies to consider the future of the International Catalogue of Scientific Literature was held last week by invitation of the Royal Society of London. Sir J. J. Thomson, president of the Royal Society, took the chair. The conference was attended by delegates from Denmark (Prof. Martin Knudsen), France (Prof. A. Lacroix), Holland (Prof. G. van Rijnberk), India (Sir H. H. Hayden and Dr. S. W. Kemp), Japan (Prof. H. Nagaoka), New Zealand (Prof. A. Dendy), Norway (Dr. Rolf Laache), Queensland (Sir Edw. Parrott), South Africa (Sir T. Muir), Sweden (Baron Alströmer), Switzerland (Dr. H. Escher, Dr. Marcel Godet, and Dr. H. H. Field), United States of America (Prof. L. E. Dickson, Mr. L. C. Gunnell, Dr. S. I. Franz, and Dr. Robert M. Yerkes), Victoria (Prof. E. W. Skeats), and Western Australia (Mr. G. B. Rushton). The Royal Society was represented by three of its officers (Sir J. J. Thomson, Sir David Prain, and Mr. J. H. Jeans), together with Prof. Henry E. Armstrong, Dr. F. A. Bather, Dr. P. Chalmers Mitchell, and Sir Arthur Schuster. The Italian delegates, having been delayed in the railway journey, were unfortunately not in time to take part in the proceedings.

The conference was called to consider whether any modifications in the present Catalogue are advisable and how the difficulties created by the war can best be overcome. It is well known that the Royal Society, in its "Catalogue of Scientific Papers," has undertaken to make an index of all books and papers on scientific subjects published during the nineteenth century. Sixteen quarto volumes of this important catalogue have already appeared. Four more volumes will probably be sufficient to complete the Author Catalogue for the period 1800–1900. A corresponding Subject Catalogue is also being published.

In view of the ever-increasing number of scientific publications, the Royal Society realised that it could not continue to index the scientific literature of the whole world, but that such an undertaking should be carried out by a division of labour, each country indexing its own literature, the several catalogues so prepared being sent to a central bureau in London, where they should be combined and published in annual volumes. The "International Catalogue of Scientific Literature" was the outcome. It undertook to index scientific literature published after January 1, 1901.

More than thirty countries joined in the scheme, each agreeing to index its own scientific literature upon cards which should be sent to London for incorporation in the printed volumes. Fourteen annual issues, each of seventeen volumes, have now been published indexing the scientific literature of 1901–14. It was found that the sales and subscriptions to the volumes very nearly covered the cost of production.

It might have been predicted that a work of this kind, requiring harmony between workers of so many nationalities, could not be carried out without international jealousy and friction. Such has not proved to be the case. The greatest goodwill has existed between the various regional bureaux in the different countries and the central bureau in London.

The outbreak of war interrupted the work by restricting intercourse between the nations. The finances of the catalogue have also suffered from the loss of subscriptions from Austria, Germany, Hungary, and Russia. At the same time the cost of printing and publishing has more than doubled. It was in these circumstances that the Royal Society convened last week's conference.

The delegates, while agreeing that it is essential that scientific literature should be fully indexed in order that the results of researches in every country might be made known quickly to all, entered into a full discussion as to how this indexing should be done, and passed in review the different agencies now engaged in such work.

They came to the conclusion that, even though a change be made in the future in the method of indexing, it is imperative to continue the International Catalogue of Scientific Literature in its present form until the literature published up to the end of the year 1915, and possibly also that up to the end of the present year 1920, has been catalogued. In this way the important scientific work carried out during the war period will become available for reference at an early date and continuity in the work of indexing be maintained. This recommendation of the conference will come before the council of the Royal Society at their October meeting, and we are confident that the council will wish to give effect to the proposal if sufficient funds can be obtained.

A considerable sum of money will be required. It is estimated that the rise in salaries, wages, paper, and everything connected with printing and publishing is so great that an annual issue of the International Catalogue will now cost about 17,000*l*. In addition to the annual expenses, working capital of considerable amount will be required. The sum mentioned at the conference was, we believe, 34,000*l*., this being the cost of two annual issues.

There is here an opportunity for someone to make a generous donation in aid of science. The Royal Society cannot be expected to provide the large sums now required out of its own resources. The society has already spent much money in the preparation of the Catalogue of Scientific Papers, and has lent 7500*l*. to the International Catalogue and made a further donation of 1100*l*. from its funds. Contributions from European countries are invited, but may prove difficult to obtain owing to the adverse rates of exchange. It would be a great misfortune if a work of this importance came to an end through lack of funds. We have here a league of nations engaged in making the results of scientific inquiry widely known; every effort should be made to help this league to live through what is evidently the critical period of its existence.

The question as to the future of the Catalogue after the completion of the twentieth issue was referred to a committee of the delegates for further consideration. Amongst other questions this committee will examine how far the work of the International Catalogue can be brought into relation with the many existing agencies for the publication of abstracts of scientific papers.

In addition to the abstracts prepared by many of the scientific societies and to those published in periodical collections dealing with special subjects, there are card catalogues such as that under the charge of Dr. H. H. Field, of Zurich. It was suggested at the conference that these should be taken into account in fixing the form which the International Catalogue should take in the future.

The immediate problem, then, is to secure the indexing of the scientific literature published during the war. While this is being done, arrangements can be made for the efficient continuation of the work of cataloguing the scientific literature of the world.

The International Congress of Mathematicians.

THIS congress was opened at Strasbourg University on September 22 by the Rector, M. S. Claréty. The officers of the congress were then elected as follows:—*Honorary President:* M. Camille Jordan. *President:* M. Emile Picard. *Vice-Presidents:* Prof. Leonard Dickson, Sir Joseph Larmor, Prof. Nörlund, M. de la Vallée-Poussin, M. H. Villat, and M. Volterra. *Secretary:* M. Koenigs.

The delegates numbered 188 and represented 26 nations, amongst which may be mentioned Argentina (4), Australia (1), Brazil (1), Canada (1), Czecho-Slovakia (12), India (2), Japan (2), the Philippine Islands (1), Poland (4), Russia (1), and Serbia (2). The expenses of the congress, including the publishing of the proceedings, have been completely provided for. Of the sum required, 78,000 francs was contributed by public bodies, by industrial and commercial concerns, and by private persons. An interesting fact is that the French Government made its contribution of 10,000 francs through the Ministry of Foreign Affairs, thereby recognising, it would appear, that such a congress has a certain significance in international politics. The subscriptions of delegates produced a further sum of 12,000 francs.

On Thursday, September 23, a general lecture was given by Sir Joseph Larmor on "Questions in Physical Indetermination." Sir Joseph said that of the three physical deductions upon which the validity of Einstein's theory depended, the two which had been verified by experiment, namely, the motion of the perihelion of Mercury and the deflection of light-rays by the sun, could be made to result equally well from a theory involving an æther. But the third Einstein prediction, the displacement of solar spectral lines, was inconsistent with any æther theory. In his opinion, it would be found, when conclusive observations had been made, that the third prediction was not verified. The doctrine that the universe is completely "full" originated with Descartes. The same doctrine was held by Newton, Huygens, Faraday, Fresnel, and Maxwell, but as a much more precise conception. The vortex theory and the elastic solid æther theory had had their day, but there was no reason at present why we should not admit the existence of an æther—a new æther the properties of which were so different from those of ordinary matter that they could be expressed only in terms of non-Euclidean space. The alternative was complete abstraction, the absence of a basis on which to found our theories. The essence of Newtonian space, as enunciated in the works of Lie and Helmholtz, was the possibility of the existence of rigid bodies in motion. Newtonian space was the space of mechanics, for which $dx^2+dy^2+dz^2$ was invariant.

For Faraday and Maxwell, on the other hand, radiation was fundamental. The characteristic of Maxwellian space was *complete transmission*. A pulse travelled without change of form and without leaving anything behind—a principle that was in accord with experiments in light. This was the space of Minkowski, for which the corresponding invariant expression was $dx^2+dy^2+dz^2-c^2dt^2$.

As with Sir Joseph Larmor, so with most of the other contributors to the subject of relativity, the endeavour was directed towards the elimination of those paradoxes which the human mind finds it difficult to accept rather than towards the further development of the theory itself. Thus M. Guillaume, setting forth from the remark that in the theory of relativity we were dealing with the apparent positions of bodies and that the difficulties of the theory arose from the fact that their "real" positions were supposed unknown, offered an alternative analysis in which the initial "real" positions of bodies were supposed known. He obtained results in which some of the paradoxes disappeared. M. Guillaume stated, however, that he had been in correspondence with Prof. Einstein, and had not been able to bring about a reconciliation of the two points of view.

The second general lecture, on "Relations between the Theory of Numbers and other Branches of Mathematics," was delivered on Friday, September 24, by Prof. Leonard Dickson, of Chicago. Prof. Dickson showed how the problem of obtaining rational solutions of certain classes of homogeneous equations was connected with the known properties of certain surfaces and with the theory of hypercomplex numbers.

In a lecture on the teaching of mathematical physics M. Volterra said that what might be called "analytical physics" now constituted an integral whole. Newton had reduced the problem of the universe to a problem in ballistics, and upon this basis Lagrange had founded his analytical mechanics. In a similar way the constitution of matter was for the modern physicist a problem in electricity, and we awaited a new Lagrange. At the present time there were two distinct methods of teaching mathematical physics in universities. The first might be called the *monographical* method. The student followed in succession separate courses in hydrodynamics, optics, and so on. The weakness of this method was that there was no grasp of the subject as a whole. In the other method the student started with a course of mathematical analysis, and, so equipped, he proceeded to the various branches. The fault here was that in the first part of the course he was working without seeing his objective; he did not understand the purpose of his work or see its special difficulties. The course that M. Volterra advocated consisted of three parts. The first, on more or less historical lines, carried the student as far as the general equations. The second part was a discussion of those equations, including a classification of them according to their characteristics and a classification of the problems according to the methods of solution. The third part was the solution and discussion of specific problems. This scheme left for separate treatment those portions of analytical physics which depended upon the calculus of probability, as well as thermodynamics and some minor branches.

M. de la Vallée-Poussin in his lecture, "Sur les fonctions à variation bornée et les questions qui s'y rattachent," dealt with the fundamental theory of integration in the light of Baire's classification of functions. All classes of functions (Baire) are integrable in the sense of Lebesgue. Stieltjes's integral

$$\int_a^b f(x)d\alpha(x)$$

can be defined by the process of Lebesgue, and it exists for all Baire functions f. The functional $U(f)$ (Fréchet and Volterra), which has an assigned value for each of the elements f of a set, can be transformed into a Stieltjes integral. By making use of the univocal correspondence, established by Peano, between the points interior to a rectangle and the points on a segment of a line, functionals depending upon two arbitrary functions can also be reduced to simple Stieltjes integrals.

The subject of the fifth lecture, which was given by Prof. Nörlund, of Copenhagen, was "Les équations aux différences finies." The lecturer gave a very complete discussion of the solutions of equations of the types

$$\tfrac{1}{2}\{\phi(x+\omega)+\phi(x)\}=f(x), \quad \tfrac{1}{\omega}\{\phi(x+\omega)-\phi(x)\}=g(x).$$

In an interesting communication Prof. W. H. Young proposed a new definition, which does not involve an approximation by means of tetrahedra, for the area of a curved surface. The proposal is, first, to define the "area of a curve" as the square root of the sum of the squares of three integrals of the form

$$\int ydz - zdy.$$

Then, the surface being determined by the equations

$$x=f_1(u, v), \qquad y=f_2(u, v), \qquad z=f_3(u, v),$$

suppose the domain of u, v to be divided up into elementary rectangles in the u, v plane. The area of the surface is the limit of the sum of the areas of the corresponding elementary curves.

Prof. Weiss, the director of the Strasbourg Institute of Physics, gave an account of the methods of sound-ranging in use in the French Army during the war. The method normally employed was the same as that in use in the British Army. A useful alternative was the method *à courtes bases*, in which six or more microphones were placed in pairs. The microphones of each pair were about a hundred metres apart, so that the gun locus became a straight line (asymptote), and at once gave the direction of the hostile gun. The installation was very simple, and could be made in an hour, while single sets of observations could be reduced and reported in a minute. This method was used, not for the accurate location of gun emplacements, but for determining quickly which one of the known hostile batteries was in action. Guns were also successfully located by observations of the *onde de choque*. The normals to this wave-surface determine a caustic which is nearly constant in form for high-velocity shells. To locate the gun emplacement, a standard caustic drawn on tracing-paper was fitted by trial to the normals determined by the instruments. This method was used when atmospheric conditions made the spherical wave imperceptible, and, although less accurate, it gave very good results. A case was quoted where 80 per cent. of the hostile emplacements were correctly located solely by *ondes de choque*.

In the course of the congress receptions were held by the Committee of Organisation, the Société des Amis de l'Université de Strasbourg, the Mayor of Strasbourg, and the Commissaire Général (M. Alapetite).

At a concert organised by the Société des Sciences du Bas-Rhin, the delegates had the pleasure of hearing *'s Elsasslied* sung by the mixed choir of the Concordia-Argentina Choral Society. The delegates were entertained at the conclusion of the proceedings at a banquet given by the Organising Committee.

The invitation conveyed by Prof. Leonard Dickson to hold the next congress in New York in 1924 was accepted, and a further invitation was received to hold the congress of 1928 in Belgium. H. B. H.

Disorders of Symbolic Thinking.

DISCUSSION AT THE CONGRESS OF PHILOSOPHY AT OXFORD.

SEVERAL subjects of direct scientific interest were discussed at the Congress of Philosophy held at Oxford on September 24–27. One of the greatest importance, because based on recent clinical and experimental research, was the discussion introduced by Dr. Henry Head in a paper entitled "Disorders of Symbolic Thinking due to Local Lesions of the Brain." It raised the whole problem of the relation of language to thought while concentrating attention on the significance of certain definite observations—cases of young men who had received cerebral injuries in the war—in which the injury to the brain had affected the power of articulation.

Dr. R. Mourgue, of l'Asile de Villejuif, also contributed a paper, and was announced to take part in the discussion. He was unable to be present, however, and his place was taken by Prof. Bergson.

Dr. Head said that his general conclusion from the cases he had studied experimentally, where gross destruction of brain-tissue had resulted in loss of speech, was that there always remained elements in thought which were not associated with words. Speech is a discriminative movement capable of fine degrees of adjustment, essentially an intellectual mechanism. Even in the gravest cases of aphasia the patient is evidently fully aware of his emotions, and can express them clearly in gesture and action. Under the influence of emotion he may even use words or phrases which he is quite impotent to evoke voluntarily. Speech can be disturbed, or even totally lost, without reducing the patient's intellectual capacity or of necessity producing grave intellectual defect. All the early work of investigation of aphasia had been vitiated by the conception that speech was a well-defined intellectual function, strictly localised in some particular site in the brain. Attention was concentrated, therefore, on correlating the extent of anatomical destruction on this site with the character of the disorder of speech. The fundamental error at the root of all this work is its ignoring of the physiological changes which intervene between the anatomical lesion and the psychical states with which it is associated. Destruction of the substance of the brain disturbs the act of speech only because it interferes with the physiological processes necessary for its perfect execution.

Dr. Head then described the nature of his experiments and the means he had devised to discover the physiological processes with which the particular injuries had interfered. In the older theories auditory images were supposed to be responsible for "memories" of words, and these were said to be stored up in certain areas of the cortex. The hypothesis is entirely unable to explain the phenomena of aphasia. Patients who cannot name consecutively a series of objects in front of them can choose them correctly when the name is given either orally or in print. It is the name, not the auditory image, which is lacking. The loss of the power to use words is not due to a destruction of images.

What, then, Dr. Head asked, are the functions which are disturbed in aphasia? The true answer had been given so long ago as 1868 by Hughlings Jackson, though its significance was not then seen. The chief mental activity disturbed by unilateral lesions of the brain was declared to be the use of words in propositions. The loss of function in aphasia might therefore be indicated as that of "propositionising." But though this term suggests a conception which covers the larger number of facts, it does not comprise every aspect of the loss of function. Dr. Head suggested, therefore, that these functions should be spoken of as "symbolic thinking and expression," though even this phrase does not quite satisfactorily define the group of processes affected. It is not all symbolic representations, but symbols used in a particular manner which suffer in these disorders. There are four fairly well marked groups of functions into which he now proposed to divide "symbolic thinking and expression" on the ground that they are dissociated in different ways under the influence of organic injury. These are (1) verbal defects, (2) syntactical defects, (3) nominal defects, and (4) semantic defects.

Dr. Mourgue's contribution was in no sense opposed to Dr. Head's conclusions. It dealt with a rather different aspect of the case, and seemed indeed to supplement the general theory in a remarkable way. Dr. Mourgue had given particular attention to some characteristic cases of aphasia in which the sufferers were themselves skilled in the treatment of the disorder and able on recovery to record and analyse their experience. The particular cases cited were the autodiagnosis of Dr. Saloz and Prof. Forel, and also a case recorded by van Woerkem. In all these cases the speechlessness of the aphasic state was comparable with the kind of indistinctness of psychical elements often experienced in the dream state. There was complete preservation of intuitive thought, but absence of imagery, or at least of verbal imagery. The will is unaffected, and may even show exaltation, but there is an absence of discrimination and differentiation—characters which, from a somewhat different point of view, Prof. Bergson has described as essentially belonging to intelligence.

Prof. Bergson said that the communication which Dr. Head had presented constituted a complete rejection of the theory of aphasia which for a long time had been classic. It offered in its place the quite new theory that aphasia was the disorder of a special faculty of symbolising, which might be said to be a certain aspect of intelligence. The classical theory of aphasia might be described as a complete metaphysic. So long ago as the years 1892 and 1893 he had himself been led by a question of pure metaphysics to study the relation of mind and body. He found that philosophers had given us only very vague ideas on this subject, and he determined, therefore, to study the facts of the relation without any philosophical presuppositions. It was extraordinarily ambitious, for he had no technical-scientific equipment. Gradually, however, the problem of the relation of mind and body transformed and narrowed itself into the problem of the relation of memory to the brain, then of the memory of words, and then of the meaning of words. Surprise followed surprise. The theory of Broca then held the field, complicated by the work of Kussmann and Lichtheim. Nerves converge on nervous centres, there are strange communications between the centres, the path from A to B is not the same as the path from B to A, and every theory called for some new theories to explain each particular case studied. He appealed to his neurologist and psychologist friends, but he was ill-received; and when some years later he attacked their theories in his book he was looked on with pity. He was not surprised, therefore, when Prof. Pierre Marie gave the results of his anatomical researches, based on Broca's work, and, indeed, on a restudy of the actual brain which Broca had dissected. Long before this, psychology had itself shown the old theory to be impossible. The theory had, in fact, broken down before a psychology of common sense which called for scarcely any effort of introspection. A perception, in fact, is already memory, for a perception has duration. A part of the perception is memory, therefore, even while the perception still remains. Where does perception begin to be past? All the hypotheses were contradicted by simple self-observation. Prof. Pierre Marie proceeded to demonstrate a new theory of aphasia. He reduced it to two things: (1) A certain disorder of articulation which he named *anarthrie*, and (2) a certain enfeeblement of intelligence.

Prof. Bergson then referred to his own studies of aphasia. What had struck him most forcibly in the records of a great number of cases was a certain powerlessness in the patient to analyse or decompose his perception. Deafness to words was a concomitant symptom rather than a distinct factor. There were cases where persons after complete recovery and restoration had described their experience by saying that they heard perfectly well, but seemed to be listening to a continuous sonorous blur. One of Charcot's patients could hear the clock strike quite well, but could not distinguish the strokes. In verbal blindness, another form of aphasia, it is very remarkable to observe in some of the cases the difficulty the person has to decompose and analyse his perception. He will want, for example, to write a letter of the alphabet, and may succeed, but he will begin where he would not ordinarily begin; he is seen to lack the sense of the organisation of the letter, and when he produces it he has not synthetically constructed it. When we listen to persons speaking a foreign language we are in the condition of some of these aphasics. We hear perfectly, but we cannot repeat the whole of the sounds; they appear to us crushed, as it were, into a formless mass without bones or joints, a sonorous continuity. He had himself, following another line of investigation, been led to attribute capital importance to nascent movements, tendencies, and outlined actions—movements sketched, as it were, and not carried out. An idea is a grouping together of virtual actions. The continuity of thought is simply a continuity of attitudes and of virtual movements not executed, sometimes scarcely delineated. The brain, and in particular the cerebral cortex, indicates an enormous number of initiated actions. Instead of considering the spinal cord as a diminished brain, we ought to think of the brain as a completed spinal cord. Coming back to the special case of aphasia, he asked himself whether, in order to understand speech, we had not got to undertake a work of disintegration of the movements of articulation, neither completely voluntary nor completely automatic. There are certain beginnings of movements which are not carried out. They are partly automatic, partly voluntary, for our mind projects our actions in advance of their accomplishment.

Prof. Bergson concluded by expressing his profound admiration of Dr. Head's researches on the question of aphasia; they appeared to him of capital importance for psychology, and even for metaphysics.

University and Educational Intelligence.

BIRMINGHAM.—An appeal is being issued for 500,000*l*. in aid of the funds of the University. The finances are in a critical condition; there is a debt of 130,000*l*., which absorbs at present 8000*l*. per annum, necessary extensions of building have had to be made, the staff is deplorably underpaid, and the entry of new students is a heavy one. In spite of the 25 per cent. increase in the fees of new students, these fees will still represent only about 30 per cent. of the cost of providing the instruction, so that the greater the entry the greater the need for money.

This session the working of the faculty of science will be rearranged, much of the work previously done by the meetings of faculty being delegated to Boards of Studies. The latter consist of professors and selected members of the non-professorial staff, and the following boards have been constituted: Mathematics, physics, chemistry, engineering, and biology. It is hoped that the new arrangement will do something towards relieving the congestion of business in the faculty, which has recently been serious. The boards will report to the faculty.

CAMBRIDGE.—Dr. Ff. Roberts, Clare College, has been appointed junior demonstrator in physiology, and Mr. T. R. Parsons, Sidney Sussex College, additional demonstrator in physiology.

The Vice-Chancellor has announced a very generous gift of 25,000*l.* from Sir Dorabji Tata, Gonville and Caius College, towards the expense of new buildings for the engineering school. A further anonymous gift of 2000*l.* has also been received. Part of the new buildings are already very nearly complete. Amongst the large entry this year are to be found fifty officers of the Royal Engineers and a small number of officers from the Royal Air Force and the Corps of Signals—a welcome connection between the Services and the scientific side of the University. The number of naval officers in residence has been reduced owing to the heavy pressure on the accommodation. The question of the admission of women to the University comes up for discussion in the Senate House on Thursday, October 14.

DR. JAMES G. GRAY, lecturer in physics at the University of Glasgow, has been appointed to the newly established Cargill chair of applied physics in the University.

THE *Times* announces that Mr. T. D. Owen, a leading Welsh metallurgist, has given 10,000*l.* to the University College of North Wales for the foundation of a chair in his name of electrical engineering and hydro-electrics.

DR. J. NEWTON FRIEND, hitherto headmaster of the Science and Technical School, Victoria Institute, Worcester, has succeeded Dr. T. Slater Price as head of the chemistry department of the Birmingham Municipal Technical School.

DR. MARION B. RICHARDS, of the chemistry department of Aberdeen University, has been appointed assistant to Dr. R. H. A. Plimmer, head of the biochemical department of the Rowatt Research Institute in Animal Nutrition, Aberdeen.

IT is announced by the *Times* that Prof. A. B. Macallum, professor of biochemistry in the University of Toronto, and administrative chairman, honorary Advisory Council for Scientific and Industrial Research of Canada, has accepted the new chair of biochemistry at McGill University.

DR. C. DA FANO will begin a special course of eight lectures on "The Histology of the Nervous System" in the physiology lecture theatre of King's College, University of London, on Wednesday, October 13, at 4.30 p.m. The course is free to all students of London colleges and to medical men and others on presentation of their visiting-cards.

AT a meeting of the Old Students' Association of the Royal College of Science to be held on Tuesday next, October 12, at the Imperial College Union, Prince Consort Road, South Kensington, London, S.W.7, Mr. J. W. Williamson will deliver an address entitled "The Proposed University of Science and Technology: Can a Useful and Worthy University be Based on Pure and Applied Science?" The chair will be taken at 8 p.m. by the president of the association, Sir Richard Gregory.

IN connection with the University Extension Board of the University of London, Prof. John Cox will commence on October 8, at 7.30 p.m., an interesting course of lectures on "The Bases and Frontiers of Physical Science" at Gresham College, Basinghall Street, E.C.2. The first part of the courses will be devoted to a review on the broadest possible lines of the concepts and laws of Nature on which traditional physics has been built up. The later lectures will deal with Einstein's views and the principle of relativity. Admission to the first lecture is free.

Societies and Academies.

PARIS.

Academy of Sciences, September 13.—M. Léon Guignard in the chair.—F. E. **Fournier**: The apparent displacement of some stars in the total eclipse of the sun of May 29, 1919.—A. **Blondel**: The calculation of electric cables by the use of vectorial functions with real notation. The method described has the same advantages as when imaginary quantities are employed, but only real quantities are utilised in the demonstration. It is based on the introduction of vectorial series.—V. **Smirnoff**: Some points of the theory of linear differential equations of the second order and automorphic functions.—E. **Jouguet**: The velocity of waves in elastic solids.—C. **Camichel**: The transmission of energy by the vibrations of water in pipes. Remarks on some recent publications of M. Constantinescu, and a statement of the work done by the author on the same subject.—E. **Canals**: The estimation of calcium and magnesium in different saline media. A study of the conditions under which, in acetic acid solutions, it is possible to separate completely calcium and magnesium from salts of iron and aluminium.—G. **Zeil**: The *rôle* of building corals in lithospheric re-adjustments.—C. **Störmer**: Some rays of aurora observed on March 22, 1920, which reached a height of 500 km. The aurora borealis of March 22 was photographed from seven stations under favourable conditions. The stations were connected by telephone, and simultaneous photographs were taken from two or three stations at a time. About 620 photographs were obtained, and they show that the summits of some of the rays reached an altitude of 500 km. above the earth.—A. **Chevalier**: The origin of the cider apple-trees cultivated in Normandy and Brittany.—F. **Vlès**: The spectral properties of the tetanus toxin. Spectrophotometric studies of the ultraviolet absorption spectra of the effects of heating and of the addition of antitoxin to solutions of the tetanus toxin.—A. **Marie** and L. **MacAuliffe**: The influence of life in Paris on the race. A study of 1509 Parisians of the poorer classes, 850 of whom were born of provincial parents, 294 of Parisian parents, and the remainder of one Parisian and one provincial parent. The Paris climate and town life lead to modifications which are thus summarised: The hair and eyes less pigmented than in the rest of France, more marked cranial development in proportion to height, and shortening of the limbs.—J. L. **Dantan**: Budding in *Antipathella subpinnata* and *Parantipathes larix*.

HOBART.

Royal Society of Tasmania, August.—His Excellency Sir W. L. Allardyce, president, in the chair.—H. H. **Scott** and C **Lord**: *Nototherium Mitchelli.* Its evolutionary trend: the skull and such structures as related to the nasal horn. In their third paper on the

Smithton discovery the authors deal with a mass of data relating to the evolutionary trend of the Nototheria and the structure of the skull. They also deal with a reclassification of the genus. The Nototheria are a group of animals that in Tasmania became extinct late in Pleistocene times. They were generalised, and yet in part specialised. They retained the racial characteristics that can be relegated to five geological periods—that is, from the pre-Eocene to the latest Pleistocene. They show similar developments to those of the perissodactyl ungulates, and, without leaving a single modern representative to carry on their race in totality, they left many characters scattered through their marsupial allies, the kangaroos, wombats, and native bears, which still grace our woodlands to-day. In dealing with the taxonomic data relating to the skull the authors recognise two well-marked groups, namely: Group i., Megacerathine, and group ii., Leptocerathine.—H. T. Parker: Mental efficiency. A study of the results obtained by testing children by the Binet-Simon scale.

Books Received.

The Cactaceæ: Descriptions and Illustrations of Plants of the Cactus Family. By N. L. Britton and J. N. Rose. Vol. ii. Pp. vii+239+xl plates. (Publication No. 248.) (Washington: Carnegie Institution.)

Geometrical Investigation of the Formation of Images in Optical Instruments. Embodying the Results of Scientific Researches Conducted in German Optical Workshops. Edited by M. von Rohr. (Forming vol. i. of "The Theory of Optical Instruments.") Translated by R. Kanthack. Pp. xxiii+612. (London: H.M. Stationery Office.) 2*l.* 5*s.* net.

Technical Handbook of Oils, Fats, and Waxes. By P. J. Fryer and F. E. Weston. Vol. i.: Chemical and General. Third edition. Pp. xii+280+xxxvi plates. (Cambridge: At the University Press.) 15*s.* net.

Commonwealth of Australia. Papua. Annual Report for the Year 1918–19. Pp. 119. (London: Australia House, Strand.)

The Human Atmosphere (The Aura). By W. J. Kilner. Pp. vii+300. (London: Kegan Paul and Co., Ltd.) 10*s.* 6*d.* net.

Mathematical Papers for Admission into the Royal Military Academy and the Royal Military College and Papers in Elementary Engineering for Naval Cadetships and Royal Air Force. November, 1919, and July, 1920. Edited by R. M. Milne. Pp. 34. (London: Macmillan and Co., Ltd.) 1*s.* 9*d.* net.

Diary of Societies.

THURSDAY, OCTOBER 7

ROYAL AERONAUTICAL SOCIETY (at Royal Society of Arts), at 5.30.—Major-General Sir F. H. Sykes: Civil Aviation.

CHILD-STUDY SOCIETY (at Royal Sanitary Institute), at 6.—Dr. C. W. Kimmins: The Handwriting of the Future.

ROYAL SOCIETY OF MEDICINE (Obstetrics and Gynæcology Section), at 8.—The President: Spoon-shaped Depressed Birth Fracture of the Frontal Bone treated by Elevation.—Dr. M. Kerr: (1) The Surgery of the Uterus Bicornis Unicollis, with a case of Resection of the Uterus followed by two Normal Pregnancies; (2) The Intra-vesical Repair of Inaccessible Vesico-vaginal Fistula.—Dr. A. J. McNair: A Case of Placenta Prævia with Vasa Prævia.—H. Briggs: (Presidential Address), The Female Pelvic Floor. (Neurology Section), at 8.45.—Dr. H. Head: (Hughlings Jackson Lecture), A New Conception of Aphasia.

FRIDAY, OCTOBER 8.

ROYAL SOCIETY OF MEDICINE (Clinical Section), at 5.30.—Z. Cope: The Clinical Significance of Shoulder-pain in Upper Abdominal Lesions.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—R. A. Malby: A Miniature Alpine Garden.

MONDAY, OCTOBER 11.

BIOCHEMICAL SOCIETY (at King's College), at 5.

ROYAL SOCIETY OF MEDICINE (War Section), at 5.30.—Wing-Commander Martin Flack: Medical Requirements for Air Navigation.

MEDICAL SOCIETY OF LONDON (at 11 Chandos Street, W.1), at 8.—Annual General Meeting. At 8.30.—Sir William Hale-White: (Presidential Address), Then and Now.

TUESDAY, OCTOBER 12.

SOCIETY FOR THE STUDY OF INEBRIETY (at Medical Society of London), at 4.—Dr. J. A. Davidson, and others: Discussion on Special Clinics for Inebriates.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—(Annual Traill Taylor Memorial lecture), Prof. A. E. Conrady: The Present State of Photographic Optics.

WEDNESDAY, OCTOBER 13.

INSTITUTION OF AUTOMOBILE ENGINEERS (at Royal Society of Arts), at 8.—Sir Henry Fowler: Presidential Address.

HUNTERIAN SOCIETY (at Sion College), at 9.—Sir George Newman: The Ministry of Health as an Instrument in Preventive Medicine.

THURSDAY, OCTOBER 14.

OPTICAL SOCIETY (at Imperial College of Science and Technology), at 7.30.—H. A. Hughes and P. F. Everitt: The Field of View of a Galilean Telescope.—B. K. Johnson: The Calibration of the Divided Circle of a Large Spectrometer.

INSTITUTION OF AUTOMOBILE ENGINEERS (at 28 Victoria Street), at 8.—Graduates Meeting. Messrs. Chatterton and Watson: Factors affecting Power Output.

ROYAL SOCIETY OF MEDICINE (Neurology Section), at 8.30.—Dr. E. S. Reynolds: (Presidential Address), The Causes of Nervous Disease.

FRIDAY, OCTOBER 15.

ROYAL SOCIETY OF ARTS (Indian Section), at 4.30.—T. M. Ainscough: British Trade with India.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Prof. A. Keith: Demonstration on the Contents of the Museum.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—A. Keighley: An Evening in Lakeland.

ROYAL SOCIETY OF MEDICINE (Electro-Therapeutics Section), at 8.30.—S. Gilbert Scott: Presidential Address.

SOCIETY OF TROPICAL MEDICINE AND HYGIENE, at 8.30.

SATURDAY, OCTOBER 16.

PHYSIOLOGICAL SOCIETY (at Guy's Hospital), at 4.

The Site of the University of London.

THE Senate of the University of London will at its next meeting be called upon to make a definite decision regarding the Government's offer of the Bloomsbury site. Mr. Fisher has intimated, and in our opinion not unreasonably, that the offer cannot remain open longer.

The matter has been very fully canvassed during the recess, and the Senate has had leisure and opportunity to consider the issues involved by acceptance or rejection of the Government's offer. For reasons which we have already given, we most earnestly hope that the Senate will decide to adopt the report of its sites committee, which, it is understood, has with certain reservations recommended acceptance of the offer. The discussions of the last few months, so far as they have been relevant, have served only to strengthen our conviction that a refusal will mean the indefinite postponement of a step which is both urgent and necessary for the proper development of the University.

The fact that so much of the discussion has been irrelevant and misinformed is in itself evidence, if evidence were needed, of the failure of the University to impress itself upon the imagination and intelligence of many who are genuinely concerned for higher education in London. Correspondence in the Press has shown beyond doubt that there does not exist any widespread knowledge either of the magnitude of the present activities of the University, or of the nature of its present urgent needs.

The attention which has been given to the suggestion that "The University" should migrate to Hampstead is an illustration. Ken Wood is a delightful spot, and entirely suitable for a residential college or for hostels. But a dozen Ken Woods could not contain the teaching work of the University, and, what is more, they are not wanted. The University of London, or any University of London, must permeate London. Its thousands of students must be distributed, as they are now, throughout London—in the incorporated colleges, in the various "schools" from Kensington to the Mile End Road, in all the great hospitals, and in institutions easily accessible to evening workers. This or some similar arrangement is a necessity for a University of London, and no one building, whether at Hampstead or Bloomsbury or elsewhere, could or should contain the teaching work of the University.

The urgent needs of the University are, we take it, two. They are the provision of suitable administrative headquarters and of a new home for King's College. The need for providing a unifying and co-ordinating centre for the manifold activities of the University is patent. The lack of an adequate home peculiarly and distinctively associated with it has been an obstacle to its progress since its reconstitution. The buildings at South Kensington, dignified though they be, were not designed for their present purpose; they are not suitable for it, nor are they easily accessible. Further, so long as they continue to be known as "The Imperial Institute" rather than "The University," confusion must inevitably persist.

The case is clear for a new building which shall provide accommodation for the administration, for the libraries, for examinations, and for a meeting place where the multitudes of the teachers and students of the University can come together for business and recreation.

The need for a new home for King's College is no less pressing. It has long out-grown the buildings in which it has lived for nearly a century, and its removal to some other site is imperative.

Bloomsbury is indisputably the most convenient quarter both for an administrative centre and for the new home of King's College, and it is the absence of any real alternative to it that is the strongest argument in its favour. The accessibility, the proximity of University College, and of other university organisations, allow and encourage co-operation and obviate the waste of time and the profitless wear-and-tear which are inseparable from the present arrangement.

There remains the question of finance, which we have from the beginning recognised as the really serious question. This has been complicated, unnecessarily we believe, by a comparison of the supposed value of the present King's College site with the Bloomsbury site; but if the former is, as appears to be admitted, inadequate for its purpose, a comparison of site values seems beside the point, and it is surely no derogation to a good bargain that both parties derive benefit from it. The criticism that the Government should continue to be responsible for rates and maintenance charges is of a different kind. Here we think the Senate was on strong ground, and we are glad that it has elicited from Mr. Fisher a statement that these charges will continue to be borne by the Government.

We are glad, too, to see the explicit declaration of the President of the Board of Education that acceptance of the Bloomsbury site will not close the door against building grants from the Treasury. Apart from the technical obstacle to a Government pledging its successors to expenditure for this purpose, it is, we think, apparent that at the present time the Government, faced with demands for economy, might well hesitate to promise unconditionally a large sum for buildings. On the other hand, we are convinced that if the University embarks in earnest upon the provision of a building, neither this nor any future Government could or would withhold its support.

We can only repeat our most earnest hope that the University will decide to accept the Government's offer. The present time may not be the most propitious for embarking upon an appeal for funds, but we are convinced that a courageous policy is the right one, and that the Senate, if it fails to take advantage of the opportunity now offered to it, will have done a serious injury to the future of the University, and lost for many years any claim upon the Government or the public.

Women at Cambridge.

AT Cambridge to-day, October 14, is to be held the official discussion of the proposal to admit women to the membership of the only University in the Empire which gives women no rights. Weeks of somewhat bitter fighting in the Press will follow, and the vote should be taken towards the end of this term or early next term. We will for the moment consider only how the interests of scientific teaching and research are affected by the proposals.

Two reports are to be presented for discussion. Report A proposes a simple statute for adoption, the net result of which is to give women the same opportunities and rights within their own colleges as men have in theirs. They will, as at present, attend the regular courses of teaching in the University and take the University examinations. There will, however, be this difference: success in the examinations will secure for them a degree, as in the case of men students, and women will be able to compete for University prizes, scholarships, and studentships from which they are now debarred. The degree will secure for them in due course, as for men, voting power in the University; at present they receive only the Parliamentary vote for the University member, and a place in a published class list in return for success in the University final examinations. Thus it is proposed that an anomalous and unsatisfactory state of affairs should be ended, and equality of opportunity secured for men and women inside the University. Provision is rightly made in the proposed statute to secure the rights of past students of Girton and Newnham to degrees.

As regards the colleges, the supporters of Report A recognise fully the need to guard against men and women both being members of the same residential college. They therefore propose that the University shall refuse to recognise in any way a woman as a member of a men's college or a man as a member of a women's college. The University has no power to stop a men's college from admitting a woman, but it can see to it that a woman shall gain nothing, so far as the University is concerned, by joining a men's college, and that is what Report A provides for. It should be added that, in this matter, full support is given by the authorities of Girton and Newnham Colleges. The bogey of the mixed college is conjured up only by the supporters of Report B in the hope of securing votes for their scheme. At any rate, they suggest no steps to guard against it.

By the alternative scheme proposed in Report B, the University is to give its blessing to the foundation of a women's University at Cambridge, and to express a desire to continue to afford to students of the new University the privileges as regards instruction, examination, and access to libraries, museums, and laboratories which are at present accorded to students of Girton and Newnham Colleges. This gives the women their degrees, not of Cambridge University, but of a new University at Cambridge. There are arguments on both sides on this point based on sentiment. One real grievance, at any rate, is partly met. No guarantee is, however, offered that existing facilities generally given to women will be continued. They are now admitted to laboratories and lectures only by the courtesy of professors and other teachers. Cambridge is at present suffering from severe pressure on its accommodation. Under Report B women might well be crowded out from laboratories to make room for members of the University—this is fully recognised by the supporters of Report B; that is to say, the report amounts to a desire to assist in the teaching of women so long as the number of men students leaves room for them and no longer. It is no wonder that the councils of the women's colleges at Cambridge have emphatically repudiated such a scheme, and have declared that if Report B is adopted at Cambridge they would take no steps to promote the incorporation of Girton and Newnham Colleges as a separate University. It is no longer possible, in our view, for a university, in sorting out its excess applicants for entry, to take sex as the first and supreme test: intellect and the needs of the nation are both safer tests in the interest of the university and of learning.

One more point in which Report B singularly fails to make good the claims of its supporters may be briefly mentioned. As regards the admission of women to the men's colleges, and through the colleges to the University, it leaves the door wide open as it has stood since the Sex Disability (Removal) Act. It is Report A, and not Report B, which takes safeguards against what is admitted on all sides to be undesirable. It is Report A which, with this precaution, gives women the fullest equality of opportunity with men inside the University.

Lunar Tables.

Tables of the Motion of the Moon. By Prof. Ernest W. Brown, with the assistance of Henry B. Hedrick. Sections i. and ii., pp. xiii + 140 + 39; section iii., pp. 223; sections iv., v., vi., pp. 99 + 56 + 102. (New Haven: Yale University Press; London: Humphrey Milford; Oxford University Press, 1919.) Price, 3 vols., 4 guineas net.

THE appearance of Prof. E. W. Brown's lunar tables marks the accomplishment of an arduous task of the highest importance to astronomy. In the two centuries which have elapsed since the time of Newton more than a score of tables have been published. The majority of them naturally belong to the eighteenth century, and no longer possess any practical interest apart from the theories on which they were based. If they did not always mark any very distinct advance in accuracy beyond their predecessors, they generally aimed at including a greater number of inequalities more precisely determined, and systematic observation of the moon was all the time accumulating the material which could be used for comparison with theory and the better determination of the fundamental constants. Newton himself discussed eight lunar inequalities. Euler in his memoir of 1772 included twenty-one inequalities each in the longitude and the radius vector and sixteen in the latitude. This was only a beginning. As time went on and the standard of achievement grew more exacting it is not surprising to find that the number of men who possessed both the ability and the patient energy to elaborate complete and independent theories of the moon's motion and to reduce them to the form of practical tables became notably smaller. Thus when Burckhardt's tables of 1812 had once been adopted in such annual publications as the Nautical Almanac, overcoming the rival claims first of Bürg and later of Damoiseau, they continued in use for the best part of half a century, although their deficiencies ultimately amounted almost to a scandal, and their form rendered it particularly difficult to reconstruct the underlying theory and to apply the needful corrections. A serious error in the parallax according to these tables was found and corrected by Adams.

The Greenwich lunar reductions undertaken by Airy, by which the results of eighty years' observations were made available, proved the need for greatly improved tables, and provided the most valuable material on this side for making an advance. By that time it was known that Hansen was engaged in lunar researches having for their ultimate object the preparation of entirely new tables, and their appearance was eagerly awaited. But for a time difficulties threatened to intervene. Born in Schleswig in 1795, Hansen is an outstanding example of that singularly rare class, the self-taught mathematician. Owing nothing to academic education, he succeeded Encke in 1825 in the direction of the observatory at Gotha, and thereafter until the end of his long life refused all offers of preferment, though observatory and stipend were alike of the most modest. In these circumstances he received help from the Danish Government, but when this was discontinued in 1848 owing to financial stringency and the steady progress of the work was in danger, the British Admiralty came to the rescue on the representation of Airy in 1850, and not only provided the comparatively small sum needed to complete the work, but also undertook the expense of printing the tables, which accordingly were ready for distribution in 1857. As his earliest researches on the subject were published in 1829, it may be taken that the work filled the main part of Hansen's life for a period of about thirty years.

No excuse is needed for recalling these circumstances at the moment, sixty years later, when Hansen's tables are on the point of being finally superseded. They are not faultless, it is true, and for many years past certain corrections introduced by Newcomb have been adopted in the national ephemerides. But, on the whole, they have served the practical needs of two generations admirably. In Hansen's theory, on which the tables are based, the number of periodic terms had grown to about three hundred. Those which depend on the solar action were for the most part well determined, but those which arise from planetary action were neither complete nor accurate. It is but fair to remember, however, that in previous tables the latter class of terms had been ignored altogether. Considered purely as tables in the technical sense, Hansen's possess acknowledged merits. As a practical computer himself, he had the advantage of great experience and exceptional natural gifts. It is said that in a matter of four-figure logarithms he rarely had need to refer to the tables.

But during the later stages of his researches Hansen was not the only worker on the large scale in the field of lunar theory. Some ten years earlier Delaunay had begun the construction of a theory in purely algebraic form by an original method of integration, and by 1867 that part which depends on the direct action of the sun had been completed and published. His intention had been to add those complementary parts which still remained necessary and to proceed to the reduction of the whole to a numerical and tabular form. This was not to be. Historical events supervened and delayed the progress of the work. Then in 1872 he lost his life by drowning, and his life's work, which had always been pursued without assistance, came to an untimely end. Yet his projects were destined to be accomplished by other hands. The planetary inequalities were calculated by Radau in an admirable memoir, and under his direction the reduction of Delaunay's theory to tabular form was completed before the death of Radau in 1911. From 1915 the lunar ephemeris in the "Connaissance des Temps" is based on these tables. Prof. Brown remarks justly that the value of the purely algebraic development is not seen at its best in the numerical form, owing to the slow convergence of certain classes of coefficients. He also criticises the form of the tables, but this is a matter which will chiefly concern the French computer, and need not affect our appreciation of an independent lunar ephemeris. The value of Delaunay's method is not confined to his own application of it to the lunar theory. But even this can be no ordinary work, which, executed within a few years of Hansen's, assumes a new vitality after lying dormant for half a century.

The new tables of Prof. Brown will be used for the first time in the Almanacs of 1923, and a confident hope may be expressed that they will continue in use for a very long time to come. They are the final outcome of thirty years' work, and, long as this time is, Prof. Brown is to be congratulated equally on the rapidity and on the thoroughness of his labours. For the number of terms now included falls little short of 1500, and, so far as can be now seen, the expression of the effects of purely gravitational action cannot profitably be pushed further. All this work, which is completely new from the beginning, was not contemplated as an integral plan from the start, but grew by successive stages, as Prof. Brown tells us, out of a suggestion by Sir G. H. Darwin to make a study of Hill's papers. The preparation of the theory, which was published in the Memoirs of the Royal Astronomical Society, was finished in 1908, and the liberality of Yale University in undertaking the whole cost of the tables made it possible to proceed with plans for the final stage without delay and without anxiety. Thus the author has been spared some of the cares which fell to the lot of Hansen. None the less, the British Admiralty has once again played a small part in the matter, though in a different way. With proofs and MS. continually crossing the Atlantic during the war, it is recorded that only one set of returning proofs was lost.

It is unnecessary to recall the details of the author's theory. Hill, to whom its foundations are very largely due, was, like Hansen, a practised computer. Though his researches in this field have incidentally enriched celestial mechanics, and even mathematics in general, with new and fertile conceptions, his motive was essentially a practical one. It was to find a path which would lead to the highest possible accuracy in the final results with the greatest economy of labour. The soundness of his ideas can be properly tested and appreciated at no stage short of the fulfilment which Prof. Brown has given to them in this great work. There can be no doubt not only that Prof. Brown has accomplished a worthy and most valuable task, but that he has also with equal judgment employed in the course of it the best available methods.

Sections ii.–vi. contain tabular matter exclusively. The explanation of the tables is contained in the ten chapters of section i. This appears to be a model of clearness. Except in chronological questions and in special researches the ordinary astronomer rarely has occasion for single places of the moon outside the range of the hourly ephemeris provided in the Almanacs. The chief function of the tables therefore lies in the calculation of this ephemeris from year to year, and this fact has been kept in view in their arrangement. Advantage has been taken of Hansen's example to the extent deemed profitable, and a number of original devices have been introduced, including a new scheme of re-entrant arguments. By these means it is believed that the computation of an ephemeris will be at least as rapid as with Hansen's tables, in spite of the inclusion of about five times as many terms. An accumulation of errors in the sums of many tabular entries is unavoidable. From this source probable errors of $0{\cdot}04''$ in the longitude or latitude, and of $0{\cdot}003''$ in the parallax, are expected after these co-ordinates have been finally contracted to one decimal place less. Imperfections in the adopted constants and cumulative small defects of theory may raise these amounts to $\pm 0{\cdot}1''$ and $\pm 0{\cdot}05''$ respectively. Clear instructions are given for making such adjustments in the fundamental constants as may hereafter prove necessary. But there need be no illusion that the moon will actually follow the strict gravitational path laid down so carefully in these tables. As it is, the empirical term

$$+10{\cdot}71'' \sin\{140{\cdot}0^\circ(t_c-18{\cdot}5)+170{\cdot}7^\circ\},$$

with a period of 257 years, has been admitted in the longitude, with consequential changes in the arguments of some other terms. In magnitude this is comparable with the great Venus term, and the explanation of it is still to seek. Discrepancies will recur, and the advantage to be expected from the new tables is that they will no longer be entangled with the errors of a faulty ephemeris. If this hope is realised—and there is no reason to doubt that it will be—unstinted gratitude will be due to Prof. Brown and to those who have assisted him either by active collaboration or by financial aid.

The tables have been printed in England at the Cambridge University Press. The paper is of an unusually sumptuous and durable quality appropriate to a work of lasting value which will have to bear repeated handling for a long time. The type is admirably clear. Only one superficial point suggests adverse comment. The pagination is peculiar. In their present form the tables consist of six sections in three volumes. Each section, of length varying from 39 to 223 pages, is paged independently from 1 onwards. In whatever form the work is finally bound, this will surely prove an inconvenient plan for any purpose, such as the correction of errata. A continuous sequence would have been preferable. But perhaps there will be no errata (beyond one already noted), and in any case the blemish, if it be one, is trivial.

H. C. P.

Genesis, Evolution, and History.

The Evolution of the Earth and Its Inhabitants. By Joseph Barrell and Others. A Series of Lectures delivered before the Yale Chapter of the Sigma Xi during the Academic Year 1916–1917. Pp. xiv+208+iv plates. (New Haven: Yale University Press; London: Humphrey Milford; Oxford University Press, 1918.) Price 10*s*. 6*d*. net.

THIS book consists of five lectures by five experts, who deal with various aspects of evolution. The range extends from the nebula to modern civilisation, and the wonder grows that one word can cover it all. We feel as if the word "evolution" were in danger of becoming like a household knife—used in so many ways that it tends to become useless. The use of the same term for so many different kinds of becoming is apt to suggest that they are all describable by the same formulæ. To avoid this fallacy, might it not be well to find differentiated terms, such as *genesis* in the domain of things, *evolution* in the realm of organisms (keeping *development* for the becoming of the individual), and *history* for the kingdom of man?

The first lecture deals with the genesis of the earth and of the parent solar system, and, the establishment of the earth having been accounted for, its subsequent changes are traced until the time of its becoming a fit home for life. Prof. Barrell adopts the theory of the origin of the earth as a secondary spiral nebula heaved off from the central sun as the result of tidal forces produced by the close approach and passage of another star. He favours the hypothesis of earth-growth by the rapid infall of planetoids (not by Chamberlin's "slow accretion of planetesimals") and the hypothesis of an earth initially molten.

The second lecture, by Prof. Schuchert, discusses the changes of the earth's surface and climate during geologic time, which the author is inclined to put at about 800 million years. The constant shrinkage of the earth leads to an instability of surface that brings about periodic changes, not only in the areal space-relations of water and land, but also in the shapes and heights of the lands. As the lands are elevated, the weathering becomes more active and the high places are brought down to the sea. The waters are thus to a certain extent displaced, and periodically flood more or less of the lands. Every now and then, when the lands are largest, highest, and driest, a cold period sets in and disarranges the whole organic world. During these critical times the earth is scenically grand, and the struggle for existence unusually intense. The over-specialised types give place to smaller, less specialised, more plastic types. The unadaptive types become extinct, or are pressed into corners and refuges. Some adaptive stocks find relatively easy haunts, as in the sea, but from such there evolves no great mentality. The highest organisms, with the greatest mentality, have evolved on the land, "where the struggle for existence is fiercest, because of the constant necessity of adaptation to an environment subject to intense changes. Organic supremacy is attained only through constant vigilance."

In the third lecture Prof. L. L. Woodruff gives a clear and critical account of the various suggestions that have been made in regard to the origin of organisms, cautiously favouring the uniformitarian idea that they arose from not-living matter upon the earth.

Of great interest is the fourth lecture, in which Prof. R. S. Lull discourses on "the pulse of life," attempting to link up cause and effect; "to find those forces which are responsible for the more or less rhythmic accelerations of evolution shown by the fossil record. The main cause is found to be climatic change, which in turn has as a chief controlling factor earth-shrinkage and the consequent warping of the crust." In a very fresh and suggestive way, Prof. Lull discusses some of the crises in organic evolution and their physical correlates. Thus he deals with the establishment of the lime-secreting habit, the origin of vertebrates, the emergence of terrestrial vertebrates, the evolution of the terrestrial foot, the origin of reptiles, the establishment of warm-bloodedness, the appearance of birds and mammals, man's arboreal apprenticeship, his descent from the trees, and his subsequent ascent far above the level of climbing. He submits a very striking curve to show the correspondence between the pulse of life and the heavings of the earth's broad breast. To mention a concrete factor, he shows how *aridity* probably affected the evolution of dinosaurs.

In the fifth lecture Dr. Ellsworth Huntington deals with the influence of climate on civilisation. Human progress depends, he says, upon three resources, and constitutional energy. But climate has a great influence on each of these, especially the last—a thesis which the lecture graphically illustrates. Some of the great steps in civilisation are discussed, and likewise some of the relatively recent climatic changes; the problem is to correlate the two. The author admits that, so far as inherent mental capacity is concerned, climate is in one sense a minor factor; that it is more important as regards material resources, but is far from being the sole factor; and that even when energy is considered, the effect of climate may readily be neutralised by several other factors, such as lack of resources or lack of ability. But the point to be emphasised is that climate is one of the great factors which must be reckoned with in any attempt to understand the history of civilisation.

The five essays are at a high level, the authors evidently giving of their best. There are a number of vivid illustrations, and Prof. Lull's "pulse of life" diagram makes a deep impression. We strongly recommend the book to serious students as a notable contribution to the study of the various modes of the great process of becoming.

J. A. T.

Fertilisers and Parasiticides.

Chemical Fertilisers and Parasiticides. By S. Hoare Collins. (Industrial Chemistry.) Pp. xii+273. (London: Baillière, Tindall, and Cox, 1920.) Price 10*s.* 6*d.* net.

MR. COLLINS has followed up his book on plant products by another on chemical fertilisers and parasiticides, of approximately the same size and intended for the same kind of reader. The book gives a good general account of fertilisers, and it includes numerous tables of data which will be found useful to the specialist.

Artificial fertilisers are of great interest to British chemists, as they were first used in this country and for many years the industry remained in British hands. The beginning was made in 1843, when Lawes took out his first patent for the manufacture of superphosphate; the industry developed greatly when the Chilean deposits of nitrate of soda began to be worked largely by British enterprise, and when sulphate of ammonia was recovered from coal-gas and from coke-ovens. It underwent further expansion in the 'eighties, when Wrightson showed the value of basic slag, followed in the 'nineties by the demonstrations of Dobbie, Gilchrist, Somerville, and Middleton. Only one important section has remained outside British hands—the potash fertilisers, which were formerly controlled by German interests, but now will be worked by the French companies.

Mr. Collins deals mainly with the sources and methods of manufacture of fertilisers and only incidentally with their use on the farm, giving simply such information as the ordinary salesman would need. Liberal use is made of the Rothamsted data, which supply the best demonstrations of the value of the nitrogenous and potassic fertilisers and of superphosphate. Cockle Park, Northumberland, gives the best demonstration of the value of basic slag.

Striking data are shown as to the improvement in the soil effected by the use of fertilisers. Thus at Cockle Park basic slag not only increases the yield of herbage for hay or for grazing, but also leads to an increase in the percentage of nitrogen in the soil—the result of an increased development of clover. After eleven years' treatment with basic slag the percentage of nitrogen in the soil of Tree Field, Cockle Park, has increased from 0·185 per cent. to 0·236 per cent., a gain of about 850 lb. per acre. Neither sulphate of ammonia nor nitrate of soda brought about an appreciable increase in nitrogen content.

A good but short description is given of the deposits of nitrate of soda in Chile, and also of the deposits of nitrate of potash in India. The manufacture of sulphate of ammonia is described, and the account brought up to date by reference to some of the more recent processes. In view of the importance of this industry we should have liked to see a fuller classification of methods and descriptions of typical direct, semidirect, and indirect processes: the average student of agricultural chemistry has usually no access to modern books in which these are described. An account is given of the Haber process, which will prove of interest now that the method is to be worked in this country.

Superphosphate naturally occupies considerable space, and a useful table shows the composition of the natural phosphates used as raw material. Here, too (as in the case of sulphate of ammonia), one would have liked more information from the works: more might have been told of the different types of dens in use in this country and, before the war, in Belgium. The introduction of electrical power has resulted in certain modifications in methods.

In discussing compound fertilisers no reference is made to the "base"—an organic material often acidulated, or a seed meal—used to obtain proper condition.

From the laboratory side, however, the book is very good, as would have been expected from the author, and as it has no English competitor a good reception should be assured. It contains much useful information that the student could not readily obtain elsewhere.

Lectures on Folk-lore.

Psychology and Folk-lore. By Dr. R. R. Marett. Pp. ix+275. (London: Methuen and Co., Ltd., 1920.) Price 7*s*. 6*d*. net.

CONTROVERSY is commonly interesting, if only for the fact that it appeals to a man's pugnacious instincts; and most readers like to be invited to take sides. Eight of the eleven papers in this book were originally lectures, and in most of them Dr. Marett argues vigorously against what he regards as a lifeless manner of attacking the problems of folk-lore. He states his position in the first paper, and stands by it staunchly all through the volume. To him it is perfectly clear that every scrap of folk material is ultimately due to the more or less primitive reactions of the individual mind. Now nobody can understand either the productions or the modes of operation of the human spirit, he believes, by merely looking at them from the outside. The prime problem of all folk-lore is to enter into a man's thoughts, fancies, and emotions when he is confronted by certain definable situations. But simply to study objectively the changes which folk material has undergone in the course of its history is only to gather together a lot of dry bones. The psychologist is needed to put flesh on them, and to breathe into them the breath of life. Dr. W. H. R. Rivers is thereupon, in the most pleasant manner possible, held up as an awful example of the soulless sociologist.

As to this some comments may be made. First, bones *are* needed to make a man, after all. Secondly, the distinction which Dr. Rivers has made, and quite consistently observed, between psychology and sociology is one framed specifically in the interests of method and of clear definition. It is preposterous even to hint that Dr. Rivers has urged that an objective, sociological study can cover anything like all of the ground of interest of folk-lore. He has shown, both by his words and also by his example, that the studies of psychology and sociology must proceed side by side. But he has all along been concerned to utter a much-needed protest against the fashion of mixing up psychological, sociological, biological, and ethical modes of explanation in the customary haphazard manner.

It is very interesting to consider precisely what, in Dr. Marett's opinion, psychology really has to say at present concerning the problems he discusses. The main subjects of his consideration are: War and Savagery; Primitive Values; The Psychology of Culture Contact; The Transvaluation of Culture; Origin and Validity in Religion; Magic or Religion; The Primitive Medicine Man;

and Progress in Prehistoric Times. Much of what he has to say has a metaphysical or an ethical import, and much is in the way of kindly comment upon fellow anthropologists. If, however, we search for the psychology, we find absolutely no new principle discovered, no new method of analysis proposed, nothing that definitely "sticks in the mind" as marking a clear advance. We are told in many graceful ways that the folk-lorist is to account for his materials "in terms of a self-active, self-unfolding soul"; we learn that man's emotional nature remains relatively stable, though historical conditions constantly change; that religion is a way of life, and not a set of propositions offering themselves to belief; and that suggestibility is peculiarly effective in the primitive community. In many ways the most interesting paper is the brief one on "The Transvaluation of Culture." Here a real attempt is made to analyse the forms of transference of folk materials which commonly occur as a result of the interplay of cultures. The analysis is extremely interesting, but not sufficiently developed, and this criticism applies to the whole book.

In the final paper on "Anthropology and University Education" Dr. Marett says many good things well.

The book is most pleasing to read throughout, for it could scarcely be better written. Yet it is disappointing. It is too vague and too general. Modern psychology can do more for folk-lore than Dr. Marett makes clear, and at the same time it has everything to gain and nothing to lose by a clear recognition of the equal value and necessity of an objective, sociological method of approach. F. C. BARTLETT.

Elementary Chemistry.

(1) *Intermediate Text-book of Chemistry*. By Alexander Smith. Pp. vi+520. (London: G. Bell and Sons, Ltd., 1920.) Price 8*s*. 6*d*. net.
(2) *College Text-book of Chemistry*. By William A. Noyes. Pp. viii+370. (New York: Henry Holt and Co., 1919.)

THE above titles may be misleading to English readers, the ground covered by each book being practically of Matriculation standard. The authors have, however, conveyed in addition interesting information not usually found in English text-books of similar character. The chemistry of common life and of industry receives brief treatment, and these elementary books should prove interesting to the advanced English student who, in preparing for examinations, has attained detailed knowledge of such matters as the syntheses of alkaloids and other things he is never likely to see, but has been left in ignorance of chemical processes in the body, the growth of plants, the manufacture of such things as glue, ink, bread, candles, and soap, and most of the applications of chemistry to daily life.

(1) The fundamentals of chemical theory receive careful consideration in both books; that of Prof. Smith treats in detail of the theory of electrolytic dissociation and its applications. Exception might be taken to the treatment of Avogadro's law and its relation to atomic weights. This is dealt with in the same way by both authors. The molecular weight is defined as the weight of a gaseous substance filling a volume of 22·40 litres at S.T.P., and the atomic weight of an element as the least weight found in this volume of any one of its gaseous compounds. No reason is given when the definitions are stated as to why 22·40 litres has been chosen, and it is only in the case of ideal gases that the definitions are valid. This method leads Prof. Smith to say, for instance, when describing hydrogen chloride (p. 123): "The density of the gas (weight of 1 c.c.) is 0·001628. Of more interest to the chemist is the weight of 22,400 c.c. or 22·4 liters (the gram-molecular volume), namely, 36·468 grams. This is the molecular weight of the substance. As we have seen (p. 77), it is made up of 1·008 g. of hydrogen combined with 35·46 g. of chlorine." This statement, if taken literally, is incorrect. If it is not to be taken literally, why should three places of decimals be given?

Although Scheele was the first to discover oxygen, the claims of Priestley as an independent discoverer have not so far been questioned. We now learn from Prof. Smith that Priestley is "incorrectly credited with the 'discovery' of the element," and that he described the gas as "unbreathable and noxious (poisonous)." In reality, Priestley breathed the gas himself, and recommended its use in pneumonia. The statement on the same page that oxygen was discovered by Bayen in April, 1774, is another piece of historical inaccuracy. The memoir of Bayen to which reference is doubtless made (*cf*. "Opuscules," vol. i., 1798) contains no indication that this experimenter knew that the "air" given off on heating mercuric oxide differs from common air (*ibid*., pp. 252, 312, and the editor's introduction), which is the real point at issue. Equally unfortunate is the statement that the law of conservation of energy is due to "J. R. Mayer (1842), Colding (1843), and Helmholtz (1847)," without a mention of Joule!

It seems a pity that such spelling as "woolen," "mantel," "ladeled," "marvelous," and "sulfur" should minimise the value of a text-book to English students in schools, where the rest of the curriculum has to be kept in mind by the teacher.

(2) Prof. Noyes's text-book is particularly interesting and suggestive, and very well got up, with the exception of the illustrations. The treatment is in general more concise than in the other volume, but loses nothing in the way of clearness and accuracy. It should prove a useful book to teachers in the higher forms of schools who wish to add to the interest of their lessons. The summaries at the ends of the chapters will be found useful in revision, and there are numerous suggestive questions and exercises. The elements of organic chemistry, in so far as they concern daily life, are treated in a most interesting manner, and the book should prove serviceable to students of domestic science.

It may fairly be said of both books that they are of a higher order of interest and accuracy than is usual in English books of the same standard. There is too much tendency to follow stereotyped lines in most cases in English books, which no doubt results from a desire on the part of the writers to conform to what they imagine to be useful for examinational purposes. The American writers as a whole are free from this infirmity. J. R. P.

Our Bookshelf.

Moses: The Founder of Preventive Medicine. By Capt. Percival Wood. (Biblical Studies.) Pp. xi+116. (London: S.P.C.K.; New York: The Macmillan Co., 1920.) Price 4*s*. net.

Capt. Percival Wood is, of course, not the first to recognise Moses as the founder of preventive medicine, but he has marshalled his evidence in an interesting and compelling manner in the light of modern research. Thus he ascribes the third plague that smote the Egyptians, that of lice, as the indirect result of the first plague of fouled water-supply, remarking that it does not take long in a warm climate to become infested with lice when personal hygiene is neglected. The frogs, similarly, were driven on to the land by the fouling of the water, and the myriads of dead frogs tended to breed the flies of the fourth plague. The lice and the flies and the rain, together with the destruction of their crops by locusts and hail, would likewise tend to engender epidemic disease among the famine-stricken Egyptians, and hence the culminating plague of all, that of death (the selection of the firstborn in the narrative is a dramatic detail added by a later hand).

The author passes in review the legislation on hygiene and on the control of infectious diseases, and the regulations regarding dietetics. Finally, the diet of the Israelites during their wanderings is considered. The nature of manna is problematical. There was evidently a lack of proper food, and the people probably suffered from deficiency diseases—dwarfs, "broken-footed," and "crook-backs" are mentioned, conditions that might result from rickets. As a popular and accurate description of an ancient system of hygiene this book can be cordially recommended.

R. T. H.

Structural and Field Geology: For Students of Pure and Applied Science. By Dr. James Geikie. Fourth edition, revised. Pp. xxiv+454+lxix plates. (Edinburgh: Oliver and Boyd; London: Gurney and Jackson, 1920.) Price 24*s*. net.

The demand for a fourth edition of this handsome work is sufficient testimony to its educational value. The volume reflects the lucid teaching of its author, and the present editor, Dr. Robert Campbell, has found it desirable to make alterations only in definitions and in descriptions of minerals and rocks, in accordance with current usage. Chemical formulæ, which are so useful in suggesting alliances among rock-forming minerals, are still studiously avoided, except in the case of simple oxides. This is surely now unnecessary, when some knowledge of chemistry must be required of all students of a scientific subject. Though Dr. James Geikie expressly stated that he did not write for specialists, a very little more would have held the interest of the reader.

The great aim of the book, however, is the realisation that rocks are to be studied out of doors, and that structural geology is based upon what the earth itself reveals. The selection of full-page photographic illustrations, from those of mountain-crests like Goat Fell to those of rock-surfaces as they actually are seen in Nature, calls us urgently to the field. Contrast the majestic gloom of the Torridonian and Cambrian masses in Plate lxviii with the sunlit and periwinkled rocks on the Arran shore in Plate xliii, and you perceive the artist in the field-surveyor. It is a compliment to the publishers, as well as to the memory of the author, to say that this is a gift-book of a high attraction. G. A. J. C.

Notes Pratiques sur l'Observation Visuelle des Etoiles Variables. Par Maurice E. J. Gheury de Bray. Extrait de *Ciel et Terre.* (Published by the Author: 40 Westmount Road, Eltham, S.E.9.) Price 2*s*. 4*d*. post free.

The careful and persistent observation of variable stars has risen from being the occasional hobby of a few observers to one of the most important branches of stellar physics, from which far-reaching deductions have been drawn concerning star-life, absolute magnitudes, and the structure of the universe. The number of variables is now so large that a considerable army of workers is required. The author's aim is to enlist recruits, and the field of work that he recommends is that of the long-period variables of large light-range, since visual estimates of light-difference are sufficient in these, while the Cepheids and eclipse-variables call for more refined methods and more highly trained observers. The use of charts for identifying the variable and comparison stars is explained, also the "fraction" and "step" methods of estimating light-intervals, the drawing of the light-curve, and the deduction of the epochs of maximum and minimum. The amateur who contemplates extensive work in this field is wisely recommended to join the variable star section of the British Astronomical Association; its director makes a selection of the stars needing observation, and divides the work among its members.

The physical explanation of variation lies outside the scope of the little book, but something is said about the resemblance between light-curves and the curve of sun-spot activity.

It may be noted that the author, though he writes in French, has been resident in England for many years, and is a lecturer at the Woolwich Polytechnic.

Military Psychiatry in Peace and War. By Dr. C. Stanford Read. Pp. vii + 168. (London: H. K. Lewis and Co., Ltd., 1920.) Price 10*s.* 6*d.* net.

This very interesting and valuable work deals with the mental disorders encountered in the Army in peace and war. The author was, until the time of the armistice, in charge of D block at Netley, a clearing hospital through which passed practically all the mental cases arising in the various theatres of war. He has made every use of his very exceptional opportunities, not only carrying out careful observations and records of the 3000 cases which passed through his hands, but also following up the later history of these cases after their transfer from Netley to other hospitals.

Detailed descriptions of the various forms of mental disorder are given, together with statistical facts and charts illustrating their frequency and incidence; and the military organisation developed during the war to deal with the sufferers from mental disease is interestingly described. The author belongs to the school which believes that mental disorders are essentially biogenetic, and that they are the result of a failure on the part of the organism to adapt itself to the environment in which it has to live. In this failure of adaptation an essential part is played by psychological factors, and throughout the book emphasis is laid upon their importance. A preliminary chapter on the psychology of the soldier deals with the various mental forces the action and interaction of which may lead to the outbreak of disorder.

The book is essentially a medical work, and can scarcely be recommended to those without technical knowledge of the subject, but it should prove of the utmost value to the psychiatrist, and constitutes a noteworthy addition to the medical library of the war.

Wasp Studies Afield. By P. Rau and Nellie Rau. Pp. xv + 372. (Princeton: University Press; London: Oxford University Press, 1918.) Price 8*s.* 6*d.* net.

To those surveying the boundary between instinct and reason there is no more fruitful field than the fossorial wasps, with which this book is chiefly concerned. The greater part of Mr. and Mrs. Rau's illuminating volume is descriptive of the actions of individuals; but the last chapter is an impartial judicial summary, from which we extract the following items:—(1) There are very definite and ironclad instincts. (2) Despite these instincts, which are constant in each species, there is much variation in the behaviour of the individuals. (3) There is a display of the expression of emotions. (4) There is much aptitude for learning, display of memory, profiting by experience, and what seems to us rational conduct. No reader of these pages can deny that these conclusions are abundantly justified by the facts narrated.

The most complete portion of the present work is the careful series of experiments on the "homing" of the social wasp *Polistes pallipes.* These prove beyond question that "homing" is no special faculty, but depends entirely upon experience and associative memory of surrounding objects.

A few misprints, *e.g.* "most" for "moist," p. 347, "fililng" for "filling," p. 363, and the omission of a whole line after l. 8, p. 365, require attention if further editions of this otherwise admirable work are contemplated. O. H. L.

Internal-Combustion Engines: Their Principles and Application to Automobile, Aircraft, and Marine Purposes. By Lieut.-Commr. Wallace L. Lind, U.S.N. Pp. v + 225. (Boston and London: Ginn and Co., 1920.) Price 10*s.* net.

Commander Lind addresses his preface from the United States Naval Academy at Annapolis, and the book doubtless represents the instruction there given on the subject of the internal-combustion engine. For such a purpose the book is very well suited: the theoretical work is sufficiently elementary, and the sections describing practice, although apparently slight, are just such as young cadets can grasp and appreciate, whilst realising how much there is behind to be worked at if they should think of preparing themselves for specialist courses. Such books are *sui generis*—they make little appeal to trained engineers and are too vague for university courses, but for their own special purposes they are excellent. They enable an officer to have enough general knowledge to give adequate directions to the ratings under him.

The sections devoted to motor fuels and carburettors are much fuller than the rest of the book, and are evidently written by one who has given special attention to these topics. The point of view is American, and the illustrations mainly relate to trans-Atlantic models, though reference is made to some of the more important European types—quaintly mentioned in one place as those of the "belligerent nations of Europe."

A Monograph of the British Orthoptera. By W. J. Lucas. Pp. xii+264+xxv plates. (London: The Ray Society, 1920.) Price 25*s*. net.

We heartily welcome the appearance of this useful work, for there is no doubt that a complete monograph, on any order of insects, is a great stimulus to its further study in the country concerned. Our British Orthoptera have been rather neglected in the past, but Mr. Lucas's papers, which have regularly appeared in the entomological magazines, have done good service in awakening an interest in our native species. No one, therefore, is better qualified than he is to write a Ray Society volume on the order. The book is strong on the biological side, habits, times of appearance, and distribution being adequately treated, and many interesting facts are thus collected together. We should have liked to see a fuller account of the structure of Orthoptera and some remarks on their internal organisation, but recognise that the author probably has had to limit his pages very considerably owing to the expense of publication. The earwigs are regarded as a sub-order rather than as constituting a separate order: out of twelve families only one—the Ectobiidæ—contains indigenous species. The crickets are represented by four species, including the remarkable and seldom observed mole cricket (Gryllotalpa). Only nine species of long-horned grasshoppers are known with certainty to be natives, though possibly *Phaneroptera falcata* may eventually prove to be indigenous. There seems to be but a single record of a Locustid from Scotland and, in fact, our scanty British fauna compares very unfavourably with the 160 Western European representatives of the Locustodea. Of the short-horned grasshoppers, Mr. Lucas recognises eleven species, but none are migratory locusts. The twenty-five plates illustrating the work are on the whole adequate, though we fear Nos. 7, 14, and 19 have reproduced the objects concerned on too small a scale to be of very much service. These can scarcely fail to be a source of disappointment to the author, who is an expert in the art of delineation.

A. D. I.

Grain and Chaff from an English Manor. By A. H. Savory. Pp. viii+311. (Oxford: Basil Blackwell, 1920.) Price 21*s*. net.

The village described is Aldington, in the Vale of Evesham, situated at the foot of the Cotswold Hills, and the author sets out his recollections of the people and the village life as he has known them during his residence. It is not a survey in the ordinary sense; it is rather a record of the trivial features of everyday life during the past thirty years in the village, which will no doubt prove of interest to readers who enjoy reading about country matters. The details of the farming are not described, and although figures are sometimes mentioned in connection with prices, there are no dates to give precision or to allow of any check. The book is concerned almost wholly with the village inhabitants, and its interest is literary rather than scientific.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

The British Association.

We are hoping to reply in due course to the criticisms which have been made in the columns of Nature on the present position of the British Association, but in order to do so with proper effect we are inviting from various presidents and secretaries of Sections an expression of their own views of the correspondence. We hope that it may be possible to summarise these views for the benefit of your readers without undue pressure of space. Meanwhile, it may be of interest to give at full length the following remarks from the president of Section A. It should be remembered that these were not written for publication, but, as above stated, for our consideration along with other similar documents, and publication *in extenso* has been permitted by Prof. Eddington only at our special request.

H. H. Turner.
John L. Myres.

New College, Oxford, October 10.

It is important not to confuse two distinct aims: (1) to make the proceedings less specialised, and (2) to make them more popular. I believe that in practice these two aims are often found even to be opposed. The committee of Section A has often arranged joint discussions with other Sections—a typical way of broadening our proceedings—but not in the least with the idea of attracting the public. I think the idea was that, by bringing together a number of experts with different points of view, a discussion would result which would advance science, but would necessarily be rather beyond the comprehension of most of us.

(1) I am all in favour of avoiding specialisation. The meeting of the British Association is a unique occasion in the year, and is wasted if the programme is on the same lines as those of the specialised societies which meet frequently. I would, however, deprecate the idea that the chief means of accomplishing this must necessarily be by joint meetings of Sections; this may be encouraged in moderation, especially between those Sections which (some of us think) might well never have separated. Where, as in Section A, we have a wide range of subjects the adherents of which do not usually meet together during the year, there is less need to join other Sections, and there would often be difficulty in finding a large enough room.

The drawback to a joint discussion is the multiplicity of speakers and the absence of a unifying purpose; that is how those to which I have listened strike me. If, for example, Section A should decide to give some time next year to aviation problems, I think it would be more profitable, not to arrange a joint meeting with the Engineering Section, but to invite an expert (an engineer, perhaps) to set the problems before Section A in a non-technical way. No doubt other engineers will come to hear him and make remarks on his paper; but he will have had a definite task before him to make the problems and results clear to astronomers, mathematicians, geophysicists, etc., not to argue with other experts about stalling angles and other mysterious technicalities. An illustration of this was provided this year when Prof.

Bragg addressed the Geology Section on X-rays and crystal structure; I think this was as useful as a joint meeting with Section A would have been.

(2) I very much doubt the assumption commonly made that the application of science to life and industry is what the public want to hear about. It may be good for them to hear about it, but we shall have to gild the pill with more attractive subjects, such as the age of the earth, the excavations at Cnossus, the properties of prime numbers, or Einstein. The public that we are trying to reach may be interested in the application of X-rays to atomic structure, but a paper on the latest X-ray apparatus in the hospitals would be hopelessly dull. May we not draw a moral from the fact that the best-attended Section at Cardiff seems to have been that which devoted its whole programme to pure science and scarcely touched on any industrial applications? To lay stress on the valuable material *results* of science may be the best way of touching the pockets of commercial magnates, but the British Association has also the missionary task of encouraging interest in the *methods* of science and of spreading the true scientific spirit.

The question remains: Can anything be done to set forth in a more popular way the methods of science in the towns we visit? I think anything that is done must be outside our Sectional proceedings. To popularise them would merely result in the majority of professional scientific workers staying away, leaving only those interested in scientific propaganda. Although some of our ablest men of science have the gift of being able to deliver attractive popular lectures, the majority have no special aptitude or inclination for this, and there is no reason whatever why they should. If they have trained themselves to be able to explain their work lucidly to those who have been educated to understand and criticise, they have done their part, and may leave to others the work of propaganda. We must avoid the painful spectacle of a brilliant investigator placed in an unfamiliar position before a popular audience and trying to talk down to them—a task performed much better by a man with a tenth of his knowledge, but who has practised the art of popular lecturing. Moreover, the public wants his very latest conclusions, stated without the conditions and reservations which they do not understand; and when next year he alters his opinion in the light of further advances, they will deride him and men of science generally for advertising sensationally themselves and their half-baked conclusions. It is right that we should try to make some more direct return to the public in the towns the hospitality of which we enjoy; but the difficulties and dangers are so obvious that it is desirable to proceed very cautiously.

References to the good old days of the Association, when Kelvin, Maxwell, and others would argue by the blackboard and the audience could watch new discoveries emerging, produce in my mind an effect opposite to that apparently intended. It makes me realise how greatly the Association has advanced since then. In these days, too, we have a big X, Y, Z whose views on any subject under discussion would have delighted the audience, and their presence and happy way of saying the right thing or putting an encouraging question when it was needed cannot be too highly valued. But more often X shook his head, and a whisper from the Recorder reminded me that X (a name scarcely known to the majority present) had made a life-study of the particular problem, and it was he who enlightened us. The great democracy of scientific workers is a product of the newer age, and nowhere does one feel that sense of equality and fraternity so convincingly as at the British Association.

A. S. EDDINGTON.

WITH reference to the views expressed by correspondents in NATURE as to the future of the British Association, based, it would seem, in large measure on the rather disappointing attendance at the recent meeting at Cardiff, it appears to me there were reasons for this irrespective of any decadence of the Association. May not the date being so near the height of the holiday season—viz. the end of August rather than the beginning of September, as on so many previous occasions—be accountable for the absence of some members? In these times there are more counter-attractions than formerly for scientific workers and others interested in scientific or professional subjects in connection with their own special annual gatherings. Having yielded to the claims of these, they cannot afford the time or expense of attending the British Association meeting in addition. For example, a friend of mine residing in South Wales, whom I hoped to meet at Cardiff, expressed his regret at not being able to be present, as he had to expend all his spare time during the first two weeks in August at the national Eisteddfod of Wales at Barry and the annual meeting of the Welsh Bibliographical Society also held there, and at the Cambrian Archæological Association meeting in Gower. In some instances the increased railway fares (and no reduction as formerly) and hotel and other expenses acted as deterrents, and not any falling off of interest in the Association that kept many away. The bulk of the usual attenders at the British Association belong to the class who have been most severely hit by the present hard times.

WILSON L. FOX.

Carmino, Falmouth, October 5.

Recapitulation and Descent.

THE passage entitled "Recapitulation as Proof of Descent" in Dr. Bather's "Fossils and Life" (see NATURE for September 30, p. 162) calls for critical comment, inasmuch as it is representative of inconsequent reasoning current in several text-books commonly in use among students.

If experimental breeding justified the inference that a mutant form should recapitulate the characters of its ancestral stock, the observed fact that developmental stages in the life of an organism frequently resemble adult forms which are antecedent to it in the time process would constitute a cogent consideration for regarding these antecedent forms as ancestral to such an organism. But genetic investigation does not at present lead to such a prediction, and hence it is perfectly evident that recapitulatory phenomena do not provide direct evidence for evolution. Hitherto experiment has not thrown any light on the genetic significance of recapitulation, except so far as to suggest that factorial elimination rather than any "perennial desire of youth to attain a semblance of maturity" (whatever this may mean) is the key to "the omission of some steps in the orderly process."

As Sedgwick many years ago emphasised, for the purpose of the general theory of evolution recapitulatory phenomena are of interest only as extending the law of unity of type; while the value of embryological data for phylogenetic speculations resides logically in the fact that the embryologist studies the entire sequence of structural arrangements which characterise a living organism, whereas the comparative anatomist of adult life pays attention to only one of them.

It is easy to appreciate that in a generation which was obsessed with the "immutability of species" recapitulatory phenomena would greatly influence the minds of persons otherwise slow to recognise the varying degree of similarity and dissimilarity in the combination of genetic characters which living forms exhibit; the palæontologist shows that these varying degrees of similarity and dissimilarity have been brought about by progressive differentiation in both time and place; but, as Dr. Bather rightly insists, succession (progressive differentiation) does not of necessity imply descent. The final step in the argument for evolution (*i.e.* the theory that progressive differentiation has been effected through the agency of the process of reproduction) is that organisms are known to be derived only from pre-existing organisms, and that new genetic characters are from time to time differentiated in the actual course of normal generation; hence to interpret the diversity of genetic characters in living forms *in terms of experience* it can only be inferred that such diversity has been brought about in the course of descent.

It appears to me that the paramount necessity for clear statement on the logical position of the evolution theory is: (1) To recognise that much of the reasoning employed in the past originated in the emotional atmosphere created by popular prejudice and hostility; and (2) while appreciating the fact of specificity (genetic stability), to dispense entirely with the arbitrary notions connected with the term "species" as employed by systematists. It is interesting to note in conclusion that Darwin himself regarded the facts of ontogeny as an extension of the law of unity of type rather than a contention *sui generis* in favour of the theory of evolution.

LANCELOT T. HOGBEN.

Imperial College of Science,
South Kensington, S.W.7, October 2.

I AM much obliged to you for letting me see Mr. Hogben's most interesting letter, and I thank him for emphasising the fact that the mutants of the experimental breeder do not show such recapitulatory phenomena as do the mutations of the palæontologist. Since this point was dealt with, however imperfectly, in the address, I surmise that Mr. Hogben has considered only the extract published in NATURE. His statement of "the final step in the argument for evolution" appears to me consequent, but I am not yet prepared to admit that my statement was inconsequent. Neither, I fear, is absolutely conclusive. Consequent or inconsequent, I did my best to view the problem without prejudice or emotion, but I plead guilty to some attempt at humour.

F. A. BATHER.

A Fracture-surface in Igneous Rock.

THE accompanying photograph (Fig. 1) was taken by me some years ago during the construction of the Shirawta Dam, Bombay Hydro-Electric Works, India. It shows a curious fracture surface due to a heavy gelignite detonation in finely crystalline "trap" rock. So far as I can remember, I had seen other examples of this phenomenon, but photographed this as it was a particularly good one, and I thought it would be of special interest to "elasticians."

B shows the "splash effect," having its origin at the bottom of the 1½-in. diameter vertical drill-hole A. C is a two-foot rule used to fix the scale. E is the vertical edge of a fault (or possibly a dyke) in the "trap" rock. D points to one of the faint radial "splash" lines that form a sort of aurora about the explosion centre A.

It will be noticed that the "splash" at B looks like the fluting of a large fossil. The Deccan "trap," however, is an igneous rock, and, of course, has no fossils in it. Tentative explanations that may be advanced are (*a*) that the pressure at A was so enormous at the moment of detonation that an actual flow of the rock took place; (*b*) that the fluted surface is the result of unequal stress distribution due to "interference" between waves reflected from the three reflecting surfaces. These surfaces are: (1) The rock surface some 10 ft. to 20 ft. above and parallel to the foot-rule C. (2) The face of the fault E. (3) The original face of the cutting lying in a plane parallel to the plane of the paper and, at the most, 2 ft. in a line normal to the paper from the points A and B.

The distance to the original face before the blast would not be more than 6 in. to 1 ft. from the top of the drill-hole shown. The hole was drilled in the side of the rock cutting having a "batter" of about one in five, at the stage when the photograph was taken. The drill-hole A would probably be about 3½ ft. deep, and the point A about 5 ft. above the floor of the cutting.

It should also be mentioned that the site of this explosion was the side of a rock cutting about half a mile long, with level bottom leading to the Shirawta-Walwhan tunnel. The rock cut at the shallow end would be about 3 ft. deep, and at the tunnel end about 40 ft.; its top width was 20 ft.,

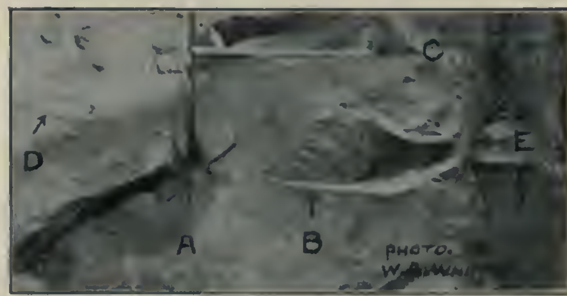

FIG. 1.—Splash-like fracture-surface due to gelignite explosion in rock A, base of 1½" diameter drill-hole and origin of explosion; B, fluted "splash effect"; C, 2-ft. rule, to fix scale; D, one of a number of radial "splash" lines.

and its width at the bottom was, at that date, from 5 ft. to 10 ft.

Samples of rock similar to that blown away from A were weighed, and their specific gravity worked out at between 2·720 and 2·752 (taking the weight of a cubic foot of water as 62·5 lb.).

(Prof. B. Hopkinson calculated that the maximum pressure at the face of an explosion of 1 oz. of guncotton is of the order 100 tons per sq. in., and that this maximum is attained in 1/400,000th of a second.)

Since writing the above, it has been suggested that the phenomenon is a large example of conchoidal fracture. In any case, I think the photograph will be of interest to readers of NATURE.

A Visual Illusion.

THE visual illusion described by Mr. Turner in NATURE of October 7, p. 180, may be seen very well by looking steadfastly at a long luggage train as in, for example, counting the trucks at about 100 yards distance. Immediately after the train has passed, the embankment appears to slide along in the opposite direction.

A. E. BOYCOTT.

17 Loom Lane, Radlett, October 10.

The Behaviour of Time Fuzes.

By PROF. A. V. HILL, F.R.S.

THE time fuze is a device for exploding a shell at any desired interval after it is fired. Before the late war the time fuze was used mainly with shrapnel shell, to burst the shell in the air and so propel the bullets down on to the objective. For this purpose the ordinary "powder-train" fuze gave—considering its simplicity—remarkably good and consistent results; at any rate so good that no serious impetus had been given to a proper scientific study of its properties under a variety of conditions. The development of anti-aircraft gunnery, however, in which the employment of a percussion fuze was useless, and in which the target moved so fast that no preliminary "ranging" on it was possible, not only required a much greater reliance to be placed on the accuracy of the time fuze, but also subjected it to much more severe conditions than had ever occurred before. The conditions referred to were those set up by variations of velocity, air pressure, spin, and temperature. Moreover, the enormous quantity of powder suddenly required for military use made it difficult for the manufacturers to produce it with the same quality and consistency as of old. All these factors led to a series of extraordinary difficulties in connection with time fuzes, such as irregular burning and a wholesale failure to burn at all; these difficulties were never completely overcome in practice, but they stimulated a much fuller investigation of the factors governing them, and have resulted in a far greater understanding of the physical behaviour of fuzes. As so often happens in the history of knowledge, urgent practical need led to scientific discovery.

The powder train fuze consists of one or more rings of highly compressed gunpowder forced into a metal groove. The ring is fired by a detonator at the moment the shell is accelerated in the barrel, and after a certain amount of it, adjustable beforehand, has been burnt it ignites a pellet which fires a second detonator which explodes the charge. The "fuze-setting," determining the length of powder to be burnt, and therefore the time of burning, is adjusted by turning the ring round an axis parallel to that of the shell. The gases produced by the combustion escape from a hole in the fuze, usually at the side, but sometimes in the nose. The position of this hole is of great importance, as will be shown below.

In a fuze at rest the time of burning is proportional to the length of powder burnt, and it has long been known that the rate of burning is a function of the atmospheric pressure. Very exact relations have been established between the pressure and the rate of burning under a variety of conditions, though their explanation is by no means clear, and some very interesting problems in the physical chemistry of combustion are provided by them. The gunpowder, of course, burns inside a closed ring, supplying its own oxygen, so that the effect of pressure is simply one of pressure as such. In the fuze fired in a shell from a gun the time of burning is by no means proportional to the length of powder burnt; usually the rate of burning is greatest at first (*i.e.* when the velocity of the shell is highest), decreasing gradually as the shell slows up until a more or less constant value is attained. In some fuzes, however, the rate of burning is least at first, increasing later on. Indeed, in some cases the same fuze may show one phenomenon when fired in one shell, and the opposite when fired in another. This complex relation between length of powder burnt and time of burning has received a complete explanation in the theory of the "dynamic pressure" at the escape holes. When a body moves rapidly through the air the pressure at any given point varies with the speed, and at any given speed varies from point to point of the shell. So completely does this theory explain the phenomena that an observed relation between "fuze-setting" and time of burning has been used even in the converse way to determine the pressure at a variety of points on the head of a shell moving at various speeds up to 1600 ft. per second. It is possible, of course, for the "dynamic pressure" to be a negative one—*i.e.* to be a "suction"—in which case, if it be sufficiently large, the powder may refuse to burn at all, and the shell will be "blind." This will be the case if the escape hole be too far back from the nose of the shell, or be under the lee of a projection on the fuze. It is necessary to take particular account of these factors in the design of the fuze body.

The scientific development of the theory of fuze burning dates largely from a trial carried out in the winter of 1916–17 at Portsmouth, in which a large number of fuzes of the same type and "lot" was fired to various heights up to 20,000 ft. in exactly similar shells, from five different 3-in. guns differing only in respect of their muzzle velocities. The results were very peculiar, and at first almost incredible; it was found that the effect of a given fall of atmospheric pressure in the upper air, whether in lengthening the time of burning or in producing a liability to irregularity and "blinds," was far greater in the case of a shell fired from a high-velocity gun than it was in the case of one fired from a low-velocity gun—quite independently of what its actual velocity might be at the moment considered. A given fuze in a given shell, moving at a given velocity, at a given reduced atmospheric pressure in the upper air, might be expected to burn at a definite fixed rate. It did not! The rate of burning depended on the previous history of the shell—viz. on the velocity with which it had left the muzzle of the gun. What effect could this previous velocity have left upon it? The mystery was so complete that one was clearly on the eve of a discovery. Various theories were put forward to account for it, such, for example, as that the shell "yawed" from its path to a degree varying from gun to gun, the "yaw" being supposed to affect the pressure at the escape holes, and therewith the time of burning. The true explanation, however, proved to be the hitherto unsuspected effect of "spin"—*i.e.* the angular velocity of the shell about its axis, and this factor has since proved practically the most important one in the behaviour of a powder train fuze. The shell, in order to secure stability in its flight, is given a high angular velocity by the rifling of the gun working on the copper driving-band. In all the guns employed (varying in velocity from 900 f.s. to 2500 f.s.) the twist of the rifling was 1 turn in 30 calibres—*i.e.* in 30 times 3 in. or $7\frac{1}{2}$ ft. This gave angular velocities varying from 7200 to 20,000 revolutions per minute in the five guns. The angular velocity of a shell falls off comparatively slowly in flight, so that it could be regarded as approximately constant along the trajectory of each gun. The peculiar differences observed in the gun trials could be explained only as an effect of spin, and it was clearly necessary to carry out spinning trials on fuzes "at rest"—*i.e.* without forward velocity—to see if the effect of spin could be isolated. Such trials were carried out at speeds up to 30,000 r.p.m., and an enormous effect of spin was established. It was possible to double the time of burning of a fuze, or even to make it cease burning altogether, merely by spinning it. The effects of a fall of pressure also were exaggerated by spin, as was shown in the laboratory at University College, by spinning a fuze under reduced pressure.

The explanation of this effect of spin is interesting. It could not be due to any "dynamic pressure" effect at the escape holes, or to a centrifugal effect on the gases in the groove; these were investigated and found to be far too small. The real explanation is the centrifugal effect on the slag produced by the gunpowder in its combustion. When the spin is high the gunpowder, warmed, softened, and just ignited by the combustion of the previous layer, is "spun" outwards to the outer edge of the groove before it has had time properly to burn and to ignite the next layer; consequently, combustion is slower, and may fail altogether. The absence of any effect of spin in the case of a special powder giving no slag, as well as the fact that "blind" fuzes are found to have failed first on the *inside* edge of the ring, make it clear that the centrifugal effect on the slag is the prime cause of the trouble. At 30,000 r.p.m., a spin reached in fuzes fired from small guns, it is almost impossible to attain any accuracy at all. The rapid increase of fuze-trouble with spin is due to the fact that the centrifugal effect varies as the *square* of the spin.

One obvious means of avoiding the excessive effect of spin was to reduce the rifling of the gun and therewith the rotation of the shell. The possibility of doing this is strictly limited, as with too low a spin the shell becomes unstable. Two similar guns were rifled respectively 1 turn in 30 and 1 turn in 40 calibres, and in all respects the fuzes fired from the latter were found to behave more satisfactorily, thus confirming the results and predictions of laboratory trials. All similar guns were provided thereafter with the smaller rifling, with good effects.

Another factor affecting the behaviour of fuzes is their temperature. This effect, also previously unknown, is a smaller one, but by no means negligible. A fuze burns more quickly at a higher temperature, and allowance must be made for this in accurate firing. A curious phenomenon arises in connection with this. It was usual to test a fuze at rest as well as in the gun, and in the case of some long-burning fuzes at rest the fuze heats itself by its own combustion to such an extent that its time of burning is seriously decreased. This "self-heating" effect does not occur in a fuze fired from a gun, which is cooled by its passage through the air. Consequently, for accurate comparison with gun trials the fuze fired at rest must be cooled while it burns—*e.g.* by subjecting it to a rapid spray of water. This was actually done in later trials, the fuze being rotated in a closed box at any required spin and pressure, and subjected the while to a rapid jet of water to ensure the constancy of its temperature.

We may summarise as follows: The rate of burning of a fuze is a function of the total pressure at its escape holes, which is made up of the atmospheric pressure A and some function $f(v/V)$ of v its velocity and V the velocity of sound. It is a function also of the spin S and of the temperature T. Expressed mathematically, the rate of burning is equal to $F[\{A+\rho f(v/V)\}, S, T]$, where F is some complicated function of the three variables. It is easy to see that fuzes are likely to cause trouble when subjected to conditions, as they were in the late war, far exceeding in severity any under which they had previously been used; and to foretell that in the next war—if there be one—reliance will be placed mainly on clockwork fuzes unaffected by these various factors.

The Iridescent Colours of Insects.[1]

By H. Onslow.

III.—Selective Metallic Reflection.

In the two preceding articles various insects have been described and illustrated, which owe their principal iridescent effects to the colours of "thin plates" and to the diffraction of ribbed structures or "gratings." However, more than one physicist of repute has stated that most insect colours are due to selective metallic reflection. The arguments against this theory, as applied to scales, were considered in the first article; briefly, they are due to the facts that both reflected

[1] Continued from p. 183.

and transmitted colours disappear when scales are immersed in fluids of a highly refractive index, and that all colours vanish when scales are subjected to pressure, as could scarcely be the case if the colours were due to some molecular structure, such as a film of aniline dye.

Now in the case of scaleless beetles and in many other iridescent structures, including bees and dragon-flies with bright, metallic wings, (1) the colour does not disappear on exerting pressure; (2) the reflected colour does not disappear on immersion in fluids of high refractive index, even when penetration is facilitated by a vacuum; and (3) the transmitted colour, so far as this can be seen, also persists. It is worth noting that the data which Michelson relies on to show the similarity in the behaviour of polarised light, when reflected from iridescent insect structures and films of aniline dye, fit the wing-cases of beetles much more closely than they do the wings of butterflies or the feathers of birds.

Sections *1* and 2 of Fig. 1 show typical iridescent wing-cases. Section *1* is that of the common green Rose Beetle (*Cetonia aurata*) and section 2 that of a beetle with a peculiar sheen (*Anomala dussumieri*), due to the numerous dome-shaped protuberances, *b*, seen in section. The surface of the chitin is protected by a thin cuticle, *c*, 0·5μ thick, but there appears to be no structure likely to produce colour. It is clear that this film cannot cause the colour, because the wing must have a protective sheath of some sort, otherwise the colour would disappear as soon as the surface came into optical contact with a refractive fluid. Consequently it is very important to determine exactly at what depth the colour-producing layer is situated, in order to decide whether there is room for an adequate structure to exist above it.

For this purpose a wing-case was carefully polished under the microscope with a paste of the finest carborundum and cedar-wood oil. On removing the surface-layer, a very remarkable change of colour was observed to have taken place. Sections were cut from suitable portions of the polished area, the exact colour and position of which could be determined. A composite picture of three different sections is shown in *3* (Fig. 1). To the extreme right of section *o* the cuticle, *c*, is untouched, but further on it is partly removed, and the lowest point seems to have been reached near *b*, in section *n*. Somewhere here the colour changes to magenta, but as soon as the irregular dark line dividing the cuticle from the lower layers is passed all colour vanishes, and the black chitin is exposed, as at *a*, in section *m*. Thus it appears that this line running underneath the cuticle is the seat of the colour-producing layer, and its extreme depth is about 0·5μ below the surface. This figure, which was obtained with the microscope, was checked by an indirect method of measurement, and the two results were found to agree with sufficient accuracy.

There appears to be a choice between two alternatives: (1) the colour may be due to a single thin film, which must lie under a protective sheath of some description, or (2) it may be produced by a layer having properties similar to an aniline dye. Although it is possible to show that under suitable conditions single films could, by interference, produce colours as bright as those shown by beetles, the second alternative appears the more probable. This is principally because of the exceedingly small distance between the surface of the wing-case and the lowest limit of the colour-producing layer. Within the space of 0·5μ, room

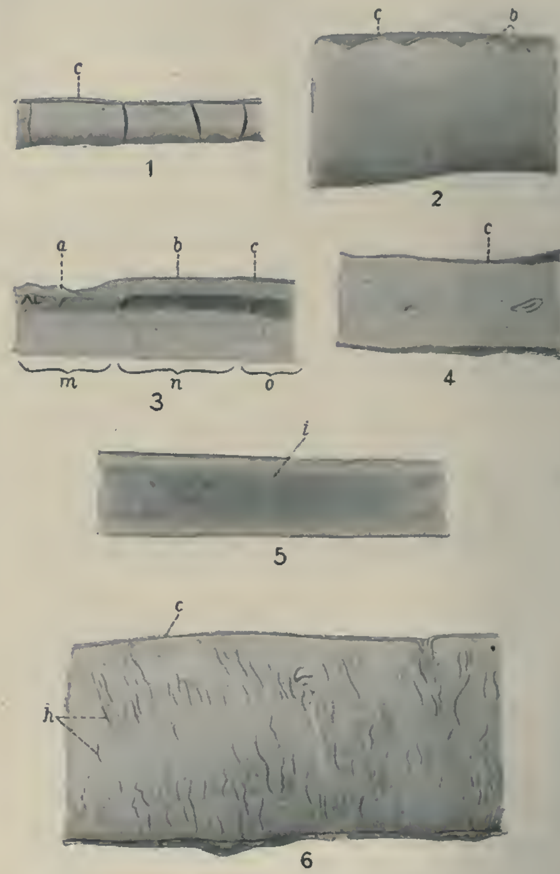

FIG. 1.

1, Surface layer, or "*Emailschicht*," of *Cetonia aurata*. *c*, surface cuticle.

2, Wing-case of *Anomala dussumieri*. *c*, cuticle; *b*, knobs or bosses.

3, Composite section of *Plusiotis resplendens* after polishing. *m*, underlying chitin; *n*, magenta portion: *o*, unpolished portion; *a*, black chitin; *b*, magenta film; *c*, surface cuticle.

4, Wing-case of *Thlaspidomorpha balyii*. *c*, surface cuticle.

5, Hair of *Chrysochloris aurea*. *i*, imbricated scales.

6, Scutum of tick *Amblyomma hebraeum*. *c*, surface cuticle; *h*, black hair-like canals filled with air.

These sections were all drawn to the scale μ=1 mm. with Zeiss 2 mm. apochromat, N.A. 1·4, and Comp. Oc.

must be made both for the protective cuticle and for the thin film itself. This might, indeed, be just possible, but is unlikely, because of the peculiar sequence of the colours caused by reducing the thickness of the iridescent film in polishing.

This appearance is difficult to describe, and must be seen to be appreciated fully. On polishing the brilliant gold beetle *Plusiotis resplendens*, no effect is at first seen, except perhaps a slight dulling of the lustre. The golden surface, scarred and scratched by the polishing crystals, remains unaltered for a period, which appears to depend on the thickness of the cuticle. Then, at a certain depth, the gold is suddenly replaced by a metallic magenta, and where this is seen to shine through a very thin film of gold, a silvery-blue effect is produced. On continuing to polish, the magenta rapidly disappears, revealing the black underlying chitin. These changes may be closely imitated by gently polishing a thin film of gold deposited electrolytically on copper. Similar effects are also seen when a copper sheet is gently heated in the steam-oven until films of oxide are formed. It is worth mentioning that Mallock has shown, by means of polishing experiments, that the coloured films of steel oxide are not due to interference in the manner usually supposed.

In the case of these beetles it may be objected that the colour of a thin film *would* change if its thickness were reduced by polishing in the above way. The change of colour, however, would be gradual, and not abrupt as is the case. Moreover, the sequence of colours would be different from that which actually occurs, as, for instance, when bluish-green and green wing-cases change to crimson or scarlet.

Some Iridescent Colours which Depend on Moisture.

The small beetles, forming the group known as Tortoise Beetles, throw considerable light on the question of surface colours by their behaviour in various fluids. Many of these beetles are golden when alive, or when preserved in spirit, but brown when dry. The colour, however, returns on soaking them in alcohol, but not in all other organic fluids. Section 4 (Fig. 1) is cut from a wing-case which has a thin cuticle, *c*, and is in other respects almost exactly like that of an ordinary scaleless beetle that retains its colour after drying. Moreover, the colour does not disappear under pressure, but here the resemblance ceases, for, curiously enough, the golden glitter remains, even after the cuticle has been polished away, so long as the surface is kept moist. In fact, almost the whole wing-case may be ground away before the metallic lustre disappears. It is obvious, from this curious behaviour, that the whole thickness of the surface layer of chitin is concerned, when in a moist condition, in reflecting a lustre, somewhat in the same way as pebbles on a beach glitter in the sunshine when washed by an advancing wave. Even vertical cracks in the chitin are seen to have golden sides. The reason for this behaviour is clear. When dry, aqueous alcohol and certain fluids can penetrate the cuticle, but other organic fluids cannot. The colour does not return immediately after immersing the beetle, but it must soak, because the protecting cuticle is pervious only with some difficulty. For the same reason, once it is wet, the colour takes some time to disappear, because the cuticle prevents the moisture from evaporating, as it must no doubt do when the beetle is alive. The fact that the whole thickness of the chitin layer reflects metallic colour suggests that, in scaleless beetles, colour may be due to a skin of chitin having the same properties as that of the Tortoise Beetles, but with the surface so polished that moisture is not necessary for the development of the colour.

Some of the most interesting beetles of this group are those which, though colourless when dry, develop a brilliant iridescence on being moistened with a wet brush. There is a remarkable bug with these properties, named *Pycanum rubens*, which is a bright apple-green when alive or in spirit, but a dull purple-brown when dry. Experiments were made in various fluids, and it was found that in alcohol, which was completely dehydrated by metallic calcium, immersion produced no colour. But the slightest trace of water caused the colour to return, and dilute acid had the effect of making it more or less permanent. Pressure experiments showed that there was no surface colour due to a molecular structure, because the colour completely disappeared, to return again as soon as the pressure was removed, just as the colours of thin films should do. These and other observations made it probable that the colour arose in a thin membrane with, like gelatin, a specific power of absorbing water, but not other organic solvents. When dry, the membrane must be too uneven to cause regular reflection, but as soon as it is swollen with water it can give the colours of thin films.

The third example of this type of iridescence was found in certain metallic ticks first described by Prof. Nuttall. When dry, they are a dull ochre, and in most anhydrous fluids a matt silver, like freshly cut aluminium, but in aqueous fluids they show bright metallic colours, both green and red. Reference to a section of the scutum, 6 (Fig. 1), shows that a protective cuticle, *c*, covers a thick layer of chitin interpenetrated by innumerable tiny air-canals, *h*. It is probable that, when dry, the white light reflected from this air renders all structural colours invisible; but when an aqueous fluid, which can penetrate the cuticle, fills these canals, the dark background produced clearly shows up the colours which may, or may not, be due to an absorbent membrane, as in the case of *P. rubens*.

In the course of these investigations many other very interesting iridescent structures were examined, for a description of which there is here no space. Many of these revealed no adequate colour-producing structure, and they present a most interesting field for further research. Among the most striking objects are the green metallic wings of certain bees and dragon-flies, such as some of the Carpenter bees, and *Neurobasis chinensis*. These very brilliant and thin structures behaved in many ways like the wing-cases of scaleless beetles. There are also the iridescent eyes of many Diptera, and the amazing iridescent hairs of a mammal, the Cape Golden Mole, *Chrysochloris aurea*, 5 (Fig. 1), showing the fine imbricated scales, *i*. In addition there are the brilliant *setae* of the "sea-mouse," a marine worm (*Aphrodite aculeata*). In plants not many iridescent structures are found, with the exception of the beautiful Pteridophyte, *Selaginella Wildenovii*, which glistens with a very strong blue and purple metallic sheen.

Obituary.

ARTHUR SIDGWICK AS NATURALIST.

THE admirable notice of the late Arthur Sidgwick in the *Times* of September 28 describes him as "naturalist," as well as "scholar" and "politician." It is a true and just description. The love of natural history developed early, and was always one of the strong and essential elements in his intellectual life.

Sidgwick was twenty-seven, and had been a master at his old school—Rugby—for three years, when Wallace's article "On Mimicry and other Protective Resemblances among Animals" appeared in the *Westminster Review* for July, 1867, and it had the same effect upon him as, in its later form, reprinted in the "Essays on Natural Selection," it had on the present writer. A few months after reading it, Sidgwick, on November 9, read his paper "On Protective Resemblances among Insects" before the Rugby School Natural History Society (pp. 23–26 of the report for 1867), in which he not only gave an admirable review of the article, but was also able to draw on his own past experience as a naturalist for illustrations. There is one slip in his reference to Wallace's account of Bates's epoch-making paper, for he spoke of the Heliconidæ and their Leptalis mimics as "white," whereas they are brightly coloured, while the Leptalis, abandoning an ancestral white, have become brightly coloured also.

Among Sidgwick's original observations in the paper, the following are quoted by Wallace in his revised essay (p. 45 of the 1875 edition):—

> I myself have more than once mistaken *Cilix compressa*, a little white and grey moth, for a piece of bird's dung dropped upon a leaf, and *vice versa* the dung for the moth. *Bryophila glandifera* and *perla* are the very image of the mortar walls on which they rest; and only this summer, in Switzerland, I amused myself for some time in watching a moth, probably *Larentia tripunctaria*, fluttering about quite close to me, and then alighting on a wall of the stone of the district, which it so exactly matched as to be quite invisible a couple of yards off.

Observations of this kind were far from well known in those days, only a few years after the appearance of the "Origin of Species."

Sidgwick was a man of strong opinions; what he believed he believed intensely. Yet, with all this, he was exceptionally modest. I recall a later paper of his on the same subject as the earlier, read before the recently established Oxfordshire Natural History Society. In the discussion some criticisms were passed upon the relative value of the destructive agencies of which he had spoken. He accepted the remarks of much younger members with perfect kindliness, and ended by saying that he hoped "to do better next time."

These memories lead naturally to thoughts of his simplicity, and with it his delightful and infectious boyishness. One came in to ask for his ever-ready help in coining some scientific term, and found him testing his latest toy, a little typewriter, and then everything must give way to a race between the player and the writer—the latter much handicapped by the banging of the machine; or a simple form of billiard table had displaced the heaps of books, and a game must be played; or a chunk of marzipan emerged and must be shared.

Sidgwick's sympathy with the aims of science in university life was not bounded by his love of natural history. In the conflicts which often arose, and were bound to arise, between the old, which is really modern, and the new, which is a return to the ancient ways, Sidgwick always supported science. I never knew an exception in the years when we were closely associated.

Among the notices and memories of Arthur Sidgwick I have seen, there has been no reference to the two volumes of "School Homilies," addressed, from 1870 onwards, to the boys in Canon J. M. Wilson's House at Rugby. The addresses deal, as Canon Wilson says in his introduction, "with apparently commonplace subjects, but they lifted every subject out of the commonplace." They should be read by everyone who wishes to know the man and all that he stood for.

E. B. P.

BY the death of M. LOUIS DUCOS DU HAURON we lose one of the foremost pioneers in the photography of colour. M. du Hauron was born on December 8, 1837, and died on August 31 last. *La Nature* of September 25 publishes a portrait taken in 1877, and the *British Journal of Photography*, Colour Supplement, of October 1 gives the portrait by which he is generally known, taken evidently some years after the other, and a useful chronology of his work. It seems that he began the study of luminous sensations in 1859, and that by 1862 he had worked out a method of colour photography by means of three colour filters and complementary printing; but his chief contributions to the subject are contained in two small volumes, which, unfortunately, are now very rare—"Les Couleurs en Photographie: Solution du Problème," published in 1869, and "Les Couleurs en Photographie et en particulier l'Héliochromie au Charbon," published in the following year. In these publications he enunciated the principles of three-colour photography, including even the present "screen-plate" processes, such as the autochrome, Paget, and others. It was impossible then to carry out these processes satisfactorily, because it was not until 1873 that Vogel discovered the possibility of sensitising plates for colour, and it was still later that gelatine plates were commercially manufactured. M. du Hauron was a pioneer also in motion photography, stereoscopic work, and other matters.

THE death occurred on September 27 of DR. D. LLOYD ROBERTS at the age of eighty-four years. Dr. Lloyd Roberts was born in 1835 at Stockport, and received his medical education at the old Manchester Royal School of Medicine, and afterwards in the hospitals of London and Paris. In 1857 he obtained the diplomas of M.R.C.S. (Eng.) and L.S.A.; two years later he received the degree of M.D. from the University of St. Andrews, and became F.R.C.P. (Lond.) in 1878. During this period he was appointed honorary physician to St. Mary's Hospital for Women and Children, a post which he retained until his death. In 1902 Dr. Lloyd Roberts was president of the section of obstetrics of the British Medical Association, and he was also a member of numerous other medical societies. He contributed many papers to medical journals, and as early as 1876 published "The Practice of Midwifery," the fourth edition of which was issued in 1896. In other spheres he will be remembered as the editor of Sir Thomas Browne's "Religio Medici," first published in 1892, and for a short pamphlet read in 1914 before the Dante Society of Manchester on "The Scientific Knowledge of Dante."

MANY geologists in this country will regret to learn that their old friend, SVEN LEONHARD TÖRNQUIST, the doyen of Swedish geologists, died at Lund on September 6 from hæmorrhage of the brain. Törnquist's work on graptolites is familiar to all who deal with Lower Palæozoic palæontology and stratigraphy, and his writings on the geology of the beautiful Siljan district in Dalecarlia and on the relations of the Leptæna limestone have been a guide to many visitors for more than half a century. Papers were received from him up to the present year, for he still retained vigour of mind and body.

WE much regret to announce the death on October 1, at sixty-eight years of age, of PROF. ITALO GIGLIOLI, professor of agricultural chemistry in the Royal University of Pisa, Italy. Also of PROF. YVES DELAGE, professor of zoology at the Sorbonne, Paris, and member of the Academies of Science and Medicine, on October 8, at sixty-six years of age.

THE death is announced, on October 4, at sixty-five years of age, of DR. MAX MARGULES, secretary of the Zentralanstalt für Meteorologie und Geodynamik at Vienna.

Notes.

ON Monday, October 11, H.R.H. the Prince of Wales returned from his seven months' tour of the West Indies and our Colonies in the Pacific Ocean. When the Prince set out on March 17 it was intended that he should pay a visit to the Indian Empire, but this has been deferred until next year out of consideration for his health. However, during his long journey he has had an opportunity of seeing some of the diverse lands and peoples which go to make up the British Empire. To the credit of science, it can be put on record that during the whole course of the tour the Prince was never for a day out of touch with London. Telegraphy and "wireless" have made continual communication possible. It is also noteworthy that, in spite of encountering bad weather, the *Renown* kept to her time-table with great accuracy; marine engineers are to be congratulated on this remarkable achievement. The experience which the Prince has gained is invaluable to one who will some day have the task of ruling the Empire. His Majesty the King has voiced this sentiment in a letter which was addressed to the Secretary of State for the Colonies for transmission to the Governors-General and Governors of the Colonies which have been visited. He says: "May such mutual intercourse create fresh ties of confidence and devotion between the Throne and the generations, present and future, of these great lands, and thus promote the unity, strength, and prosperity of the Empire." The experience is also of importance in the study of problems of the moment, of reconstruction and all that it entails. That the Prince himself appreciates this is apparent from the following words from his reply to the address of welcome made by the Mayor of Portsmouth: "We are still, I fear, only at the beginning of the labours which are necessary to restore our credit and prosperity after the prolonged strain of the war, and I am deeply interested in our problems of reconstruction, which all parts of the nation must pull together to solve."

IN 1901 the German troops in Peking removed a number of old astronomical instruments from the city wall, and they were sent to Germany and erected at Potsdam. By the Treaty of Peace it was stipulated that they were to be restored. Col. Yate, hon. secretary of the Central Asian Society, announces in the *Times* of October 8 that twenty huge cases containing these instruments have arrived in China. Six of the instruments were constructed in 1673 by Father Verbiest, S.J., and one in 1715 by Father Kegler, S.J., and these are all copies of Tycho Brahe's instruments. To make room for them on top of the wall Verbiest removed thence two old instruments, which afterwards were put up in a court at the foot of the wall, where they stood until 1901. These two instruments had been erected in 1279 by the astronomer Ko-Show-

King from designs by the Persian astronomer Gemal-ed-din, and they are of considerable interest, being the earliest known equatorials. It is curious that Marco Polo never mentioned them, though he was at Peking when they were erected; but excellent pictures of them are given in Yule's "Book of Ser Marco Polo," third edition, vol. i., pp. 448 *sqq*.

THE *Morning Post* of October 7 contains the interesting announcement that next Saturday, October 16, a memorial tablet to Descartes is to be unveiled at Amsterdam. The tablet has been placed on No. 6 Westermarkt, the house where Descartes resided during the summer of 1634. Prior to the unveiling there will be a gathering at the University, at which M. René Doumic, director of the *Revue des Deux Mondes*, and Prof. Cohen, formerly of Amsterdam University, will speak. Descartes, who was born in 1596, came of a well-to-do family of Touraine, and was always in easy circumstances. Educated by the Jesuits, then the rising schoolmasters of Europe, he afterwards continued his mathematical studies with Mersenne and Mydorge. At the age of twenty he adopted the military profession, and saw active service with the Bavarian Army during the early part of the Thirty Years' War. The first ideas of his philosophy and of his analytical geometry are said to have come to him in three dreams on the night of November 10, 1619, when bivouacked at Neuberg, on the Danube. Descartes resigned his commission in the spring of 1621, spent the next few years in study and travel, and in 1629 settled in Holland, where he found the freedom from distraction necessary to the production of his great works. Twenty years later he accepted the invitation of Queen Christina to take up his residence in Sweden. The Queen wished to found an academy with Descartes at its head, but all her designs were frustrated by his death at Stockholm on February 11, 1650. Buried first in Sweden, his remains were afterwards taken to Paris, where after several removals they now rest in the church of St. Germain-des-Prés.

REPRESENTATIONS have on several occasions been made to the Government of the Union of South Africa, in particular by the council of the Royal Anthropological Institute, that it was urgently necessary that the study of the native population should be officially recognised and placed upon a properly constituted basis. The Government has, consequently, been much impressed by the great and urgent need for the scientific investigation of the ethnology, history and languages, customs, and religious beliefs of the Bantu race, and has now agreed to render substantial aid in the establishment of a school of Bantu life and language. Several university centres in the Union have from time to time asked for assistance to establish chairs in these subjects, but, acting on the recommendation of a Departmental Committee, the Government has decided that, for the present at any rate, it is desirable to concentrate such work. A school will, therefore, be established in connection with the University of Cape Town. A representative Committee, which includes the Secretary for Native Affairs, is now sitting to discuss the general scheme. It is anticipated that professors of Bantu ethnology and Bantu language will be appointed as a nucleus of the school at an early date.

SIR FRANK W. DYSON, Astronomer Royal, has been elected an honorary member of the American Astronomical Society. Prof. Kapteyn, of Groningen, is the only other living honorary member of this society.

UNUSUALLY warm and fine weather prevailed over England during the five days from October 5 to 9. On each day the sheltered thermometer at Greenwich was 70° or above, and the highest reading was 73° on October 5. On two of the nights the minimum temperature was 57°, and on two other nights 56°. The mean maximum temperature for the five days was 71° and the mean minimum 55°, both of which were 10° above the normal. There have been slightly warmer days at Greenwich very occasionally in the early part of October, the highest temperatures recorded since 1841 being 81° on October 4, 1859, and 79° on October 4, 1886. During the last eighty years there have been only twenty-two Octobers with a temperature so high as 70°, and only two previous Octobers, 1859 and 1869, with five consecutive days of 70° or above. In recent years the warmest weather in October occurred in 1908, when the thermometer exceeded 75° on each of the first four days, but the nights were much cooler than this year. Prior to the present year the thermometer at Greenwich has only once touched 70° in October during the previous nine years.

ON Thursday, October 7, at University College, London, Sir W. H. Bragg delivered a public introductory lecture on the history of science. A course of lectures on the general history and development of science was first introduced into the college curriculum last session. The course was specially required for students training for the new diploma in journalism instituted by the University of London. It was felt, however, that facilities for the study of the subject might be welcomed by a much wider circle, considering the important part played by scientific ideas and methods in the advancement of civilisation. Moreover, since the subject is obviously vast, it was deemed desirable to provide, so far as possible, courses on the history of special sciences in addition to the course on the general history of science. Accordingly, the number of lectures and lecturers for the new session has been increased considerably. A general introductory course will be given by Dr. A. Wolf; a course on the biological and medical sciences by Dr. C. Singer (first and second terms), and by Prof. W. M. Bayliss and Prof. J. P. Hill (third term); a course on Egyptian science by Prof. Flinders Petrie; a course on the history of astronomy by Prof. L. N. G. Filon; Mr. L. T. Wren will lecture on the history of mathematics (second term); and during the third term Sir W. H. Bragg, Prof. Garwood, Mr. Orson Wood, and others will deal with the more important developments of physical science during the nineteenth century. It is hoped that in due course there will be established at the college a flourishing school in the history of science in which teaching and research will both receive due attention.

Prof. F. Francis, professor of chemistry in the University of Bristol, has been elected a corresponding member of the Belgian Royal Academy of Medicine.

A Ramsay memorial fellowship of the value of 300*l.* a year for three years has been founded by subscriptions received from the Swiss Government and from Swiss donors through the good offices of Prof. Ph. A. Guye, of Geneva. The first fellow to be elected is M. Etienne Roux, of Vich (Vaud), Switzerland, who has decided to work in the laboratories of Prof. W. H. Perkin at Oxford.

Viscount Haldane, O.M., will give an address on "The Industrial Question" to members of the Institute of Industrial Administration at the Central Hall, Westminster, on Saturday, October 23, at 8 p.m. Sir Lynden Macassey will take the chair. Invitation tickets may be obtained from the hon. secretary, Mr. E. T. Elbourne, 110 Victoria Street, S.W.1.

The Thomas Vicary lecture of the Royal College of Surgeons of England will be delivered on Thursday, November 11, at 5 o'clock, by Sir D'Arcy Power, who will take as his subject "The Education of a Surgeon under Thomas Vicary." The Bradshaw lecture of the same institution will be delivered at 5 o'clock on Monday, December 6, by Sir Berkeley Moynihan. The subject will be "The Surgery of the Diseases of the Spleen."

The annual May lecture of the Institute of Metals for 1921 is to be delivered on May 4 next by Prof. T. Turner. The annual general meeting of the institute is to take place on March 9 and 10, 1921, at the Institution of Mechanical Engineers. The May lecture will be given in the same hall. An interesting programme of lectures in connection with the local sections of the institute at Birmingham, Glasgow, and Sheffield has been prepared. Among the lecturers are Lord Weir of Eastwood, Dr. W. Rosenhain, and Prof. C. H. Desch.

With reference to the letter which appeared in Nature for August 5 last, p. 709, on the loss of fragrance in musk plants, it is interesting to note that Mrs. W. H. Cope, joint secretary of the Birmingham Field Naturalists' Club, has observed a similar absence of perfume from all the musk plants which she purchased in the open flower market this year. The observation was corroborated by other members of the club, and a suggestion was made that the loss of odour was due to the atrophy of scent-producing cells consequent on a change in the type of insects by which fertilisation was effected.

The Rev. S. Claude Tickell informs us that a movement is being promoted at Santa Barbara, California, whereby all egg-collectors are invited to accumulate local eggs, with a view to world-wide exchange with other collectors. We agree with Mr. Tickell that the movement is crude and cruel, and that "recollection" by drawing should be substituted for "collection" and the consequent molestation of wild birds. For this purpose Mr. Tickell advocates the establishment of complete, permanent collections of birds' eggs in the museums of the larger towns so that children might have opportunities of drawing and memorising the eggs; this might do away with the thousands of incomplete and transitory collections which exist at the present time.

It is a very charming and modest account of Winchester College Museum that the Rev. S. A. McDowall contributes to the October issue of the *Museums Journal*. We do not gather from it how much use is made even of the Greek and Roman collections in actual school work, but that the boys out of school-hours are encouraged to take part in curatorial activities appears from the statement that "a collection of local spiders owes its existence to the keenness of a boy still in the school." By leading boys on in this way to take the first steps in research, school museums and school natural history societies may do more than professed classes. Two excellent photographs of the interior of the museum, by a boy in the school, are reproduced as one of the plates. Among much else that is of interest in the varied contents we note a discussion by Mr. E. E. Lowe of the Public Libraries Act of 1919 and its effect on the future policy of (municipal) museums.

In the *Geographical Review* for April–June (vol. ix., No. 4) Dr. V. E. Shelford has a long article, well annotated with bibliographical references, on the aquatic biological resources of the United States. While much attention has been given to water-supply for domestic purposes, to water-power, and to the disposal of sewage, Dr. Shelford points out that other aspects of aquatic resources are more or less neglected. These include, in addition to marine fisheries, fresh-water fisheries and mussels, the provision of fish-ways in rivers, the breeding of edible frogs and turtles in swamps and lake-margins, the preservation of insect-destroying birds, and the cultivation of certain aquatic plants of economic value. Dr. Shelford further makes a special plea for the preservation of large swamp areas unless their presence can be shown to be actively detrimental to health. The pollution of rivers and coastal waters is condemned as harmful to natural resources.

The Congo Expedition of the American Museum of Natural History is the subject of a short article, accompanied by a map, in the Bulletin of the museum (vol. xxxix., p. xv.). The expedition, which spent more than six years in the Congo, returned to New York in 1915 with some 20,000 vertebrate and more than 100,000 invertebrate zoological specimens, besides large collections in anthropology and botany. The district explored was in the north-east of the Belgian Congo, from the Aruwimi River to the head-waters of the Welle River. The leader of the expedition was Mr. H. Lang, who was assisted by Mr. J. P. Chapin. It is proposed to publish the results in four series: scientific papers, which will be collected into twelve volumes after appearance in the Bulletin; special memoirs; three ethnological albums; and the narrative of the expedition. As some acknowledgment of the generous co-operation of the Belgian Government in the work of the expedition, it has been decided to present a duplicate set of the collection to the Congo Museum at Tervueren, near Brussels.

THE hall illustrating the "Age of Man" in the American Museum of Natural History, New York, is now approaching completion, and Prof. H. F. Osborn gives some account of it in the journal of the museum, *Natural History* (vol. xx., No. 3). Besides the collection of plaster casts and specimens, there are beautiful wall-paintings by Mr. C. R. Knight, representing scenes in the life of the various races of prehistoric man and of the large mammals by which they were surrounded in different parts of the world. There are also hypothetical bust-restorations of Pithecanthropus, Eoanthropus, Neanderthal man, and Crô-Magnon man; while a completely restored figure of Neanderthal man is now being attempted. Critics may be disposed to think that existing evidence is too slender to justify some of the conclusions about man's ancestry which the exhibition suggests, but there can be no doubt that so attractive a presentation of the subject will stimulate wide interest in it in America.

WE have recently received vol. xvii., part v., of the Annals of the South African Museum, containing two systematic papers, one on the Crustacea, the other on the spiders, of South Africa. The former is the sixth contribution by Mr. K. H. Barnard on the crustacean fauna of South Africa, and deals with further additions to the list of marine Isopoda; 73 species are here recorded, 45 being described as new. The list of South African marine Isopoda now includes about 170 species.

IN his presidential address to the Eugenics Association of America (*Scientific Monthly*, September) Dr. Stewart Paton pleads for a more definite and exact knowledge of man in order that the study of eugenics may be directed on sound lines, and especially points out the importance of the study of the personality—the reactions of the human machine as a whole to the conditions actually met with in life. A body of investigators specially trained in the difficult art of studying the personality—which cannot be judged only from the point of view of the physiologist or psychologist—is essential for future progress.

MISS E. A. FRASER has investigated the pronephros and the early development of the mesonephros in the cat (*Journal of Anatomy*, vol. liv., part iv., July, 1920), and finds that the embryonic excretory system of this animal is one continuous organ, the degenerate anterior end passing posteriorly into the fully developed mesonephros. A pronephric ridge is developed as a thickening of the somatic wall of the intermediate cell-mass. During the formation of this ridge and immediately lateral to it a series of cœlomic chambers becomes cut off from the general body-cavity, each chamber communicating with the body-cavity by a narrow passage. Such chambers do not appear to have been observed previously in a mammal, and it is suggested that they represent vestigial pronephric chambers, each with a peritoneal funnel. They soon undergo a change, and from the region of the eleventh somite backwards they close off from the body-cavity and form an almost solid longitudinal cord, which later becomes divided into a series of vesicles, the central cavity of each of which arises secondarily. Though it is difficult to demonstrate that the longitudinal cord of tissue in which the vesicles arise is actually derived from the pronephric chambers, this interpretation seems to be the correct one. If so, then the pronephric chambers are homologous with the Malpighian capsules.

DURING the course of recent ecological work on the Irish coast—near Dublin and in Galway Bay—collections were made of the mites (Acarina) occurring in the inter-tidal area, and Mr. J. N. Halbert has described the material in a paper published in the Proceedings of the Royal Irish Academy (vol. xxxv., B7, 1920). The species dealt with, which are such as can be reasonably considered as habitual denizens of the inter-tidal area, do not apparently exhibit any striking modifications to suit them for a semi-aquatic life, *e.g.* the breathing organs present no modification. The majority of the species possess, in common with many purely terrestrial species, a smooth, shining epidermis or a covering of hairs, which serves to protect the surface of the mite from becoming wetted. The usual habitat of these mites is in sheltered places—crevices, rock-fissures, and under embedded stones—such as have been for long undisturbed, and where air is imprisoned during high tides. Higher up on the shore, at about high-water mark, a few species have succeeded in establishing themselves where they are only occasionally wetted or sprayed. The zonal distribution of the inter-tidal mites is shown in a table, from which it is seen that below the upper zone, named the orange lichen zone (from the occurrence there of Physcia, Lecanora, etc.), the number of species becomes suddenly much less. The list contains seventy-seven species, twelve of which are new, and a new genus is described.

CLOUDINESS in the United States is the subject of an article by Prof. R. De C. Ward in the *Geographical Review* for April–June (vol. ix., No. 4, 1920). The article contains a useful bibliography of the subject and a new map showing the mean annual cloudiness. The regions of maximum cloudiness appear to be the Great Lakes and the St. Lawrence valley in the east and the northern part of the Pacific Coast in the west. The desert regions in the south-west naturally experience least cloud. Over most of the country the difference between the amount of cloud in the cloudiest and in the least cloudy months is only 10–20 per cent., but in the regions of maximum cloudiness it is 30 per cent. or more, and in the western plateau region it is more than 40 per cent.

THE microscopic examination of the structure of metals and other substances by the aid of light reflected from a polished and etched surface has proved of such great value that Mr. F. E. Wright, of the Geophysical Laboratory of the Carnegie Institution, Washington, has gone carefully into the question as to how far it might be possible by such an examination in polarised light to determine the optical constants of the materials present in the surface. The result of his work is published in No. 7 of the Proceedings of the American Philosophical Society for the current year. Unfortunately, Mr. Wright finds that these constants cannot be satisfactorily found by the method, although there is no difficulty in ascertaining whether the substances seen are crystalline or not by the rotation of the plane of polarisation of plane polarised incident light. Tests of colour, hardness, and behaviour under the action of solvents still remain the most trustworthy for the determination of the substances exposed at the surface.

AMONG the announcements of forthcoming books just issued by the Oxford University Press is one which should appeal especially to readers of NATURE, viz. vol. ii. of "Studies in the History and Method of Science," edited by Dr. C. Singer. The work will contain the following contributions:—Greek Biology and its Relation to the Rise of Modern Biology, Dr. C. Singer; Medieval Astronomy, Dr. J. L. E. Dreyer; Leonardo as Anatomist, H. Hopstock; Science and Hypothesis, Dr. F. C. S. Schiller; The Asclepiadæ and the Priests of Asclepius, E. T. Withington; History of Anatomical Injections, F. J. Cole; The Scientific Works of Galileo, J. J. Fahie; Unity in Modern Scientific Thought, F. S. Marvin; Four Armenian Tracts on the Structure of the Human Body, F. C. Conybeare; Roger Bacon and the State of Science in the Thirteenth Century, R. Steele; A History of Palæobotany, Dr. E. N. A. Arber; Science and Metaphysics, J. W. Jenkinson; and Archimedes' Principle of the Balance and some Criticisms upon it, J. M. Child. The same publishers also promise "A History of Greek Mathematics," by Sir Thomas Heath, in two volumes.

SIR ISAAC PITMAN AND SONS, LTD., have in preparation a new series of Technical Primers, the aim of which is to present a sound technical survey of fundamental facts, principles, equipment, and practice in volumes covering ultimately all phases and branches of technology. The earliest volumes will deal with Continuous-Current Armature Winding, Belts for Power Transmission, Municipal Engineering, Water-Power Engineering, Photographic Technique, Foundrywork, Pattern-Making, Hydro-Electric Developments, The Electric Furnace, Small Single-Phase Transformers, Pneumatic Conveying, The Electrification of Railways, and The Steam Locomotive.

THE Cambridge Pocket Diary for the academic year 1920–21 has been issued by the Cambridge University Press, price 3*s*. In addition to the information usually found in diaries, a complete list of University officials, dates of examinations and of meetings of officials, and local information, such as Cambridge telephone numbers and the train service to London and to Oxford, are included in this convenient little book.

THE United States Coast and Geodetic Survey has published a short list (No. 109) of its publications since January 1, 1914, which is supplied free of charge to those interested. The list includes papers in geodesy, magnetism, cartography, and hydrography.

Our Astronomical Column.

THE ITALIAN ASTRONOMICAL SOCIETY.—This society is commencing the publication of the third series of its Memoirs. Vol. i., No. 1, has just appeared, and contains several papers of interest. The Rev. J. G. Hagen writes on the galaxy and the "Via Nubila"—a name that he suggests for a stream of nebulæ, both luminous and dark, having its maximum density in the well-known nebulous region round the galactic North Pole. G. Armellini contributes a paper on the gravitational potential of the galaxy, and endeavours to explain certain small anomalies in the motion of the planets Saturn and Neptune by stellar perturbations. It is, however, fairly clear that on any reasonable assumption of the mass of the stellar system its differential action within the planetary family must be wholly inappreciable. A. Bemporad publishes a series of comparisons of 32 Geminorum with the neighbouring stars ξ and ϵ Geminorum, made with a wedge photometer between December and March last. It is concluded that the magnitude of 32 Geminorum varies between 6·5 and 7·2 in a period of 2·43 days; the light-curve is not given, but it is stated to be "of the usual type of short-period variables, with a pronounced secondary maximum." E. Bianchi notes that the minor planet (44) Nysa varied in light with a range of half a magnitude in a period of thirty-six days; these observations were made in March and April, 1913. On the other hand, observations in 1920 indicate the much shorter period of $3\frac{1}{4}$ hours; this is presumably an effect of rotation, in which case the monthly variation previously observed needs some other explanation. Other papers deal with the giant and dwarf stars (G. Zappa); measures of the sun's diameter, which appear to show some variation in the value in the course of the sun-spot cycle (A. Prosperi); and stellar spectra with an objective prism (G. Abetti).

THE COLOUR OF NEBULOUS STARS.—Sir W. Herschel discovered 130 years ago that certain stars were surrounded by nebulous envelopes, and made the correct deduction that the latter were gaseous, not stellar. These objects play an important part in theories of cosmogony, and deserve careful study. The *Astrophysical Journal* for July contains a paper by F. H. Seares and E. P. Hubble which establishes the interesting fact that these stars are redder by about one colour-class than would be expected from their spectral type. This was first noted visually by Hubble in one or two cases; a systematic campaign was therefore planned with the Mount Wilson 60-in. reflector, using the method of exposure ratios. About fifty stars were examined, being roughly half of the known objects of this type. Their spectra are mainly of type B, with a few early A's, one Oe5, and one G5. Check stars were photographed at the same altitude to determine the plate constants. The stars mainly lie in two groups, and the mean excess of colour-class for these groups is 1·28 and 0·88. In a few cases where the effect does not appear it is stated that the visual aspect suggests that the star is not really in the nebula, but accidentally projected upon it.

There is a discussion of possible explanations; the most straightforward is that the red colour is produced by molecular scattering in the nebulous envelope. Fluorescence in the nebula near the star's surface is also suggested; alternatively, that the presence of the envelope may have an influence on the star's constitution. It is noted that if the envelope were composed of particles above a certain size, general, and not differential, absorption would result, so that this may explain the non-occurrence of the phenomenon in a few cases.

Our Conceptions of the Processes of Heredity.*

By MISS E. R. SAUNDERS, F.L.S.

I.

BY the term "inheritance" we are accustomed to signify the obvious fact of the resemblance displayed by all living organisms between offspring and parents, as the direct outcome of the contributions received from the two sides of the pedigree at fertilisation; to indicate, in fact, owing to lack of knowledge of the workings of the hereditary process, merely the *visible* consequence—the final result of a chain of events. Now, however, that we have made a beginning in our analysis of the stages which culminate in the appearance of any character, a certain looseness becomes apparent in our ordinary use of the word "heredity," covering as it does the two concomitant essentials, genetic potentiality and somatic expression—a looseness which may lead us into the paradoxical statement that inheritance is wanting in a case in which, nevertheless, the evidence shows that the genetic constitution of the children is precisely like that of the parents. When we say that a character is inherited no ambiguity is involved, because the appearance of the character entails the inheritance of the genetic potentiality. But when a character is stated not to be inherited it is not thereby indicated whether this result is due to environmental conditions, to genetic constitution, or to both causes combined. That we are now able in some measure to analyse the genetic potentialities of the individual is due to one of those far-reaching discoveries which change our whole outlook, and bring immediately in their train a rapidly increasing array of new facts, falling at once into line with our new conceptions, or by some orderly and constant discrepancy pointing a fresh direction for attack.

The earliest attempts to frame some general law which would co-ordinate and explain the observed facts of inheritance were those of Galton and Pearson. These schemes, however, take no account of the physiological nature of this as of all other processes in the living organism. They have, in consequence, failed to bring us nearer to our goal—a fuller comprehension of the workings of the hereditary mechanism. Progress in this direction has resulted from the method of inquiry which deals with the unit in place of the mass. The revelation came with the opening of the present century, for in 1900 was announced the rediscovery of Mendel's work, actually given to the world thirty-five years earlier, but at the time leaving no impress upon scientific thought. It chanced that in each pair of characters selected by Mendel for experiment the opposites are related to each other in the following simple manner: An individual which had received both allelomorphs, one from either parent, exhibited one of the two characteristics, hence called the dominant, to the exclusion of the other. Among the offspring of such an individual both characteristics appeared, the dominant in some, its opposite, the recessive, in others, in the proportion approximately of three to one. This is the result which might be expected from random pairing in fertilisation of two opposites, where the manifestation in the zygote of the one completely masks the presence of the other. As workers along Mendelian lines increased and the field of inquiry widened, it soon, however, became apparent that the dominant-recessive relationship is not of universal occurrence. It likewise became clear that the simple ratios which obtained in Mendel's experiments are not characteristic of every case. Mendel's own results were all, as it happened, explicable on the supposition that the two alternative forms of each character were dependent on a *single* element or factor. We now know, however, that many characters are not controlled by one single factor, but by two or more. One of the most familiar instances of the two-factor character is the appearance of the colouring matter anthocyanin in the petals of plants such as the stock and sweet pea. Our proof that two factors (at least) are here involved is obtained when we find that two true breeding forms devoid of colour yield coloured offspring when mated together. In this case the two complementary factors are carried, one by each of the two crossed forms. When both factors meet in the one individual, colour is developed. We have in such cases the solution of the familiar, but previously unexplained, phenomenon of reversion. Confirmatory evidence is afforded when among the offspring of such cross-bred individuals we find the simple 3 to 1 ratio of the one-factor difference replaced by a ratio of 9 to 7. Similarly, we deduce from a ratio of 27 to 37 that three factors are concerned, from a ratio of 81 to 175 four factors, and so on. The occurrence of these higher ratios proves that the hereditary process follows the same course whatever the number of factors controlling the character in question.

And here I may pause to dwell for a moment upon a point of which it is well that we should remind ourselves from time to time, since, though tacitly recognised, it finds no explicit expression in our ordinary representation of genetic relations. The method of factorial analysis based on the results of inter-breeding enables us to ascertain the least possible number of genetic factors concerned in controlling a particular somatic character, but what the total of such factors actually is we cannot tell, since our only criterion is the number by which the forms we employ are found to differ. How many may be common to these forms remains unknown. In illustration I may take the case of surface character in the genera Lychnis and Matthiola. In *Lychnis vespertina* the type form is hairy; in the variety *glabra*, recessive to the type, hairs are entirely lacking. Here all glabrous individuals have so far proved to be similar in constitution, and when bred with the type give a 3 to 1 ratio in F_2 (Report to the Evolution Committee, Royal Society, i., 1902). We speak of hairiness in this case, therefore, as being a one-factor character. In the case of *Matthiola incana* v. *glabra*, of which many strains are in cultivation, it so happened that the commercial material originally employed in these investigations contained all except one of the factors since identified as present in the type and essential to the manifestation of hairiness. Hence it appeared at first that here also hairiness must be controlled, as in Lychnis, by a single factor. But further experiment revealed the fact that though the total number of factors contained in these glabrous forms was the same, the respective factorial combinations were not identical. By inter-breeding these and other strains obtained later, hairy F_1 cross-breds were produced giving ratios in F_2 which proved that at least four distinct factors are concerned (Proc. Roy. Soc., B, vol. lxxxv., 1912). Whereas, then, the glabrous appearance in Lychnis always indicates the loss (if for convenience we may so represent the nature of the recessive condition) *of*

* From the opening address of the President of Section K (Botany) delivered at the Cardiff meeting of the British Association on August 24.

one and the same factor, analysis in the stock shows that the glabrous condition results if *any factor out of a group of four* is represented by its recessive allelomorph. Hence we describe hairiness in the latter case as a four-factor character.

It will be apparent from the cases cited that we cannot infer from the genetic analysis of one type that the factorial relations involved are the same for the corresponding character in another. That this should be so in wholly unrelated plants is not, perhaps, surprising, but we find it to be true also where the nature of the characteristic and the relationship of the types might have led us to expect uniformity. This is well seen in the case of a morphological feature distinctive of the N.O. Gramineæ. The leaf is normally ligulate, but individuals are occasionally met with in which the ligule is wanting. In these plants, as a consequence, the leaf-blade stands nearly erect instead of spreading out horizontally. Nilsson-Ehle ("Kreuzungsuntersuchungen an Hafer und Weizen," Lund, 1909) discovered that in oats there are at least four, and possibly five, distinct factors determining ligule formation, all with equal potentialities in this direction. Hence, only when the complete series is lacking is the ligule wanting. In mixed families the proportion of ligulate to non-ligulate individuals depends upon the number of these ligule-producing factors contained in the dominant parent. Emerson (Annual Report of the Agricultural Experiment Station of the University of Nebraska, 1912) found, on the other hand, that in maize mixed families showed constantly a 3 to 1 ratio, indicating the existence of only one controlling factor.

From time to time the objection has been raised that the Mendelian type of inheritance is not exhibited in the case of specific characters. That no such sharp line of distinction can be drawn between the behaviour of varietal and specific features has been repeatedly demonstrated. As a case in point, and one of the earliest in which clear proof of Mendelian segregation was obtained, we may instance Datura. The two forms, *D. stramonium* and *D. tatula*, are ranked by all systematists as distinct species. Among other specific differences is the flower colour. The one form has purple flowers, the other pure white. In the case of both species a variety *inermis* is known in which the prickles characteristic of the fruit in the type are wanting. It has been found that in whatever way the two pairs of opposite characters are combined in a cross between the species, the F_2 generation is mixed, comprising the four possible combinations in the proportions which we should expect in the case of two independently inherited pairs of characters, when each pair of opposites shows the dominant-recessive relation. Segregation is as sharp and clean in the specific character flower colour as in the varietal character of the fruit.

Among the latest additions to the list of specific hybrids showing Mendelian inheritance, those occurring in the genus Salix are of special interest, since heretofore the data available had been interpreted as conflicting with the Mendelian conception. The recent observations of Heribert-Nilsson ("Experimentelle Studien über Variabilität, Spaltung, Artbildung und Evolution in der Gattung Salix," 1918) show that those characters which are regarded by systematists as constituting the most distinctive marks of the species are referable to an extremely simple factorial system, and that the factors mendelise in the ordinary way. Furthermore, these specific-character factors control not only the large constant *morphological features*, but also *fundamental reactions* such as those determining the condition of physiological equilibrium and vitality in general. In so far as any distinction can be drawn between the behaviour of factors determining the varietal as opposed to the specific characters of the systematist, Heribert-Nilsson concludes that the former are more localised in their action, while the latter produce more diffuse results, which may affect almost all the organs and functions of the individual, and thus bring about striking alterations in the general appearance. *S. caprea*, for example, is regarded as the reaction product of two distinct factors which together control the leaf-breadth character, and also affect, each separately and in a different way, leaf form, leaf colour, height, and the periodicity of certain phases. We cannot, however, draw a hard-and-fast line between the two categories. The factor controlling a varietal characteristic often produces effects in different parts of the plant. For example, the factors which lead to the production of a coloured flower no doubt also in certain cases cause the tinging seen in the vegetative organs, and affect the colour of the seed. Heribert-Nilsson suggests that fertility between species is a matter of close similarity in genotypic (factorial) constitution rather than of outward morphological resemblance. Forms sundered by the systematist on the ground of gross differences in certain anatomical features may prove to be more akin, more compatible in constitution, than others held to be more nearly related because the differentiating factors happen to control less conspicuous features.

Turning to the consideration of the more complex types of inheritance already referred to, we find numerous instances where a somatic character shows a certain degree of coupling or linkage with another perhaps wholly unrelated character. This phenomenon becomes still further complicated when, as is now known to occur fairly frequently, somatic characters are linked also with the sex character. The results of such linkages appear in the altered proportions in which the various combinations of the several characters appear on cross-breeding. Linkage of somatic characters can be readily demonstrated in the garden stock. Some strains have flowers with deeply coloured sap, *e.g.* full red or purple; others are of a pale shade, such as a light purple or flesh colour. In most commercial strains the "eye" of the flower is white owing to absence of colour in the plastids, but in some the plastids are cream-coloured, causing the sap colour to appear of a much richer hue and giving a cream "eye." Cream plastid colour is recessive to white, and the deep sap colours are recessive to the pale. When a cream-eyed strain lacking the pale factor is bred with a white-eyed plant of some pale shade, the four possible combinations appear in F_2, but not, as we should expect in the case of two independently inherited one-factor characters, in the proportions 9 : 3 : 3 : 1, with the double recessive as the least abundant of the four forms. We find instead that the double dominant and the double recessive are both in excess of expectation, the latter being more abundant than either of the combinations of one dominant character with one recessive. The two forms which preponderate are those which exhibit the combinations seen in the parents, the two smaller categories are those representing the new combinations of one paternal with one maternal characteristic. In the sweet pea several characters are linked in this manner, viz. flower colour with pollen shape, flower colour with form of standard, pollen shape with form of standard, colour of leaf axil with functioning capacity of the anthers. If in these cases the cross happens to be made in such a way that the two dominant characters are brought in one from each side of the pedigree instead of both being contributed by one parent, we get again a result in which the two parental combinations occur more frequently, the two recombinations or "cross-overs" less often than we should expect. In the first case the two characters appear to hang together in descent to a certain extent, but not completely; in the latter, similarly to repel each other.

This type of relationship has been found to be of very general occurrence. The linked characters do not otherwise appear to be connected in any way that we can trace, and we therefore conclude that the explanation must be sought in the mechanism of distribution. Two main theories having this fundamental principle as their basis, but otherwise distinct, have been put forward, and are usually referred to as the *reduplication* and the *chromosome* view respectively. The reduplication view, proposed by Bateson and Punnett (Proc. Roy. Soc., 1911), rests on the idea that segregation of factors need not necessarily occur simultaneously at a particular cell-division. The number of divisions following the segregation of some factors being assumed to be greater than those occurring in the case of others, there would naturally result a larger number of gametes carrying some factorial combinations and fewer carrying others. If this differential process is conceived as occurring in an orderly manner it would enable us to account for the facts observed. It has, however, to be said that we cannot say *why* segregation should be successive, nor at what moments, on this view, it must be presumed to occur. On the other hand, the conceptions embodied in the chromosome hypothesis as formulated by Morgan and his fellow-workers ("The Mechanism of Mendelian Heredity" (Morgan, Sturtevant, Muller, and Bridges), 1915) are, in these respects, quite precise. They are built around one cardinal event in the life-cycle of animals and plants (some of the lowest forms excepted), viz. the peculiar type of cell-division at which the number of chromosomes is reduced to half that to be found during the period of the life-cycle extending backwards from this moment to the previous act of fertilisation. In the large number of cases already investigated the chromosome number has been found, as a rule, to be the same at each division of the somatic cells. We can, in fact, take it as established that it is ordinarily constant for the species.

These observations lend strong support to the view that the chromosomes are persistent structures—that is to say, that the chromatin tangle of the resting nucleus, whether actually composed of one continuous thread or not, becomes resolved into separate chromosomes at corresponding loci at each successive mitosis. The reduction from the diploid to the haploid number, according to the more generally accepted interpretation of the appearances during the meiotic phase, is due to the adhering together in pairs of homologous chromosomes, each member of the set originally received from one parent lying alongside and in close contact with its mate received from the other. Later, these bivalent chromosomes are resolved into their components so that the two groups destined one for either pole consist of whole dissimilar chromosomes, which then proceed to divide again longitudinally to furnish equivalent half chromosomes to each of the daughter nuclei.

The obvious close parallel between the behaviour of the chromosomes—their pairing and separation—and that of Mendelian allelomorphs which similarly show pairing and segregation, first led to the suggestion that the factors controlling somatic characters are located in these structures. The ingenious extension of this view which has been elaborated by Morgan and his co-workers presumes the arrangement of the factors in linear series after the manner of the visible chromomeres—the beadlike elements which can be seen in many organisms to compose the chromatin structure—each factor and its opposite occupying corresponding loci in homologous chromosomes. From this conception follows the important corollary of the segregation of the factors during the process of formation and subsequent resolution of the bivalent chromosomes formed at the reduction division. We should suppose, according to Morgan, in the case of characters showing *independent* inheritance and giving identical Mendelian ratios whichever way the mating is made and however the factorial combination is brought about, that the factors controlling the several characters are located in *different* chromosomes. Thus in the case of Datura already mentioned the two factors affecting sap-colour and prickliness respectively would be presumed to be located so far apart in the resting chromatin thread that when separation into chromosomes takes place they become distributed to different members. Where unrelated characters show a *linked* inheritance the factors concerned are held, on the other hand, to lie so near together that they are always located in one and the same chromosome. Furthermore—and here we come to the most debatable of the assumptions in Morgan's theory—when the bivalent chromosome composed of a maternal and a paternal component gives rise at the reduction division to two single dissimilar chromosomes, these new chromosomes do not always represent the original intact maternal and paternal components. It has been observed in many forms that the bivalent structure has the appearance of a twisted double thread.

Already in 1909 cytological study of the salamander had led Janssen (*La Cellule*, xxv.) to conclude that fusion might take place at the crossing points, so that when the twin members ultimately draw apart each is composed of alternate portions of the original pair. Morgan explains the breeding results obtained with Drosophila by a somewhat similar hypothesis. He also conceives that in the process of separation of the twin lengths of chromatin cleavage between the two is not always clean, portions of the one becoming interchanged with corresponding segments of the other, so that both daughter chromosomes are made up of complementary sections of the maternal and paternal members of the duplex chromosome. On the main issue, however, both schemes are in accord. A physical basis for the phenomenon of linkage is found in the presumed nature and behaviour of the chromosomes, viz. their colloidal consistency, their adhesion after pairing at the points of contact when in the twisted condition, and their consequent failure to separate cleanly before undergoing the succeeding division.

According to Morgan, the frequency of separation of linked characters is a measure of the distance apart in the chromosome of the loci for the factors concerned, and it becomes possible to map their position in the chromosome relatively to one another. In this attempt to find in cytological happenings a basis for the observed facts of inheritance, our conception of the material unit in the sorting-out process has been pushed beyond the germ-cell, and even the entire chromosome, to the component sections and particles of the latter structure.

To substantiate the "chromosome" view the primary requisite was to obtain proof that a particular character is associated with a particular chromosome. With this object in view it was sought to discover a type in which individual chromosomes could be identified. Several observers working on different animals found that a particular chromosome differing in form from the rest could be traced at the maturation division, and that this chromosome was always associated with the sex-character in the following manner. The female possessed an even number of chromosomes so that each egg received an identical number, including this particular sex-chromosome. The male contained an uneven number, having one fewer than the female, with the result that half the sperms received the same number as the egg including the sex-chromosome, and half were deficient in this particular chromosome. Eggs fertilised with sperms containing the full number of chromosomes developed into females, while those fertilised with sperms lacking this distinctive chromosome produced males. Morgan made the further discovery in the fruit-fly, *Drosophila ampelophila*, that certain factors controlling various somatic characters were located in the sex-chromosome. The inheritance of these characters and of sex evidently went together. The sperms of Drosophila are therefore conceived as of two kinds, one containing the same sex-chromosome as the eggs, the so-called X chromosome, and the other a mate of a different nature, the Y chromosome, which appears to be inert and unable to carry the dominant allelomorphs.

Instances of sex-linked inheritance are now known in many animals, some of which are strictly comparable with Drosophila; others follow the same general principle, but have the relations of the sexes reversed, as exemplified by the moth Abraxas, which has been worked out by Doncaster (Rep. Evolution Committee, iv., 1908), whose sudden death we have had so recently to deplore. Here the female is the heterozygous sex, and contains the dummy mate of the sex-chromosome.

(*To be continued.*)

The Department of Scientific and Industrial Research.

By J. W. WILLIAMSON.

THE Report of the Committee of the Privy Council for Scientific and Industrial Research for the year 1919–20[1] is of great interest to all those who are watching with sympathetic anxiety the attempt, embodied in the Department of Scientific and Industrial Research, to secure greater and better organised State aid for scientific research without subjecting the research worker to such Governmental control as would stifle his spirit and energies. The present report is the Committee's fifth annual report, and the Report of the Advisory Council which is subjoined, before proceeding to record the past year's work, takes the occasion to give a brief survey of its labours during the past five years.

The Government has entrusted to the Department during the past year new responsibilities. The Geological Survey and Museum of Practical Geology were transferred to the Department on November 1 last, and a Geological Survey Board has been appointed under the chairmanship of Sir Francis Ogilvie. At the beginning of this year the Cabinet decided that means should be adopted so to organise the scientific work that was needed for the fighting Services as to avoid unnecessary overlapping, to secure the utmost economy of *personnel* and equipment, to facilitate the interchange of scientific knowledge and experience between all the Departments concerned, and to provide a single direction and financial control for all work of a fundamental nature of civilian as well as military interest. It directed that the Department should establish a series of co-ordinating Boards, and that these Boards should include technical representatives of each of the fighting Services and of such civilian Departments as might be materially interested in their work, as well as independent men of science. Three Boards, one for chemistry, one for physics, and one for engineering, have been established, and these, with the existing Radio Research Board, form the nucleus of the scheme. These new arrangements are, obviously, an attempt to apply the principles of the co-operative conduct of research to Government Departments, and as the Advisory Council points out: "If firms competing with each other for existence can combine, as they have done, for their common benefit, it ought not to be more difficult for the members of a national service to do so merely because they are attached to different Departments of the Government."

[1] Report of the Committee of the Privy Council for Scientific and Industrial Research for the Year 1919–20. (Cmd. 905.) Pp. 120. (London: H.M. Stationery Office.) Price 1s. net.

The review of the past five years' work of the Department is a satisfying and promising record. The programme, it is explained, falls under four main heads: (1) The encouragement of the individual research worker, particularly in pure science; (2) the organisation of national industries into co-operative research associations; (3) the direction and co-ordination of research for national purposes; and (4) the aiding of suitable researches undertaken by scientific and professional societies and organisations.

Since the establishment of the Department, 136 maintenance grants have been made to students and 89 to independent workers, while 48 grants have been made to provide professors with research assistants of scientific standing. During the four academic years in which grants could be made, approximately 50,000*l*. was distributed in grants of the various kinds referred to, and it is anticipated that during the next academic year the distribution will amount to about 45,000*l*. The great majority of the grants have been made for work in the fundamental sciences. The Advisory Council goes on to say: "And here a word of explanation is needed in view of ill-informed criticism of our policy. No conditions are attached to the grants made to workers whose sole aim is the extension of knowledge, either as to the line of their work or as to the use to be made of the results. If they propose to make commercial use of their discoveries we require them to consult us, because at this point they are leaving the field of pure investigation. But, subject to this single condition, their tenure is as free as, and in some respects more free than, that of a scholarship, fellowship, or professorship."

With respect to the organisation of industries into research associations, the present position is that eighteen research associations have been established, and that five others have been approved by the Department and will shortly receive their licences from the Board of Trade. Of the 1,000,000*l*. fund it is estimated that the Department is committed at the present time to a total expenditure of nearly 450,000*l*. on account of the established research associations, and to a further expenditure of at least 120,000*l*. on account of those approved but not yet licensed. The total commitments out of the 1,000,000*l*. fund are expected shortly to reach 800,000*l*., and the report observes: "It is clear that the sum placed at our disposal is not likely to be more than sufficient to aid the associations either formed or likely to be formed." There is much sanity in the reply of the Advisory Council to the criticism, actual or hypothetical, that much greater scientific results of value to industry would have been produced if the 1,000,000*l*. had been spent directly upon research done at the National Physical Laboratory and other research laboratories up and down the country. "Had the million been spent on research directed by the Government itself, its effect upon manufacturers would at the best have been destructive of their self-reliance, and at the worst a free gift to their competitors in other lands." We agree. Critics of this side of the Department's activities do not seem to recognise that to throw responsibility for research on the industries themselves is the surest way to educate the industries to appreciate the difficulty and the value of research.

A word may well be said here as to the statement in the report that at the end of the five years' period the research associations "must be prepared to continue without subvention from the State." The general principle is undoubtedly sound, and in the case of industries with large aggregations of capital there need be little fear that, having set their hands to the plough, they will turn back when the support of the State fails. For them the five years is probably a sufficient period. But there are industries, relatively small when measured either by the capital available or even by their production, which are, nevertheless, of vital importance to the State—"key" industries from their character rather than from their size. For these it may be necessary that State aid should be prolonged for more than the five years' period if, for them, the benefits of this research movement are to be consolidated and extended.

On the question of the conduct and co-ordination of national research the report truly observes that if the scheme for co-operative research in the several industries is to be a permanent success, provision must also be made for dealing with certain fundamental problems which are of such wide application that no single industry, however intelligent or highly organised, could hope to grapple with them effectively. The first of these basic problems is fuel. The Fuel Research Board was appointed in 1917 under the directorship of Sir George Beilby. A brief account of the activities of this Board is given. It includes such questions as "Gas Standards and the Development of the Gas Industry," "Peat as a Source of Fuel," "Pulverised Fuel," and problems of the production and utilisation of alcohol for power and traction purposes. Other instances of these "national researches" briefly reviewed in the report are the conservation of coal and mineral resources, the preservation of food, and the research into building materials and construction.

In the section dealing with the aiding of suitable researches undertaken by scientific and professional societies and organisations it is stated that grants have been made for the work on hard porcelain at the Stoke-on-Trent Central School of Science and Technology, that on glass technology at Sheffield University, and that on technical optics at the Imperial College of Science and Technology.

In concluding its short summary of the first five years' work the Advisory Council well says: "A longer period for review is specially necessary in our case, for research cannot be expected to produce results at short and regular intervals. Indeed, the expectation that it will is a misconception which has stood largely in the way of its consistent use by manufacturers, and has strained the patience of a public apt to think that the placing of an Act upon the Statute Book and the creation of a new organisation are all that is necessary to reach a desired end. If art is long in comparison with life, science, in spite of all its brilliant achievements, is longer still." That truth needs to be ever in the minds of those who deal with research.

The University of Birmingham.

ON Friday last, October 8, a number of influential representatives of Birmingham and the Midlands were the guests of the University of Birmingham at a luncheon in the Great Hall of the University at Edgbaston. The Chancellor (Lord Robert Cecil) presided, and the object of the gathering was to make known the need for increased financial assistance for the University.

Funds are urgently needed "to extinguish the debt of the University (130,000*l*.); to pay the staff of the University a living wage; to provide the necessary new accommodation and staff for the existing departments of science, arts, medicine, commerce, and education; to provide in all faculties facilities for research urgently needed in the public interest; to meet the greatly increased cost of administration and upkeep; and to enable the University to maintain its position among modern universities."

The Chancellor in calling upon Mr. Austen Chamberlain to speak welcomed him as one of the Members of Parliament for Birmingham, as Chancellor of the Exchequer, and more than all as the son of his father. Mr. Chamberlain, speaking first as a citizen of Birmingham, outlined the history of the civic expansion of the city in the days of his father, when the strenuous efforts of the leading men succeeded in making Birmingham a worthy metropolis of the Midlands, their work culminating in the foundation of the University. Speaking for the Government, he gave expression to the surprise with which they had learned the extent to which the country had been dependent upon university learning for success in the Great War. Now he "would say to an audience drawn from a great business community centring in Birmingham that if such services can be rendered by university learning in war-time, is it not certain that those services are equally necessary to our prosperity as a nation, and the prosperity of this city and district, amidst the difficulties and developments which have followed on the restoration of peace? Upon the recognition as a great community of the national and civic importance of such an institution as the University depends the ability to hold our place among the cities of the kingdom and the Empire."

The Government was fully aware of the immense importance of universities, and ready to back its opinion of that importance. It had spent for many years immense sums on elementary education; it had spent considerable sums on secondary education; but all too little on university education. Mr. Chamberlain had undertaken, unless he was prevented by overwhelming financial reasons, to submit to Parliament for next year a grant of 1,500,000*l*., and he had undertaken to consider—and though he could not promise, he hoped he might be able to do something in that direction—a further special non-recurrent grant in order to adapt the federated universities' scheme of pensions to the case of the older men who had joined and served the universities long before that scheme was in existence, and therefore on retirement would, without extraneous aid, receive only the smallest pittance from it. He hoped the grant would be on that basis for a term of years. What the University of Birmingham would get out of this depended on Sir William M'Cormick's Committee, which would advise the Government. He attached great importance to the advice of that Committee on the administration of the grant. "The less Government interference the better. Whatever you do, don't sacrifice your independence; don't come to that condition, one of those which brought Germany to her ruin." Professors of universities must be independent men, free to express their individual thoughts, subject to such control as the Chancellor or the authorities of the University might think right to impose on them. He did not want direct Government control or interference; he did not want party "pull"; he did not want anything to govern the grant except the relative merits of the recipients. Therefore he attached great importance to the independent Committee of Sir William M'Cormick, which had secured the confidence of every University which it was called upon to examine, and had been a real friend and of real assistance to those universities.

The Government had laid down general lines for the guidance of that Committee. In the first place, it could not encourage any university to undertake new developments before it had made adequate provision for that which already existed. If any grants are expected in respect of new developments, it must approve these new developments as being suitable to the general scope of the university in which they are proposed. Moreover, the work done must be of university standard. Finally, the grant would depend on the amount of local support given by the city and the Midlands. "If the citizens of Birmingham, if the towns and counties round, do not care enough for their University, and all that it means to them, to give it adequate local support, then whatever the Member for West Birmingham might be allowed to say, the Chancellor of the Exchequer will tell you flatly that if you do not value your Midland University you cannot expect the taxpayer at large to pay for conveniences for you to which you yourselves will not contribute." He most earnestly hoped that the citizens of Birmingham, and the counties and boroughs which surrounded them, would co-operate to make the University a common source of learning and of wealth for them all.

The Principal (Mr. C. Grant Robertson) read a letter from the President of the Board of Education, who wished success to the appeal, and remarked that "all over the country we are faced with the paradox that while the nation has never derived more benefit from its universities, these institutions have never found it more difficult to carry on their existence."

Mr. Grant Robertson pointed out that 42 per cent. of the students of the University came from Birmingham itself, 42 per cent. from the region round about, and the remainder from distant parts, and he hoped that the surrounding districts would contribute accordingly; at present their contribution was not one-tenth of that given by the City of Birmingham. He emphasised the underpayment of the staff; he believed that there was not one of them who could not double his income by leaving the University at that moment. By what moral right did we expect gifted men to give services at a wage which in industry would be regarded as contemptible? Professors could no more be improvised than admirals or generals. Facilities for research were indispensable; a university in which research did not flourish was a crippled institution. There was, too, a growing and insistent demand for extra-mural work that ordinary men and women might benefit. This demand must be met, but it could not be met without money. It was a most promising sign that the people were turning to the university to learn the duties and solve the problems of citizenship. They were asking for instruction in subjects which went to the root of civic life—history, political theory, economics, and civics—and by giving this instruction the universities would be doing much to make democracy safe for the world.

The problems of the present and near future were commonly called economic; they were really spiritual and moral, and they could not be solved by merely material remedies. We were victors in the war, and our universities might be made potent instruments in the spiritual, moral, and intellectual reconstruction of society. This might be an inauspicious time for an appeal, but the University was faced with a crisis; it must either act or succumb.

In the evening the Lord Mayor (Alderman William Cadbury) presided over a meeting in the Town Hall. Lord Robert Cecil made an eloquent appeal, showing the discreditable state of this country in the matter of university education as compared with the United States, with Germany, and, most of all, with Scotland. It was a curious fact that in England people seemed to think that anyone could use his mind without special training. This was a grave fallacy, and a university was essential to provide the necessary mental training which was so vital to us as a nation. With the increasing responsibility which was being thrust upon the people (in foreign politics, for example), it was of the utmost importance that the working classes should have full opportunities of receiving education, and especially university education.

Mr Neville Chamberlain, M.P., appealed especially to the manufacturers, banks, insurance companies, and others dependent on industry for their money. He contrasted the business methods of forty years ago with those of the present, showing that to-day—when even directors are supposed to know something of the business they direct—a constant supply of highly trained young men such as the University of Birmingham can provide is an essential factor in the success of our national commerce. If it paid men to invest large sums of money in securing the raw materials of their business, it must pay them even more to invest a modest sum in maintaining the efficiency of an institution which turns out brains—quite as important as raw materials in the success of a business.

A resolution—"That this meeting, recognising the importance of the University of Birmingham in the commercial, intellectual, and social life of the Midlands, and convinced of its need for greatly enlarged funds, cordially supports the appeal now to be issued"—was carried unanimously.

At the close of the meeting the Pro-Vice-Chancellor (Alderman Clayton) announced that a sum of 200,000*l.* had been conditionally promised.

Aeronautics at the Science Museum, South Kensington.

THE collection of aeronautics in the Science Museum has been recently rearranged, and now occupies one of the galleries of the new Science Museum Buildings in Exhibition Road, South Kensington. Many important additions have been made to it, so that visitors can study the development of aeronautics from early times in the many objects of great historical interest, while the progress made in aviation during the last six years is represented by numerous exhibits which have been recently acquired.

The collection is arranged in six sections: Aeroplanes and aeroplane models, aeroplane construction, engines, instruments, experimental apparatus, and ballooning.

In the first of these an object of especial historical interest is the Henson flying machine model of 1842–45, which bears a striking resemblance to the modern monoplane, but was doomed to failure chiefly on account of the lack of a light engine of high power. Early pioneer work in gliding is illustrated by Lilienthal's glider, similar to the one on which the inventor met his death in 1896.

The development of the modern aeroplane can be followed in the series of scale models by which the machines of the Brothers Wright, Voison, Farman, Blériot, Santos-Dumont, and the German Taube are represented. Among the full-size machines are the only existing machine of Cody and the Vickers-Vimy Rolls-Royce aeroplane which crossed the Atlantic last year.

In the section devoted to aeroplane construction are examples of historical and modern propellers, and actual portions of early and modern aeroplanes in which the methods of construction may be compared. Portions of an early Wright biplane have been preserved, and the visitor can operate and study the control mechanism of this machine.

The collection of aeroplane engines ranges from the early steam engines of Henson and Maxim to the modern high-power petrol engine, and the collection of engines of types used during the war, including British, French, Italian, as well as German, models, is of great interest.

A wind-channel and a water-channel for experimental work may be seen in operation; the principal instruments used in aerial navigation and reconnaissance are also shown. Balloons and airships are not as yet fully represented, but to all sections additions are continually being made.

University and Educational Intelligence.

Cambridge.—An extension of the metallurgical department of the chemical laboratory, provided by the generosity of the Goldsmiths' Company, was opened on October 5 by the Prime Warden. It includes rooms for the study of high temperatures, general metallographic research, assaying of gold and silver and their ores, a balance-room, and general provision for students working at analytical and general metallurgy.

E. K. Rideal has been elected a fellow of Trinity Hall, and H. Glauert and A. D. Ritchie fellows of Trinity.

We learn from *Science* for September 17 that the University of Buffalo has received from O. E. Foster a gift of 400,000 dollars for the erection of a chemistry building. It has also received anonymous gifts of 250,000 dollars towards endowment and of a library building.

A course of ten public lectures on "Medieval Contributions to Modern Civilisation" will be delivered at King's College, London, during the present term on Wednesdays at 5.15. Philosophy will be dealt with on October 27 by Prof. H. Wildon Carr, and Science on November 3 by Dr. Charles Singer. Other subjects are Religion, Art, Literature, Education, Society, Economics, and Politics.

The *Pioneer Mail* for September 17 states that the Bill to establish and incorporate a Moslem university at Aligarh has been passed by the Imperial Legislative Council. The Viceroy congratulated the Mohammedan community on the new institution, and several Mohammedan members expressed their thanks to his Excellency for his interest in the provision of educational facilities for their community.

In a public address delivered during the course of the recent second annual conference of the Reading and District Teachers' Association, Mr. H. A. L. Fisher, President of the Board of Education, stated some facts relative to the cost of education. In the last two years the net total expenditure has risen from 19½ millions to 45¾ millions, *i.e.* the cost of education has been more than doubled. The largest part of this increase is represented by additions to the salaries of teachers, of whom there are now nearly 200,000 in the public service. The additions to salaries amount to 130 per cent. increase on pre-war salaries, while the cost of living during the same period has risen by 152 per cent.; this increases the cost per child by 119 per cent. Before the war, local education authorities bore 53 per cent. of the expenses incurred, and the Board of Education 47 per cent.; now the position is exactly reversed. Mr. Fisher is of opinion that developments under the Education Act of 1918 and the cost of putting into effect the recommendations of the two Burnham Committees which are now sitting will give rise to a steady increase in the cost of education.

The report of the University of Leeds for the year 1918–19 has been received. Full lists are given of the professorial and executive staff, before entering upon the report proper, which, it is worth noting, is the fifteenth which has been issued since the charter was acquired in 1904. It reviews the growth of the University from the autumn of 1918 to the spring of 1920, although the statistics and accounts are mostly confined to the session 1918–19. During the period under review the number of students taking full-time courses has been doubled; unfortunately, only one-sixth of this number enjoy collegiate life in the limited number of hostels available. The financial strain caused by the increased demand for higher education bears heavily on the University, and in consequence an appeal for 500,000*l*. has been issued. During the war more than fifteen hundred members served in his Majesty's forces, and some five hundred casualties were sustained. The head of the chemical department acted as chief chemical adviser to the Home Forces, and other members of the faculty undertook the responsible duties of testing varnishes, of manufacturing antiseptics and drugs, of testing high explosives, etc. The leather, engineering, textile industries, and colour chemistry departments also took active parts in researches instituted by the Government. Among the grants which have been made to the University, the most important is a sum of 36,000*l*. from the Treasury as an annual grant, and a further non-recurrent sum of 9000*l*. for the session 1920–21. An annual grant of 3800*l*. for five years has also been made towards the maintenance of the School of Agriculture. A number of friends of the late Sir Swire Smith from Keighley and district have raised the sum of 3000*l*. for the endowment of a fellowship, open to graduates of any faculty, for the purpose of conducting research. The remainder of the report is devoted to a statement of the deaths, resignations, and appointments of University officials. Towards the end of the report each department is taken separately, and an account of its work during the past academic year given.

Societies and Academies.

PARIS.

Academy of Sciences, September 20.—M. Léon Guignard in the chair.—H. **Lecomte**: The radial secretory canals of wood. The usual direction of these canals in the tissues of the stem and root is parallel to the length of the organ, but a system of radial secretory canals may, in a large number of plants, be superimposed on the longitudinal system. These radial canals have been noted by Trécul and others, but have hitherto been regarded as exceptional cases. In the genera Pinus, Picea, and Larix the radial canals are now found to be present in all cases, and numerous examples were also found in other species.—P. **Humbert**: Hypercylindrical functions in space of $n+2$ dimensions.—J. **Soula**: Remarks on the investigation of the singular points of a function defined by a development in Taylor's series.—J. **Andrade**: The geometrical interpretation of the Résal-Caspari method.—A. **Véronnet**: Values of the flattening of the earth obtained by calculation and by measurement.—A. **Buhl**: The formula of Stokes in space-time.—M. **Flajolet**: Perturbations of the magnetic declination at Lyons during the second half of 1919 and the first half of 1920. The observations are tabulated in six groups between calm days and perturbations greater than 30′. On August 11, 1919, and March 4, 1920, the disturbances were very large and outside the scale of the recorder.—H. **Coupin**: The resistance of seedlings to starvation. The seedlings of seventeen species of plants grown in the dark in distilled water lived from fifteen to sixty days.—F. **Vlès**: The production of difference spectra of toxin cultures. Further study of the changes produced in the absorption spectra of toxin cultures by heating and by the addition of antitoxin.—C. **Lebailly**: The prevention and treatment of aphthous fever by the serum or blood of cured animals. Experiments were made on more than five hundred animals. The immunity produced by the injection was of very short duration, in some cases less than fifteen days. Good results were obtained in the treatment of infected animals, provided that the injections were made as soon as possible after the disease was recognised.

CAPE TOWN.

Royal Society of South Africa, August 18.—Dr. A. Ogg, vice-president, in the chair.—P. A. **van der Bijl**: Note on *Lysurus Woodii* (MacOwan), Lloyd. The fungus described was found in a rhubarb trench in Natal. It is entirely distinct from the genus Anthurus.—C. **Pijper**: A prehistoric rock-sculpture from the North-Eastern Transvaal. Circular and semicircular stone markings are described, with photographs, from the Lijdenburg district, not far from stones engraved with cup-and-ring markings, which the author has previously described.—J. **Moir**: Colour and chemical constitution, part xii. The calculation of colour from the tautomeric theory. Assuming that the tautomerism C·C·OH⟶CH·C·O has the value λ 94, the tautomerism $C{\cdot}C{\cdot}NH_2{\longrightarrow}CH{\cdot}C{\cdot}NH$ the value λ 98, and the tautomerism $C{\cdot}C{\cdot}CH_2{\longrightarrow}CH{\cdot}C{\cdot}CH$ the value λ 103, it is shown that the molecule of a coloured substance can generally be dissected into tautomeric pieces, loaded with non-tautomeric portions which have very little effect on the colour (λ 7 to 20 only). On adding up the values of all the pieces the result agrees closely with the λ observed in the coloured substance. Yellow and orange substances have 3 or 4 tautomerisms, pink and purple substances 4 or 5, and blue and green substances 5 or 6.

SYDNEY.

Royal Society of New South Wales, August 4.—Mr. James Nangle, president, in the chair.—Dr. W. G. **Woolnough**: A geological reconnaissance of the Stirling Ranges of Western Australia. The Stirling Range is an isolated mountain block situated about sixty miles north of Albany. It is composed of interbedded quartzites and slates, devoid of fossils, and probably Proterozoic in age. While locally folded, faulted, and overthrust, the rocks are mostly horizontally stratified. The sedimentary formations are surrounded by a vast expanse of gneissic rocks, probably Archæozoic in age. After discussing the various possible explanations of the structural features observed, the author arrives at the conclusion that the sedimentary rocks were originally preserved in a long east-west fault trough, and suffered peneplanation with the rest of the "Darling Plateau" of Western Australia. Later, on the uplift of the peneplane, the old fault planes were rejuvenated, with the result that the original senkungsfeld was converted into a horst. A generalisation, which may be of far-reaching importance, is suggested, namely, that the granites of Australia lying west of a line joining Adelaide with Cloncurry are all Pre-Cambrian in age.—R. H. **Cambage** and H. **Selkirk**: Early drawings of an aboriginal ceremonial ground. The rough drawings were made by Surveyor-General Oxley in his field-book at Moreton Bay in 1824, and show the plan of a spot, as Oxley writes, "where the natives meet after a war with adverse tribes to make peace." This appears to be the first drawing showing the lay-out of a ceremonial ground of this nature in Australia, and has remained in obscurity for ninety-six years.

Methods and Aims of Anthropology.

PROF. KARL PEARSON'S presidential address to the Anthropological Section of the British Association at the recent Cardiff meeting sounded a note of challenge which it is not usual to hear from the chair. Yet perhaps few of his audience were inclined to agree with him in this case that "a Daniel had no right to issue judgment from the high seat of the feast." In science, perhaps even more than in other departments of human affairs, criticism is the breath of life, and perfection, if it were attainable, might prove perilously akin to stagnation.

Although Prof. Pearson disclaimed any intention of speaking in a controversial spirit, his address was in fact a severe indictment of the traditional subject-matter and methods of anthropology. "Why is it," he asked, "that we are Section H and not Section A?" Anthropology should be the "Queen of the Sciences," the crowning study of the curriculum. If, in fact, it does not occupy this position, whose is the responsibility and what is the reason? His address was at once an answer to these questions and an attempt to suggest a remedy for what he feels to be the present unsatisfactory position of the science.

Anthropologists will cordially endorse Prof. Pearson's contention that the claims of anthropology as a leading science have not received full recognition, either from the State or the universities: they are unlikely, as a body, to agree with him as to the cause. For in his view the responsibility lies with the tradition of the orthodox school, in respect both of subject-matter and of method. Anthropology, and in particular anthropometry, he maintains, has produced no results of utility to the State, and its methods are not of such a kind as to afford either the training of the mind or the doorway to a career which would attract young men entering the universities. His chief criticism was directed against the subject-matter of anthropometry, the multitudinous observations on "height-setting," and the censuses of hair and eye colour, "things dead almost from the day of their record." But further, he went on to say, the bulk of the recorders were untrained, and the associated factors, without which the records were valueless, were usually omitted. The anthropologist, seizing the superficial and easy to observe, had let slip the more subtle and elusive qualities on which progress depends. It was the psycho-physical and the psycho-physiological characters, and not the superficial measurements of a man's body, which carry the greater weight in the struggle of nations. On this ground Prof. Pearson refused to admit the plea of the supporters of "science for its own sake," who argue that researches not immediately "utile" will be useful some day, as has happened in the case of the study of hyperspace. Anthropometric studies, he holds, must turn to more certain appreciations of bodily health and mental aptitude if they are to be useful to the State.

It is perhaps worth while to note that the two points to which Prof. Pearson directs attention are not entirely in the same category. One is a question of the subject-matter of the science, the other of method. In the case of the latter it is true that anthropometric records have sometimes been vitiated by lack of training in the observer; and it is equally true that associated factors have not always been recorded. But both these are remediable defects which will tend to disappear with increased facilities for training and increasing knowledge of essential relations in the facts to be observed. Neither, unless shown to be inherent in the subject-matter or unavoidable, can permanently affect the position of the science.

But Prof. Pearson went further. He was not prepared to allow that the material furnished by the present methods of anthropometrics was even indirectly of value as an indication of a close association between physical characters and soundness both of body and of mind. His grounds for this view were twofold. In the first place, he maintained, purity of race is merely a relative term; but even granting the hypothesis of pure races, it is known by mass observation that (as a result of interbreeding) elements belonging to one race are found in association in the same individual

 K

with those belonging to others. A tall but brachycephalic individual will combine Alpine mentality with blue eyes. Prof. Pearson also referred to the case of Charles Darwin, whom he took as a typical English individual, purely English in mentality, and showed that his ancestry contained elements from every race in Europe. Even if at any time there had been association of physical and mental characters, it would break down by intermingling, except in cases specially isolated by natural or social conditions, as, for instance, in the non-intermarrying caste groups of India.

Having demonstrated the failure of the orthodox school of anthropologists, Prof. Pearson put forward three propositions as a basis of reform. "Anthropologists must not cease," he said:

"(1) To insist that our recorded material shall be such that it is at present, or likely in the near future to be, utile to the State.

"(2) To insist that there shall be institutes of anthropology . . . devoted to the teaching of and research in anthropology, ethnology, and prehistory.

"(3) To insist that our technique shall not consist in the mere statement of opinion on the facts observed, but shall follow, if possible with greater insight, the methods which are coming into use in epidemiology and psychology."

Anthropologists will agree, it may be assumed, as to the desirability of the object set out in the second of these propositions; they may even be prepared to give to the third a qualified support. But to confine scientific research to aims immediately recognisable as utilitarian, as Prof. Pearson's first proposition would seem to suggest, is a limitation which very few scientific workers, anthropologists or others, would, and none should, accept. Nor in this case is it necessary. The study of ethnological problems on the lines at present pursued by physical anthropology does not necessarily exclude the study of what Prof. Pearson calls vigoriometry and psychometry—the science of man is wide enough to embrace them both. Is it not a little premature to condemn anthropometrics? The study is not of great age; it is still at the stage of gathering evidence, and as this accumulates the problems change in character; methods are being tested and varied, and data are re-examined continuously. Finally, anthropologists themselves are convinced that the problems they hope ultimately to solve are worth while.

On the other hand, anthropologists deplore the fact that the State does not make greater use of their results. The claims of the science as a basis of legislation, and as an essential preliminary in the training of those who have to administer the affairs of, at any rate, our subject races, have repeatedly been urged upon the Government. There is, however, justice in Prof. Pearson's criticism that the anthropologist too often has omitted to show that his problems have a very close relation to those of the statesman and reformer. On this ground alone Prof. Pearson deserves well of the science if, as a result of his strictures, he should succeed in inducing anthropologists to state from time to time the broad issues involved in their research. In support of his views, Prof. Pearson states that the Governments of Europe have had no highly trained anthropologists at their command, and, as a consequence, the Treaty of Versailles is ethnologically unsound. Is this in accordance with the facts? It was surely the case that when the terms of that treaty were under consideration each country interested in the settlement of international boundaries produced masses of facts based upon the researches of skilled ethnologists. Unfortunately, the facts were selected or distorted to suit the ends of the parties interested. Where impartial conclusions were available, as in the case of the Balkans, they had to be set aside on political grounds. The defects of the Treaty of Versailles are defects of the politician, and do not lie by default at the door of the man of science.

The extensive political propaganda based upon a distorted ethnology which followed the Armistice illustrates one aspect of a flagrant misuse of scientific data. Prof. Pearson refers with approval to the manifesto of the German anthropologists, in which is sketched a programme of study in ethnology and folk-psychology of savage and civilised peoples, by which they hope to aid their country to recover its lost position in the world. Science is made subservient to a purely political end. Prof. Pearson himself speaks of speeding up evolution as an outcome of anthropological studies, and of breeding out the troglodyte mentality in man. But by whom and on what grounds is the direction of the evolutionary process to be determined? The end of science is truth, and its function is the investigation of facts and their relations, and not the formulation of ideals. The past history of anthropology teaches us that it has not been to its advantage that it has meddled in politics or in humanitarianism. To say that this or that type is desirable, that this or that mentality should be cultivated, is not the work of the anthropologist, but of the social reformer.

The Durability of Maritime Structures.

Committee of the Institution of Civil Engineers. appointed to Investigate the Deterioration of Structures of Timber, Metal, and Concrete Exposed to the Action of Sea-water. First Report of the Committee. Edited by P. M. Crosthwaite and Gilbert R. Redgrave. Pp. 301 + xxxiii plates. (London: The Institution of Civil Engineers; H.M.S.O., 1920.) Price 30s. net.

THE deterioration of buildings from ordinary physical causes has always been one of the most important considerations before the engineer and the architect, and in preparing their designs they have been under the necessity of adopting precautions and protective measures of various kinds. But the destructive influences which have to be counteracted under ordinary atmospheric conditions become tenfold more active and pernicious in a marine environment. The acidity and salinity of sea-water; the fluctuations of tidal level; the alternations of wetness and dryness in rapid and rhythmic sequence; the impact of waves, producing vibration; the penetration of wind-driven spray and the insidious attacks of marine organisms—all these result in an intensification of the ordinary process of decay. Although the phenomena are well known and their effects only too patent, yet until recently definite and trustworthy evidence as to the rate and extent of deterioration was not readily obtainable. Conditions varied greatly with the locality. Counteracting agencies, some obscure in origin, necessitated modifications in general conclusions. Records were but indifferently kept. For these and other important reasons, the Institution of Civil Engineers felt it imperative, in a matter of such vital concern, to set to work to collect such data as were available, and to institute investigations and experiments on a scientific basis. It accordingly appointed a committee of thirteen engineers of high standing and reputation, who co-opted four additional members, and these gentlemen have just issued their first report. Some forty ports in various parts of the world were selected as the field of inquiry, and memoranda furnished by the respective local engineers, or abstracts therefrom, as to the condition of typical existing structures, are incorporated in the report.

The volume commences with an abstract from the Proceedings of the Institution of Civil Engineers of information contained in various papers relating to the subject. This has been prepared by Mr. G. R. Redgrave, who collates the data under the heads of timber, concrete, iron and steel. Mr. H. W. FitzSimons, in conjunction with Mr. F. T. Brooks, contributes a useful article on the value of timber as a material for marine structures, with botanical observations and notes. Next is a short monograph on marine boring animals, prepared by Dr. Calman, of the department of zoology, British Museum. This classifies the information at present available relative to the Teredo and its allies, their habits and distribution. Dr. Friend follows with a paper on the corrosion of iron and steel, and the remainder of the book is taken up with the special reports (fifty-two in all) from engineers in different localities. There are two summaries at the end of the volume; the first, prepared by Mr. M. F. G. Wilson, is a synopsis of the local reports in regard to special features, and the second is a general report embodying the findings of the committee on the investigations as a whole.

The volume is, undoubtedly, a most useful collection of data and results, collected at considerable trouble, and for the first time collated in order and degree. At the same time, the diversity of testimony is so evident, and the lacunæ are so considerable, that the preliminary impression created is one of greater perplexity than before. Even Mr. Wilson has found it difficult in several cases to reconcile conflicting statements, nor can the local engineers always explain certain inconsistencies in the records of their experience. This is, perhaps, most particularly noticeable in regard to the depredations of marine organisms. Thus, of the activity of Limnoria on creosoted pitchpine, it is recorded that of two 14-in. square piles, located only 40 ft. apart in Holyhead Harbour, within a period of nine years one was reduced to 9 in. in diameter, while the other showed no sign of attack. In the estuary of the Mersey, adjacent to the open sea, the Teredo has been found only "in a few cases," and causes no trouble; at Bombay its ravages have been so devastating as to lead to the abandonment of timber for permanent sea works. Thus at the present stage it is only possible to form conclusions of a somewhat broad and tentative character, which will be the subject of closer investigation and later review.

The idiosyncrasies of timber-destroying organisms are particularly stimulative of inquiry, and not the least interesting feature of the report is Dr. Calman's study of their anatomical structure, development, and method of attack. The organisms include the ship-worm (Teredo), the gribble (Limnoria), Sphæroma, and Chelura. The first is a mollusc, the others are crustaceans. The family Teredinidæ is a comprehensive one, and includes not only the typical genus Teredo, but also the allied genera, Xylotrya and Nausitora. Species of the same genus, moreover, differ widely in habits, in habitat, and in geographical distribution. The "Teredo," as so designated by the engineer, may comprise at least some twenty or thirty different species. Some thrive in brackish water; others do not; *Teredo navalis* is intolerant of it. *Nausitora Dunlopei*, a tropical species, commonly lives in perfectly fresh water. Generally, it has been found that timber piles in muddy, or sewage-contaminated, water are least subject to attack, from which it seems evident that shipworms require clear and fairly pure water for their effective development. Notwithstanding the advantage derived in certain cases by the treatment of timber with creosote, it is noteworthy that no completely protective antidote has been discovered. Greenheart is the timber which offers most effective resistance to attack.

The corrodibility of iron and steel is a branch of the subject admitting of but slow determination, so-called "acceleration tests," having proved untrustworthy. The percentage of impurities and the precise composition of alloys are of fundamental importance. The first effect of chromium is that of increasing corrosion, but a further addition effects a retardation. Sir Robert Hadfield has informed the committee that he is experimenting with an alloy of iron and chromium which manifests considerable resistance to sea-water corrosion. The committee details certain arrangements which they have made with Sir R. Hadfield and Dr. Friend for testing the rate of corrosion of medium carbon steel, mild steel, "Galahad" non-corrosive steel, nickel steel, Swedish charcoal, iron, and cast iron. The duration of the experiments may extend to twenty years.

The most important findings of the committee include the following: Creosoting as a protective treatment for Baltic timber is justified at the home ports, but not in tropical waters; reinforced concrete is a more suitable material for adoption where the sea-worm is very active; and ordinary concrete, whether in block form or in mass, produces thoroughly permanent work, if carried out in the properly specified manner.

BRYSSON CUNNINGHAM.

Tropical Disease and Administration.

War against Tropical Disease: Being Seven Sanitary Sermons addressed to all interested in Tropical Hygiene and Administration. By Dr. Andrew Balfour. Pp. 219. (London: Baillière, Tindall, and Cox, 1920.) Price *12s. 6d.* net.

AN essential in medical treatment is that the patient shall have faith in the professed healer; his rulings must be accepted as well as his drugs. Hence, in a period when empirical observations were the necessary substitute for scientific investigation, occasionally it might not have been conducive to the bodily safety of the physician were the patient to doubt the soundness of the deductions therefrom. Argument was therefore successfully evaded by an assumption of mystery too deep for ordinary mortals to fathom; drug roots were gathered with incantations by moonlight—the fever-stricken patient submitted to being deprived of a breath of fresh air. With the physician of the present day, so far as drugs are concerned, the awe inspired by mysticism to some extent remains; professional ethics—to the advantage of the patient—ordain secrecy, but the crude rulings of the past have been superseded by the dicta of the science of hygiene, which insist that "prevention is better than cure." Its devotees demand, not professional mysticism, but world-wide propaganda. Nowhere, in the interests of life, is this more necessary than in those portions of the world vaguely termed the "tropics," where even useful, though ancient, empirical sanitary deductions have been forgotten, or have become inapplicable in the press of life accompanying modern civilisation.

It is a matter of common experience that whilst the average educated layman is capable of discussing the *rôle* of certain mosquitoes, flies, fleas, lice, and ticks in the spread of disease, he fails to understand that, not only philanthropy, but also the prosperity of commerce, facilities for intercommunication with areas supplying raw material and the availability of suitable labour therefor, very largely depend upon the prevention of preventable diseases in the tropics. Hence, if it were possible to convey to the busy layman where action is requisite and what measures are applicable, undoubtedly a great impetus would be given to applied hygiene. To this end that well-known authority upon sanitation in the tropics, Dr. Andrew Balfour, director of the Wellcome Bureau of Scientific Research, London, has written the work under notice.

The larger part of this work is occupied by a record of travels in Africa, Mesopotamia, the West Indies, and South America. *Inter alia*, much interesting information is given as to makeshift sanitary methods employed during the late war. The final chapters deal with the necessities and measures requisite for the central administration of public health, as exemplified by a suggested Ministry of Health for Egypt on lines proposed by a Commission appointed for that purpose.

Throughout the lightly written and interesting pages of this book Dr. Balfour has steadily maintained the underlying object of his travels, namely, taking his reader from area to area of the tropics, demonstrating existing sanitary defects and the possibilities of improvements were the existing fruits of medical research applied, and showing where further light on disease ætiology is requisite. He has thus met a long-felt want by placing at the disposal of both the medical and the lay reader valuable information hitherto unobtainable without toiling through masses of scientific publications or dry official reports. No politician need reflect that the matter thus condensed does not concern the prosperity of the Empire; no administrator dealing with tropical races will fail to perceive that there is here much matter that will aid decision when the multitude of counsellors confuse with diverse schemes to the same end, and demand finance instead of conferring wisdom; nor need the man of commerce hesitate in arriving at the conclusion that there is an indissoluble connection between production and the health state of labour. To the intending tourist the word pictures of scenery and the description of the characteristics of races must be a source of much interest. Indeed, even the humorist will find that there is scarcely a page which does not yield a specimen of that genial "pin-prick" banter with which the Scot is wont to drive home truths he conceives his audience has failed sufficiently to evaluate. W. G. K.

Yearbooks of Universities.

(1) *Athena: A Yearbook of the Learned World. The English-speaking Races.* Edited by C. A. Ealand. Pp. viii + 392. (London: A. and C. Black, Ltd., 1920.) Price 15*s*. net.

(2) *The Yearbook of the Universities of the Empire,* 1918–1920. Edited by W. H. Dawson. (Published for the Universities Bureau of the British Empire.) Pp. xiv + 503. (London: G. Bell and Sons, Ltd., 1920.) Price 15*s*. net.

(1) SIMULTANEOUSLY with the publication of the first volume of "Athena," "Minerva: Jahrbuch der gelehrten Welt" has made its reappearance after the war. It is described as the twenty-fourth yearly issue, 1920, the previous edition being for the year 1913–14. "Athena" is a stately volume (8½ in. by 5½ in.) of 392 pages. "Minerva," of just half the cubic capacity, contains 1148 (*plus* 118) pages. "Athena's" learned world is restricted to the English-speaking races. "Minerva" takes cognisance of all civilised peoples; although, as was inevitable, the editor has but little information to give regarding the universities and other institutions of higher learning of the countries with which, until recently, Germany was at war. Italy is an exception. The *personnel* and other particulars of the Italian universities and learned societies are given as fully as in pre-war editions. Of the great majority of British and American institutions the permanent features alone are set forth in a few lines. The editor is careful to state that figures, *e.g.* the number of books in a library, relate to the year 1914. In the rare instances in which a calendar of a British or a catalogue of an American university has been obtained, the names and offices of the members of the staff are set forth; but a study of the list will, usually, reveal its date.

Nevertheless, in accuracy, the advantage does not in all things lie with the English book. Turning first to the account in "Athena" of our two most famous universities, we read that Cambridge numbers 2700 students, Oxford 4582. The Vice-Chancellor of Cambridge is still Sir Arthur Shipley, although his successor, elected on June 1, 1919, entered upon office the following October. None of the names of the proctors and pro-proctors of Oxford tally with the University Calendar, 1920. Looking up the obituary notices of university professors which have appeared in NATURE during the past twelve months, we miss but one name from the lists given in "Athena" as those of members of existing university staffs. Some names of men who died still earlier are retained. It is not remarkable that "Minerva's" keen-sighted eyes have failed to discover the existence of the universities of Benares (1916) and Patna (1917); but such an oversight is less excusable in Ἀθήνη, who is not γλαυκῶπις only, but also νικηφόρος. The information given regarding the constitution and functions of the universities is very scanty. Under the names of the various British universities at home and overseas, we are told the number of terms in the year (without dates), the number of students (frequently omitted), in some cases the budget, and in all the degrees conferred and the colours of the hoods appropriate to each degree.

The statement that in the University of Durham the D.D. hood is of "scarlet cassimere, lined with palatinate purple silk," is, no doubt, of general interest, but the half-page devoted to the hoods of this university might possibly have been more profitably used. Even in this connection there are some curious irregularities. The hoods of the University of Wales (Cardiff) are carefully described as to form, material, and colours; but we find the list repeated under the heading "University College of North Wales, Bangor," which is not a degree-giving institution. The "University

College of Wales, Sea Front, Aberystwyth," is not similarly distinguished. No development of the past three years has so greatly interested the universities of the United Kingdom as the institution of the Ph.D., yet there is, so far as we can find, no reference to this new degree. The budgets of some of the American universities are likely to make a Briton envious—Wisconsin, for example, has a revenue of 3,532,306 dollars; but it may well be for his peace of mind that Columbia, Harvard, Leland Stanford Junior, and others have modestly declined to disclose their wealth. The statement "No particulars received" follows the names of a large number of American and some British universities overseas.

(2) The aim of the "Yearbook of the Universities of the Empire" is different from that of the other two books. Each of the fifty-nine universities of the Empire finds it necessary to publish a calendar; the stouter, the more dignified. In the Yearbook all essential information regarding the origin of the university, its history and equipment, admission, faculties, degrees, scholarships, fees, hostels, etc., from each of these calendars, is reduced to a few pages. The names and offices of all members of the staff are recorded, and "since a statement of the sources of the various degrees held by university teachers gives, in small space, information regarding the educational history of their holders, much trouble has been taken in ascertaining their source." Under the heading "The Years 1916–19" events of interest in the life of the university, such as benefactions received, new posts created, alterations of curricula, etc., are recorded.

Comparing the present edition with the one which preceded it (1916–17), we note that the universities are no longer placed alphabetically throughout, but arranged in groups—England and Wales, Scotland, Ireland, Canada, Australasia, South Africa, India—with an admirable introduction preceding each group. A feature of the book which will make it of great and permanent interest is the Appendix on the Universities and the War. It is a summary of the services, other than combatant (these had been, in part, dealt with in the 1915 edition), rendered by the universities. "So numerous and varied have these been that it is impossible, in looking back, to picture the war as progressing towards a successful issue without them." This record, brief as it is, persuades the reader of the justice of the editor's remark. The compression within a book of this size of so much and such varied information reflects great credit not only upon the editor's diligence, but also upon his skill.

Encyclopædic Chemistry.

Phosphore, Arsenic, Antimoine. By Dr. A. Boutaric and A. Raynaud. (Encyclopédie Scientifique: Bibliothèque de Chimie.) Pp. iii+417. (Paris: Octave Doin, 1920.) Price 9.50 francs.

THIS book is one of the forty volumes on chemistry forming part of an encyclopædia of science which is expected to run to about a thousand volumes. The treatment aims at a compromise between text-books and dictionaries—the books being intended at the same time for reading and for reference. This is obviously a very ambitious scheme, and it raises the question as to whether such a compromise between matter and style is one which is likely to be useful. In the opinion of the reviewer, books intended for reference should aim at giving the fullest possible information in the smallest possible space. If the elementary rules of grammar are satisfied, the busy worker will be content, and questions of style have little interest for him. The references to original literature should in each case be checked carefully with the originals, and no differentiation should be made between the nationalities of the various discoverers. Although the well-known treatises compiled by German authors are not perfect, they are all we possess which have any pretension to completeness, and have proved of inestimable service to thousands of chemists of all nationalities. A proposal to publish such works in English has not proceeded beyond the stage of discussion, great as are the possibilities of success if trustworthy compendia could be issued within a reasonable period.

The book under review is written in a clear and readable style, and the descriptions and references are such as might be expected in a moderately advanced text-book. They are not nearly so complete as might reasonably be required in an encyclopædic work. The index is also far from satisfactory. The bulk of the references are to publications in the French language, and in more than one instance grave injustice is done in the text to workers of other nationalities. This is much to be regretted; science has no nationality, and in a search for information such questions have not the slightest interest for the reader. If this inclination is to be followed in further volumes to be issued, the reviewer has no hesitation in saying that the usefulness of the work will be profoundly prejudiced. It may, for instance, be more gratifying to the author to attribute the formulation of the equation for a unimolecular reaction to Berthelot, but as the prior publications of Harcourt and Esson and of Wilhelmi are readily accessible, and well known, at least to English chemists, the impression on the reader is far from satisfactory. Other instances of like nature could be quoted.

J. R. P.

Our Bookshelf.

The British Charophyta. By James Groves and Canon George Russell Bullock-Webster. Vol. i. Nitelleæ. With Introduction. Pp. xiv + 141 + xx plates. (London: The Ray Society, 1920.) Price 25*s*.

This monograph of the British Charophyta is a valuable addition to the literature of British botany. It has also a personal interest for many British botanists as representing the work on this group, embracing much of the leisure of forty years, of the brothers Henry and James Groves, to the former of whom the volume is fittingly dedicated. In 1880 Messrs. H. and J. Groves published in the *Journal of Botany* a "Review of the British Characeæ," in which an attempt was made to give an account of all the then-known British species, with illustrations and some particulars as to their variation and distribution. This was the first of a series of papers by the same authors, in which have been included descriptions and figures of fresh species added from time to time to the British list, records of distribution, and other notes. The present monograph, in which Canon Bullock-Webster co-operates, is the carefully considered outcome of these years of work. The systematic portion, which includes the first of the two subdivisions (Nitelleæ and Chareæ) of the group, is preceded by an introductory section dealing with the growth and structure of the Charophyta generally, and their distribution and affinities; this is well illustrated by numerous text-figures from various sources, and several plates. Each of the species is beautifully represented in a lithographed plate, mainly from drawings by Miss Mary Groves. The authors recognise six genera of Charophyta, five of which, Nitella and Tolypella, comprising the Nitelleæ, and Nitellopsis, Lamprothamnium, and Chara, included in the Chareæ, are represented in Britain. The key to all the British species, which precedes the general systematic account, includes thirty-two species, in several of which distinct varieties are recognised. Under each species there is a complete account of the synonymy with reference to previous publications, a full description in English, and an account of the distribution; notes on variation, affinities, and nomenclature are also added.

Monografia de l'Ordre dels Rafidiòpters (Ins.). By R. P. Longí Navas, S.J. (Publicacions de l'Institut de Ciències.) Pp. 93. (Barcelona: Institut d'Estudis Catalans, 1918.)

Father Navas is well known as a student of the taxonomy of that miscellaneous assemblage of insects formerly included in the old Linnean order of the Neuroptera. In the monograph before us he deals with the curious and remarkable "snake-flies." Their position in any scheme of classification has long been a difficulty, and opinions thereon are very diverse. Father Navas prefers to follow Handlirsch and to regard them as constituting an order of their own—the Raphidioptera. Others merge them along with the "alder-flies" (Sialidæ) to form the order Megaloptera, while a third alternative is that followed by some entomologists of combining the Megaloptera with the Plannipennia into a single order, Neuroptera. We are inclined to follow the intermediate course, as there is little doubt that the Raphidiidæ have their nearest allies in the Sialidæ, although they are more highly specialised than the latter.

The present monograph is exclusively systematic—only eight lines are devoted to the larval stages, for example—and the sole observations on structure deal entirely with those characters of the external anatomy which are utilised by the systematist. Two families are recognised, comprising thirteen genera and seventy-one species. The greater number of genera occur in Europe and North America; only one genus is African, and four are Asiatic, but none are peculiar to either of those continents. In Britain we have four species comprised within three genera, but the group has been hitherto so little collected that in the next decade we shall probably totally revise our views on its geographical distribution. The author has done a service in bringing together the various species within a single memoir, and his keys and descriptions will enable the different forms to be identified. Of the forty odd figures, many are sketchy and rather deficient in detail.

A. D. I.

Some Famous Problems of the Theory of Numbers and in particular Waring's Problem: An Inaugural Lecture delivered before the University of Oxford. By Prof. G. H. Hardy. Pp. 34. (Oxford: At the Clarendon Press, 1920.) Price 1*s*. 6*d*. net.

The theory of the integral numbers is a subject in which it is frequently easy to conjecture new results and extremely difficult to prove them. An example of a result which must have been based on conjecture is known as Waring's theorem, that every positive integer is the sum of nine (or fewer) positive cubes, of nineteen (or fewer) biquadrates, and so on. A proof of this result, asserted in 1782, was first approached by Prof. Hilbert, of Göttingen, who showed in 1909 that every integer n is the sum of a finite number not exceeding $g(k)$, independent of n, of exact kth powers. It has been established, by transcendental analysis developed long since the days of Waring, that $g(3)=9$ as asserted by him, but whether $g(4)=19$ is still uncertain, though this number has been shown not to exceed 37. The only positive integers known to be inexpressible as a sum of eight cubes (at most) are 23 and 239.

Prof. Hardy and Mr. Littlewood have recently developed a new method of applying properties of the Riemann zeta function to the type of problem to which Waring's theorem belongs. In his inaugural address to the University of Oxford on his appointment as Savilian professor of geometry, Prof. Hardy gives a most lucid account of the work on which he has been engaged along with Messrs. Littlewood and Ramanujan. The whole of it is expressed in non-technical language, and many gaps in the theory are explained. We specially note the first few pages as forming a model introduction to a professor's inaugural address. A statement on p. 15 needs amendment, integers expressible as a sum of two squares being of either of the two forms

$$M^2P \text{ or } 2M^2P,$$

where P is a product of positive primes $4k+1$.

W. E. H. B.

On Gravitation and Relativity: being the Halley Lecture delivered on June 12, 1920. By Prof. R. A. Sampson. Pp. 24. (Oxford: At the Clarendon Press, 1920.) Price 2*s*. net.

THERE is a special appropriateness, as Prof. Sampson points out, in choosing a gravitational subject for the Halley Lecture, in view of the important part that Halley played in securing the publication of the "Principia." The lecture is an able *résumé* of the various speculations on the subject, from Galileo's "Dialogues" and Newton's hypothesis of æther-pressure down to Einstein's theory. The author evinces the highest admiration for Einstein's skill in devising a formula which expresses his results "without redundancy, defect, or effort, and whose boldness, range, brilliance, and resounding successes" have commanded universal attention; but on proceeding to examine the formula in detail he confesses to his dislike of some of the devices employed, in particular imaginary time and the obliteration of the distinction between past and future. He alludes to Newton's experiment of the rotating bucket and to Foucault's pendulum experiment as establishing the possibility of detecting the absolute direction of an axis of rotation. It will probably be admitted, even by the convinced relativist, that it is of advantage to students to have the claims of the older "common-sense" kinematics placed before them in an attractive form, which the author has certainly done.

A. C. D. CROMMELIN.

A Primer of Air Navigation. By H. E. Wimperis. Pp. xiv+128. (London: Constable and Co., Ltd., 1920.) Price 8*s*. 6*d*. net.

THIS book provides an interesting and sound introduction to the subject of finding one's way in the air. In many ways the investigation of methods of air navigation is based on nautical experience, but the author points out that the reverse process is beginning to apply. The chief differences appear to arise from the greater speed of aircraft as compared with the steamship, and the considerable altitudes above sea-level reached by the aeroplane and airship. Height in itself gives a wider range of vision, and in clear weather allows a greater permissible error in dead-reckoning without loss of port than is required for a ship seeking harbour. These points are clearly brought out in the little book under notice, and the various steps involved, both of observation and calculation, are developed simply. Whilst non-mathematical in character, we suggest that "Air Navigation" would provide a suitable starting-point for the more complex studies of advanced works and, what is perhaps more important in the present state of aeronautics, encourage capable students to extend the subject into regions yet unexplored. The main ideas of navigation are illustrated by examples from the great flights of the post-war period—Atlantic and Australasian. The correction for wind for aircraft is more important than that for tide and steamship, and clouds interfere with surface observations to an undesirable extent. Such difficulties, at any rate near land, will be countered by the use of direction-finding wireless telegraphy, a subject dealt with in one of the chapters of the book, which may be recommended as covering the essentials of present-day knowledge.

A Junior Inorganic Chemistry. By R. H. Spear. Pp. viii+386. (London: J. and A. Churchill, 1920.) Price 10*s*. 6*d*. net.

ALTHOUGH this does not seem to possess any features differentiating it from many other elementary text-books on chemistry, it is clearly written, and obviously the work of an experienced teacher. In some cases the information is not up-to-date, as on p. 128, where it is stated that "experiments carried out with the most elaborate precautions have shown that 1 grm. of hydrogen combines with 7·98 grm. of oxygen." Ozone is said (p. 177) to have "a faint, peculiar smell." Although molecular formulæ and equations are used freely from p. 152, the molecular theory is not explained until p. 278 is reached. Instructions for experiments are given throughout the book, which provides a good introduction to chemistry.

Part i. of the book, containing the first thirteen chapters, which lead up to, but do not include, the atomic theory, is published separately at the price of 5*s*. net. It provides an introductory course for junior forms in schools.

Atomic and Molecular Theory. By D. L. Hammick. Pp. 82. (Winchester: P. and G. Wells, 1920.)

As an exposition of the simple applications of the atomic theory to chemistry, this account leaves little to be desired in clearness and accuracy. Nothing, however, is said of the recent work which has put the atomic theory on an entirely new basis, and the point of view is that of twenty years ago. One cannot now truthfully say that "Dalton's hypothesis merely restates the facts about the elements and their modes of combination in terms of atoms and, as an 'explanation,' is not very satisfying."

Organic Chemistry for Medical, Intermediate Science, and Pharmaceutical Students. By Dr. A. Killen Macbeth. Pp. xi+235. (London: Longmans, Green, and Co., 1920.) Price 6*s*. 6*d*. net.

As an introductory text-book for the classes of students indicated in the title, this should be very useful. It is clearly written, and provided with exercises. One might have wished for a little more experimental detail; beginners in organic chemistry are liable to get into the habit of "removing hydroxyl groups," or "adding halogen atoms to double-bonds," or similar hypothetical operations, when they are asked to describe some simple laboratory operation. Chap. xviii., on "Schematic Representation," should be found helpful by students, as the subject is not usually dealt with in text-books. Slight weakness in physico-chemical theory is sometimes detected—*e.g.* on p. 5, with reference to fractional distillation, one finds only the misleading statement that "the more volatile vapour passes on to the condenser, and a sharp separation is effected." The elementary facts of fractional distillation are not often explained in text-books on organic chemistry.

Lead: Including Lead Pigments and the Desilverisation of Lead. By Dr. J. A. Smythe. (Pitman's Common Commodities and Industries.) Pp. vii+120. (London: Sir Isaac Pitman and Sons, Ltd., n.d.) Price 3*s*. net.

Dr. Smythe's interesting account of the mining, extraction, and uses of lead should be found useful by teachers and students of chemistry, as well as entertaining by the general reader. The illustrations, partly reproductions of old cuts from Agricola and partly of modern plant, add considerably to the interest and value of the book. A good description is given of the manufacture of white lead, and of the methods of separating silver from argentiferous lead.

Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of Nature. *No notice is taken of anonymous communications.]*

"Momiai."

In Gen. Alexander Cunningham's "Ladak," 1854, p. 237, we have probably the first mention of this substance among the mineral productions of that country. Gen. Cunningham says: "The common *momiai* of Indian medicine is, of course, a manufactured article; although not made, as generally asserted, of the melted fat of Abyssinian boys who have been roasted for the purpose. . . . The original *momiai* was only mummy, which at one time was held in much repute in Europe."

It is interesting to note that the extraction from young children still finds belief in India; further, that it is made again a strong lever in the hands of dangerous agitators to disturb and rouse the feelings of the people and set them against their rulers.

I am led to write on this because in the *Morning Post* of September 29 there is a communication from its Calcutta correspondent (dated September 3) which is worth reading just at present, when all is not going well in India, events taking place which recall the days before the Mutiny of 1857. "A crazy rumour and its effects" is the subject I especially notice, a part of which I must quote; it is so similar to what was in circulation in the Mutiny year:

"At Khargpur, the Swindon of one of the largest railways in India, the ignorant people, including some of the workmen in the railway workshops, had been for some time much excited over a ridiculous and false rumour which still obtains currency all over the country wherever large building works are in contemplation, to the effect that the Government wanted a number of children for sacrifice, without which the buildings of the new district headquarters could not stand. In this instance the people believed that several men had been authorised by the District Magistrate to wander throughout the district kidnapping children. The rumour obtained such wide currency that the District Magistrate went to Khargpur several times, and both the executive and the railway authorities did their best to remove the superstitious belief. The District Magistrate also issued notices in the vernaculars contradicting the rumour."

History is repeating itself. In April, 1857, I was on my way to join the Kashmir Survey Party at Rawul Pindi; there the first rumblings of the coming Mutiny were heard by me. Very few Europeans then had a notion that such a conflagration was soon to come. Warnings were not taken seriously, and were more often received with ridicule. There was unrest in many forms, not so widespread as it is now. To give an idea of the reports then in circulation, one of my servants, on returning from the city where he had gone to make purchases, came at once to ask me whether it was true that the Queen of England was sending out to India an army of several lakhs of men to force the population of India to be Christians. I told him it was nonsense, and asked where he had heard it. He said two Faqirs (religious mendicants) were preaching on the invasion in the streets of the city. The story had evidently made an impression on him, and it led to my having a conversation with another native, in which I heard for the first time of *momiai*, and was told that we sahibs made it. He gave me a very circumstantial account: that children were kidnapped, hung up by the heels, head downwards, and an incision made in the breast from which flowed the wonderful substance which gave us so much power. To prove his words, my informant, who was a Kashmiri resident in Rawul Pindi, said he could show me the very bungalow in which all this was done. It turned out to be the Masonic Lodge—"The Star in the East," I think it is called—situated in the cantonment of Rawul Pindi—the "Jadu Ghur," or mystery house, as it is always called by the natives. In my wanderings in the Kashmir Himalaya up to 1863 the story of the "Jadu Ghur" would crop up. It was thoroughly known in Kashmir, on into Ladak, and extended, I believe, into Central Asia, wherever Kashmir merchants are to be found.

I much fear my explanation of what is done in a masonic lodge, and of what its use is, did little to alter whatever was in the mind of my informant. I do know that these impossible tales carry enormous weight for evil among the mass of the people, both male and female. Their dissemination should be watched and met. "The Viceroy's suggestion that a dangerous agitation in India can be allowed to take its own course unguided and unimpeded by those in authority" is folly, and shows utter ignorance of the people he has been sent to rule.

H. H. Godwin-Austen.

Nore, Godalming, October 3.

Ewing's "Thermodynamics."

THE very appreciative review of my book on "Thermodynamics for Engineers," which appeared in NATURE of September 16 over the well-known initials "H. L. C.," points out what is certainly a mis-statement. Will you kindly allow me space to correct it?

On p. 123, in speaking of the Mollier chart, the co-ordinates of which are the total heat I and the entropy ϕ, I should have said that the critical point is "near," not "at," the point of inflection of the boundary curve. It is, as "H. L. C." suggests, a little above the point of inflection. The isothermal line which passes through the critical point suffers inflection in touching the boundary curve there. The line of constant pressure which passes through the critical point also has a singular point there, namely, a point at which

$$\left(\frac{d^2I}{d\phi^2}\right)_p = 0, \text{ and } \left(\frac{d^3I}{d\phi^3}\right)_p = 0.$$

Without undergoing inflection, it has a "stationary tangent" at the critical point. These features of the curves of constant temperature and of constant pressure which pass through the critical point are apparent in the $I\phi$ chart for carbonic acid, given on p. 148. It will also be apparent from that chart that the point at which both these singularities occur lies a little above the point of inflection of the boundary curve itself.

The following corrections should therefore be made on p. 123 of my book:

In line 1, for "at" read "near."

In the footnote, delete the last two sentences and substitute: "Hence also, at that point,

$$\left(\frac{d^2I}{d\phi^2}\right)_p = \left(\frac{dT}{d\phi}\right)_p = 0, \text{ and } \left(\frac{d^3I}{d\phi^3}\right)_p = \left(\frac{d^2T}{d\phi^2}\right)_p = 0,$$

since on the $T\phi$ chart the constant-pressure line through the critical point runs level and suffers inflection there. Thus on the $I\phi$ chart the constant-pressure line through the critical point has zero curvature there, though it does not suffer inflection."

Also, on p. 149, line 1, for "coincides with" read "is a little above." J. A. EWING.

The University, Edinburgh, October 13.

A Diver's Notes on Submarine Phenomena.

SIR RAY LANKESTER in one of his delightful popular papers describes how he found that the glowing light produced by rubbing quartz pebbles together could still be got when the rubbing was done under water, as, for example, when holding the pebbles submerged in a bucket. On the supposition that if the effect were connected with entangled or surface-adhering air it should be enhanced under a high pressure, an experiment was made. My occupation involves a good deal of diving work, and on a recent occasion I took down a few suitable pebbles to a depth of 21 fathoms. On rubbing them together sparks were produced to just about the same extent as when tried in a few inches of water. The light on the bottom was dim enough to allow of the sparks being seen, yet visibility was relatively good.

Wave-action at this depth can be very violent. The wreck of a freshly sunk Atlantic liner at the same place was battered to pieces in the course of a single gale, and the large stones strewing the bottom are flung about amongst her remains whenever there is a big, long swell running. As many of these stones are quartz, there may probably be considerable illumination on such occasions.

In connection with light under water, I may mention that if, as often happens, one's hand gets cut when working at a fair depth the blood streaming out into the water looks quite black, like ink, at the source, thinning out to a bluish cloud as it gets more diluted with sea-water. No trace of redness can be made out. Similarly, an abrasion looks like a dab of tar on one's hand. I presume that this effect is caused by the absence of red rays, which are cut off by the upper layers of water, and that it could be predicted; but I do not understand why in the same circumstances crabs (*C. pagurus*) look as red as they do on deck.

The volume of air in his dress at a given time is a matter of much importance to a diver. He has to control his buoyancy to suit the work in hand, and on a change of depth must rapidly adjust the valve to maintain the same volume during and after the change of pressure. Failure to do so results in a "squeeze" or a "blow-up," either of which may be fatal.

Fish with swim-bladders must have a similar practical interest in this application of Boyle's law, and a diver who considers the matter will be able to sympathise with them in the difficulties they must often encounter from their relatively slow means of adjusting volume.

Usually when a mine or similar explosion takes place under water numbers of swim-bladdered fish float to the surface. Stunned or injured, they have risen above the depth for which they were adjusted, and the resulting expansion of the bladder gases then overcomes any efforts they may make and surges them upwards, hopelessly out of control. In addition to the distension so often described, many of them, as I have found, are killed by rupture of the bladder and resulting internal hæmorrhage. It is curious that the escaped gas from the bladder often finds its way into the heart and great vessels, producing a condition like that due to compressed-air illness.

The diver going down to a wreck where blasting has been going on generally finds that numbers of fish have fallen to the bottom through a converse process and are lying there dead. On a recent occasion where blasting was going on almost daily the accumulation of dead pollack, pout, horse-mackerel, etc., on the bottom attracted swarms of spotted and spiny dogfish, which could always be seen cruising about among the wreckage, often with dead fish in their mouths. The blasting, of course, went on just the same, and heavy charges were often fired in the midst of these shoals, but I have never been able to find a dead dogfish on the bottom (having constant negative buoyancy, they always sink when dead). On the contrary, I have (from the ship) seen them rise to the surface immediately after an explosion in pursuit of the stunned swim-bladdered fishes and tear them to pieces as if nothing had happened. Dogfish have no swim-bladder, and its absence enables them, as in this case, to dash from a hydrostatic pressure of 57 lb. per sq. in. to atmospheric pressure and back again with their prey without ill-effects. Moreover, it is probably this absence of an included gas space which renders them so immune to submarine explosions.

Another point about swim-bladders. In the North Atlantic sunfish and basking sharks idling at the surface of deep water, with positive buoyancy yet without swim-bladders, are familiar and somewhat puzzling objects. With such means as one has aboard ship I find the specific gravity of skates to be 1063 and of spotted dogfish 1068; the latter sink quite fast when they stop swimming for a moment. Presumably a basking shark would have a similar specific gravity, yet it floats. To catch one and solve the problem is not easy, but a friend kindly harpooned a sunfish for me. It was 3 ft. long and weighed 115 lb. The body was completely enclosed in a rigid case of some tough tissue resembling cartilage to the naked eye, but extraordinarily light. This shell varied from 0·75 to 1·25 in. in thickness except about the head, where it was very massive. It could be dissected off in slabs, and the thicker of these floated when thrown overboard. With the absence of bone, an immense fatty liver, and this queer, buoyant cuirass, I think we have the solution in the case of the sunfish.

Old Irish Maps.

THE fact that I have been able to refer your reviewer to an important map with which he was previously unacquainted is some compensation for the necessity for his last sentence (NATURE, October 7, p. 180).

A few years ago I spent some weeks among the maps in the library of the Geological Society of London, and tried to settle the question of the dates and editions of Griffith's maps. Since your issue of October 7 I have re-examined the evidence, with the additional help of a volume of Dublin addresses, once the property of Prof. Phillips, which I have recently obtained. The only conclusion I have been able to arrive at is that the Irish and English literature on the subject is vague and contradictory.

The writer of Sir Richard Griffith's obituary in the *Geological Magazine*, 1878, p. 525, states: "So long ago as the year 1812 the first outlines were attempted of . . . a geological map of Ireland. No labour seemed to Griffith too great in order to carry out this great work satisfactorily. *Four editions* of it were published, the latest of which was issued in 1854." Judd (*loc. cit.*, 1898, p. 149) tells us the large map of Ireland was exhibited in 1838 and published in March, 1839, and a *second edition* was published in 1855.

On June 13, 1839, Griffith read a paper (Journ. Geol. Soc. Dublin, 1839, p. 78) on "Presenting to the Society the Geological Map of Ireland in the Large Scale, the Result of my Labours for Upwards of Thirty Years." Later (*loc. cit.*, 1857, p. 294) he read a similar paper on "Preparing the *Last* Edition of my Geological Map of Ireland dated April, 1855." Close (Journ. Royal Geol. Soc. Ireland, 1879, p. 141) stated: "Very shortly after that [April, 1838], in the same year, the large map . . . was brought out, though for some reason which does not appear it was not regularly published so as to be accessible to all until March 28, 1839, the date which is inscribed upon it"; and (p. 142): "In June, 1840, only fifteen months after the last-mentioned edition, a new issue appeared. . . . In the short time mentioned changes had been made in the map in no less than forty places." We also learn (pp. 144–45) that a small edition of the map was published, and in 1855 a revised and the last edition was issued.

Apjohn (*loc. cit.*, 1841, pp. 158–59) states that as early as February, 1841, "in point of fact, *three maps* have been published by Mr. Griffith, first, a map on a comparatively small scale . . . and subsequently a *first* and *second* edition of his large map. We have already seen how great are the discrepancies between the two larger maps"—this, be it noted, being *before* the publication of the 1853 and 1855 editions.

The Geological Society possesses a large map "revised in 1853," and a smaller map (*circa* 1860) by Griffith is "copied from the large map of 1853."

So among these conflicting contemporary statements as to dates and editions I may be pardoned, after this lapse of time, for requiring to be "corrected."

A Visual Illusion.

MR. TURNER should have consulted some standard work on experimental psychology before claiming a visual illusion as "new" (NATURE, October 7, p. 180) and advancing an explanation which experiment has shown to be wholly inadequate to account for the retinal after-sensations of movement. The effects are quite independent of movements of the eyes, and as truly "sensory" in character as the after-effects of colour and brightness.

C. S. MYERS.

Gonville and Caius College, Cambridge,
October 17.

THE phenomenon referred to by Mr. Turner and by Prof. Boycott in NATURE of October 7 and 14, pp. 180 and 213, was described by Aristotle in his treatise on dreams ("Parva Naturalia") thus: "Also, the senses are affected in this way when we turn quickly from objects in motion, *e.g.* from looking at a river, and especially from looking at swiftly flowing streams. For objects at rest then seem to be in motion."

The phenomenon has since been rediscovered times out of number, *e.g.* by Purkinje in 1825, R. Adams in 1834, Johannes Müller in 1840, Sir David Brewster in 1845, etc. I reinvestigated it experimentally, and published the results of this research, together with a historical survey, as a monograph, "On the After-Effect of Seen Movement," in the *British Journal of Psychology* (Monograph Supplements, No. 1, Cambridge University Press).

A. WOHLGEMUTH.

70 West End Lane, London, N.W.6,
October 18.

THE visual illusion described by Mr. Turner and by Prof. Boycott in NATURE of October 7 and 14 was described by me in NATURE of October 18, 1917 (vol. c., p. 126), and commented on by Dr. F. J. Allen and others on pp. 146, 165, 225, and 325 of the same volume. It had also been described in NATURE, vol. lxx., p. 107, and vol. lxxviii., pp. 225, 277, and 305. It was also pointed out by me in vol. c., p. 284, that the phenomenon had been fully described by Dr. John Aitken in the *Journal of Anatomy and Physiology*, vol. xiii., p. 322. The illusion may, perhaps, be best seen by looking through a microscope and slowly rotating the stage; as soon as the rotation is stopped the field appears to be revolving in the opposite direction, and so strong is the illusion that the stage may again be rotated very slowly in the original direction for 10° or 15° and will appear to the eye to be perfectly still. The same phenomenon may be seen when a pianola roll is stopped, the roll appearing to be slowly moving backwards. In some forms of pianola there is, in front of the record, a glass panel on which is a small knob for opening and shutting the panel; if the finger is placed lightly on this knob while the roll appears to be running back, I have the very curious tactual illusion that the knob is also moving upwards, and that it presses more and more against the finger. One or two others, however, with whom I have tried the experiment do not perceive the tactual illusion.

Possible New Sources of Power Alcohol.

By C. SIMMONDS.

TWO reports have recently been issued dealing with various aspects of the fuel question. The first[1] is devoted largely to a consideration of the supplies of alcohol which might be made available for use as a motor fuel; the second[2] includes a note upon the production of alcohol from coke-oven gas, with a memorandum describing the process now being developed experimentally for the purpose. In the present article it is proposed briefly to survey the position as regards alcohol, leaving aside the question of alternative motor fuels.

As noted in the first of the two reports, the enormous and rapidly increasing consumption of liquid fuels is tending to exceed production, so that it is very important to supplement those now employed by developing the use of new ones in every possible way. In the United Kingdom the quantity of petrol received during 1914 was about 120 million gallons; the imports in 1919 had risen to 200 million gallons, and the estimate for the present year is 250 million gallons.

It is now accepted that alcohol, either alone or mixed with other liquids, can be used to replace petrol in internal-combustion engines, the most suitable fuel being probably a mixture of alcohol with benzol, or with benzol and ether. But to get alcohol we must first obtain the raw materials. These are, in the main, starch- or sugar-containing plants. So far as this country is concerned, grain (barley), potatoes, and mangolds would appear to be some of the most suitable crops: the last has not hitherto been used for the purpose to any large extent. Reckoning, for present purposes, a gallon of alcohol of 95 per cent. strength as equivalent to a gallon of petrol, how much of these raw materials should we require to supply the 250 million gallons which represent our annual consumption of petrol?

We should want more than 4 million tons of barley, or 12½ million tons of potatoes, or 25 million tons of mangolds. Roughly, the total annual production of potatoes in the United Kingdom is only one-half, and of the other two materials barely one-third, of these quantities. The barley we produce is already largely used in the making of malt; the potatoes and mangolds are foodstuffs. Since this country is very far from being self-supporting in the matter of food, no considerable proportion of these crops could be diverted to increase the production of alcohol. They command a much higher price as foodstuffs than could be paid for them as sources of "power" alcohol.

Our own case is fairly typical of the position in general. Foodstuffs, whether produced at home or abroad, will probably for some time yet be too valuable for use on any large scale as sources of alcohol. Meanwhile, what of possible new sources?

As regards synthetic methods of making alcohol, there are only two which, so far, have come near to commercial success. One of these is the manufacture from calcium carbide, itself produced from coke and limestone. The carbide yields acetylene, which by appropriate chemical treatment is converted into acetaldehyde; and the aldehyde, when mixed with hydrogen and passed over heated nickel as catalyst, is reduced to alcohol. The process was to have been worked on a large scale in Switzerland, but little has been heard of it lately. It may have been remunerative during the war, but has not developed as much as was expected, and appears now to be hanging fire. In any case, cheap power for making the carbide is essential; and according to some German calculations it would be more profitable to convert the carbide into cyanamide, and use this as a fertiliser to increase the potato crop for conversion into alcohol. A much better yield would thus be obtained.

The other synthetic method is based upon the utilisation of a by-product. The gas emitted from coke-ovens consists mainly of hydrogen (50 per cent.) and methane (25 per cent.), with smaller quantities of nitrogen, water vapour, and tarry impurities, and about 2 per cent. of ethylene. After a preliminary purification of the crude gas to eliminate tarry matters, ammonia, naphthalene, and benzene hydrocarbons, the greater part of the ethylene can be absorbed in strong sulphuric acid, forming ethyl hydrogen sulphate, which, when diluted with water and distilled, yields alcohol. Experiments have shown the possibility of obtaining 1·6 gallons of alcohol per ton of coal carbonised, and according to some estimates the cost of manufacture would be about 2*s.* per gallon. Assuming a similar yield from all the coal carbonised in British coke-ovens (about 15 million tons per annum), the yearly supply of alcohol from this source would be about 24 million gallons. The manufacture, however, is at present only in the early stages, and it is too soon to judge what the permanent prospects are. But, even if the suggested yield of 24 million gallons is eventually reached—and this, for various reasons, is unlikely—it would be less than one-tenth of our present petrol consumption. It would be a very acceptable contribution, but insufficient. An increase of 100 million gallons or more should be aimed at.

Thus, for the moment at least, we are still dependent upon fermentation methods for any considerable increase in the supplies of alcohol. We come back, therefore, to the question of fermentable raw materials.

Still dealing with the needs and possibilities of

[1] "Fuel for Motor Transport." An Interim Report by the Fuel Research Board, Department of Scientific and Industrial Research. (1920.)
[2] "Fuel Economy." Third Report of the British Association Committee. (1920.)

the United Kingdom, it may be said that to produce an additional 100 million gallons of alcohol we should have either to devote about 847,000 more acres to potatoes at the present average yield of 5¼ tons per acre, or else to increase this yield to something above 9 tons on the present acreage. For the same quantity from mangolds an additional 513,000 acres would be required, or else a yield of 34½ tons per acre instead of the present average of about one-half this amount. Two suggestions have been made towards the possibility of effecting this increase. One is that by a greater use of fertilisers and better cultivation the crop yield might be raised sufficiently to meet the demand even with the present acreage, or with a relatively small increase. As regards potatoes, more than 10 tons per acre have been obtained in various Irish districts, so that an average of 9 tons does not seem impossible. The figures given by the Fuel Research Board for the mangold crop in 1919 work out to 16½ tons per acre, but some years ago the average was 20 tons, and 24–30 tons have been mentioned as obtainable. If the normal crop of mangolds under good conditions is anything like the last estimate, no very great increase in yield and acreage together would be required to give the raw material for 100 million gallons of alcohol.

The second suggestion is that, leaving apart the land at present cultivated for foodstuffs, waste land might be reclaimed and devoted to carbohydrate crops for alcohol production, so that there would be no diminution of present food supplies. Again turning to Ireland, there are, according to a recent writer, thousands, and even hundreds of thousands, of acres of waste land which could, without any great expenditure of money, be utilised for the purpose. In this country some small-scale experiments on reclamation are actually in progress at Holton Heath, where several acres of heath land have been reclaimed and planted with artichokes for a practical study of the question. At present, however, the work is not sufficiently advanced to allow of useful deductions being made.

The general conclusion arrived at in the interim report of the Fuel Research Board is that the production of alcohol in any considerable quantities from vegetable materials grown in the United Kingdom is not economically possible, owing to (1) insufficient acreage; (2) high cost of cultivation, harvesting, and manufacture; and (3) the fact that the most suitable raw materials are also important foodstuffs. The two suggestions noted above might go far to meet the first and third points, but the second still remains, and it is, of course, a crucial one. In tropical and sub-tropical countries, where land is plentiful, labour cheap, and sunshine abundant, it may be quite practicable to grow vegetable substances such as cassava, arrowroot, and maize at such a cost as will make them very important sources of alcohol. Maize has been much used in the past, but just now its price—no doubt an abnormal one—precludes its use on a large scale. In regions such as South Africa and South America, however, two or even three crops can be secured yearly, and it has been urged that with proper organisation and development this raw material could, under conditions of mass-production, become one of the most important supplies.

Turning now to other possibilities, one of the first to be mentioned is the utilisation of cellulose materials as sources of alcohol. Two processes are already well known; others are in the experimental stages only. The cellulose of sawdust and other wood waste can be hydrolysed with acids and partly converted into fermentable sugars. This process has been under trial for several years in America, but has not yet definitely established itself as a successful manufacturing operation in normal times. In countries where wood pulp is made, a considerable quantity of alcohol is obtained from waste sulphite liquor, a by-product which contains a small percentage of fermentable sugars produced during the treatment of the wood. An interesting recent proposal (Rogers and Bedford) is one for obtaining alcohol from rice straw and husk, a cheap raw material available in large quantities. The straw is softened by steaming, and treated with hydrochloric acid or with calcium hypochlorite and chlorine to disintegrate the fibres, then pulped, and the hydrolysis of the cellulose and starchy matters completed by means of diluted hydrochloric acid. After the conversion to sugar is finished, the acid is neutralised, and the solution of sugars fermented and distilled. It is understood that arrangements have been made for large-scale experimental trials of this process in India, with the view of ascertaining whether the production of fuel alcohol from these and similar cheap cellulose materials can be definitely established.

Experiments are also in progress to ascertain whether a micro-organism can be obtained which will effect the direct conversion of cellulose into fermentable sugar. Success on the lines of this or the preceding process would open out the prospect of utilising a large amount of waste cellulose substances as sources of alcohol.

Among other possible new sources may be mentioned a tuberous plant, *Polynnia edulis*, growing in the Andes, which is said to be now under trial in France. The tubers range up to 2 lb. in weight, and have a carbohydrate content comparing favourably with that of mangolds. A special sugar beet is also being experimented with. Little information, however, is available yet as to whether, in the matter of yield and cost, these plants offer any marked advantages over those now in use.

Our general survey indicates, therefore, that, although the home production may be appreciably increased, it is mainly to the organisation and development of our overseas resources that we must look for any very considerable increase in our supplies of alcohol cheap enough to be used as fuel.

The Natural History of Everyday Creatures.[1]

MISS FRANCES PITT has given us a delightful book of personal observations on the everyday creatures that may be met with in garden, meadow, and hedgerow—the mice, birds, frogs, toads, and other animals that every person comes across. She records what she has seen and learnt, and is plainly an observer of experience and insight. She shows the interest of the life at our doors, and makes it clear that there is a great deal still to be discovered. Her book is strongly to be recommended for young people, not only because of its interest and its simplicity of style, but also because of its scientific temper.

FIG. 1.—A toad climbing. From "Wild Creatures of Garden and Hedgerow."

We feel at every turn that here is an observer who has a great respect for facts. We recommend the book to young people—there is no writing down to them, but we are sure that many people who are not young in years will enjoy the author's observations thoroughly and learn much from them. The photographic illustrations are excellent.

The book begins with bats, which are bundles of peculiarities and puzzles. Let us take an example of Miss Pitt's method. When a bat, hawking in the twilight, makes a dash after an insect and catches it, it often apparently tumbles through the air for a foot or two. This is because the bat, having grabbed its insect, bends its head down into its interfemoral pouch, where its prey cannot escape, and crunches it quickly as the bat goes on flying. Now Miss Pitt won the confidence of a pipistrelle to such a degree that it sat on her hand and ate all the flies it could get—making nothing of twenty to thirty at a meal. "My little pipistrelle had hitherto caught and pouched all its food when on the wing, and from habit felt compelled to try and pouch the flies I gave it, though sitting in an attitude that made this almost impossible. The result was that time after time it tumbled over, and would right itself with such a puzzled and bewildered look! However, the difficulty of doing the proper thing did not stop it eating."

The bank-vole matches the soil, dead leaves, and withered grass so wonderfully well that it is very safe so long as it does not move; but if it moves too soon the kestrel drops on it like a stone. Miss Pitt kept three in a large glass-sided cage, and proved their fear of attack from above. "They did not take any notice of things moving beside them, but the slightest thing overhead sent them dashing for cover or made them crouch like stones where they were. The cage was arranged to be as much like part of a bank as possible." Of great interest is the story of a young thrush which took about a week to learn how to deal with snails. "It was very evident that he learnt by experience, and that the snail-cracking habit of the thrush is not a specialised instinct, but arises from the tendency of this bird to beat on the ground and thus kill any food, like a big worm, which cannot easily be managed. My thrush would beat and hammer anything that was at all troublesome or which he did not understand." This is the kind of observation that gives the book a high value. Dealing with shrews, Miss Pitt says: "It is only by watching these small animals that one can gain any idea of their untiring energy, intense vitality, and their great pugnaciousness. They are perhaps the most quarrelsome creatures in the world! If lions and tigers were as fierce, active, and fearless in proportion to their size, as shrews and moles are in comparison with their little bodies, what awful creatures they would be!" In regard to the death of large numbers of common shrews in the autumn, the author favours the theory that these animals are "annuals." Here, as in some other parts of the book, there is a useful exposure of the nonsense that is often talked about the misery and cruelty of wild Nature. "If to us it seems dreadful that death should be always on the watch

[1] "Wild Creatures of Garden and Hedgerow." By Frances Pitt. Pp. ix+285. (London: Constable and Co., Ltd., 1920.) Price 12s. net.

for them, it seems almost certain that the small animals enjoy their life to its utmost." We come next to a sympathetic study of frogs and toads. The toad's eyes are described as of "a pale metallic brown with reddish lights like flickering fires in their depths." This is good, but we do not like the suggestion that *iris* and *pupil* are synonymous, and we should not ourselves speak of the toad *ejecting* its poison. It is interesting to learn that toads will go over a mile to a particular breeding-pond—perhaps a sort of "homing." Miss Pitt's workmanship is first-class throughout, but she excels herself in dealing with mammals. What a fine picture she gives of the long-tailed field-mouse, with "great black eyes looking ready to jump out of its head," which washes itself when the least upset, a great climber, a burglar of bee-hives. If the tail is suddenly seized, it *skins*, and the animal escapes, very like "a special arrangement to enable its owner to get away from hawks and owls." The mouse does not bite off the skinned bone, as some books say; the caudal vertebræ dry up and fall off of their own accord.

We thought we knew something about moles, but we have learned much from Miss Pitt. For their size they are extraordinarily fierce and strong; they fight furiously, and it is doubtful whether a weasel could master one. On one occasion a mole moved a nine-pound brick, which is like a man moving more than three tons. Their rate of digestion is past belief, and they require meals almost continuously. One that was supplied with forty worms in the late afternoon was dead next morning—with an empty stomach. "Whatever you do, don't despise the 'poor little mole,' . . . in its dark tunnels it fights, hunts, feasts, mates, and enjoys life with quite as much gusto as the creatures of the light and air."

Miss Pitt made a fine experiment with a very young common rat, still blind, feeble, and very naked. She gave it in a diplomatic way to a cat, whose litter had been reduced to one—about ten days old. "I could hardly hope that the cat would be so good, or shall I say so foolish, as to nurse such an utterly different baby as the rat!" But that was what happened. The rat was accepted, cleaned, fed, fondled, tended, and treated just like the kitten along with which it was reared. Even after another family came to occupy the cat's attention, she remained on friendly terms with the rat and often paid him a visit. The cat in question had been a good ratter, but after the adoption ratting was done with!

In the study dealing with the pied-wagtails, willow-wrens, and great tits of a garden, the author notes that the parent wagtails worked for sixteen hours a day, and in that time brought food about 192 times to the nest; and it is not merely the going to and fro; there is the searching for insects in between. It is suggested, by the way, that the willow-wren's domed nest serves to keep the sun off the young birds, which are greatly distressed by heat. There is a lively account of the slow-worm, the common lizard, and the grass snake; thus in reference to the local life of the discarded tail of the slow-worm we read: "Fancy being able, when threatened by a foe, to throw off such an important part as a tail, and slip away, while it dances on the ground and occupies his attention." We have often found students puzzled by the expression "casting or shedding *the skin*"; and as Miss Pitt explains that the skinned tail of a field-mouse dies, perhaps she may be fairly asked to explain why a snake which sheds "many skins" is able to live on. It is new to us that the skeleton of the slow-worm shows rudiments of *legs*. We make such trivial observations because the book is so perfect.

FIG. 2.—The long-tailed field-mouse. From "Wild Creatures of Garden and Hedgerow."

A study of the short-tailed field-vole, prolific, harmful, greedy, but very likeable, raises a number of interesting points. The dull, dark brown fur is a good instance of prolonged sifting: "It is not that it matches either the stems of the grass, or the bare earth, but it goes wonderfully well with the shadowy places between the plants." Who can explain why a comfortably caged mother, captured along with her litter of six, will coolly and collectedly, after a careful toilet, remove one baby after another from the nest, and give each a sharp and fatal bite? The ways of mice and men! We have left to the end the story of the hedgehog, which Miss Pitt defends from many calumnies. Its appetite for a dead rabbit or the like has doubtless given some basis for misinterpretation. We doubt whether it is quite correct to say that the rolling-up musculature (*orbicularis panniculi*) of the hedgehog is also used in raising the spines, but perhaps Miss Pitt means merely that the contraction of the cap-like sheet is a factor in making the spines stand out firmly. We like what is said in regard to the individuality of hedgehogs and other beasts of the field. Miss Pitt is to be congratulated on a book which takes its place in the first rank of works on field natural history. It is a personal record of clever, patient, and sympathetic observation. J. A. T.

Obituary.

Prof. Yves Delage.

By a large number of zoologists, who have known the charm of Roscoff Marine Station during the last twenty years or more, the death of Prof. Yves Delage on October 8 will be felt as a personal loss. It was not merely that Prof. Delage grudged no time or trouble if he could help one with a piece of work; it was the impressive sincerity of the man and the simplicity with which he wore his learning. He had an encyclopædic knowledge of the shore-fauna and of the literature of biology, but he encouraged the learner with a Darwin-like humility. His devotion to science was singularly complete. All through his life, with an extraordinary intensity, he was preoccupied with biological and psycho-biological problems, and he did not often unbend his bow except for the simple pleasures of domesticity and the open air.

Yves Delage was born at Avignon in 1854 and educated at various provincial schools. He was greatly influenced in his student days by de Lacaze-Duthiers, whom he afterwards succeeded both at the Sorbonne and at Roscoff. It was under this master that he acquired a great liking for "microtomy" of a rather different sort from that which the word now suggests. We mean what Delage himself called "patient dissections under the microscope," the kind of investigation which he illustrated in his thesis (1881) on the vascular system of sessile-eyed Crustaceans. That he did not, however, stand so aloof as Lacaze-Duthiers did from the use of the microtome was shown in subsequent researches, such as those dealing with the development of sponges (1887). After a period of assistantship to Lacaze-Duthiers, of whom he always spoke with great reverence, Delage became professor at Caen and director of the adjacent Marine Station at Luc. He soon returned, however, to the Sorbonne, and was actively at work there until quite recently. He was elected a member of the Institute in 1901, about the time when he assumed full charge at Roscoff; he received the degree of LL.D. from Aberdeen University when he attended the quatercentenary celebrations in 1906; and he was awarded the Darwin medal by the Royal Society in 1916. For some years past his eyesight had given way badly, but his mental vision was unimpaired.

Delage's scientific industry was at once a reproach and an inspiration to those who knew him; it was almost incredible. His great book on "Heredity and the Great Problems of General Biology" (1895, second edition 1903) is a monument. It is marked by erudition, clearness of exposition, fair-mindedness, and keen criticism. We have temperamentally a great admiration for his judicial way of balancing evidence, sometimes so judicially that the reader's mind is left in a state of indecision. His own view was definitely neo-Lamarckian, and he had many a thrust at Weismannism. Then there are the twenty volumes or so of "L'Année Biologique," a very valuable series of critical summaries of current biological memoirs, even the last volume containing many contributions from Delage himself. Again, there are the half-dozen volumes of the "Traité de Zoologie Concrète," in which he was ably assisted by M. Hérouard and others. Besides these there were smaller undertakings, such as the very successful volume, written along with M. Goldsmith, on "Modern Theories of Evolution" (1909), and a similar volume on "Parthenogenesis" (1913).

Delage's most important contributions to zoology and biology have been (1) his fine study of the life-history of the extraordinary Crustacean parasite Sacculina, (2) his precise work on the development of sponges, and (3) his remarkable experiments on artificial parthenogenesis, with which his name (along with that of Jacques Loeb) will always be associated. We recall also the strange experiments on "merogony" and researches on the semicircular canals and otocysts. The study of the ear had a great fascination for him. Nor can we forget a long paper on a whale stranded near Luc, for it was in this connection, about 1885, that we had in our student days, working at the Luc laboratory, our first knowledge of Delage. We suppose that he made mistakes in his work like other distinguished men, but surely his life was marked by what he said Lacaze-Duthiers had by example taught to his school—"la persévérance, la suite dans le travail, la conscience dans l'observation, la sobriété dans les inductions théoriques."

Delage was at work at Roscoff this summer and autumn, and it is surely not unfitting that the last subject of his eager scientific analysis should have been *dreams*, on which we believe he had recently completed a treatise. A young student who returned last month from a working holiday at Roscoff has given us a pleasing glimpse, with which we close our appreciation. Every day after lunch it was Delage's habit to sit for a while in front of the laboratory so that any student might know he was then and there at home.

J. Arthur Thomson.

ASTRONOMY in Italy has suffered three heavy losses within a few months in the deaths of Riccò, Millosevich, and Celoria. GIOVANNI CELORIA, who died in Milan on August 18, was born in Piedmont in 1842, graduated at the University of Turin in 1863, and then studied astronomy at Bonn and Berlin. On returning to Italy he was appointed by Schiaparelli an assistant at the Brera Observatory, Milan, where he remained almost all his life, becoming director in 1900, on Schiaparelli's retirement, and himself retiring in 1917. Celoria's astronomical studies were devoted mainly to the structure of the star system; he repeated some of Sir W. Herschel's work on star-gauging, though with a much smaller telescope, and inferred the comparative thinness of the star-stratum in the direction of the north galactic pole from the fact that in this region he could see as many stars as Herschel had seen. He did useful work in another direction by collecting and discussing the records of several total solar eclipses the tracks of which crossed Europe in the Middle Ages, and he was able to fix the boundaries of totality with considerable precision; his work has been utilised by Dr. Cowell and others in the discussion of the secular acceleration of the moon. Celoria was also interested in geodesy, and held for a long time the chair of that subject in the Technical College of Milan. He was elected an associate of the Royal Astronomical Society in 1917.

WE regret to note that the death of MR. GEORGE TANGYE is announced in the *Engineer* for October 15. Mr. Tangye started business in Birmingham, with four other brothers, in 1858. The firm was a very modest undertaking at the start, but came rapidly into prominence on account of the successful launching of the *Great Eastern* steamship, which was accomplished by use of the Tangye hydraulic jack. The firm was one of the first to introduce steam-engines with interchangeable parts; its products in many fields of engineering have now a world-wide reputation. Mr. Tangye lived for many years at Heathfield Hall, formerly the home of James Watt. He carefully preserved Watt's garret workshop, and brought together a fine collection of relics of Boulton and Watt, which he finally gave to the city of Birmingham.

THE death is announced in *Engineering* for October 15 of SIR JOHN MCLAREN, who was well known in Leeds engineering circles. Sir John was born in 1850, and finished his education at Durham University. He started in business in 1876 with his brother, and his firm carried out many important contracts. When the war broke out he was made chairman of the board of management of the National Factories for Munitions in Leeds. He was a member of the Institution of Civil Engineers and of the Institution of Mechanical Engineers.

BY the death of MR. HENRY STEEL on October 7, chairman of the United Steel Companies, many organisations with which he was prominently connected have suffered a severe loss. Mr. Steel was educated in Brussels and at the University of London. The combine of which he was chairman included many large firms, and had a capital of more than 9,000,000*l*. He became a member of the Iron and Steel Institute in 1886.

Notes.

PROF. T. W. EDGEWORTH DAVID, C.M.G., F.R.S., professor of geology in the University of Sydney, has been appointed a Knight Commander of the Order of the British Empire (K.B.E.) for services in connection with the war.

THE gold medal of the Royal College of Physicians, which is awarded by the college every three years for distinction in public health, was presented to Dr. W. H. Hamer, Medical Officer of the County of London, on Monday, October 18.

THE Emil Fischer memorial lecture will be delivered by Dr. M. O. Forster at the ordinary scientific meeting of the Chemical Society on Thursday, October 28, at 8 p.m. By the courtesy of the Institution of Mechanical Engineers, the meeting will be held in the lecture theatre of that institution.

THE expedition sent by the Norwegian Government, in command of Capt. G. Hansen, to lay depôts for Capt. Roald Amundsen has returned safely, having accomplished its task. The *Times* announces that Capt. Hansen, after wintering in the Eskimo settlement at Thule, started northward in March this year, accompanied by several Eskimo who had previously served with Peary. The march was along the coast of Greenland by Smith Sound and Kane Basin. North of Franklin Island fast sea-ice several years old enabled the expedition to cross Kennedy Channel to Grinnell Land. With some difficulty, due to extremely rough pack, Cape Sheridan was rounded and the goal of the march reached at Cape Columbia, the most northerly point of Grant Land. There the last of a series of depôts was laid which will enable Amundsen, if his Polar drift brings him to the neighbourhood, to abandon his ship and travel southward by easy marches to the Danish settlements in Greenland.

THE first Pan-Pacific Scientific Conference met at Honolulu on August 2–20, when some noteworthy resolutions were carried (*Science*, September 24). Dealing with the promotion of scientific education, the conference recommended that the compensation for instruction and for research in science should be increased in order that young men may enter upon scientific careers without sacrificing all hopes of reasonable monetary returns; and, further, that men of exceptional attainments should be given rewards which may be comparable with those offered by commercial undertakings. A resolution was also passed advocating that efforts should be made to keep the public fully informed of the progress of science and of its bearings on the affairs of the world. Resolutions which concerned more nearly the institutes and universities of the Pacific countries dealt with the training of teachers and lecturers, with the provision of fellowships, and with the migration of research students to institutions providing the best facilities for their own class of work. The conference recommended that the exchange of teachers between institutes in different countries should be encouraged with the object of widening the outlook of these instructors. Fellowships to which adequate stipends were attached ought to be regarded as rewards for scientific work, and substantial prizes given as rewards for young investigators who achieve notable results. It was also agreed that a clearing-house of information relative to opportunities for scientific study and research in the Pacific area should be established.

SIR W. H. BRAGG delivered a public lecture at University College, London, on October 7, as a general introduction to the courses on the history of science to be delivered there. After referring to the origin of these courses, the lecturer said there must be something innate in mankind to prompt an interest in Nature and to foster a belief in cosmic order in spite of apparent chaos. Already in the earliest civilisations, in ancient Egypt and Babylonia, we see the beginnings of that close study of Nature which has continued with varying success throughout the ages. It is in the nature of things for old views to be superseded. There has, however, been more of evolution than of revolution in the history of scientific ideas. Each generation tries to correlate all the facts known to it, and it can do no more. Newton correlated all his facts; Einstein has to take into account facts unknown to Newton. There is no finality in science. A belief in finality would lead to stagnation. The history of science is interesting in many ways. It reveals the steps that have led up to our present orientation; it traces the evolution of the great scientific conceptions—like the atomic theory, for example; it shows the development of potent scientific instruments like the thermometer, etc.; it tells the story of the fruitful application of scientific discoveries—wireless telegraphy, for instance; it has the great human interest of showing how workers drawn from all sorts and conditions have co-operated in the building up of science; and it narrates many an inspiring epic of heroic struggle and perseverance, of triumph and tragedy, in the disinterested pursuit of noble ends. No wonder, then, that throughout the country there is awakening a new interest in the history of science. The subject offers a valuable educational opportunity. It merits the serious attention of teachers and journalists and all whose business it is to teach how things have come to be what they are; and it is well adapted to serve all those who seek to improve their education by non-vocational studies that will add to the interest and joy of life.

AMERICAN philologists have long been occupied in elucidating the complex of dialects spoken by the Indian tribes. The more important languages have been fully investigated, but there still remain some minor linguistic groups which are gradually coming under inquiry. The Tunica, Chitimacha, and Atakapa languages, spoken within historical times in territory now incorporated with the States of Mississippi, Louisiana, and Texas, form the subject of a monograph by Mr. J. R. Swanton, published as Bulletin 68 by the Bureau of American Ethnology. The first, the Tunica, is now spoken by only some half a dozen persons in a small reservation. For our knowledge of these languages, now practically extinct, we are indebted to Dr. A. S. Gatscher, whose collections were made in 1886, and further researches among the scanty survivors by Mr. Swanton have added little new information. This scholarly monograph gives a grammar and comparative vocabulary of these three closely allied forms of speech.

THE native tribes which occupied the vast region extending eastward from the Mississippi to the Atlantic are now understood to belong to at least seven linguistic stocks. Of these groups the Algonquian was the most numerous, followed by the Muskhogean, Iroquoin, Siouan, Timucuan, Uchean, and Tunican, all differing to such a degree that one would not have been intelligible to the other, and often within the same linguistic family the various tribes spoke different dialects. Thus such a diversity of languages and a great range of climatic conditions, mountains, prairies, swamps, and lakes produced a variety of customs influenced by natural conditions and environment. In perhaps no way are these variations more pronounced than in the forms of the dwellings of the various tribes. This subject is fully illustrated in the monograph (Bulletin 69) by Mr. D. I. Bushnell, jun., issued by the Bureau of American Ethnology. In this we have an investigation of ancient village sites occupied by the various tribes, and the nature of the buildings erected by peoples in various stages of culture, which is full of interest.

IN the September issue of the *Entomologist's Monthly Magazine*, Mr. F. W. Edwards deals with the habit of certain midges (Ceratopoginæ) of sucking the juices of other insects. This propensity has long been known, but Mr. Edwards's exact observations appear to be the first connected series conducted in this country. The blood-sucking habit among the females of this group of insects possibly first arose from the partiality of its members for attacking other insects. Few people who have used their gardens towards dusk have escaped the irritating punctures caused by these minute flies.

IN the Transactions of the Entomological Society of London (July, 1920) is a paper by Dr. G. D. Hale Carpenter on the forms and Acræine models of the Nymphaline butterfly, *Pseudacraea eurytus Hobleyi*, on the islands of Lake Victoria. Contained therein are some observations bearing upon the explanation of the theory of mimicry by natural selection. The object of the author is to show that in the presence of greater numbers of models the mimics are found to be true to type, but that when they outnumber the models many transitional and other varieties are preserved. The paper is a confirmation and extension of the author's earlier article published in March, 1914. The destruction of butterflies, so far as selective action is concerned, is held to be mainly the work of young birds which have to learn what to eat and what to avoid. Thus in 1914, when the models were extremely abundant, any member of a combination would have been more likely to be the distasteful Acræine. The young birds would therefore leave that combination alone, while varieties of the Pseudacræa not conforming to the model would be destroyed. As the birds grew older, and in localities where the models had become scarcer, one must suppose that the birds had forgotten what the latter tasted like, so that no one form of Pseudacræa had much more chance of surviving than any other. This explanation presupposes that the bird fauna stays on an individual island and does not fly from one to another. Dr. Carpenter has already brought forward some evidence which suggests that this is actually what does occur.

MESSRS. A. S. KENNARD AND B. B. WOODWARD have published in the Proceedings of the Malacological Society for September some "Nomenclatorial Notes relating to British Non-marine Mollusca." After discussing the names of various species of Testacella and Helix, they point out that the genotype of Ancylus is *Patella lacustris*, Linn., and that *Ancylus fluviatilis*, which belongs to a different genus, must be called Ancylastrum. This is a most unfortunate conclusion, because it is the latter species that has given the name to the well-known Ancylus Lake and Ancylus Clay of the late Glacial period in North-West Europe. Scarcely less regrettable is the authors' desire "to once again point out" that the name Bulinus is not available for "the Egyptian shells [*sic*] which play the part of host to Bilharzia," or, indeed, for any mollusc. They may be right, but we do not agree that because O. F. Müller adopted Adanson's pre-Linnean name Bulinus for four species, one of which was that imperfectly described by Adanson, his action "of course involves the acceptance of [Adanson's] shell as the type of the genus." The authors are so severe on Dr. Annandale for thinking that the name Bulinus (or Bullinus) ought to be preserved because of its wide currency, that one is astonished to find them, almost with the same penful, writing of Bilharzia, which they must know to be a synonym of Schistosoma. It is doubtless their misfortune rather than their fault that pages which blame the eccentric Fitzinger for neglect in proof-reading should themselves exemplify that form of carelessness.

FROM Buenos Aires we have recently received a copy of *El Hornero*, a journal of Argentine ornithology published by a recently established society, La Sociedad ornitológica del Plata, constituted for the encouragement of the study of the birds of the southern portion of South America. The journal derives its name *Hornero* from the Spanish word denoting one of the most characteristic birds of Argentina, known to Englishmen as the oven-bird and to science as *Furnarius rufus*, and an illustration of the birds and their curious massive nest built up of clay adorns the cover of each issue. The present number contains a carefully prepared list of the different species of penguins found along the coasts of Argentina drawn up by Señor R. Dabbene, the editor of the journal, and a list of 254 species of birds found in the neighbouring Republic of Uruguay from the pen of Señor J. Tremoleras, of Montevideo. Mr. A. G. Bennett, of Port Stanley, in the Falkland Islands, contributes some notes on the habits and distribution of the marine birds of that distant outpost of the British Empire, illustrated by reproductions of photographs taken by himself. The parasitic Mallophaga of the Argentine are treated of at considerable length by Dr. F. Lahille, who has himself described 31 out of the 159 species known to exist in the Argentine; and, finally, Prof. Lucas Kraglievich has an article on the fossil birds of the Republic, in which he discusses the relationship of Phororhacus with the recently-described Diatryma of the Eocene beds of the United States. There are a number of shorter articles and notes, with an ample bibliography of recent publications dealing with South American ornithology, and the general get-up and editing of the journal reflect great credit on the Sociedad ornitológica del Plata and the editor, Señor Dabbene.

MR. W. H. TALIAFERRO records (*Journ. Exper. Zool.*, vol. xxxi., No. 1, July, 1920) the results of observations on the reactions to light in *Planaria maculata*, planned with the object of ascertaining how far, in this Turbellarian, the function of the eyes in the reactions to light can be correlated with the histology of these organs. Hesse (1897), who worked with certain Triclads which were negative to light, and hence moved away from the source of stimulation, maintained that this reaction was due to the fact that the sensory cells or rhabdomes were shaded by the pigment-cup which partially enclosed them, whereas when the worm turned in any other direction the pigment-cup did not shade all the rhabdomes. When certain of the rhabdomes were illuminated, as in the latter case, the animal turned so as to bring the sensory region of the eye again into the shadow of the pigment-cup. Hesse therefore maintained that the localisation of the photic stimulus is the specific function of the pigment-cup, which enables the animal to direct its course away from the source of light. Mr. Taliaferro has carried out experiments on normal Planaria and on others from which one of the eyes, or a portion thereof, has been very carefully removed. He shows that the rhabdomes in the eye are arranged in two localised sensory regions. Illumination of one set is followed by the animal's turning towards the side containing the eye, while illumination of the remaining rhabdomes is followed by the animal's turning in the opposite direction. The observed reactions can be explained without assuming (with Hesse) that the pigment-cup acts as a localiser of photic stimuli. Light must strike a given rhabdome parallel to the long axis of the latter in order to cause stimulation; thus the position of the long axis of the rhabdome results in a localisation of photic stimulation. Light entering the pigment-cup from any given direction illuminates the rhabdomes in a definite area, and a large proportion of these have their long axes directed parallel to the stimulating rays of light.

We have received from Prof. H. F. Osborn reprints of some interesting brief notes on vertebrate fossils in the American Museum of Natural History, New York. A good drawing is published of a newly mounted skeleton of Moropus, the strange odd-toed hoofed mammal from the Miocene of Nebraska, in which the large hoofs are sharply pointed and deeply cleft as in some edentates (Proc. Nat. Acad. Sci., vol. v., pp. 250–52, 1919). Prof. Osborn concludes that this must have been a forest animal, and that the peculiar feet were used, not for digging, "but largely for the pulling down of the branches of trees." A drawing of a restored and mounted skeleton of a long-jawed mastodon (Megabelodon) from the Pliocene of Texas shows well the comparatively short limbs of the earlier elephant-like mammals (Proc. Nat. Acad. Sci., vol. v., pp. 265–66, 1919). Beginning apparently in northern Africa, these long-jawed mastodons reached Europe in Lower Miocene times, and appeared in America (Texas) in the Upper Miocene, attaining a gigantic size in the Middle Pliocene. The monograph of the Titanotheres is progressing, and Prof. Osborn describes some new fragments of jaws from the Eocene of Colorado (Bull. Amer. Mus. Nat. Hist., vol. xli., art. xv., 1919). The Jurassic Dinosaurs are also being actively studied, and some valuable notes on the original specimen of the gigantic sauropod, Camarasaurus, from Colorado, are published by Prof. Osborn and Mr. C. C. Mook (Proc. Amer. Philos. Soc., vol. lviii., pp. 386–96, 1919). The authors agree with Dr. W. J. Holland that the axis of the skull in the sauropods inclines downwards from the vertebral axis as an adaptation for browsing, and they give some striking restored sketches of the head of Camarasaurus as they think it appeared in life.

The Memoirs of the Geological Survey of India (vol. xlvii., part 1) contain an extremely interesting account of the mines and mineral resources of Yunnan by Mr. J. Coggin Brown. Yunnan is the most southwesterly of the provinces of China, and is of importance from the British point of view because it forms the eastern boundary of Burma and Assam; it has been but little visited by Europeans, and Mr. Coggin Brown's explorations thus afford authentic information upon an extensive area which has hitherto been most imperfectly studied. The more important mineral products which he has described comprise coal, iron, copper, lead, silver, zinc, tin, arsenic, gold and salt. In addition to Tertiary lignite, coal of Mesozoic, Triassic and Carboniferous age is known, and the author is of the opinion that the province contains considerable quantities of coal, some of which, at any rate, is of good quality. He does not think there is much probability that coal can be exported in competition with other coalfields of the Far East, but holds that it will find its chief demand in supplying the local railways and local domestic and metallurgical requirements. Iron ores occur in many places, and the production of cast-iron, castings, wrought iron and steel is sufficient for all local requirements, which are, of course, by no means extensive. The native methods of iron-smelting are well described, and it is interesting to find that the Chinese have developed charcoal blast-furnaces 25 ft. in height and 7 ft. across the boshes. The author does not think that there is much room in Yunnan for the development of iron-smelting upon modern European lines, but that the native smelters will gradually learn to improve their own methods. It is stated that copper has been smelted in Yunnan for at least a thousand years, but although copper ores are widely distributed the industry appears to be a declining one. The same seems to be true of lead and silver, but the production of tin, on the other hand, is in a flourishing condition.

Some interesting facts showing the limits of the continental United States which have been compiled by the United States Geological Survey are published in *Science* of September 24. The gross area of the United States is 3,026,789 square miles, of which 2,973,774 square miles are land and the remainder, 53,015 square miles, water; this is exclusive of the area occupied by the Great Lakes and that within the three-mile limit on the Atlantic and Pacific seaboards and in the Gulf of Mexico. The most southerly point of the mainland is Cape Sable, Florida, which is in latitude 25° 7′ N. and longitude 81° 5′ W.; this point is really forty-nine miles further south than the southernmost point of Texas, which often appears in maps to be the most southerly part of the land territory of the United States. The most easterly point is West Quoddy Head, near Eastport, Maine, in longitude 66° 57′ W. and latitude 44° 49′ N.; and the most westerly Cape Alva, Washington State, in longitude 124° 45′ W. and latitude 48° 10′ N. A small detached land area of northern Minnesota provides the most northerly point, in longitude 95° 9′ W. and latitude 49° 23′ N. The distance from the most southerly point of Texas due north to the forty-ninth parallel, the boundary line between the United States and Canada, is 1598 miles. From West Quoddy Head due west to the Pacific Ocean is 2807 miles, while the shortest distance from the Atlantic to the Pacific across the United States is 1152 miles, measured from the neighbourhood of Charlestown, South Carolina, to San Diego, California. The Canadian boundary line from the Atlantic to the Pacific is 3898 miles in length; the Mexican, from the Gulf of Mexico to the Pacific, 1744 miles. The Atlantic coast-line measures 5560 miles, the Pacific 2730 miles, while that washed by the Gulf of Mexico is 3640 miles in length.

Blue Hill Meteorological Observatory has issued its observations and investigations for the year 1919 as vol. lxxxiii., part 4, of the Annals of the Astronomical Observatory of Harvard College, U.S.A. The work has been done under the direction of Prof.

Alexander McAdie. Consecutive observations have now been published for thirty-four years. Atmospheric pressure, air temperature, vapour pressure, relative humidity, cloudiness, wind direction and velocity, and precipitation are given twice daily, at 8 a.m. and 8 p.m., throughout the twelve months, and the means and totals are entered for each month with the differences from the normals for the thirty-four years, 1886 to 1919. Wind frequency is given for each month and for the year for each 45° of the compass, and the mean and highest wind velocity. The duration of sunshine and the percentage of the possible amount are also included. Phenomena showing the advance of the season for each of the thirty-four years are given, such as thawing of ponds, last snowfall and last frost in spring, first blossom and first ripe fruit, first snowfall in autumn, and ponds frozen. There are numerous constants and averages for the thirty-four years, such as days with snow, hail, thunderstorms, and fog. Rainfall and snowfall and mean temperatures for each month of the thirty-four years are entered in tables. In the introduction a slip has been made in transposing the references to tables ix. to xi. A detailed description is given by Prof. McAdie of "a quick method of measuring cloud heights and velocities," which will doubtless be useful at aerographic stations.

Batavia Observatory has issued a volume of 140 pages, giving in detail the meteorological and magnetical observations for 1915, and also the meteorological results for the several months for the fifty years 1866 to 1915 and the means for the whole period. The work is published by the Government of East India, under the supervision of Dr. W. van Bemmelen, the director. For half a century hourly observations of many of the elements have been uninterrupted. A change has been made in the position of the barometer during 1915 which reduces the daily range of temperature of the attached thermometer from 5° C. to only a few tenths of a degree—an important factor when searching for the diurnal range of atmospheric pressure. For wind velocity the factor 3 has been used as formerly for the reductions, but it is found that the true factor decreases with the increasing velocities of wind. The results for fifty years probably give in many cases means which will vary little by any increase in the length of the period, but the fifty years may contain cycles the means for which may differ considerably among themselves. Rainfall results are given for fifty-two years, and breaking these into two periods of twenty-six years, the monthly averages are very different. Roughly speaking, the rainfall for the latter twenty-six years, 1890–1915, has increased in the southern winter months and decreased in the southern summer months. Magnetical observations are given only for 1915; there are curves showing the monthly deviations of the magnetic components from the mean yearly values.

The Report of the Committee on the Standardisation of the Elements of Optical Instruments just issued by the Research Department contains much information of prime importance to instrument-makers. It fixes standard focal lengths and diameters for telescope objectives, angles of prisms for binoculars, and diameters of tubing and of screws and pitches of the latter. It strongly advocates interchangeability amongst the products of the different manufacturers, and points out that two years ago the screws nominally of the same size turned out by one optical firm only in the country were interchangeable amongst each other. That firm has in a most public-spirited way offered to supply the chasers and gauges necessary to secure interchangeability. The adoption by the Committee of the inch as the unit of length will not permit of the principle of interchangeability being extended to instruments of Continental manufacture.

In the September issue of the Journal of the Franklin Institute Dr. F. E. Pernot has written an interesting and important paper on submarine-cable signalling. Dr. Pernot gives the results of experiments carried out by the members of the Signal Corps Research Laboratory of the U.S. Bureau of Standards. Several successful attempts were made to increase the carrying capacity of a submarine cable by superposing an alternating current on the existing system of direct-current signals. It is pointed out that currents of several frequencies can be used simultaneously, as each message can be separated by a suitable tuning device. The author is to be congratulated on having determined the physical constants of a submarine cable at various frequencies, both by calculation and by experiment. It is shown that the design of suitable apparatus becomes a straightforward problem. Actual trials of these methods with cables as long as 700 km. were made, the results being in all cases completely satisfactory. With longer cables difficulties were experienced, but the experiments indicated that it was possible to superpose at least one alternating current on the existing duplex system of an Atlantic cable. From the theoretical point of view it is interesting to note that the high-frequency resistance of a submarine cable is greater than that computed by Kelvin's formula. The effects of the steel armouring and the uncertainty in the position of the return currents would probably account for this. It was found that 5 microvolts at the receiving end gave good signals with the powerful amplifiers which are now available.

"The Gases Dissolved in Water" formed the subject of the Streatfeild memorial lecture delivered by Mr. J. H. Coste at the Finsbury Technical College on October 14. In a brief historical sketch reference was made to the work of Henry, Dalton, and Bunsen on the estimation of gases dissolved in water, and to that of Dittmar in connection with the *Challenger* Expedition. Curves were shown to illustrate the results of Adeney's work on the rate of aeration of air-free water, and reference was made to the investigations of Tornøe, Winkler, Roscoe, and Dittmar on the variation with temperature of the volumes of gases dissolved in water, results being given for distilled water and sea-water. The absorption coefficients determined by Bohr and Bock were given, and a curve depicting the manner in which solubility of oxygen in water falls with rise of temperature was shown. A method of collecting samples from any depth was illustrated, and Winkler's method for estimating the volume of dissolved air in water explained. The lecturer referred to the utility of this work in such diverse fields as public health and oceanography, and indicated the importance of dissolved air to subaqueous plant and animal life. The function of submerged green plants in absorbing carbon dioxide and liberating oxygen was explained, and it was stated that large quantities of oxygen in excess of saturation were found after a period of plant activity in bright light. One function of this dissolved oxygen is to maintain a healthy condition in water by oxidising submerged refuse—a process largely dependent upon the presence of living organisms. Reference was also made to geological changes due to dissolved carbon dioxide, to hardness produced by the same gas, and to the corrosive action of water containing dissolved air as exemplified by the oxidation of ironwork in hot-water radiators, and by the corrosion observed in all steam-raising systems owing to the oxygen dissolved in the feed-water. At the close of his lecture Mr. Coste referred in eloquent terms to the work done at Finsbury College during the past thirty-five years, and deplored the fact that the closing of the college was contemplated.

Engineering for October 8 gives some interesting particulars regarding fabricated ships constructed in the United States. It will be remembered that these ships were so arranged as to permit the separate parts to be manufactured by a large number of firms and then assembled at the shipyard. The fabricated freighter has now been afloat long enough to experience sufficiently varied conditions to reveal its seaworthiness. It is a known fact that steamers of this kind have been able to forge ahead in the teeth of storms that have driven larger boats of the usual build to leeward. Replacements in cases of breakdown or injury have been made very promptly. Two steamers, one of which was a fabricated vessel, collided, and each smashed a hawse-pipe; the fabricated vessel was repaired from stock in a few hours, whilst repairs to the other ship took six weeks. Reports made by masters and chief engineers reveal the soundness of the hulls and their unusual tightness and freedom from leakages in the cargo-bilges, etc. Up to April 1 of the current year 120 fabricated craft had been launched from the twenty-eight ways of the Newark Bay shipyard, the keel of the first having been laid in December, 1917—a feat which constitutes a record. It is proposed to carry on this yard, and the Submarine Boat Corporation has taken it over from the Government. The programme provides for extensive developments of both the yard and its neighbourhood, with the idea of making that point a highly equipped port of entry and departure, with dry docks and other repair conveniences.

WE learn that the X-ray and electro-medical business of the High Tension Co. has been purchased by X Rays, Ltd. Arrangements have also been made whereby Mr. Mortimer A. Codd, the author of a well-known book on the subject of high-tension apparatus, becomes the director of research for X Rays, Ltd. The direct association of an X-ray research laboratory with a manufacturing firm has yielded such astonishing results in America that one may look with confidence to the similar plan which has been initiated in this country.

WE are informed that the head offices of Siemens Brothers and Co., Ltd., and of Siemens Brothers Dynamo Works, Ltd., will be removed shortly from Palace Place Mansions, Kensington, London, W.8, to Caxton House, Westminster, London, S.W.1.

Our Astronomical Column.

THE NOVA IN CYGNUS.—This object has continued to decline in brilliancy at a fairly steady rate. Mr. Denning writes that since the end of August the star has lost light at a rate equivalent to one-tenth of a magnitude daily. The nova has exhibited features differing in several respects from those of the bright novæ of 1901 (Perseid) and 1918 (Aquilid), which showed remarkable fluctuations in their declining stages and presented phenomena analogous to those of ordinary variable stars. It seems, in fact, as though the new stars of 1901 and 1918, after their great outburst and quick decline, were subject to a series of minor outbursts affecting them at short and fairly regular intervals.

No such disturbances have apparently been observed in the case of Nova Cygni. At Bristol, during the fifty-five nights from August 20 to October 13 inclusive, the star was observable on forty-seven nights, and it has now become a rather faint telescopic object, its magnitude on October 7 being only 8¼.

It is remarkable that since 1848 twelve new stars have been discovered which were visible to the naked eye, although during the preceding 150 years not one nova was recorded.

CONNECTION OF PLANETARY NEBULÆ WITH HELIUM STARS.—*Astr. Nach.*, No. 5065, has an article by Herr H. Ludendorff on this subject. Herr Ludendorff alludes to the puzzling fact that the planetary nebulæ show a high average velocity in the line of sight, while the helium and Wolf-Rayet stars, with which they have spectroscopic affinity, have a conspicuously low one. It was at first thought that the number of nebulæ on Keeler's list, which was twelve, might be insufficient to deduce a trustworthy mean. But the publication of a much larger list of ninety-six nebulæ by Campbell and Moore has increased the mean radial velocity from 25 to 30 km./sec. It becomes very difficult to make any plausible scheme of cosmogony into which these nebulæ will fit. The low radial velocity of the helium stars is generally explained by their large mass on the assumption that the law of equipartition of energy applies to stellar velocities. There is, however, evidence of considerable mass in the case of the planetary nebulæ also. Campbell noted spectroscopic evidence of rotation in several cases. Combining these with van Maanen's parallaxes, Herr Ludendorff finds values for the masses of four planetaries as 14, 19, 162, and 28, that of the sun being unity. In view of this difficulty, he re-examines the evidence that spectroscopic binary systems give of the masses of the B stars, and states that it appears that those with the largest mass have also the largest radial velocity, and that the same rule appears to hold for the Wolf-Rayet stars.

While this result may help to bridge the gulf between the planetaries and kindred types of stars, it only removes one difficulty to create another. It remains to give a reasonable explanation of the increase of velocity with mass, which is quite opposed to preconceived ideas.

Our Conceptions of the Processes of Heredity.*

By MISS E. R. SAUNDERS, F.L.S.

II.

THE behaviour of the sex-chromosomes as here outlined suffices to account for the occurrence of sex-linked inheritance, but the relations found to hold between one sex-linked character and another need further explanation. If a cross is made involving two sex-linked characters, the F_1 females when tested by a double recessive male are found to produce the expected four classes of gametes, but not in equal proportions, or in the same proportions in the case of different pairs of sex-linked characters. Partial linkage (coupling) occurs of the kind which has already been described for the stock and the sweet pea. The parental combinations predominate, the recombinations ("cross-overs") comprise the smaller categories. The strength of the linkage varies, however, for different characters, but is found to be constant for any given pair. Since the sex-linked factors are by hypothesis carried in the sex-chromosomes, a clean separation of homologous members at meiosis should result in the characters which were associated in the parents remaining strictly in the same combination in each succeeding generation. The fact that this is not the case has led Morgan to conclude that an interchange of chromosome material must take place at this phase among a proportion of the gametes, and that the percentage of these "cross-overs" will depend on the distance apart of the loci of the factors concerned. This phenomenon of linkage may also be exhibited by pairs of characters which show *no* sex-linkage in their inheritance. The factors involved in these latter cases must presumably, therefore, be disposed in one of the chromosomes which is not the sex-chromosome.

To this brief sketch of the main points of Morgan's chromosome theory must be added mention of the extremely interesting relation which lends strong support to his view, and the significance of which seems scarcely to admit of question, viz. that in *Drosophila ampelophila* there are four pairs of chromosomes, and that the linkage relations of the hundred and more characters investigated indicate that they form four distinct groups. It is scarcely possible to suppose that the one fact is not directly connected with the other. The interesting discovery of Bridges (*Journ. Exper. Zool.*, vol. xv., 1913) that the appearance of certain unexpected categories among Drosophila offspring, where females of a particular strain were used, coincided with the presence in these females of an additional chromosome adds another link in the chain of evidence. On examination it was found that in these females the X chromosome pair occasionally failed to separate at the reduction division, and, consequently, that the two XX chromosomes sometimes both remained in the egg, and sometimes both passed out into the polar body. Hence there arose from fertilisation of the XX eggs some individuals containing *three* sex-chromosomes, with the resulting upset of the expectation in regard to sex-limitation of characters which was observed.

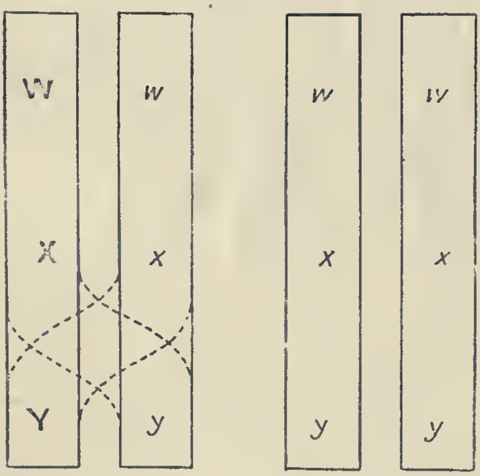
It, however, remains a curious anomaly that in the cross-bred Drosophila male no corresponding crossing-over of linked characters, whether associated with the sex-character or not, has yet been observed. His gametes carry only the same factorial combinations which he received from his parents. For this contrast in the behaviour between the sexes there is at present no explanation. The reverse condition has been described by Tanaka (Journ. Coll. Agr., Sapporo, Japan, 1913–14) in the silkworm. Here interchange takes place in the male, but not in the female.

It must, then, be acknowledged that Morgan's interpretation of the cytological evidence has much in its favour. The striking parallel between the behaviour of the chromosomes and the distributional relations of Mendelian allelomorphs is obvious. The existence in *Drosophila ampelophila* of four pairs of chromosomes and of four sets of linked characters can scarcely be mere coincidence. The employment of the smaller physical unit in accounting for the reshuffling of characters in their transmission commends itself in principle. The necessity for postulating the occurrence of some orderly irregularity in the hereditary process in order to explain the phenomenon of partial linkage is, it will be seen, inherent alike in both theories. When, however, we come to examine the general applicability of Morgan's theory, we are confronted with a considerable body of facts among plants which we find difficult to reconcile with the requirement that factorial segregation is accomplished by means of the reduction division. An instance in which this is particularly clearly indicated is that of the sulphur-white stock. I have chosen this example because here we have to do with two characters which are distinguished with the utmost sharpness, viz. plastid colour and flower form. The peculiar behaviour of this strain is due to the fact that not only are the two factors for flower form (singleness and doubleness) differently distributed to the male and female sides of the individual, as in all double-throwing stocks, but the factor controlling plastid colour likewise shows linkage with the sex-nature of the germ-cells. As a result every individual, even though self-fertilised, yields a mixed offspring, consisting chiefly of single whites and double creams, but including a small percentage of double whites. So far as the ovules are concerned, the mode of inheritance can be accounted for on either theory. According to the reduplication hypothesis, the factors XY, producing singleness, and W, giving white plastids, are partially coupled so as to give the gametic ratio on the female side 7 WXY : 1 WX*y* : 1 *wx*Y : 7 *wxy* (or possibly 15 : 1 : 1 : 15).[1] On the chromosome scheme the factorial group WXY must be assumed to be disposed in one member of the bivalent chromosome formed at meiosis, the corresponding recessive allelomorphs *wxy* in the other. If the three factors be supposed to be arranged in the chromosome in alphabetical order, and if, on separation, a break take place between the loci of the two factors for flower form (as shown), so as to give "cross-overs" of Y and *y* in about 12 per cent. of the gametes, the occurrence of such "cross-overs" would fulfil the required conditions. But the case of the pollen presents a distinct difficulty on this latter view. The sulphur-white stock is distinguished from both the Drosophila and the Abraxas type by the fact that none of the male germs carry either of the dominant characters. In place of the XX—XY form of sex-linked inheritance in the former type and the WZ—ZZ in the latter, we should need to regard this form as constituting a new class, which we might represent as DR—RR, thus indicating that both members of the bivalent chromo-

* From the opening address of the President of Section K (Botany) delivered at the Cardiff meeting of the British Association on August 24. Continued from p. 227.

[1] The letters X and Y are used here to denote particular factors, not, as in Morgan's scheme, the entire sex-chromosome.

some on the male side appear to be inert and able to carry only the recessive characters, and hence are represented as RR, in contrast with the DR pair of the female side. By this formula we can indicate the behaviour of the several double-throwing strains. It is, besides, becoming clear, I think, from recent results that there is no "crossing-over" of these factors on the male side in the F_1 cross-breds. But the real difficulty is to explain why these factors are confined to the female side in the ever-sporting individual. This may result from aberrant behaviour or from loss of chromosomes at some point in pollen development. On this point I hope that evidence will shortly be available. Failing such evidence, the presumption is that the elimination of XY (and in one strain of W) must have taken place *prior to*, and not *at*, the moment of the maturation division. Morgan's proposal to fit the pollen into his scheme for Drosophila by having recourse to hypothetical lethal factors does not appeal to the observer, who finds the pollen all uniformly good and every ovule set. Other examples suggesting premeiotic segregation can be quoted, notably cases among variegated plants and plants showing bud sports, where somatic segregation appears to be of regular occurrence.



Ovules Pollen

It has been argued from time to time that any scheme representing the mechanism of heredity which leaves out of account the cytoplasm must prove inadequate. This general statement has been expressed in more definite form by Loeb ("The Organism as a Whole," 1916), who holds that the egg cytoplasm is to be looked upon as determining the broad outlines—in fact, as standing for the embryo "in the rough," upon which are impressed in the course of development the characteristics controlled by the factors segregated in the chromosomes. The arguments in favour of the view that the cytoplasm, apart from its general functions in connection with growth and nutrition, is the seat of a particular hereditary process are mainly derived from observation upon embryonic characters in certain animals, chiefly Echinoderms, where the inheritance appears to be purely maternal. It has been shown, however, that such female prepotency is no indication that inheritance of the determining factors takes place through the cytoplasm. Other causes may lead to this result. It has been observed, for example, that hybrid sea-urchin larvæ, which at one season of the year were maternal in type, at another were all paternal in character, showing that the result was due to some effect of the environment. Again, where the hybrid plutei showed purely maternal characters it was discovered by Baltzer (*Archiv für Zellforschung*, vol. v., 1910) that in the earliest mitoses of the cross-fertilised eggs a certain number of chromosomes fail to reach the poles, and are, consequently, left out of the daughter nuclei. The chromosomes thus lost probably represent those contributed by the male gamete, for in both parents certain individual chromosomes can be identified owing to differences in shape and size. After this process of elimination, those characteristic of the male parent could not be traced, whereas the one pair distinctive of the female parent was still recognisable. In the reciprocal cross where the first mitosis follows a normal course the embryos are intermediate in regard to the character of the skeleton, thus affording proof of the influence of the male parent. Another type of case is found in the silkworm. Here a certain rate-character determining the time of hatching out of the eggs has been shown to exhibit normal Mendelian inheritance, the appearance that it is transmissible by the female through the cytoplasm alone being delusive. The eggs are always laid in the spring. According as they hatch out immediately so that a second brood is obtained in the year or do not hatch out for twelve months, the female parent laying the eggs is described as bivoltin or univoltin. Now the length of interval before hatching is obviously an egg-character, and therefore maternal in origin. Consequently, when a cross is made between a univoltin female and a bivoltin male the eggs laid are not cross-bred in respect of this character, any more than the seed formed as a result of a cross is cross-bred in respect of its seed-coat, which is a maternal structure. The silkworm mother being univoltin, the eggs will not hatch out until the following spring. The F_1 mother will, in turn, lay eggs which again take twelve months to hatch, since the long-period factor is the dominant. It is not until the eggs of the F_2 generation are laid that we see the expression of the character introduced by the bivoltin father. For some of the egg batches hatch at once, others not for twelve months, showing that of the F_2 females some were univoltin and some bivoltin, and hence that the egg-character in any generation depends upon both the maternal and the paternal antecedents of the female producing the eggs.

Consequently, in the case of an egg-character the effects of inheritance must be looked for in the generation succeeding that in which the somatic characteristics of the zygote become revealed. We find, in fact, that in almost all instances where the evidence is suggestive of purely cytoplasmic inheritance, fuller investigation has shown that the explanation is to be found in one of the causes here indicated. The case of some plants where it has been established that reciprocal hybrids are dissimilar still, however, remains to be cleared up. We know nothing as yet of the cytology of these cases, and it is not improbable that the interpretation may be found in some aberrant behaviour of the chromosomes. An instance in a plant type where a definite connection appears traceable between chromosome behaviour and somatic appearance has been recently emphasised by Gates (*New Phytologist*, vol. xix., 1920), who attributes the peculiarity of the *lata* mutation in Œnothera (which has arisen as a modification at different times from each of three distinct species) to an irregularity in meiosis in the germ mother-cells whereby one daughter-cell receives an extra duplicate chromosome which is lacking in the sister-cell. The cell with the extra chromosome fertilised by a normal germ produces a *lata* individual. On the chromosome view every normal fertilised egg contains a double set of chromosomes, each carrying a complete set of the factor elements. Hence, if some of the one set become eliminated, we can still imagine that a normal, though undersized, individual might develop. The converse relation, where increased size goes with multiplication of chromosomes, was discovered by Gregory (Proc. Roy. Soc., B, vol. lxxxvii., 1914) in a Primula, and occurs also in *Œnothera gigas*, a mutant derived from *Œ. Lamarckiana*. It is interesting in this connection to recall the results obtained by Nemec (*Jahrb. f. wiss. Bot.*, xxxix., 1904, "Das Problem der Begruchtungsvorgänge," 1910) as the result of subjecting the root-tips of various plants to the narcotising action of chloral hydrate. Under this treatment cells undergoing division at the time were able to form the daughter nuclei, but the production of a new cell-wall was inhibited. The cells thus became binucleate. If on recovery these cells were to fuse before proceeding to divide afresh a genuine tetraploid condition would result. So few cases of natural tetraploidy have thus far been observed that we have as yet no clue to the cause which leads to this condition.

The conclusions to which we are led by the considerations which have here been put forward are, in the main, that we have no warrant in the evidence so far available for attributing special hereditary processes to the cytoplasm as distinct from the nucleus. On the other hand, there is a very large body of facts pointing to a direct connection between phenotypic appearance and chromosomal behaviour. In animals the evidence that the chromosomes constitute the distributional mechanism may be looked upon as almost tantamount to proof; in plants the observations on Drosera, Primula, Œnothera, and Sphærocarpus are in harmony with this view. When we come, however, to the question of linkage and general applicability of the conception of "crossing-over" as adopted by Morgan and his school, we are on less certain ground. In Drosophila itself, the case which the scheme was framed to fit, the entire absence of "crossing-over" in the male remains unaccounted for, while the evidence from certain plant types appears to be definitely at variance with one of its fundamental premises. If segregation at the recognised reduction division is definitely established for animal types, then we must conclude that the sorting-out process may follow a different course in the plant.

The question as to what is the precise nature of the differences for which the Mendelian factors stand is constantly before the mind of the breeder, but we are only now on the threshold of investigation in this direction, and it is doubtful whether we can as yet give a certain answer in any single instance. Still less are we able to say what the actual elements or units which undergo segregation may be. In the case of such allelomorphic pairs as purple and red sap colour or white or cream plastid colour, it may be that the difference is *wholly qualitative*, consisting merely in the formation or non-formation of some one chemical substance. But the majority of characteristics are not of this hard-and-fast type. Between some the distinction appears to be one of *range*—to be quantitative rather than, or as well as, qualitative in nature, and range must mean, presumably, either cumulative effect or a force or rate difference. It may well be, for example, that with some change in physiological equilibrium accompanying growth and development, factorial action may be enhanced or accelerated, or, on the other hand, retarded or even inhibited altogether, and a regional grading result in consequence. Range in a character is not confined to, though a common characteristic of, individuals of cross-bred origin. It may be a specific feature, both constant and definite in nature. For example, a change as development proceeds from a glabrous or nearly glabrous to a hairy condition is not an unusual occurrence in plants. In the stock such a gradational assumption of hairiness is apparent no less in the homozygous form containing a certain weak allelomorph controlling surface character, when present with the factors for sap colour, than in those heterozygous for this or some other essential component. We see a similar transition in several members of the Scrophulariaceæ, *e.g.* in various species of Digitalis, in *Antirrhinum majus*, *A. orontium*, *Anarrhinum pedatum*, Pentstemon, and Nemesia. In perennials an annual recurrence of this change of phase may be seen, as in various species of Viola and in *Spiraea ulmaria*. In some, perhaps in all, of these cases the allelomorphs may stand for certain states of physiological equilibrium, or such states may be an accompanying feature of factorial action. A change of phase may mean an altered balance, a difference of rhythm in interdependent physiological processes. In the case, for instance, of a certain sub-glabrous strain of stock in which the presence of a single characteristically branched hair or hair-tuft over the water-gland terminating the midrib in a leaf otherwise glabrous is an hereditary character, it is scarcely conceivable that there is a localisation in this region of a special hair-forming substance. It seems more probable that some physiological condition intimately connected with the condition of water-content at some critical period is a causal factor in hair production, and that this condition is set up over the whole leaf in the type, but in the particular strain in question is maintained only at the point which receives the largest and most direct supply. In this same strain a leaf may now and again be found lacking this hydathode trichome in an otherwise continuous hair-forming series, an occurrence which may well result from a slight fluctuation in physiological equilibrium such as is inherent in all vital processes—a fluctuation which, when the genetic indicator is set so near to the zero point, may well send it off the scale altogether. If, as is not improbable in this and similar cases, we are concerned with a complex chain of physiological processes, investigation of the nature of the differences for which the allelomorphs stand may present a more difficult problem than where the production of a particular chemical compound appears to be involved. In such a physiological conception we have probably the explanation of the non-appearance of the recessive character in certain dominant cross-breds.

Up to this point we have treated of the organism from the aspect of its being a wholly self-controlled, independent system. As regards some characteristics, this may be regarded as substantially the case—that is to say, the soma reflects under all observed conditions the genetic constitution expressed in the Mendelian formula. Correspondence is precise between genotypic potentiality and phenotypic reality, and we have so far solved our problem that we can predict certainly and accurately the appearance of offspring, knowing the constitution of the parents. In such cases we may say that the efficiency of the genetic machine works out at 100 per cent., the influence of external environment at 0. Our equation somatic appearance = factorial constitution requires no correction for effect of conditions of temperature, humidity, illumination, and the like. But most somatic characters show some degree of variability. Phenotypic appearance is the outcome primarily of genotypic constitution, but upon this are superposed fluctuations, slight or more pronounced, arising as the result of reaction to environmental conditions. In the extreme case the genetic machinery may, so to speak, be put out of action; genotypic potentiality no longer becomes actual. We say that the character is not inherited. We meet with such an example in *Ranunculus aquatilis*. According to Mer (Bull. Soc. Bot. de France, i., 27, 1880), the terrestrial form of this plant has no hairs on the ends of the leaf-segments, but in the aquatic individual the segments end in needle-shaped hairs—that is to say, hairs of a definite form are produced in a definite region. Again, Massart (Bull. Jard. Bot. Bruxelles, i., 2, 1902) finds that in *Polygonum amphibium* the shoot produces characteristic multicellular hairs when exposed to the air, but if submerged it ceases to form them on the new growth. Every individual, however bred, behaves in the same manner, and must therefore have the same genetic constitution. In an atmospheric environment genotypic expression is achieved; in water it becomes physiologically impossible. A limitation to genotypic expression may in like manner be brought about by the *internal* environment, for the relation of the soma to the germ elements may be looked upon in this light. Thus in the case of a long-pollened and round-pollened sweet pea, Bateson and Punnett (Report to the Evolution Committee, Roy. Soc., ii., 1905) found that the F_1 pollen-grains are all long, yet half of them carry the factor for roundness. If we take the chromosome view, and if it be presumed that the factor for roundness is not segregated until the reduction division, the cytoplasm of the pollen mother-cells may be supposed to act as a foreign medium owing to a mixture of qualities having been impressed upon it through the presence of the two opposite allelomorphs before the moment of segregation. We should, consequently, infer that the round-pollen shape is produced only when the round-factor-bearing chromosome is surrounded by the cytoplasm of an individual which does not contain the long factor. If, further, we regard the result in this case as indicative of the normal interrelation of nucleus and cytoplasm in the hereditary process, we shall be led to the view that, whatever the earlier condition of mutual equilibrium or interchange between these two essential cell constituents may be, an ultimate stage is reached in which the *rôle* of determining agent must be assigned to the nucleus.

In conclusion, I would appeal for more organised co-operation in the experimental study of genetics. It is a not uncommon attitude to look upon the subject of genetics as a science apart. But the complex nature of the problems confronting us requires that the attacking force should be a composite one, representing all arms. Only the outworks of the fortress can fall to the vanguard of breeders. Their part done, they wait ready to hand over to the cytologists, with whom it lies to consolidate the position and render our foothold secure. This accomplished, the way is cleared for the main assault. To push this home we urgently need reinforcements. It is to the physiologists and to the chemists that we look to crown the victory. By their co-operation alone can we hope to win inside the citadel and fathom the meaning of those activities which take shape daily before our eyes as we stand without and observe, but the secret of which is withheld from our gaze.

The Air Conference, 1920.

THIS Conference, consisting of representatives of aviation in all its many branches, lasted three days, and was organised by the Air Ministry in order to bring together persons interested in the subject in conditions under which urgent problems could be freely discussed with the knowledge that resolutions of the conference arrived at after such discussion would be welcomed by the Ministry as assisting the Secretary for Air in his endeavour to promote in every way the national interests depending on aeronautics.

At the luncheon at which he presided on the first day of the conference, Mr. Churchill, Secretary of State for War and Air, made this abundantly clear. The future of military aviation, he pointed out, depended on the widespread development of civil aviation. "We," he continued—"I am speaking for the Government—intend to help civil aviation by every means in our power. You know our resources are limited, but I hope the day is coming when it will be possible for us to increase to some extent the resources which are available for the development of civil aviation. I do not think three years should be too much to reconstruct the Air Service, so that fathers of every grade in our national life shall be glad to send their sons into it with the feeling that they are giving them a good start in life, with the possibility of a fine career."

In the main (he added), civil aviation must fly by itself, and the function of the Government would be to facilitate its action—to liberate, stimulate, and encourage its action. The Air Estimates had shortly to be considered. He excluded no solution which would be likely to help us through the two or three difficult years ahead of us. No one could have the slightest doubt about the ultimate future. To suppose that the world, having got into the air, was ever going to get out of it, was as absurd as to suppose that the world, having taken to steamships, was going back to schooners and sailing ships. They were gathered there to drive away pessimism and to assert their view that a great and bright future was opening for British aviation.

The conference was held, by the courtesy of the Lord Mayor, in the council chamber of the Guildhall on October 12, 13, and 14, and the room was well filled during all the sessions. The Lord Mayor himself welcomed the members, and in a few well-chosen words expressed his sense of the importance of the occasion. He then gave place to Lord Montagu of Beaulieu, whose interest in aviation is known to all. On the second day Lord Weir of Eastwood, President of the Air Council during a most critical part of the war, presided; while on the third day the chairmen were, in the morning, Lord Beatty and, in the afternoon, Lord Londonderry, Under-Secretary of State for Air, who had been detained in Ireland and was unable, in consequence, to be present at the opening sessions.

The business details were admirably arranged. A paper was read by some recognised authority on the subject under discussion, one or two invited speakers followed, and then the discussion was open to all who cared to contribute.

The conference was fortunate in that three out of the six papers were read by the members of the Air Council responsible for the subjects considered, while other members of the Council took part in the discussion. The audience thus learnt at first hand official views on these matters.

The conference was widely representative; invitations had been sent not only to airmen, to designers and builders of aircraft of all kinds, and to the representatives of aeronautical organisations, but also to the Air Attachés of foreign Powers, to members of learned societies, to representatives of various Government Departments, and to the secretaries of the Transport Workers' Federation and of the United Vehicle Workers.

Turning now to the details of the meeting, the first day was devoted to civil aviation and air services and to the operation of civil aircraft in relation to the constructor.

Major-Gen. Sir Frederick H. Sykes, Controller-General of Civil Aviation, was the author of the first paper. He dealt in detail with the growth and present position of air-mail goods and passenger services (*a*) in the United Kingdom, (*b*) between London and the Continent, (*c*) in foreign countries, and (*d*) in the British Dominions and Colonies. Under (*b*) he gave a most valuable series of statistical tables, showing the amount and type of the general traffic, the number of arrivals in and departures from the United Kingdom, the number of letters carried, customs returns, and the number of accidents. Details as to the last were very striking; the dangers of air traffic are quite small, and it was stated during one of the discussions that all the accidents for some time, so far as could be known, had originated in the failure of the engine or of one of the engine accessories.

A large map brought clearly before the eyes of all the routes actual and projected, and information was given with regard to the proposed services from Paris to Prague, Warsaw, and the Balkan States, and from London to Copenhagen, Hamburg, and Scandinavia. The importance of Egypt to the Imperial routes to Africa and the East was very clearly shown. This point was stressed later by Sir Hugh Trenchard in his paper.

The second part of Sir F. Sykes's paper dealt with the factors contributing to successful air services, and the author concluded a most valuable contribution with suggestions for the future development of those services. Referring to the recommendations of Lord Weir's Advisory Committee on Civil Aviation, he said that the more experience he obtained and the more he considered the case in regard to the scheme of subsidies which Lord Weir's Committee recommended, the more clear he was that those recommendations were sound. He appreciated the argument in favour of allowing industry to stand on its own feet, but he was strongly of opinion that civil aviation must not be allowed to die for lack of direct assistance, the need for which would only be temporary, that was to say, during the period—three to five years—during which old material was being used up, and while new and really suitable types were being evolved. Without this small stimulus it would be very difficult for transport concerns to show enterprise and vigour, even if they could live during the next year or two.

The conference was greatly indebted to Mr. White Smith, the able and energetic chairman of the Society of British Aircraft Constructors, for his paper in the afternoon. After discussing the present lack of financial success in operating air services and its main causes, and emphasising the need for improved trustworthiness, while pointing out the high standard already attained, Mr. Smith proceeded to give a series of most important statistics as to the costs of operating commercial air services, showing the capital expenditure involved in the use of various types of aircraft, the operating costs, and the necessity of improved design as shown by the operating costs.

The tables which accompanied the paper will, no doubt, be published in full, and, while they may need correction in some details—Mr. Handley Page in the course of the discussion did criticise some of the figures relating to one of his machines—they form a most valuable mine of information and must prove of immense service. The economic advantage of the large high-powered machine is very clearly brought out.

The second day was devoted to research. Between the morning and afternoon sessions on that day a most interesting visit was paid to the Croydon Aerodrome to see the arrangements for the departure and arrival of aircraft to and from the Continent and to learn something of the working of an air-port. A large number of the most modern types of machine were on view, and many members had their first flight.

Lord Weir was in the chair, as was specially fitting, for during his tenure of office as President of the Air Council he appointed a Committee on Education and Research, and thus led up to the scheme connected with the Zaharoff professorship which is now being developed at the Imperial College.

Air Vice-Marshal E. L. Ellington's paper gave a full account of the present position of aircraft research and contemplated developments—questions which, as Director-General of Supply and Research, he was specially qualified to discuss. He dealt in the case of aircraft heavier than air with trustworthiness, controllability, performance, safety and comfort, and cheapness. Particulars were also given as to airships and kite-balloons.

Capt. Barnwell, in the afternoon, dealt very fully with the technical aspects of Service and civil aviation. In the course of the discussion reference was made to the important work carried out during the war by the scientific staffs of the Royal Aircraft Establishment and the National Physical Laboratory, and the fear was expressed lest the reductions which had taken place at Farnborough were on such a scale as to impair the efficiency of the research work. It was also pointed out by several speakers that, in addition to a research staff in the scientific establishment, it is essential that builders of aircraft should be in a position to retain the services of a staff of skilled designers, whose work is necessary before the results of research can be made use of in improved machines.

During the afternoon session two resolutions were moved and carried *nem. con.* The first, moved by Major-Gen. Sir R. Ruck, was to the effect "That the Air Conference of 1920 desires to record its emphatic opinion that the rapid development of civil aerial transport is vital to the interests of the Empire, not only as a means of developing its communications, but also as an essential element in its defence, and the conference endorses the recommendations of Lord Weir's Advisory Committee on Civil Aviation and urges their adoption by the Government"; while the second, moved by Prof. Bairstow, urged that sufficient means for researches, both in the Government establishments and elsewhere, should be provided, and that steps should be taken to enable constructors to retain the services of a number of skilled designers.

On the first day a resolution had been carried urging that certain mails should be conveyed by air.

The work of the third day was no less interesting and important. In the morning Air-Marshal Sir H. M. Trenchard, Chief of the Air Staff, spoke on the aspects of Service aviation, the problem of war in the air. He discussed at some length the prospects of young officers in the Force, pointing out that all cannot be taken on permanently, and suggesting that in some cases four years in the Force might take the place of the university. In conclusion, he said that the power of aircraft to cover great distances at high speed, their instant readiness for action, their independence of physical communications, their indifference to obstacles, and the inability of an enemy unprovided with an Air Service to counter their attack, combined to encourage their use more often than the occasion warranted. The power to go to war at will was apt, in fact, to result in a thoughtless application of that power.

In the afternoon session Sir Trevor Dawson dealt with the future of airships. He thought there would be no difficulty in producing ships to travel at eighty miles an hour, thus giving an average speed, allowing for the wind, of sixty miles, and expressed the view that there would be no difficulty in running a regular trans-oceanic service once the trustworthiness and saving of time had been demonstrated. In his opinion, the time to the Cape might thus be reduced from eighteen days to five, and that to India from sixteen days to four or five.

Sir James Stevenson, Civil Member of the Air Council, stated towards the end of the discussion on behalf of the Ministry, and he thought he might say on behalf of the Government, that if a commercial syndicate would offer to take their airships and develop them as a national undertaking, it would be an easy matter to get the Government to agree to give them not only airships, but also aerodromes and the other assets.

A further resolution was passed asking the Government to reconsider the report of the Civil Aerial Transport Committee and the recommendations it contained with the view of adopting such as might now apply.

The conference, which was remarkable in many ways, closed with the usual votes of thanks, and in replying, Lord Londonderry, chairman at the concluding session, expressed the appreciation of the members for the help afforded by the Press.

There is no doubt that aviation, particularly civil aviation, will benefit from the discussions which have taken place, and still more from the fuller consideration which can be given to the papers when published in full. The hope was expressed by many that the conference may become an annual event, and thus afford a regular opportunity for the ventilation of questions of great public interest. R. T. G.

Annual Report of the Meteorological Committee.[1]

THE Report of the Meteorological Committee for the year ending on March 31 last marks the end of a definite stage in the development of the British State Meteorological Service. During the year under review four notable developments occurred: (1) The Office became attached to the Air Ministry instead of being in direct connection with the Treasury; (2) the work of the British Rainfall Organization was incorporated with that of the Office; (3) the co-ordination of the Services of the Navy, Army, and Air Force, which developed during the war, was begun; and (4) inter-Dominion and international co-operation in meteorology, which had largely been in abeyance during the war save for military purposes, began to take a more definite shape. One might add as a fifth important occurrence that the period of service of Sir Napier Shaw as Director of the Office came to an end at the close of the year, though he consented to remain in office until the appointment of his successor was carried through.

An appendix to the report gives the recommendations of the Sub-Committee of the Research Committee of the Cabinet which was appointed to lay down principles on which the State Meteorological Services should be reorganised. It is satisfactory that the wisdom of having one State organisation has been realised, and that while the constitution of the Committee provides for adequate representation of public Departments, the Royal Society and the Royal Society of Edinburgh are also represented. The constitution of the Committee provides that the Controller-General of Civil Aviation shall act as its chairman, but on the representation of the Royal Society it was agreed that a vice-chairman should be elected from amongst the representatives of scientific societies. The Director of the Office, who under the old *régime* was chairman of the Committee, ceases to be a member, but "will act generally as adviser to the Committee on all meteorological and geophysical subjects," and is made responsible for bringing before the Committee "all matters of importance relating to the application, progress, and development of the science of meteorology in which the Meteorological Service might share."

The British Rainfall Organization had a separate existence for sixty years, but it had for some time been evident that incorporation with the growing State Service was desirable, and indeed necessary. On the retirement of Dr. H. R. Mill from active duty as Director of the Organization, the transfer was carried through. Mr. Carle de S. Salter, who was associated with Dr. Mill, has been appointed superintendent of the rainfall work of the Committee, so that the continuity of the work and of the relations with voluntary observers is assured.

The overlapping of the various Meteorological Services which developed during the war was perhaps more apparent than real, but there cannot be two opinions as to the need for co-ordination under a central authority. The Navy, the Army, and the Air Force each had quite distinct and separate needs which were met by separate establishments, but the only serious overlapping which occurred arose from the creation of separate headquarters in London, provided with a staff for forecasting, and each collecting similar information. This overlapping has now, fortunately, disappeared, and a start has been made with the establishment of local civil distributive stations to take the place of war-time stations for supplying to aircraft, shipping, and the general public information derived from detailed study of the weather in a form suitable for practical use. One interesting development in this connection is the provision of an effective local organisation for Scotland, with headquarters in Edinburgh and a local advisory committee.

The effect of the war in bringing to light the value of meteorological information is well gauged by the increase in the *personnel* of the Office. In 1914 the staff of the Office comprised about 20 professional and 60 clerical and technical assistants, while on March 31, 1920, the establishment was 97 professional staff and 278 clerical and technical staff.

The inter-Dominion and international arrangements are still far from being stabilised, but one of the most important developments was a Conference of Dominion meteorologists, which concluded with the following resolution: "That this conference of representative meteorologists of the British Empire assembled together for the first time agree to continue as an association for the exchange of their views from time to time by correspondence upon scientific matters concerning the achievements, requirements, and organisation of their Services, and hereby elect Sir Napier Shaw their first president, and invite the members to submit rules for the guidance and acceptance of the

[1] Fifteenth Annual Report of the Meteorological Committee to the Lords Commissioners of His Majesty's Treasury for the Year ended March 31, 1920. Pp 88. (Cmd. 948.) (London: H.M. Stationery Office, 1920.) Price 9*d*. net.

association." This conference had been preceded by the international meeting in Brussels of representatives of the scientific academies of the Allies, at which meteorology was amongst the subjects considered. A Geodetic and Geophysical Union was set up, one of its branches being meteorology with Sir Napier Shaw as chairman and Dr. Marvin (of the U.S. Weather Bureau) as secretary. A meeting in Paris followed, summoned by the French Government, at which a new international meteorological committee was appointed, with Sir Napier Shaw as president, in continuation of the old committee. A further complication arises out of the convention relating to aerial navigation, which formed part of the work of the Peace Conference, and by Annexe G regulates "the collection and dissemination of statistical, current, and special meteorological information."

What shape international co-operation may ultimately take is sufficiently obscure, but it is satisfactory to know that Sir Napier Shaw, who has been responsible for so great a development in the past, is to continue to act as president of the new International Committee.

E. M. W.

Proposed British Institute for Geodetic Training and Research.[1]

By DR. E. H. GRIFFITHS, F.R.S., and MAJOR E. O. HENRICI.

GOOD maps are necessary for the development of a country, for such purposes as defining property boundaries, limits of mining and other concessions, and so on, as well as for such engineering purposes as railway, road, and canal schemes, hydro-electric schemes, water-supply, irrigation, etc. The importance of good charts, as well as of trustworthy information as to tides and currents, scarcely needs emphasising. An incorrect or out-of-date chart will cause losses due to delays to shipping, even if it does not lead to more direct loss. Anything that will assist in the production of up-to-date and accurate charts is of great and direct benefit to the shipping industry, and through it to the nation. Even when such work has once been completed there is no finality, as both maps and charts require periodical revision at more or less frequent intervals, according to circumstances.

The economical and speedy production of such maps and charts necessitates a thorough knowledge of the principles on which all survey work is based and of the best means of applying such principles under varying conditions. Apart from revision work, there is still a great deal of survey work waiting to be carried out, enormous areas still exist in the Empire which are surveyed very inadequately or not at all.

Very large sums have been misapplied in the past owing to a lack of appreciation of the principles which should underlie all survey work. The Egyptian Survey of 1878–88 cost some 360,000*l.*, and produced incomplete maps of some 2000 square miles. Almost the whole of the work had to be repeated in 1892–1907, when, owing to the adoption of proper methods, and in spite of many difficulties, some 13,000 square miles were satisfactorily mapped at a cost of less than 450,000*l.*

The methods to be adopted depend upon circumstances, the nature of the country, and the objects of the survey. The difficulties to be overcome vary in different parts of the world. The experiences of the various surveyors have been published in their records and reports, but these are not in an easily accessible form, nor is there any general index or summary to be found. The originals are circulated to a limited number of persons and institutions, and buried in libraries, even if their existence is not forgotten. When a new difficulty arises in any survey it has to be tackled *de novo*, though it is quite likely that similar circumstances have arisen before. In such a case it is probable that the surveyor in question does not know of it; and, even if the reports are accessible to him (which they frequently are not), the actual information he wants is most effectually buried. This leads to much waste of effort, as there is no central body to which he can refer.

As regards existing departments and institutions, the Dominion, Indian, and Colonial Surveys are all independent, and, broadly speaking, train their own staff. There are, however, good survey schools in some of the Dominions. The Ordnance Survey produces its well-known maps, which are revised periodically, and they are so complete that no extensive survey work is required by outsiders in this country. This accounts for the lack of attention paid to the subject outside Government Departments, but the result has been that the development of the science of surveying has largely stagnated in this country, the centre of the Empire.

There is, therefore, a distinct need for a school and institution in which students can be trained in the principles of survey work, and where the subject is studied as a whole. This school would also serve as a central information bureau, enabling the scattered surveyors of the Empire to keep in touch with developments, and to which they could apply for information and assistance.

It might seem at first sight that this could and should be undertaken by a Government Department, but this is scarcely possible for various reasons. There is no central authority which deals with the Government Surveys of the Empire, though a link is kept between the Colonial (as distinct from the Dominion) Surveys by the Colonial Survey Committee. The various Surveys and Departments naturally have to consider their own immediate needs first; they are usually short of funds, and consequently not in a position to carry out the work now being discussed. Even if a central authority were formed for this purpose, it could deal only with Government Surveys, and could not train surveyors and engineers for private work.

There seems little doubt that most of the Government Surveys would welcome a school from which they could recruit their staff and an institution to which they could apply for information, and which could keep them in touch with the activities and progress in other parts of the world.

The existence of such an establishment would also encourage the production of improved designs of instruments and the production of new time-saving devices; there have been many such improvements of late years, but mostly from abroad, *e.g.* invar tapes and wires for base measurement (France) and an improved levelling instrument (Germany). There are also many developments in view which require working out, *e.g.* the use of wireless time-signals for the determination of longitude in the field, survey from aircraft, etc. At present makers have little

[1] From an address on "The Urgent Need for the Creation within the Empire of a Central Institution for Training and Research in the Sciences of Surveying, Hydrography, and Geodesy," delivered to a joint meeting of Sections A and E at the Cardiff meeting of the British Association on August 27.

inducement to bring out new and improved patterns of instruments; their largest customers are engineers, who, as a rule, have had a very elementary training as surveyors, and are shy of adopting any new instrument or method.

The above remarks apply particularly to land surveying, but are largely true also of hydrographic work. India and Canada have their own Hydrographic Services, but apart from these the Hydrographic Department of the Admiralty has to deal with all the seas and coasts of the Empire, and also with such others as are not dealt with by their own Governments. The task is great, and the resources available are all too small for the work. Even in home waters there is much to be done, if only due to the changes continually taking place in all estuaries. Apart from the shifting of sandbanks, etc., much of the earlier work is not up to the standard of modern requirements.

There is no school where hydrographic surveyors can receive instruction in the principles and theory of their work, and no staff available for studying methods and instruments and bringing them up to date. The hydrographic staff of the Admiralty is recruited from volunteers amongst the younger officers of the executive branch of the Royal Navy who have passed in navigation. They learn their surveying in the surveying ships while work is in progress, and the staff of trained surveyors is at present so limited that it can give little instruction to the beginners. Many officers after serving in a surveying ship for two or more years return to ordinary duties afloat, or specialise in other branches where their knowledge of survey work is of great benefit to them. The remainder are advanced in rank *pari passu* with the officers of H.M. Fleet. The existence of a school where the theoretical side of the question could be studied would be of great benefit to all.

The principles involved in survey are the same whether applied by land or by sea, and the instruments largely the same. One establishment could usefully study and give instruction in both sides of survey work.

Survey cannot be carried out over large tracts of country without consideration of the science generally known as geodesy, which is really only survey as applied to the earth as a whole. The problems involved in this require not only world-wide data, but also high mathematical skill. Problems interconnected with these are those concerning the tides and terrestrial magnetism, both of great importance to navigation. These, again, are connected with the study of the earth's structure in its wider sense, and so with seismology and geology. These problems may all be summed up in the word "geophysics."

While a knowledge of geophysics is not necessary for every surveyor, no survey authority can function satisfactorily without it. At the same time few such authorities have the staff available for its proper study. A central institution which could be referred to for information would add greatly to the efficiency of the survey authorities.

The need for a British geodetic institute is admitted by all who are acquainted with the nature and importance of the pressing Imperial and scientific problems which depend on the great surveys. The study of such problems has hitherto been left, in characteristic British fashion, to the initiative of enthusiastic individuals or neglected altogether. Take, for example, the case of the tides—so vital a matter to our sailors. While the late Sir George Darwin still lived it could at least be said that one master-mind was devoted, with some approach to continuity, to the study of the great problems which must be attacked and solved if tidal prediction is to advance beyond its present elementary and scrappy state, but since his lamented death in 1912 the subject has lacked attention.

At the request of the British Association, Prof. H. Lamb recently reviewed the whole situation with regard to tides, and in a masterly report indicated the number and importance of the problems awaiting solution. Problems comparable in insistence are connected with the land surveys of our Empire, and a similar review of the general situation, also initiated by the British Association under the stimulus of war, directed attention to the pressing need for some determined effort to attack them. The report opened with this cogent sentence: "There is no institution, association, or department whose business it is to deal with the higher geodesy." Consideration of the report by a special committee, afterwards enlarged, developed in the direction of urging the establishment of a geophysical institute. The need for such an institute has been formally recognised as urgent by the Conjoint Board of Scientific Societies (formed during the war for the study of urgent questions), which appointed a small executive committee (which included the president and secretary of the Royal Society) to press for the immediate establishment of such an institute.

We think it would be difficult to find in any scientific matter greater unanimity amongst all the authorities concerned therein. We trust that sufficient evidence has been given as to both the national importance of the subject and the urgency of the need for action. We await the advent of the *vivus benefactor*, for, as already indicated, there is a consensus of opinion that such an institution should be established within a university by private benefactions, although assistance might, as a consequence, be forthcoming from national funds. The wide ramifications of survey, geodesy, and geodynamics into mathematical, physical, and engineering sciences call for their study in a university rather than in a departmental atmosphere.

The Imperial College as a University of Science and Technology.[1]

THE real issue is whether a useful and worthy type of university can be erected on the comparatively narrow basis of a limited group of studies. In both primary and secondary education there has been a growing tendency to evolve several distinct types of school. Is it only university cloth that must always be cut to the same pattern? If we consider the enormous complexity of modern civilisation and the degree and extent to which it is based upon science, we must think that, in the region of university education, the time has come for a further differentiation of functions, and that the first step in this development should be the creation of a new type of university based upon pure and applied science, not to supersede, but to supplement, the existing type. The normal type of university, embracing a great number of faculties, would still remain, and ought to be, the predominant and prevalent type.

Science, pure and applied, from its nature, is worthy to rank in educational and cultural values with other

[1] Synopsis of a paper on "The Proposed University of Science and Technology: Can a Useful and Worthy University be Based on Pure and Applied Science?" read before the Old Students' Association of the Royal College of Science on October 12 by J. W. Williamson.

university studies. It is qualified not less by its extent to form a foundation neither flimsy nor narrow for a university superstructure. During the past half-century science has developed not only intensively, but also so extensively as to cover vast fields of knowledge previously undreamt of. The result has been the creation of new sciences, differentiated by their own specialised literature, methods, instruments, practitioners, and societies. The step from a faculty of science in a university to a university of science and technology is in line with the steps that have given us to-day separate professors of inorganic chemistry, organic chemistry, physical chemistry, and metallurgy in place of the one-time professor of chemistry whose ambit included all these subjects.

The Imperial College was styled "Imperial" with deliberate intention from the first. From its charter it is clear that it is set to perform real university work of the highest order in science and technology. There is, moreover, a special need which the Imperial College is peculiarly marked out to fill, but which it cannot do adequately unless it has the status of a university with the power to confer degrees. A large and increasing number of students from the overseas Dominions, after completing their courses in the Dominion universities and technical colleges, go to Europe or America to take up what is essentially post-graduate scientific work, especially in its application to industry. The courses of the Imperial College completely satisfy their needs in this direction, better probably than those of any university in the United Kingdom, but the college in its present status cannot give to such overseas graduates who go through the full post-graduate courses anything more than the college diploma. On the other hand, Zurich and some American and German cities have institutes of technology granting degrees. It has already been pointed out that in the industrial and professional worlds the university degree is recognised as a hall-mark and has a commercial value. The consequence is that there is a growing tendency among these overseas graduates and scientific students to go to America instead of to England, so that they may have a veritable and recognised technological degree, and not a mere diploma, to show for the work they do; and the Imperial College is thus being starved of a type of student it was deliberately charged at its foundation to receive and train. The loss, and even the danger, to the Empire of such a tendency are obvious.

Such a university of science and technology would be the keystone of the arch of our technical colleges and polytechnics; it would influence and enlarge the conceptions of technical and scientific education throughout the country and the Empire; and it must be of great benefit to the modern industrial research movement by raising the status of technological science, by pouring out a stream of the most highly trained technologists and research workers, and by being the natural head and crown of the national recognition, so long and disastrously delayed, of the vital importance of scientific research, especially in its application to industry.

There is nothing intentionally or inherently injurious to the University of London or to any other university in the proposal to give a university status to the Imperial College. To propound as a sort of unalterable principle that for Greater London, with a population as large as that of Canada and twice as large as that of Switzerland, there must be one, and only one, university savours rather of an academic dogma than of a balanced educational perspective. The Imperial College and the University of London should be set free to work out each its own future independently of the other. They have divergent aims and interests, and it would be an injurious mistake to force them into an unworkable *mésalliance.*

Agriculture in Egypt and Cyprus.

Agricultural operations in Egypt are entirely dependent upon the Nile, and all extensions in the direction of taking fresh land into cultivation depend upon the way in which more profitable use can be made of the waters of the Nile and of the fertilising mud that it carries with it. The construction of the Aswan reservoir has rendered it possible to retain much of the flood-water, but even now a large amount is wasted that would aid in the expansion of the cultivated area if it could be conserved. Mr. G. C. Dudgeon (Bull. Imp. Inst., vol. xvii., No. 3) sets forth a statistical estimate of the possible and available water-supply, together with the theoretical annual consumption of water for the chief crops. It is suggested that if certain proposed schemes of reclamation were carried out, the whole water requirements of Egypt would be met by less than 60 per cent. of the mean annual discharge of the Nile.

Under the auspices of the Egyptian Ministry of Agriculture, special attention is being given to the various problems of crop and animal husbandry with the view of improving the agriculture of the country (*Agricultural Journal of Egypt*, vol. ix., 1919). The war emphasised the local needs, and revealed deficiencies in many directions, especially in labour, animals, and manures. Motor-tractor ploughing is now advocated, and the adoption of machine-threshing would result in better quality grain and flour, as the present native system introduces a large percentage of mud into the product which cannot be removed by any known mechanical means. As cattle manure is being used more and more as fuel, increased production is now dependent chiefly upon the use of chemical fertilisers, and there are possibilities that if cheap sulphuric acid could be produced, an appreciable supply of sulphate of ammonia and superphosphate could be turned out. Attempts are being made to improve the chief crops, and experiments with various rust-resisting Australian wheats show that some of these offer distinct possibilities for Egyptian agriculture, and are worthy of further trial.

The most important crop is cotton, so much so that the tendency is to increase the area devoted to it at the expense of that utilised for food production, and it is now necessary to import a larger proportion of food than in earlier years. The area under cotton increased steadily to a maximum in 1914 at a greater rate than the total cultivated area, but for the last twenty-three years the average yield per *feddan* has steadily decreased. This, curiously enough, is attributed chiefly to the improvement in the water-supply. The increased water-supply has not been accompanied by sufficiently increased drainage; the soils become saturated and the subsoil-water remains at a high level—a condition of things that is most unsuitable for the satisfactory growth of the cotton plant. Further, the additional supply of water has rendered possible the extension of cotton-growing to new lands which are less fertile than those which have been longer under cultivation, and the lower yields obtained have reduced the general averages. The varieties grown also influence the yield, as many recently introduced ones, possessing other very desirable qualities, give smaller crops than the older kinds.

Since its comparatively recent introduction into Egypt the pink boll-worm, *Pectinophora* (*Gelechia*) *gossypiella*, has so rapidly increased that it has for some years been the chief insect pest of cotton. Much scientific work is being done on its life-history and on its effect on the cotton crop with the view of attacking the pest in the most effective manner, as it may now be classed on a par with the Phylloxera of vines for destructiveness. Field experiments indicate that the effect of Gelechia attack may be rendered less harmful by reducing the water-supply in July and stopping it altogether after the first week in August, as by this means the yield of cotton is increased and the crop ripens earlier.

During the last sixteen years the farmers of Cyprus have exhibited an enlightened and receptive attitude towards modern agricultural methods, with the result that considerable improvements have taken place in the agriculture of the island. These changes are set forth by Mr. W. Bevan in the Bulletin of the Imperial Institute (vol. xvii., No. 3, pp. 302–58), and the resources and possibilities of the island are briefly summarised. About 1,200,000 acres are under cultivation, but another 770,000 acres are either under forest or could be cultivated. The average rainfall is about 20 in. per annum, and the climate, especially in the plains, shows considerable extremes of temperature. Agriculture is the main industry, but methods and appliances are behind the times, though improvements are being effected through the activities of the Agricultural Department. Irrigation is essential, and if a satisfactory solution of the water problem could be reached, large fertile areas which now have to remain fallow could be brought under cultivation for growing cotton and other similar crops and for extending vegetable and fruit culture. A considerable amount of stock-raising is carried on, sheep-rearing being an important industry. Cheese and butter are made from sheep's and goat's milk, largely for home consumption, though some is exported to Egypt. Poultry-farming could be made very profitable, as the climate and food-supply are suitable, but ignorance of proper management at present hinders the industry from prospering.

The chief cereals grown are wheat, barley, and oats, though maize and rye have been introduced during the last few years. Fruit-growing is of much importance, and the export trade in this respect is considerable, some amount of wine and spirits also being produced and sent abroad. Market-gardening is receiving much attention, as there is a good demand in Egypt for fresh vegetables which are raised round the "ports" of Cyprus.

Heredity and Eugenics.

DR. R. RUGGLES GATES contributes to the latest number of the *Eugenics Review* a valuable essay on heredity and eugenics. "Probably in no other species of animal or plant does the number of differences between individuals approach the number to be observed in man." "It has now become a commonplace of observation that the *differences* between organisms, as well as their resemblances, are often inherited." Heredity includes both the entailment of parental variations and the possibility of new variations. A very interesting survey is taken of the inheritance of both physical and mental characters in man. Eugenic action should include, if only there were sufficient knowledge, (1) positive selection for desirable qualities, which are frequently dominant; (2) negative selection against undesirable recessive qualities which appear in collateral or ancestral lines, and may therefore be carried in the family germplasm; (3) isolation of individuals having undesirable dominant qualities; and (4) an effort to foster matings between individuals showing the same desirable recessive quality. Another interesting feature of Dr. Ruggles Gates's paper is the discussion of the question whether there are any details of structure so small or of such a nature as to be beyond the reach of hereditary entailment. Some good examples are given of the continuance of very minute structural idiosyncrasies. As regards the inbreeding and outbreeding of human races, the author concludes that intermixture of unrelated races is from every point of view undesirable. "The more advanced race is diluted and degraded by such intermixture." "The blend is only a blend when considered *en masse*." On the other hand, interbreeding of related races or strains gives increased vigour.

University and Educational Intelligence.

ABERDEEN.—The Lord Rector, Lord Cowdray, will deliver his address in the Mitchell Hall on October 23.

Dr. J. B. Orr, director of the Rowett Research Institute, has been appointed research lecturer in the physiology of nutrition for the ensuing academical year, and Mr. R. H. A. Plimmer, chief biochemist, re-appointed research lecturer in applied biochemistry.

CAMBRIDGE.—Mr. S. M. Wadham, Christ's College, has been appointed senior demonstrator in botany, and Mr. R. E. Holthum, St. John's College, junior demonstrator.

LONDON.—In response to a request made by many of those who attended Dr. Jeffery's public lecture on Einstein's theory of relativity, a course of eight lectures on the same subject by Dr. Jeffery has been arranged at University College. The course will begin on Monday, October 25, at 6 p.m.

A course of ten public lectures on "The Development of Philosophy from Descartes to Leibniz" is being given at King's College by Prof. H. Wildon Carr on Tuesdays at 5.30 p.m. The course commenced on October 12.

OXFORD.—The new academical year has begun with a very large number of fresh entries. The colleges are almost inconveniently full, and most of the scientific departments are overcrowded. The activities of the teaching staff of both University and colleges are being taxed to the utmost. A contributing cause of the present pressure upon the resources of accommodation and teaching is the influx of women students, who are now to be seen in the academic costume lately devised for their use.

On October 14 a new departure was taken by the admission of nearly sixty women to degrees; these included the conferring of the degree of M.A. by decree on the Principals of the women's colleges and halls and of the Society of Oxford Home-Students.

A letter has been addressed by some members of the University to the professors of the arts and sciences and to members of the universities and learned societies in Germany and Austria, expressing a "desire to dispel the embitterment of animosities that under the impulse of loyal patriotism may have passed between us," and suggesting that a reconciliation may surely be looked for in the fields of arts and learning.

MR. J. R. C. GORDON has been appointed professor of materia medica and therapeutics at the Anderson College of Medicine, Glasgow.

The new session of the Aristotelian Society will be inaugurated on Monday, November 8, at 8 o'clock, when the president, Dean Inge, will give an address on "Is the Time Series Reversible?" The meeting will be held in the Conference Hall of the University of London Club, 21 Gower Street, W.C.1.

Free public lectures on physic will be delivered by Sir Robert Armstrong-Jones at Gresham College, Basinghall Street, E.C.2, at 6 p.m., on November 8, 10, 11, and 12. The subjects of the lectures will be "The Air We Breathe," "The Houses We Live In," "The Clothes We Wear," and "The Food We Eat."

The *British Medical Journal* for October 16 states that the University of Heidelberg has received 500,000 marks from Herr F. Behringer, of Bielenfeld, for the erection of an institute for the study of the chemical constitution of albumin. Until the institute is completed the researches will be carried on in the physiological institute under the direction of Prof. Kossel.

We learn from *School Life* for August 15 last that Mr. August Heckscher, of New York City, has given 500,000 dollars to Cornell University to maintain professorships of research and to provide facilities for scientific work. The persons selected for such positions will be relieved of routine teaching and administrative details in order that they may be free to devote themselves to scientific investigation and to the training of future investigators.

On October 18 the report of the Higher Education Sub-Committee on London University was adopted at a special meeting of the Education Committee of the London County Council. Mr. H. C. Gooch said that, having obtained an assurance from the President of the Board of Education that acceptance of the Bloomsbury site for the headquarters of the University would not close the door against grants from Treasury sources towards the building and equipment of the new premises, the Sub-Committee felt justified in recommending the Education Committee to ask the Council to make a conditional building grant. He moved: "That, subject to satisfactory arrangements being made between the Government and the Council of King's College for the reinstatement of King's College on the proposed Bloomsbury site, and in the event of the University of London accepting the site in Bloomsbury referred to in Mr. H. A. L. Fisher's letter dated April 7, 1920, and provided that adequate grants are made by the Government for the erection of administrative buildings on the new site, the Council is prepared to consider an application for a building grant for this purpose subject to the condition that the Council's contribution shall not exceed one-third of the contribution made by the Government in respect of expenditure not exceeding 1,000,000*l.*, and that the Council be recommended accordingly." The resolution was adopted by eighteen votes against five.

The Y.M.C.A. Universities Committee, of which Dr. D. H. S. Cranage is chairman and the Rev. Basil A. Yeaxlee secretary, has issued an admirable educational handbook for the guidance of secretaries and for providing suggestions for the building up of local educational programmes for the various branches of the Y.M.C.A. according to their respective needs. There has been established with this object an education department at the headquarters of the association, 13 Russell Square, W.C.1, from which further advice and guidance can be obtained. It is proposed to establish throughout the kingdom divisional areas connected with the local branches of the Y.M.C.A., each with its educational committee representative not only of the members, but also of the local educational activities, whether official or voluntary. The movement is chiefly concerned with the supply of adult education, the emphasis upon which should lie largely with non-vocational subjects such as religion, history, sociology, science, literature, the arts, and physical education, the technical and vocational studies being offered only when other educational agencies fail to provide them. It is earnestly advocated that one of the greatest needs of our country to-day is a democracy with the power to think and to form judgments, people who have the country's welfare at heart and are prepared to take their place as citizens, understanding clearly the implications and duties of citizenship. Having this purpose in view, the National Council has asked the universities and other bodies co-operating with the association in its war-time educational work to continue to send representatives to form the Y.M.C.A. Universities Committee, and the response has been cordial and complete, a body being formed comprised of eighty-five members representative of all the universities and the university colleges of Great Britain and other voluntary agencies. Well-defined lecture and tutorial courses upon a variety of subjects are arranged, including philosophy, history and geography, literature, art, religion and morals, economics, music and the drama, and suggestions for correspondence groups, for the formation of libraries, and for summer and week-end schools are offered.

From the *Pioneer Mail* for August 13 last we learn that an extraordinary meeting of the Senate of Allahabad University was held on August 7, at which Sir Harcourt Butler, Chancellor of the University, presided. In opening the debate, the Chancellor said that the policy in the United Provinces for higher education was the development of a number of universities of the unitary, residential, and teaching type. The first step in this direction was the establishment of an institution on these lines at Lucknow, and a Bill had been prepared and published which aimed at putting into force the recommendations of the Lucknow University Conference. The second step was that the line between university and school teaching should in future be drawn at the intermediate stage. This involved the re-organisation of secondary education. To this end it was proposed to establish a Board which would supersede the existing School-leaving Certificate Board, and be entrusted with the task of providing the preparation for university work now given in the intermediate classes of the college, and of developing a system of high secondary education. The third step to be accomplished was the re-organisation of Allahabad University. It should be divided into two parts, one, internal, being a self-contained unitary, residential, and teaching university, and the other, external, consisting of affiliated outlying colleges. In conclusion, it was pointed out that primary, secondary, and technical education would not be in any way retarded by lack of finances should the schemes for university reform be adopted. A discussion followed, and the Senate passed a resolution, moved by Dr. Sapru, approving the general scheme for establishing a university at Lucknow, but reserving its opinion as to details. Motions were also passed by which the draft Bill for the establishment of a Board for High School and Intermediate Education, and the report of the committee on the re-organisation of Allahabad University, should be referred to a Select Committee.

In Bulletin No. 50, 1919, of the United States Bureau of Education an account is given of the condition of science teaching in the schools of

Memphis, Tennessee. The bulletin is divided into four sections, dealing with the elementary schools, the central high school, the vocational high school, and the high school for coloured children. In the elementary grades no science or Nature-study enters into the curriculum. At the central high school instruction is divided into eight groups, according to the principal subject taken: Latin, history, science, modern languages, commerce, technical training, home economics, and a course in which any subjects may be taken. In five of these groups no science studies are essential; in one, one science subject is necessary, in another two are required, and in the remaining one five are compulsory. However, in six of the groups either four or five sciences are voluntary, and another offers three "elective" sciences, but in the commercial group no science studies are undertaken. The number of students actually taking scientific subjects amounts to only 28·7 per cent. of the total number of pupils on the books, and measures are suggested for ensuring that a greater number obtain some training in science. Part of the scheme suggested is that general science should be taught in the upper classes of the elementary schools. The number of teachers employed in teaching science, and in many cases their qualifications, appear to be quite inadequate to the task before them. At the vocational high school shop-work is prominent, but it is surprising to note that there are no laboratories equipped for work in science, and no teachers apparently who are competent to teach such subjects. In the high school for coloured children the condition of scientific studies is even worse; it is impossible to do anything but text-book and recitation work, and even this is done only with great difficulty on account of the constant overcrowding of the room. The whole school is reported as unclean and insanitary and in a pitiable condition.

A COPY of the regulations and syllabus of the British School of Malting and Brewing for the year 1920–21 has been received. The school is a department of Birmingham University, and deals with all branches of applied biochemistry, especially as applied to fermentation industries, to agriculture, and to sanitation. Four courses of instruction are provided—a degree course, a diploma course, a part-time series of lectures for brewers and maltsters leading to a certificate, and special short courses on malting and brewing. The lectures for the degree are recommended to students desirous of qualifying as chemists or bacteriologists in industries in which biochemistry plays an important part. A fourth year's work in the department of brewing qualifies a graduate for the diploma in that science. The diploma course is intended for students leaving school who desire training in the principles of malting, brewing, and other fermentation industries. The first two years are devoted to general scientific training as a preparation for the technical work of the third year, which consists largely of acquiring a practical knowledge of brewing and of the methods used by brewers in the judgment and valuation of barley, malt and other requisites of the trade. The part-time course for brewers and maltsters is open to all, but to qualify for the University certificate the candidate must have had two years' practical experience in brewing or malting. The ground covered is similar to that dealt with in preparation for the diploma, but the laboratory work does not go so far into the scientific side of the operations. The short courses provided are intended for those who find themselves unable to attend any of the above classes; such students share all advantages equally with diploma students. A time-table and syllabus of each course are given in the booklet. It is interesting to note that the director of the school, Prof. A. R. Ling, has been given wide powers for aiding competent research workers concerned with fermentation industries by finding accommodation in his laboratories and in other ways. Applications for such assistance should be made direct to the director of the school.

Societies and Academies.

MANCHESTER.

Literary and Philosophical Society, October 5.—Sir Henry A. Miers, president, in the chair.—Dr. A. E. **Oxley**: Recent researches in magnetism. After dealing briefly with the nature of ferro-magnetism, paramagnetism, and diamagnetism, the author considered the characteristic variations of these properties over a range of temperature varying from that of liquid air to 300° C. Practically all substances show a change of magnetic property when crystallisation takes place, and in the case of certain diamagnetic substances definite hysteresis loops with respect to temperature have been obtained. These loops are similar to those shown by nickel-steels which are ferromagnetic. The experimental results were interpreted in terms of the electron theory of magnetism, and finally extended, through Tyndall's work on the deportment of crystals in a magnetic field, to interpret the nature of crystal structure and the spatial distribution of electrons within the atom. The atomic configuration so deduced is similar to that of the cubical atom developed by Lewis and Langmuir, and distinct from that of the Bohr theory, which fails to account for the magnetic properties. It is considered, however, that these theories may be brought into line in the near future by a due recognition of the possible differences between radiating and non-radiating matter.

PARIS.

Academy of Sciences, September 27.—M. Léon Guignard in the chair.—A. **Appell**: A partial differential equation of the theory of hypergeometric functions.—F. E. **Fournier**: Concerning the apparent displacement of some stars in the total eclipse of the sun of May 29, 1919.—M. **Lugeon** and N. **Oulianoff**: The geology of the Croix-de-Fer massif. The sedimentary zone separating the massif of Mont Blanc from that of the Aiguilles-Rouges has been usually considered as a simple synclinal, but E. Paréjas has recently proved the existence of two synclinals. A study of the region between the Arve and the Trient has now shown that the structure is still more complex, a detailed description of which is given.—C. **Sauvageau**: The indigenous marine algæ capable of furnishing gelose.—V. **Burson**: A solar prominence with great radial velocities. Photographs taken on September 8 showed a prominence visible on the photograph of the lower layer—a phenomenon of great rarity. This was followed up by a series of photographs, and certain parts were shown to have a radial velocity greater than 132 km. per second.—H. **Deslandres**: Remarks on the preceding communication of V. Burson.—J. **Welsch**: Position of the springs on the concave bank of rivers in permeable limestone strata.—R. **Cerighelli**: The gaseous exchanges of the root with the atmosphere. The respiration of plant-roots placed in a confined atmosphere takes place similarly to that occurring with other plant organs; the ratio of carbon dioxide evolved to oxygen absorbed varies between 0·7 and 1·0, according to the species. These results are for detached roots; the modifications caused by contact with a very moist atmosphere and by leaving the plant attached to the roots under experiment are also described.—E. **Rousseaux** and M. **Sirot**: The nitrogenous materials and phosphoric acid during the ripening and germination of wheat.—A. J. **Urbain** and P. **Marty**: The influence of the subterranean work of the mole on the flora of the pasturages of Cantal. The effect of the work of the mole is to drain the soil, to favour the germination and growth of the seeds, and to introduce new plants, often useful.—P. **Wintrebert**: The relations between the aneural ectodermic irritability and the nervous and muscular working in the embryos of Amphibians.—A. **Krempf**: The tentacular apparatus of *Coeloplana gonoctena*.

SYDNEY.

Linnean Society of New South Wales, August 25.—Mr. J. J. Fletcher, president, in the chair.—T. G. **Sloane**: A list of the species of Australian Carabidæ which range beyond Australia and its dependent islands. Forty-four Australian species are recorded from localities outside Australia and its dependent islands as follows:—Africa 1, Amboyna 1, Aru Islands 1, Asia 6, south-east Asia 4, Borneo 1, Burma 1, Celebes 3, Ceylon 5, Egypt 1, India 2, Java 8, Lord Howe Island 2, Malay Archipelago 6, New Caledonia 12, New Guinea 10, New Zealand 3, Siam 1, Sumatra 1, and Sumbawa 3.—T. **Steel**: Dental encrustations and the so-called "gold-plating" of sheep's teeth. For many years past there have appeared from time to time in newspapers and magazines published all over the world statements as to the occurrence of a metallic encrustation on the teeth of sheep. Popularly this encrustation, being frequently of a yellow tint, has been attributed to gold, supposed to have been derived from particles of that metal scattered about the pastures. Complete analyses are given of the encrustation from sheep, ox, man, and a number of other animals, and it is shown to consist of a phosphatic salivary deposit or calculus, and to be common to the teeth of all mammals and of several other animals.—Marjorie I. **Collins**: The structure of the resin-secreting glands in some Australian plants. An account of certain types of glandular hair and of the development of the glands observed during an investigation of the resinous secretion of the bud in seven Australian genera of the natural orders Sapindaceæ, Leguminoseæ (sub-order Mimoseæ), Compositæ, Goodeniaceæ, and Myoporineæ.—Prof. W. N. **Benson**, W. S. **Dun**, and W. R. **Browne**: The geology and petrology of the Great Serpentine Belt of New South Wales. Part ix. The geology, palæontology, and petrography of the Currabubula district, with notes on adjacent regions. (1) More than ninety species are recognised, comprising corals, bryozoa, brachiopods, pelecypods, gastropods, scaphopods, cephalopods, and trilobites, of which five forms previously reported have now been for the first time critically examined, seven are new records for the State, and fifteen species and three varieties are described as new. One new genus of corals is also proposed—a simple turbinate form with a corallum of the Lithostrotion type. (2) A comparison of the Burindi fauna with the Lower Carboniferous faunal succession in the British Isles shows that, on the evidence of thirty-one British species of brachiopods in the Burindi series, it should be placed at the very base of the Viséan series or on the Tournaisian-Viséan boundary. This accords remarkably well with De Koninck's conclusions put forward forty years ago.

Diary of Societies.

THURSDAY, OCTOBER 21.

ROYAL SOCIETY OF MEDICINE (Dermatology Section), at 5.

ROYAL AERONAUTICAL SOCIETY (at Royal Society of Arts), at 5.30.—Squad.-Ldr. R. M. Hill: A Comparison of the Flying Qualities of Single- and Twin-engined Aeroplanes.—C. Baker: Night Flying.

INSTITUTION OF MINING AND METALLURGY (at Geological Society), Special General Meeting, at 5.30; at 5.45.—J. Morrow Campbell: The Origin of Primary Ore Deposits.

CHILD-STUDY SOCIETY (at Royal Sanitary Institute), at 6.—Dr. A. R. Abelson: A Psychological Study of the Delinquent Child.

FRIDAY, OCTOBER 22.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Prof. A. Keith: Demonstration on the Contents of the Museum.

ROYAL SOCIETY OF MEDICINE (Study of Disease in Children Section), at 5.

INSTITUTION OF MECHANICAL ENGINEERS, at 6.—Capt. H. Riall Sankey: Presidential Address.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—F. Martin-Duncan: Birds and Beasts from many Lands.

JUNIOR INSTITUTION OF ENGINEERS (at Caxton Hall), at 8.—A. H. Fitt: Impulse Turbines.

ROYAL SOCIETY OF TROPICAL MEDICINE (at 11 Chandos Street, W.1), at 8.30.—Prof. W. Yorke: The Present Position of Trypanosomiasis Research.

MONDAY, OCTOBER 25.

FARADAY SOCIETY AND PHYSICAL SOCIETY OF LONDON (at Institution of Mechanical Engineers), at 2.30.—Joint Discussion on The Physics and Chemistry of Colloids and their Bearing on Industrial Questions. Prof. The Svedberg: A Short Survey of the Physics and Chemistry of Colloids.—Discussion on Emulsions and Emulsification. Opener: Prof. F. G. Donnan.—W. Clayton: Emulsion Problems in Margarine Manufacture.—S. S. Bhatnagar: Reversal of Phases in Emulsions and Precipitation of Suspensoids by Electrolysis: an Analogy.—Discussion on Physical Properties of Elastic Gels. Openers: E. Hatschek and Prof. H. R. Procter.—S. C. Bradford: The Reversible Sol-gel Transformation.—Dr. J. O. W. Barratt: The Structure of Gels.—Discussion on Glass and Pyrosols. Opener: Sir Herbert Jackson.—Discussion on Non-Aqueous Systems. (a) *Nitrocellulose*. Opener: Sir Robert Robertson.—F. Sproxton: Non-Aqueous Colloid Systems with Special Reference to Nitrocellulose.—Dr. G. Barr and L. L. Bircumshaw: The Viscosity of Some Cellulose Acetate Solutions. (b) *Rubber*. Opener: B. D. Porritt: The Action of Light on Rubber.—Discussion on Precipitation in Disperse Systems. Openers: Dr. R. C. Tolman and Dr. R. S. Willows.—J. N. Mukherjee: The Origin of the Charge of a Colloidal Particle and its Neutralisation by Electrolytes.—W. Clayton: Coagulation of Inorganic Suspensions by Emulsions.—Discussion on Cataphoresis and Electro-endosmose. Opener: Prof. A. W. Porter.—Dr. W. Ormandy: Some Practical Applications of Electro-endosmose and Cataphoresis.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Prof. S. G. Shattock: Demonstration of Pathological Specimens in the Museum.

ROYAL SOCIETY OF MEDICINE (Odontology Section), at 8.—W. H. Dolamore: The Importance of Clinical Observation in Dental Surgery (Presidential Address).

MEDICAL SOCIETY OF LONDON, at 8.30.—Prof. J. B. Leathes and others: Discussion on The Determination of Degree of Renal Function.

TUESDAY, OCTOBER 26.

SOCIOLOGICAL SOCIETY (at 65 Belgrave Road), at 5.15.—H. Carter and R. Unwin: Impressions of the New Germany.

ROYAL SOCIETY OF MEDICINE (Medicine Section), at 5.30.—Dr. F. Parkes Weber: The Differentiation of the Secondary Forms of Polycythæmia Rubra.—Dr. Paterson: Notes on a Case of Transient Polycythæmia in a Child.

ROYAL ANTHROPOLOGICAL INSTITUTE, at 8.15.—Rev. R. A. Lorrain: The Wild Head-hunting Tribes of Lakherland: their Manners and Customs.

WEDNESDAY, OCTOBER 27.

INSTITUTE OF AERONAUTICAL ENGINEERS (at Royal College of Science), at 7.45.—Col. N. T. Belaiew: The Structure of Steel.

THURSDAY, OCTOBER 28.

CHEMICAL SOCIETY (at Institution of Mechanical Engineers), at 8.—Dr. M. O. Forster: The Emil Fischer Memorial Lecture.

ABERNETHIAN SOCIETY (at St. Bartholomew's Hospital), at 8.30.—Sir St. Clair Thomson: Recollections of Joseph Lister by one of his House-surgeons.

ROYAL SOCIETY OF MEDICINE (Urology Section), at 8.30.—Sir Thomas Horder: The Treatment of Sub-acute Nephritis by Decapsulation; with an Account of Four Cases.—W. Bonney: A New Operation for Nephroptosis.

FRIDAY, OCTOBER 29.

ROYAL GEOGRAPHICAL SOCIETY (at the Æolian Hall), at 5.—T. A. Barns: In the Land of the Okapi and the Gorilla.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Prof. A. Keith: Demonstration on the Contents of the Museum.

INSTITUTION OF MECHANICAL ENGINEERS (Informal Meeting), at 7.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—H. W. Bennett: Winchester: The Cathedral, the School, and the Hospital of St. Cross.

CHEMICAL INDUSTRY CLUB (at 2 Whitehall Court), at 8.—Annual Meeting.

ROYAL SOCIETY OF MEDICINE (Epidemiology and State Medicine Section), at 8.30.—Dr A. K. Chalmers: The Function of the Isolation Hospital in a General Scheme of Hospital Provision.

Museums in Education.

FOR many years past a number of people, approaching the question from diverse or even opposite sides, have agreed that our museums should do more for education, and that our educational establishments should be brought into closer touch with museums. The desire for mutual aid is expressed by representatives of science, art, classical studies, history, and industry. A discussion of the subject in the Education Section of the British Association at Birmingham in 1913 led to the appointment of a committee drawn from many sections "to examine, inquire into, and report on the character, work, and maintenance of museums, with a view to their organisation and development as institutions for education and research, and especially to inquire into the requirements of schools." A wide reference—and the committee, composed of university officers and professors, school inspectors and teachers, humanists and men of science, administrators and museum curators, has taken a wide sweep and a broad view. The final report, now before us,[1] was deferred owing to the difficulties and economies of wartime, and is now published with the forced omission of the detailed data on which the conclusions are based. This, however, makes it the easier reading, and read it should be by all interested in either museums or education.

Those who are to be educated by museums may be classed as the general public, the pupils of primary and secondary schools, students at universities and similar institutions, and, finally, postgraduate and other advanced students. In the past the attempt to reach these people has been subject to many difficulties. The name "museum" has diverse connotations; while some museums, of modern origin, are purely educational in aim, those of older foundation were not, and cannot be, primarily engines of education. None the less, the officials of the latter have long been anxious to enlarge this side of their work. The appeal to the general public, initiated by Flower in the Natural History Museum, has been followed and surpassed elsewhere, notably in the United States. With us the provision of guide-books and of the human guides so strenuously advocated by Lord Sudeley demands more money than is forthcoming. But the real difficulty in our larger museums has always been the conflicting aims of the exhibition galleries. This will not be overcome until the reference series for collectors and advanced students are separated from the more popular and elementary exhibits, just as the research collections are already separated. Above all, in every museum there is the difficulty of the overworked and underpaid curator.

Turning to the other side, we have found difficulties in the schools. The value of the museum and of museum material has not been appreciated by teachers. It was too much trouble. "When the ground is covered by manuals, why try to drag in pictures or objects which are a bother to look after, and which distract the pupil's attention from his book? And, as for taking the class to a museum, how are we to find either time or money?" Our great public schools have some excellent museums, but there is little or no evidence that they are used in school teaching. Our universities have museums, or collections specially designed for their students, but too often they compete rather than co-operate with the public museums of their neighbourhood. As for industries, they keep their own secrets, and (except in a few instances, as the Potteries museum) do not realise the value of museums for their purposes. Possibly curators, too, have not always realised the service they themselves might render to industry.

In these matters, as in so much else, the war has produced a change of conditions and a change of view. Museums have proved their usefulness

[1] British Association, Section L (Cardiff, 1920). "Museums in Relation to Education." Final Report of Committee (Prof. J. A. Green, chairman; Mr. H. Bolton and Dr. J. A. Clubb, secretaries; Dr. F. A. Bather, Rev. H. Browne, Mr. C. A. Buckmaster, Prof. E. J. Garwood, Dr. A. C. Haddon, Dr. H. S. Harrison, Mr. M. D. Hill, Dr. W. E. Hoyle, Sir H. Miers, Prof. P. Newberry, Mr. H. R. Rathbone, Dr. W. M. Tattersall, Sir Richard Temple, Mr. H. Hamshaw Thomas, Prof. F. E. Weiss, and Dr. Jessie White). Pp. 14. Price, post free, 6*d*. Six or more copies at 2*d*. each.

to the State; the public has protested in surprising fashion its affection for museums. Recent legislation has recognised this in removing the rate-limit for municipal museums, and in facilitating the promotion of museums by the education authorities of the counties and boroughs. The committee, though it welcomes this change of attitude, does not do so without warning and criticism. It recognises that municipal and national museums are not the only kinds deserving of State- or rate-aid; there are semi-private museums which need it even more. It is a little afraid of control by an "authority" that may know all about education, but certainly knows little about the governance, organisation, and financial needs of museums; and it would like to see "some national or central authority fully conversant" with such matters, to whom local museum committees might turn for advice—or perhaps something still more satisfying. Such welcome as the committee does give to the education authority seems due to its hope that the education grant will pay for the extra material and the special staff required for such desirable works as loan collections for schools or school classes in the museum. It also suggests that recent legislation may find its best fruits in establishing museums in towns as yet unprovided with them.

It is rather striking that, of the five general conclusions emphasised by the committee, the first four have reference to research. In research the universities should co-operate. To aid research, lists of contents should be published. Grants in aid should be proportioned to the research conducted by a museum, no less than to its other activities. Curators must have had a university training, fitting them for research as well as for administration. All this may not seem to have much to do with education. But the committee is right. Granted that the collection and preservation of material objects constitute the *differentia* of a museum, it is clear that the first necessity is the study of those objects. "This research must be prosecuted if museums are to fulfil their highest function, which is the advancement of Science, Art, and Industry." Research is a necessary preliminary to any and every other function of a museum, and not least to the function of education. We cannot deal here with the many practical recommendations scattered through the body of the report, and perhaps not sufficiently distinguished by type or spacing from their context. They should prove acceptable and useful to both educationists and museum officials. We would, however, reiterate our high appreciation of the committee's labours and of the firm stand that it takes on the really fundamental principles.

The chief conclusion we would ourselves draw from this report is that there is a vast body of experience relating to the proper management of museums and their use in education, and not in that alone. Much of it forms the basis of this report; much is to be found in the publications of the Museums Association and in a few books that have been published. But the local authority faced with the task of founding a museum, or of taking over and utilising one already in existence, knows nothing of all this. On this ground, then, but not on this alone, we warmly approve the suggestion that there should be a central council or board, composed of persons with knowledge and sympathy, and endowed with the requisite powers, to watch over and aid the inception of museums, to co-ordinate their work when established, and to bring them into touch with the national museums. Such a council as we have in view would certainly not wish all museums to conform to one pattern or to rigid rules, but it might save much duplication of work and expenditure and much ill-directed effort.

Scientific Methods of Design and Control in Chemical Industry.

Ministry of Munitions. Department of Explosives Supply: Preliminary Studies for H.M. Factory, Gretna, and Study for an Installation of Phosgene Manufacture. Pp. xvi+145. (London: H.M.S.O., n.d.) Price 15*s*. net.

DURING the war an enormous amount of work was done by the Department of Explosives Supply in the design of chemical plant, processes, and works, and in the construction, organisation, and control of the numerous national and other factories dealing with the manufacture of explosives and closely related substances. Lord Moulton, who was Director-General of Explosives Supply, and whose magnificent work in the cause of Great Britain and the Allies cannot be overestimated, was fortunate in having associated with him a devoted band of men of exceptional ability and knowledge. Pre-eminent amongst these on the technical and scientific side was Mr. Kenneth B. Quinan, who was responsible for the design, construction, and organisation of the works controlled by the Factories Branch. Where all worked so splendidly, it might seem invidious to single out one name. But the writer well knows that amongst the hundreds, or indeed thousands, of men who fought the war behind the front so splendidly in the Department of Explosives Supply there is not one who did not look up to "K. B. Q." as the great inspirer and organiser, or who failed to realise what the nation owed to his genius, personality, and indefatigable labour.

Mr. Quinan was also a great educator. One cannot explain this better than by quoting from the excellent preface to the present book.

"Mr. Quinan introduced methods of studying the various problems which arose and setting out the results, which were clear and very helpful to all who were connected with the erection of the plant and works, or the subsequent manufactures carried out. . . . Mr. Quinan insisted that the steps in a calculation by which certain results were obtained should be set forth so distinctly that they could easily be followed, and that the author himself might be able to trace the line of his reasoning and action after the matter had passed from his attention, without having to rack his brains to see how he had obtained his results. He thoroughly believed in the advantage of letting all those who were engaged in directing and carrying out work have the fullest possible understanding of what they were doing, and this policy bore excellent fruit in the results obtained at the works managed by the Factories Branch, which were carried on under the initial disadvantage of staff and workers largely without expert knowledge of the work they had to do."

In pursuance of this policy, every working drawing was accompanied by a well-reasoned description of the purpose and function of the various parts of the apparatus or plant, and the technical staffs at the various factories were constantly engaged, at Mr. Quinan's instigation, in studying the working of their plant, carrying out laboratory and plant researches, and vying with each other in a continuous process of improvement in the efficiency of the plant and in their understanding of the scientific principles underlying its design and operation.

It can well be imagined that, as a result of these methods, Mr. Quinan accumulated a vast amount of material, scientific and technical, of the greatest value to the nation, and especially to the young men who are destined to become the technical workers and the leaders of the next generation. It was Mr. Quinan's earnest wish that as much as possible of this material should be edited and published after the war for the benefit of the scientific institutions of the country and for all those young men who are already engaged in the chemical industries of the British Empire. It is extremely fortunate for the successful execution of this great work that the Government has entrusted it to Mr. William Macnab, who was a member of the Department of Explosives Supply throughout its whole existence (and of the original Committee of the War Office from which the Department sprang), and very closely connected with its development and with every phase of Mr. Quinan's work.

The present volume is published under the *aegis* of the Ministry of Munitions, but the continuation of the work has been entrusted to the Department of Scientific and Industrial Research, which will publish a number of other volumes. It would be impossible to exaggerate the national importance of this work. To apply scientific principles and data to the development of industrial plant and processes requires just as much scientific method, research, and intellectual labour as the discovery of the general principles and data of science. A failure to realise this, an all-too-narrow interpretation of the words "science" and "research," accounted for many errors in the past and for much of our unpreparedness when the stress of war came so swiftly upon us. There was, however, another factor, and one of cardinal importance. There existed few, if any, examples, accessible to all, and drawn from real practice, of the methods employed by the great scientific designers and creators of industry. How does one design a plant, a process, or a works? Who was there to answer that question? How did the Glovers, Deacons, Hurters, and Monds—to mention only a few great names drawn from chemical industry—set about their work? There were plenty of books on chemical technology, but not a word on the real thing, the method of research, the way to go about it. It is a supremely difficult thing to apply science scientifically and successfully. You are not free to choose your variables, or to eliminate unpleasant ones. The whole universe is on the top of you. You cannot say that you are a chemist and, therefore, do not intend to worry about the physical and engineering aspects of the problem. Unfortunately, a chemical plant is a bit of Nature, and includes, therefore, all the sciences. And Nature is not particularly concerned with the limitations of one's education or one's particular tastes and temperament. It is no doubt perfectly true that a man can learn to be a real technical chemist only by long practical experience in works. But it is of the greatest importance for the training of young men in the later stages of their work at the universities and higher technical schools that those whose capacities and temperaments incline them to industrial work should have the possibility of studying some first-class examples of how scientific principles and data are utilised and developed in the creation of processes and plant.

For the first time in the history of chemical science this is made possible by the publication of these volumes. A close study of this and the succeeding volumes will show the young chemist how physics, physical chemistry, and engineering must be combined with exact chemical knowledge. He will find here large numbers of drawings in plan and elevation which he can utilise in his study of engineering drawing as applied to chemical plant. He will see how, step by step, leaving nothing to chance, the elaborate calculations are carried out whereby from a number of fundamental data the complete flow-sheets and precise working details of large chemical factories are quantitatively developed. He will learn how every technical chemical problem involves much knowledge of physics and engineering, and he will see how much the practical chemical designer has to do with questions of heat absorption and evolution, and the transfer and transmission of heat. Most important of all, he will learn that the object of the truly scientific designer is to guess at nothing, but, if possible, to reduce everything to fundamental principles, precise quantitative data, and systematic calculation.

In the present volume the larger part—*i.e.* that relating to the design of the great Gretna works for the production of cordite and nitroglycerine—presents to the student of chemical industry and chemical engineering a unique object for study. The plan adopted by Mr. Macnab is to set forth systematically all the calculations as to quantities and capacities to be dealt with by the various sections of the plant and works. These calculations are summarised in a complete series of flow-sheets. The various sections and the general lay-out are illustrated by a large number of engineering drawings, all of which are accompanied by detailed descriptions which add enormously to their value. The "Study for an Installation of Phosgene Manufacture" is a fine piece of work, and an excellent example of Mr. Quinan's method of utilising thermo-chemical and physical data in the solution of a technical chemical problem. This "study" is a little classic, and will undoubtedly prove a source of inspiration and instruction of the very highest value. The student can here see for himself how, given certain chemical and physical data, the trained and experienced chemical designer sets to work to decide between the claims of rival processes and to develop the technical details of the selected one.

Mr. Macnab is warmly to be congratulated on the splendid way he has carried out his work. The intellectual and manual labour involved must have been very great, but they are justified by the excellence of the result. It can be stated with certainty that the present volume and its successors will constitute a handbook of applied chemical and physical science without its equal in any language. The effects as regards the scientific training of the new generation of chemical students will be far-reaching. The Explosives Supply Department had to produce in gigantic measure the chemical weapons of destruction. In these volumes the work of the Department will live for many years to come as a great and noble contribution to the edifice of reconstruction. It is earnestly to be hoped that the Government Departments now concerned will realise the vast importance of this undertaking and so publish ample editions of the various volumes. There exists here a splendid opportunity of extracting good from the terrible waste of war, and of sowing seed which will produce a rich harvest in the years to come.

One cannot put this volume down without thinking of the great days when Mr. Quinan worked at Storey's Gate. The unique professional knowledge derived from many years of technical experience, the unremitting work of a powerful and vigorous mind, and the irradiating influence of a great, genial, and unselfish personality were unreservedly put at the disposal of the British Empire. An atmosphere of good fellowship and of equal comradeship in work pervaded every branch. Everyone who came under the influence of Mr. Quinan was stimulated to put forth his best in the general cause.

These volumes will constitute an enduring memorial to the work of one of America's greatest sons, a man who did as much as anyone to win the Great War, and in doing so won the respect and affection of all who knew him.

F. G. DONNAN.

Experimental Science in India.

The Life and Work of Sir Jagadis C. Bose: An Indian Pioneer of Science. By Prof. Patrick Geddes. Pp. xii + 259. (London: Longmans, Green, and Co., 1920.) Price 16*s.* net.

THE author of this biography was fortunate in his subject: it was no hard task to write an interesting chronicle of so eventful a life and of so striking a personality. Sir J. C. Bose is equally fortunate in his biographer: his life and work are set forth with conspicuous literary skill, scientific knowledge, and sympathy with the East. The result is a singularly instructive and eminently readable book.

The story of his life shows that Sir J. C. Bose had to contend, at all stages, with difficulties of every kind. The first and most fateful was that of securing a university education in England. It is narrated how this difficulty was overcome, so that in 1881, at the age of 23, he was able to enter the University of Cambridge as a scholar of Christ's College, the college of which his brother-in-law, Mr. A. M. Bose, the first Indian wrangler, had become a member ten years previously. It may be incidentally mentioned here that Mr. Fitzpatrick, who is mentioned as one of his college friends (p. 29), is not, as stated, Master of Emmanuel College, but President of Queens' College. Having successfully completed his university career, Bose returned to India to face the next serious difficulty—that of obtaining a suitable educational post. It is explained how impossible it seemed to the official mind that a native of India should be fitted by ability and attainments for a professorship in physical science—there was no precedent for such a claim! However, chiefly by the influence of the then Viceroy, Lord Ripon, Bose was appointed professor of physics in the Presidency College, Calcutta, a post which he held until 1915. During this period he was busily engaged, not only in maintaining and increasing the efficiency of his department by securing adequate laboratory accommodation, but also in carrying on the researches that have made his name famous.

Of these researches the author gives an attractively lucid and succinct account. The first were wholly physical, and to these three chapters (iv.-vi.) are devoted. Their main subject was that of the properties of the Hertzian electric waves, by which wireless telegraphy is effected. It is of interest to note that, so far back as 1895, Bose had demonstrated the passage of these waves from one part to another of his laboratory building. In the course of this work he observed that his metallic receivers manifested signs of "fatigue," an observation which led him to a comparison, in this respect, of metals and of animal- and plant-tissues, with the result that he found them to be essentially identical (chap. vii., "Response in Living and Non-Living"). He became so deeply interested in the study of the irritability and movements of plants that for the next twenty years he devoted himself almost exclusively to it. An adequate account of his remarkable work in this direction is given in chaps. ix.-xv. The results may be summed up in the brief statement that the phenomena of irritability of animals and plants are altogether analogous, and that the multiform movements of plants are susceptible of a simple universal explanation, depending fundamentally on the quantity of stimulus received. These great generalisations were rendered possible by the employment of recording apparatus much more delicate than any previously devised, and capable of magnifying the minute movements a thousand or even a million times. The last, and the most formidable, of the difficulties to be overcome was that of securing recognition of his work. So long as Bose's researches were confined to purely physical subjects it did not arise; but when he trespassed into the domain of physiology opposition became strong in this country, though on the Continent and in America his results were received with enthusiasm. Here the antiquated idea of "water-tight compartments" in science asserted itself to such an extent that it was not for many years that justice was done. All this is fully discussed in the author's pages, where it is also made clear that ultimate triumph was due not to ability alone, but mainly to strength of character and lofty ideals.

The sub-title of the book is "An Indian Pioneer of Science." Like all pioneers, Sir J. C. Bose has had to encounter many and great difficulties and, as has been pointed out, he has, unlike many pioneers, successfully overcome them. It is to be hoped that, now that the days of storm and stress are over, he may be able to devote all his energy to the continuance of his work in the Institute that he has founded for the purpose. The volume is well got up, and is illustrated with portraits and many figures of apparatus and records. It would have been an advantage if a full bibliography of Sir J. C. Bose's works had been appended, while the index would be more useful if it were more complete.

Elementary Geometry.

Practical Geometry. By C. Godfrey and A. W. Siddons. Pp. xv+256. *Theoretical Geometry: A Sequel to "Practical Geometry."* By C. Godfrey and A. W. Siddons. Pp. xiv+104. (Cambridge: At the University Press, 1920.) Price 7s. net. (Complete in one volume.)

THE authors of these two volumes (obtainable also as a single book) regard the teaching of geometry as divisible into four stages. The first consists of little more than instruction in the use of instruments and methods of measurement, including drawing to scale. The second is an intuitive treatment of a few fundamental propositions, and merges into the third stage, which covers the whole field of the ordinary course of elementary geometry, plane and solid, treating the various theorems in an informal fashion, and explaining the methods of constructions, often without proof, in the natural order suggested by the theorems. In these stages the pupil is led to apply the results of the theorems, whether formally proved or not, both to numerical examples and to formal riders. The fourth stage knits all the theorems, previously considered, into a logical chain with formal proof. A few riders are interspersed, and there is a considerable amount of general discussion in this part of the text; the section closes with a collection of riders arranged under headings corresponding to suitable groups of propositions.

With the general changes of procedure adopted by the authors we are in entire agreement. There can be no question that boys are capable of making simple applications of the fundamental theorems of geometry long before they are able to appreciate the formal proofs, and the stimulus which work of this nature supplies is most beneficial to their mental development.

On its numerical side the exercises are very good, being numerous, varied, and interesting; on the formal side we do not consider the work quite so satisfactory; more riders of the "two-step" nature are needed, particularly, for example, in dealing with angle and tangent properties of the circle. We think also that much of the discussion, which at present bulks so largely in the text, might be omitted. We doubt whether any boy reads it, and there is much that we find hard to believe is really necessary for the instruction of the teacher at the present time, when modern methods are so much better understood than they were, say, fifteen years ago. Some drastic pruning of this kind would affect materially the size of the book, and, we think, leave its utility unimpaired, and at the same time appear to lighten the student's burden.

The printing is excellent, and the diagrams are clear and numerous. A set of answers and suggestions for class-work (which we have not seen) is issued separately. We regard the new form of this text-book as a definite advance in the right direction, and commend it to teachers.

The Evolution of Vertebrate Animals.

Die Stämme der Wirbeltiere. By Prof. Othenio Abel. Pp. xviii+914. (Berlin and Leipzig: Walter de Gruyter and Co., 1919.) Price 56 marks.

PROF. ABEL, of Vienna, is a most voluminous writer on extinct animals, and even the difficult circumstances of the time do not impair his energy and enthusiasm. He has now produced a most interesting volume summarising our present knowledge of the past history of the backboned animals, and his technical descriptions are illustrated by numerous up-to-date figures which are refreshing by their newness in a text-book. The work is not merely a laborious compendium, but is enlivened by many critical observations based on Prof. Abel's own researches.

Prof. Abel's classification will not in all respects prove acceptable. He avoids too many difficulties in the determination of affinities by an undue multiplication of sub-classes and orders. He also in some cases adopts the fantastic proposals of certain dabblers in scientific literature who discuss merely names without any acquaintance with the fossils to which they refer. The familiar generic name Ichthyosaurus, for example, completely disappears, while the almost equally well-known name Megalichthys is applied to the wrong fish. The work, however, is intended for advanced students who will be able to make allowance for these idiosyncrasies without much trouble.

According to Prof. Abel, the Cyclostomes are unknown among fossils, because the problematical Devonian Palæospondylus, with its suctorial mouth, is most likely the larval condition of Coccosteus. The earliest fishes are the Upper Silurian Anaspida. The earliest land-vertebrates, the Stegocephala, are treated at great length on account of the primitive character of the skeleton and its morphological importance. Among reptiles, the newly discovered Chelonia, from the Upper Trias of Germany, are especially striking. Some of them retain traces of true teeth. The Dicynodonts are described as "the Sirenians among reptiles." The Triassic Parasuchia and Pseudosuchia are separated from the Crocodilia. The marine Thalattosauria, from the Trias of California, are arranged with the Lacertilia. The birds are treated in the usual manner.

Among mammals, the Monotremata are regarded as unknown by fossils before the Pleistocene; and the Triassic Tritylodon is referred to the Marsupialia. The South American Tertiary Sparassodonta are also retained among Marsupialia. A few of the mammalian jaws of Jurassic age (*e.g.* Amphitherium and Stylodon) are regarded as belonging to Placentalia. The Insectivora follow, and the Primates, as usual, conclude the series of orders. The various groups are rather unequally treated, but students will be glad to have the preponderating sections on Cetacea and Sirenia as summarising Prof. Abel's own researches.

The volume is provided with two exhaustive indexes, one to morphology, the other to taxonomy, and is a most valuable work of reference, which should be added to every zoological library.

A. S. W.

Essays in Social Psychology.

(1) *Instincts of the Herd in Peace and War.* By W. Trotter. Second edition. Pp. 264. (London: T. Fisher Unwin, Ltd., 1919.) Price 8s. 6d. net.

(2) *The Century of Hope: A Sketch of Western Progress from 1815 to the Great War.* By F. S. Marvin. Second edition. Pp. vii + 358. (Oxford: At the Clarendon Press, 1919.) Price 6s. net.

(1) DR. TROTTER has not changed anything to speak of in the body of his remarkable book, which was published in 1916, but he has added a postscript of much interest. It deals first with the discouraging fact that "in a belligerent country all opinion in any way connected with the war is subject to prejudice, either pro-national or anti-national, and is very likely in consequence to be of impaired validity." The manifestations of the herd-instinct in the German people were in accordance with the type to be seen in the predaceous social animals; the manifestations of the same instinct in the British people were of the socialised type of gregarious animal—"possessing the power of evolving under pressure a common purpose of great stability." Societies in the past have failed in stability and full functional effectiveness; these defects have been due to "the drift of power into the hands of the stable-minded class, and to the derivation of moral power and enterprise from the mechanisms of leadership and class segregation." To avoid this there must be a continually progressive absorption of the individual members of the society into the general body—a movement towards a complete moral homogeneity and integration. "The only way in which society can be made safe from disruption or decay is by the intervention of the conscious and instructed intellect as a factor among the forces ruling its development." But the unanswerable question is whether the purposive foresight of the intellect will be able, more effectively than in the past, to free itself from instinctive inhibitions.

(2) Mr. Marvin has added to his stimulating book a time-chart of developments in "thought" and "action"—or culture and politics—in the last century, and he has made a number of improvements in the body of the text. On the general thesis he stands to his guns. The hopefulness of the last century has not been exhausted; on the contrary, the sources of hope are unimpaired. In mechanical science and invention, biology and hygiene, psychology and education, sociology and statecraft, literature and religion, and in other lines of development, there have been advances in the past century which seem on the whole to have made for the fuller realisation of the higher values which the racial consciousness at its best has always cherished. What Mr. Marvin's book shows, it seems to us convincingly, is that the momentum continues in a progressive direction. There is no doubt much to discourage, but all the departments of higher human activity are full of live seeds of good pedigree, and in their promise there is progress.

Our Bookshelf.

The Assessment of Physical Fitness: By Correlation of Vital Capacity and Certain Measurements of the Body. (With Tables.) By Prof. Georges Dreyer, in collaboration with George Fulford Hanson. Pp. xi + 115. (London: Cassell and Co., Ltd., 1920.) Price 10s. net.

ALTHOUGH various observers had made attempts to measure the respiratory capacity of the human body, the real pioneer work in spirometry was done about eighty years ago by John Hutchinson. Hutchinson worked out the vital capacity in relation to height, body weight, chest circumference, and age, attaching most importance to the first. He also made many observations as to the effect of disease upon the vital capacity, especially as regards phthisis. After the publication of his method of spirometry, considerable discussion arose both in this country and on the Continent as to its value in clinical medicine. By some clinicians it was held that the normal variations of health were so great as to preclude its extended use. The value of Hutchinson's figures in regard to height were early called in question, either as being too large or not of so great a value as figures calculated from the trunk length or sitting height. In the main, the results obtained by various observers were in favour of Hutchinson. In the little monograph by Prof. Dreyer and his colleague extensive tables are published showing the relationship of the vital capacity to sitting height, weight, and chest circumference. As Dr. F. S. Hobson has shown (NATURE, August 26), these tables will be of particular value to all those who are in any way interested in correlating the vital capacity with physical fitness. It is of interest that Prof. Dreyer and his co-workers have drawn conclusions contrary to those of Hutchinson in regard to the value of the sitting height, and also that age is looked upon as a factor of little or no importance up to about fifty years.

Handbook of Patent Law of All Countries. By W. P. Thompson. Eighteenth edition, completely revised. Pp. vii + 157. (London: Stevens and Sons, Ltd., 1920.) Price 6s.

THE assistance that such a book as this must give to inventors and patent agents fully justifies the issue of a new edition brought up to date with respect to British and foreign patent law and practice. The foreign section is very comprehensive —Bechuanaland and Eritrea, both of which have, we believe, issued Patent Ordinances, are the only countries we miss—though it would have been convenient if information had been given of the method of making an application in some of the smaller States that have no separate Patent Office. A very useful feature is the information given indicating the countries in which inventions relating to particular subjects should be patented. This might well be amplified in a later edition, especially with reference to the smaller States. Mr. Thompson does not refer to Luxembourg's withdrawal from the German Customs Union in December, 1918, but this is important, since, in consequence, patents granted there will presumably no longer be dependent on the corresponding patents taken out in Germany. Rumania, too, should have been included amongst those adhering to the International Convention. The British law is very well presented, though we have noticed a few errors in the statutory time limits allowed for accepting and sealing specifications. The statement on p. 14 that unless a complete specification is accepted within the statutory period it becomes public property is obviously an oversight, as such a specification is not published and remains secret. The book, however, is generally accurate, and should prove a very valuable and trustworthy guide to would-be patentees.

The Statesman's Year Book. Statistical and Historical Annual of the States of the World for 1920. Edited by Sir J. Scott Keltie and Dr. M. Epstein. Fifty-seventh annual publication. Pp. xliv+1494. (London: Macmillan and Co., Ltd., 1920.) Price 20*s*. net.

THE authors of this ever-welcome annual have conquered many difficulties in their survey of the world as it appeared in May, 1920. The maps indicate the new boundaries of South-eastern Europe and the Near East, and the new divisions of the former German colonies Togo, Kamerun, and German East Africa. In the text, however, the partitions of these ex-German territories has not been worked out. The difficulties of compilation are illustrated by the treatment of Czecho-Slovakia and Yugo-Slavia. In the first case an attempt has been made to bring together the statistics relative to the former Austrian and the former Hungarian lands, while in the second instance full details are given for Serbia only.

Mining statistics for Germany chiefly refer to 1913; there is no estimate of the probable yield of the new Germany. Hungary is incorrectly stated to have a common boundary with Germany; statistics for Croatia and Slavonia are included under Hungary, although a paragraph, which might be missed, correctly says that this area forms part of Yugo-Slavia. The list of Hungarian towns is apt to be misleading, since Arad and Temesvar have been omitted, as they are correctly included among the Rumanian towns, while Kolozsvar (Cluj), Nagyszeben (Sibiu), and Brasso (Brasov) appear in both lists. In the case of Spitsbergen it is not clearly stated that the non-Norwegian estates in Spitsbergen are not included under the sovereignty of Norway, but are extra-territorial.

These points indicate the necessarily tentative character of much of this new information. The bulk of the volume maintains the high standard of previous issues.

The Extra Pharmacopoeia of Martindale and Westcott. Revised by Dr. W. Harrison Martindale and Dr. W. Wynn Westcott. Seventeenth edition. (In two volumes.) Vol. i., pp. xxxix+1115. (London: H. K. Lewis and Co., Ltd., 1920.) Price 27*s*. net.

OFFICIAL pharmacopœias are necessarily restricted in their scope, and there are many drugs and other articles used in medicine which for good reasons find no place in them. Hence there is a recognised need for such supplementary books as the "Extra Pharmacopœia," which deal more freely than the official works do with medicinal preparations, appliances, new methods, and so forth. The fact that Martindale and Westcott's work has reached a seventeenth edition is sufficient indication that it meets a want. The single volume of the earlier editions developed into two volumes some years ago, and the most important of these (vol. i.) has become somewhat more bulky than of yore; but it can still be slipped into an overcoat pocket, in spite of its 1154 pages.

A great deal of new matter has been included in this vol. i., the requisite space having been provided in part by transferring the sections on iontophoresis, radium, thorium, and radiology to the second volume (not yet published). Among the sections which have been revised special mention may be made of those on vaccines, antitoxins, colloidal metals, and organotherapy; whilst many useful notes, particularly on the treatment of wounds, have been added to the therapeutic index of diseases. Both the medical practitioner and the pharmacist will find the volume replete with information.

White Lead: its Use in Paint. By Dr. A. H. Sabin. Pp. ix+133. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1920.) Price 7*s*. 6*d*. net.

THE information conveyed in this book is usually of a superficial character. Thus, although processes of manufacture are described, no details are given, and in the descriptions of the application of white lead in paints nothing very new comes to light. The author tells us that "it is not probable that one-thousandth of one per cent. of white lead used in paint is ever discoloured by sulphur, so it is not worth talking about." Unfortunately, however, he gives no alternative explanation of a well-known phenomenon. A similar off-hand style runs throughout the book, and cannot fail to diminish its value.

American Civil Engineers' Handbook. Editor-in-chief, Mansfield Merriman. Fourth edition, thoroughly revised and enlarged. Pp. 1955. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1920.) Price 35s. net.

THE seventeen sections into which the volume is divided cover the whole field of civil engineering, together with mathematical tables, mechanics, physics, meteorology, and weights and measures. The fact that there is but little overlapping indicates that the work of the editor-in-chief has been done thoroughly. Books of this kind must contain the information in a condensed form; in the present volume, however, the condensation has not been carried to the extent which sometimes obtains, making the contents a mere dictionary. On the contrary, each of the sections is presented in a readable form, and is profusely illustrated. British practice differs in many respects from American, but there is much in common, and so much of value in the latter as to make it almost essential for students of civil engineering to have some knowledge of American practice. In no other single book that we have seen can so much information be obtained regarding the practice of civil engineering in the United States, and we can confidently recommend the book as a useful addition to the British civil engineer's library.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The British Association.

WE must first tender you our best thanks for having, at this time of inevitable reconstruction, opened your columns to a discussion which has been of great value in showing the general trend of opinion concerning the future of the British Association. We have had the benefit of letters from presidents and secretaries of Sections in addition to those printed in your columns, and now beg to offer a few general comments. But we hope we shall not be regarded as attempting thus to closure the debate and dismiss it from our minds; rather do we regard the period of discussion, and, we would add, of experiment, as just beginning. It was with the full consciousness that much new enterprise and revision of old procedure were desirable that we invited the recorders and local secretaries to a friendly meeting at Oxford in the spring of this year, and we hope to continue at regular intervals the discussions then initiated and helpfully continued in your columns. We need only add here that as it is an essential function of the British Association to consider and act upon all suggestions tending in any way to the advancement of science, we hope that if you receive further communications for which you cannot find room you will do us the favour to forward them for our consideration.

Proceeding to general comments, we would first express satisfaction that the undoubted smallness of the Cardiff meeting has not been allowed undue weight, even by critics who did not attend and could not appreciate the unusually keen and businesslike quality of the proceedings. Many causes contributory to its smallness are fairly obvious, and incidental to recovery from the war. The high cost of travel and of living (the predatory attitude adopted by one or two of the Cardiff hotels by anticipation was particularly unfortunate), and ultimately the local tram strike, all played their part, and it is to be feared that some of them may continue operative beyond the Cardiff meeting. This we can only endure, reminding those who formerly urged that we should discourage "camp followers" that it is not for them to complain if the attendance is less.

But the important criticisms and suggestions have had a more general character. Some of them (fortunately) cancel out, as when Sir Ray Lankester advocates very careful pre-arrangement and Sir Oliver Lodge the throwing over of the time-table in favour of impromptu discussion. Sometimes the cancelling is kindly done in the same letter, as when Prof. Armstrong, another *laudator temporis acti*, first sings the praises of two long official reigns and then advocates a rapid change of officials. Parenthetically, we may correct a misstatement in his letter; the General Committee did not "relegate to a committee the appointment of a new treasurer"; it only adopted the universal practice of appointing a committee to suggest names to the council. We have, however, no wish to curb permanently the picturesqueness of Prof. Armstrong's exhibitions of hitting out at all and sundry.

But some of the points on which there is division of opinion cannot be simply dismissed for that reason, and chief among them is the very important question of the nature of the Sectional proceedings. Should they be made more "popular"; and can this be done without repelling some of our most regular and most useful supporters?

Now we fully agree that it is a very important function of the British Association to attract the public and impress the nation, but even from this point of view alone it may not be the best method to cater directly for them. Where a frontal attack may fail, more insidious methods may succeed.

One excellent method of attracting the public is to make sure of attracting the nearest living representatives of men like Huxley and Lord Kelvin, who always attracted the public. Now Lord Kelvin used to declare (Sir Arthur Schuster kindly allows us to quote his authority for the fact) that he came to the meetings of the British Association "to hear what everybody else was doing"; and the curtailment of "specialist" papers might easily drive away the very people who ensure the success of the meeting, and in some Sections certainly would do so. We need scarcely labour this point, on which Prof. Eddington has already written much good sense; but we will just add that, in spite of the existence of "special societies" in London, there are many people who have no other chance to hear "what everybody is doing." Thus there are many who are not near enough to London to attend meetings regularly; there is the growing army of science schoolmasters and schoolmistresses who can attend meetings only in the summer holidays, when the London societies do not meet; and there are the numerous members who are interested in more than one Section. All these would benefit by meetings of the Sections even if they were conducted on *precisely* the lines of specialist societies. No one, however, advocates this extreme expedient; undoubtedly the Sectional proceedings should be of a different type, but in trying to secure one good object we must not drop another, and we have reason to believe that the Sectional officers are well aware of the needs and wishes of the members, and are doing their best to satisfy them.

Next, as regards the number of Sections. Without rehearsing all the arguments in detail, it may be accepted as common knowledge that there are weighty considerations on both sides. Who, then, is to adjudicate between them? The people concerned or others? It would seem an almost necessary admission that in each particular case there must be particular considerations which can be truly evaluated only by the people concerned (who must at the same time be impressed, as we all are, by the general undesirability of multiplying Sections), and that a persistent and reasonable application from them must be seriously considered and liberally met. It does not advance science to boycott the younger sciences. Thus at the present time the Physiological Section, having tried a Sub-Section of Psychology for several years, having debated the alternative of a full Section for Psychology in several assemblies, and having met at least one powerful objection, came before the General Committee at Cardiff with an unopposed recommendation for an independent Psychological Section. No dissentient voice was raised in Committee, and no suggestion of further postponement was made. The officers (and staff), on whom fall many of the disadvantages of the multiplication of Sections, scarcely feel that they can oppose such a motion if no other opposition is forthcoming, and if the council concurs it will be to give effect to a preponderance of reasoned opinion.

On the other hand, there was some years ago a movement for the subdivision of Section A. It was fully considered by the Section and rejected, which may be taken as evidence that the tendency to subdivision is not automatic, and therefore to be resisted automatically. The practical requirements of Sections have always varied widely, and the plan of leaving the decision chiefly to the people concerned has much to be said in its favour.

Proposals for joint meetings between Sections and for closer co-operation between groups of related Sections—Mathematics, Physics, and Engineering; Zoology, Botany, and Physiology; Geography and Anthropology; or between any of these (and especially Engineering or Agriculture) and Economics or Education—are not new; they were carefully examined afresh by the council shortly before the war, and the informal conference last spring led to fresh efforts in this direction. Sir William Pope's suggestion of a special advisory body to assist in planning each annual meeting could be realised at any time by joint action of the actual organising committees of the Sections, which are constituted at the close of each annual meeting, and are often consulted by the council in Sectional emergencies during the year.

The presentation of a retrospect of recent advances of knowledge in each Section or in practical applications of scientific work is again a matter for Sectional arrangement. Formerly there were formal reports of this kind drawn up by responsible committees and presented in print for discussion; latterly such a summary has often been the theme of a Sectional president's address, and sometimes of one of the public discourses or the citizens' lectures. It would be easy for related Sections to arrange for such papers in turn, so as to cover the whole field in a cycle of years. In this and similar matters of procedure the policy of the Association has been to give the fullest freedom to the Sectional officers to adopt or modify suggestions coming in general terms from the council or from our friendly critics, and the Sectional officers have every encouragement to exchange suggestions and experiences with one another and with the general officers. The council does its best to select for evening discourses and other general discussions men eminent in science and accomplished exponents of its broader aspects; and the general officers and local executive spare no pains to ensure that they have every facility and convenience that experience may suggest. Occasional failures are, perhaps, inevitable in so difficult an art as public lecturing; the Association may fairly claim to be judged by those discourses which are remembered through the years, and they are not a few.

The circumstances of different localities vary so much that it has been difficult, and would probably be unwise, to insist on close adherence to any one type of programme. Only those who attend habitually know how flexible our arrangements are, how greatly one annual meeting differs from another, or how much of what some of our most outspoken critics desire is actually being done informally in the intervals of a very elastic time-table.

The annual tenure of presidents and vice-presidents of Sections and of the local secretaries introduces a large element of "fresh blood," and many of the best expedients for economy of time and effort have been contributed by annual officers. Recorders and secretaries hold office rather longer, but they are usually chosen from the younger members, and pass on to other duties quite as rapidly as is consistent with the continuity of experience necessary for the smooth working of a meeting. We are making considerable demands on the time of both classes of officers throughout the year, and gratefully acknowledge their keen and loyal co-operation in working out the proposals which we put before them or which result from their own experience.

We are very sensible of the difficulty of including, even into an eight days' meeting, all the opportunities for discussion or for exposition of scientific work which various critics desire; and we would beg that the experience of the meetings in 1910 and 1920, which were, perforce, limited to five working days, may not be regarded as typical of what the Association is trying to accomplish since the war. From these abbreviated meetings, however, and from the varied war experiences of our keenest members, we believe that we have learned some economies of procedure; and as our Edinburgh hosts promise us a normal Wednesday-to-Wednesday meeting in 1921, we have some hope of realising much that has been offered so frankly by your correspondents for our guidance.

To make the annual meeting more widely known in advance and its purpose better understood, we rely, first, on the co-operation of the Press, and especially of scientific and technical periodicals such as NATURE.

There is, we believe, a larger public than ever before for clearly written and accurately informed articles on scientific subjects, and especially on the public services rendered by scientific research, and we should welcome every opportunity of assisting competent reporters and other journalists to obtain trustworthy information on such matters, both at the annual meeting and in advance. But it has been an increasing trouble in recent years that representatives of the Press do not always display either the preliminary knowledge or the journalistic training which might enable them to forecast intelligibly or to chronicle accurately the substance of a scientific discussion, however fully apprehended by other classes of "camp followers." Shorthand, for example, is an accomplishment which we have almost ceased to expect of a Pressman at a Sectional meeting.

We rely on the delegates from our numerous "corresponding societies" to keep those societies informed of the Association's work, to bring on their younger members to our meetings, and to assist the local secretaries in extending the area round the place of meeting from which a full attendance of scientific workers may be expected. The fulfilment of one of our primary functions—to bring provincial scientific workers into touch with specialists gathered from afar—must depend very much upon the corresponding societies of the neighbourhood.

Most of all, however, we look to our ordinary members, and especially to those who are brought into daily contact (as teachers or in business or industry) with younger or less highly trained colleagues or subordinates, to propagate that view of the value and interest of scientific work which alone makes and maintains the fellowship of workers each "doing something else," but able and keen to appreciate the discussions, whether arranged or impromptu, of scientific leaders and men of practical ability who come to our meetings with the same object in view—"to see what everybody else is doing." "Philosophy," it has been said, "begins in wonder," and intelligent wonder, if it is to work its full effect in an eight days' "parliament" or "picnic" of science, must be caught on the flitting wing by that member of ours who is lucky enough to be there when it rises.

J. L. MYRES.
H. H. TURNER.

New College, Oxford, October 24.

THE correspondence which has followed the leading article on "The British Association and National Life" in NATURE of September 16 must have been read with deep interest by everyone who cares for the advancement of science. Since in that article reference was made to some remarks of mine called forth by my experience of the Cardiff meeting, perhaps I may be allowed a few words on the subject.

It seems to me that most of your distinguished correspondents have missed the real point altogether. They have been too much concerned with discussing ways in which the scientific value of the meeting may be increased for the benefit of the scientific man taking part. From this point of view reminiscences, alterations of Sections, joint meetings, and the like are very interesting, and no doubt important. The members of the Association who visit a town have generally a good time, and if by internal reforms they can secure a better scientific holiday no one will grudge it to them. Some of the correspondents appear to think that this should be, if not the sole, at any rate the chief object of the meetings. One of them practically warns the general public off "matters which they do not understand."

The purpose of my original remarks—and, if I am not mistaken, of your article also—was to emphasise the precisely opposite opinion, namely, that whilst the Association served the cause of the advancement of science by bringing workers in it together in circumstances favourable to discussion both formal and informal, yet it also had the duty of bringing before the general public the methods and results of scientific work. There is a cumulative effect here. None of your correspondents can deny that the general public pays us to conduct scientific research. Whether that payment is direct from the rates and taxes or indirect from gifts and bequests does not matter. The public pays, and scientific men are eternally asking for more. The public has, therefore, a right to know what it is getting for its money. Further, if the word "advancement" means anything, and if science has an object at all, what other object can that be than that of making the world a better place to live in? and how can it be advanced unless the results of its progress are made known to the people who are intended to profit by them? Scientific work is either a selfish amusement (as some of your correspondents seem to think) or it is a service of public utility. If it is a service of public utility, then the more the public realises how much it owes to scientific work, the more will the public be disposed to provide money for that work, and, consequently, the more work will be done and the more the public will be benefited. This is the cumulative effect which would follow from an ably directed scientific propaganda.

Science might well consider that favourite text: "Go ye therefore, and teach all nations, baptizing them. . . ." The British Association could be, and ought to be, a mighty engine for this purpose. And be it noted that the advice contained in this text is not only to preach, but also to baptise the converts, which is to bring them into the charmed circle themselves. The volumes of NATURE these fifty years are a record of scientific missionary work. They are full of finely worded appeals regarding the neglect of science, the need for money, the improvement of education, and so forth. But these sermons are not even preached to the converted; they are preached to the priests. What scientific heathen ever reads NATURE?

These considerations are on the high moral plane of duty—the duty which scientific men owe to the nation. Those of your correspondents who think that they are weird, yet beautiful, rare, and expensive, orchids kept in the public hothouses will never agree that they ought to be potatoes and show a good crop. But they will not be so satisfied with the scheme of things if the heating supply fails, and for this reason I should like to descend from the moral plane to the base one of money and to refer to a few facts. These facts would not be mentioned here if it had not already been necessary to state them very publicly in the district that had the honour of entertaining the Association at the recent meeting.

The Cardiff meeting cost the local committee about 2500*l*., and, in spite of all efforts, only about 1800*l*. has so far been forthcoming to meet this expenditure. I would ask your correspondents to consider the reason for this deficit. Cardiff is a wealthy city, and the "docksmen" are well known for their generosity. Large sums of money have been collected recently for such purposes as horse shows, flower shows, and missionary societies from people who mostly knew and cared as much about horses and flowers and cannibals as they do about Einstein. I think the reason is that they understood what these things were for, and they do not know what the British Association is for, because the Association has not seen fit to enlighten them. Another practical point is this. Owing to the decreased purchasing power of money the expenses of the meeting are necessarily two or three times what they were before the war, but the Mæcenas who gave a cheque for fifty guineas before the war does not now give you one hundred and twenty guineas; he still gives fifty.

Your correspondents who are preoccupied with that part of the Association's activities which concerns the meetings and discussions of scientific workers among themselves might perhaps indicate why, if scientific discussion is the be-all and end-all of the Association, the Association should wander all over the country, and even over the Empire, from year to year. Surely it would be more efficient and more convenient to have the annual meeting in the one place in which the Association prides itself on never having met—London.

Dare one suggest that perhaps these "orchids" rather like going to shows?

It is, of course, very easy to criticise and very difficult to construct. It would be presumption on my part to suggest how the Association should proceed to preach the good tidings to all the world, but no one can doubt that the thousand or so of scientific men who attend the meetings year by year could do a great thing for humanity if they chose, and could very soon discover the best means of doing it also. But the methods of the days when, as one of your correspondents recalls, crowds used to appear wherever Huxley was expected to speak are certainly ineffective to-day. To begin with, I am not aware that we have any Huxleys nowadays, and if we had I doubt if they would have that sort of hold on the common or British Association public of to-day. Scientific men should be the last to try to put new wine into the old bottles; it should be an easy matter for them to devise newer and better bottles.

An old member of the Association said to me during the Cardiff meeting: "Well, you may say what you like about it now, but it's a kinema compared with what it was when I first knew it!" I was reminded of this by a chance paragraph in the newspaper the other day describing "the most remarkable film which has ever been made in France," called "Les Mystères du Ciel," and there is no doubt that it made an impression on the Parisian correspondent of the *Observer*, who belongs to a profession which takes a lot of impressing. He lays stress on the fact that some of "the best-known experts have been glad to assist in the making of this remarkable and ingenious film, which has a real educative value." I suppose this will horrify some of our revered seniors, but really the British Association might do worse than kinematise itself a bit further. After all, rightly or wrongly, the kinema does attract and instruct the people more than the Association does, and it certainly collects their money.

Radyr, October 23.

Testing Einstein's Shift of Spectral Lines.

I AM not aware that anyone has applied centripetal acceleration to the outstanding Einstein prediction, instead of depending on solar gravitation. It is feasible to whirl a steel disc, 1 metre in diameter, at 3000 revolutions a minute; and this gives a peripheral acceleration five thousand times earth-gravity, whereas solar-gravity is only $25g$.

A few vacuum tubes braced to such a disc would give the effect of continuous illumination; and someone with refined spectroscopic appliances may be willing to try the experiment—unless there is a fallacy in the suggestion.

OLIVER LODGE.

Gullane, October 20.

Recapitulation and Descent.

IN NATURE of October 14 my friend and colleague, Mr. L. T. Hogben, contributes a thoughtful letter on "Recapitulation and Descent," on which you will, perhaps, allow me to make one or two comments. Mr. Hogben traverses the position taken up by Dr. Bather in his address to the Geological Section of the British Association that "recapitulation" in the development of animals is a proof of evolution. His objection is that "experimental breeding" does not justify the inference that a mutant recapitulates the characters of its ancestral type, and that "factorial omission" rather than "the perennial desire of youth to attain a semblance of maturity" is the key to "the omission of some steps in the orderly process."

Now I fully agree with Mr. Hogben that if by "experimental breeding" and "genetic investigation" we mean the endless and wearisome repetition of the crossing of "Mendelian mutants" with one another and with the parent species, we shall wait until doomsday before we obtain any light on recapitulation, or, indeed, on any of the other broader aspects of the evolution theory.

When the upholders of a theory confess, as does the leading British Mendelian, that it is totally unable to throw any light on the origin of adaptation —which is, after all, the very heart of evolution—the biologist must indeed regard it as bankrupt, at any rate if it claims to be a full exposition of heredity. Not all "genetic investigation," however, is of the Mendelian type, and quite recently some patient researchers claim to have accomplished something like evolution on a small scale experimentally, and to have found traces of recapitulation. I am aware that these results have been regarded by Mendelians with scepticism, as I think quite unfairly; but until the Mendelians have repeated the experiments and disproved the results, these results must stand as the relevant facts. They are beginning to come in from widely divergent sources, and the easy method of getting rid of them by doubting the *bona fides* of the researcher is no longer available.

The great evidence in favour of the reality of recapitulation is that in our survey of the animal kingdom we encounter facts which literally compel every naturalist who encounters them to interpret them in this way and no other. When, for instance, we find a tortoise with a soft, flexible skin devoid of the bony plates which support the carapace of all his brethren, and it transpires that this tortoise enters on his career as an ordinary tortoise with a regulation carapace, what other explanation than recapitulation can be possibly entertained? When, further, we find that Cœloplana, which looks like a flat-worm, and Tjalfjella, which resembles a Sponge or an Ascidian, both begin their free life as exquisite little Cydippid Ctenophores, does anyone consider it possible to doubt recapitulation, and therefore evolution? This may not be logical, but it is convincing, and as Huxley long ago said: "If a man chooses to maintain that a fossil oyster-shell is a concretion, and not the remains of an organism, it is impossible to drive him from his position by logic."

I differ totally from Mr. Hogben in believing that the "omission of factors" has anything to do with the shortening of the developmental process. Rather I am convinced that this shortening is akin to the greater quickness with which an habitual act is performed after countless repetitions. If, for instance, we compare the degenerate eyes met with in the pathological cripples known as Mendelian recessives with the degeneracy due to loss of function owing to changed habits, we meet with a totally different picture in the two cases, as anyone consulting the literature can see.

Nor can I agree with Mr. Hogben that much of the reasoning of the past originated in an emotional recoil excited by popular prejudice. The reasoning of the past reflected the burning impression created by the impact of myriads of new and unsuspected facts, and we owe Dr. Bather a debt for pointing out in his brilliant address that the old methods are perfectly sound *if properly applied*. At first they were applied in a wild and careless manner, and hence the reaction against the doctrine of recapitulation which set in, and of which Adam Sedgwick in his later years was a victim. But this reaction was no more justified than would be a reaction against Egyptology because some of the earlier Egyptologists drew rash conclusions from insufficient facts and sketched out

fascinating hypotheses which later proved to be baseless.

British Laboratory and Scientific Glassware.

THE question of the manufacture of laboratory and scientific glassware in this country is now receiving the attention of the House of Commons, together with other key industries. This matter has been the subject of considerable correspondence in NATURE, and I feel that readers of this journal will be interested to know what progress has been made in this work.

The advance made in the manufacture of laboratory and scientific glassware in Great Britain during the last five years is not only remarkable, but is also a monument to the capacity and ability of the British scientific worker. It is unnecessary to point out here the importance and necessity of scientific work or of the vessels and instruments that men of science use. That the latter must be of the finest quality and manufacture is indisputable.

At the outbreak of war men of science were absolutely dependent on supplies of German glass. They realised the danger, and at once stepped into the breach that the British manufacturer, unaided, was unable to fill. As a result of their efforts we now have the nucleus of a considerable industry in this country. While the supply is not yet equal to the demand, rapid progress has been, and is being, made.

Men of science are always critical of one another's work, and the production of these laboratory glasses has naturally led other workers to test and compare their properties with those of German and other makes. These results have been published in purely technical journals, but I feel that they have not yet had the publicity given to them that they deserve. The results of these tests are really remarkable, and prove quite conclusively that, in spite of the short time that the industry has been established, British laboratory glassware is the finest in the world. The results have never been challenged in any way, and go to show that the widely and cleverly advertised properties of German glassware are not quite so good as they have been made to appear, and that the British manufacturer has not merely equalled their best, but surpassed it.

The reports of the series of tests referred to are contained in the Journal of the Society of Glass Technology, the references being as follows:—Vol. i., p. 153: "The Attack of Chemical Reagents on Glass Surfaces, and a Comparison of Different Types of Chemical Glassware." Vol. ii., p. 219: "The Resistant Properties of some Types of Foreign Chemical Glassware." Vol. iii., p. 129: "Further Investigations of Chemical Glassware." These researches have been carried out by a department of Sheffield University.

The glasses tested have been classified (vol. ii., p. 230) under the headings "Good," "Moderate," and "Bad," and include Jena glass, Greiner and Friedrich's "R," Koln Ehrenfeld's, Swedish, Italian, French, American, and British. Of these only seven (two German, two American, and three British) remain in the "Good" class in every test. The tests include the action of (1) boiling water, (2) boiling water under pressure (autoclave), (3) $2N$-NaOH, (4) $N/10$-NaOH, (5) $2N$-Na_2CO_3, and (6) boiling HCl.

The action of boiling water at atmospheric pressure is so small on all seven glasses as to be, in the opinion of the authors of these researches, within experimental error, and is, therefore, negligible for comparative purposes.

An analysis of the table of results referred to above shows that for the remaining five tests the order of merit of the various glasses for general use is as follows: (1) A British glass. (2) A German glass. (3) A British and an American glass. (4) An American and a German glass. (5) A British glass.

This result speaks for itself, and it should be added that neither of the two German glasses in this list is Jena glass, which was found to occupy a comparatively low position in the table of results.

One of the great troubles which the manufacturer has had to face was that he was making this extraordinary attempt, not in normal, but in abnormal, times, when the supplies of raw materials and trained and unskilled labour were not available. Men skilled in the difficult art of "blowing" were almost unobtainable, yet these difficulties were gradually overcome and continued improvements made, until to-day the best British chemical glass bears comparison, from every point of view, with the products of the rest of the world.

In the early days many complaints were urged regarding the quality of the finish. This was only to be expected. It is obvious that skilled labour cannot be trained in a day, but I have no hesitation in saying that the finish of the majority of the best British makes of resistant glass is now as good as, if not better than, that of German glass of comparable composition.

One feels that the British manufacturer has at times been blamed for producing an inferior article. Unbranded glass has often been sent to chemists as British ware, whereas all the best makes of British glass are stamped with the name of the firm making it.

Unfortunately, those who were patriotic enough to manufacture this glass during the war are in danger of losing the result of their labours. Your readers know the heavy cost of experimental and research work, and will naturally realise that the British manufacturer is extremely anxious lest the results of this work should be permanently lost to the country. It is for this reason that the British manufacturer asks that the Key Industries Bill should be passed as soon as possible, to enable him to train more labour and to place this industry on a permanent and satisfactory footing.

S. N. JENKINSON,
President of the Society of Glass Technology.

"Rondels," Cookham Dean, Berkshire,
October 18.

The Behaviour of Time-Fuzes.

IT might appear that in my article on "The Behaviour of Time-Fuzes" in NATURE of October 14 I was describing my own researches. I wish to correct any impression of that kind. The original draft of my article was unsigned, but, unfortunately, I allowed the author's name (inserted by the Editor) to remain in the proof. The experiments described were made by a variety of people at Woolwich, at the National Physical Laboratory, at Cambridge, at University College, London, at Portsmouth, and elsewhere; and not least of the credit for the progress made in our knowledge of fuze-behaviour is due to certain officers of H.M. Army and Navy, on the Ordnance Committee, at the Ministry of Munitions, and at H.M.S. *Excellent*. My article, however, was intended not to apportion credit, certainly not to claim it, but to describe what I personally regard as the leading lines of development of a strange and interesting scientific by-product of the war.

October 21.

The Floor of Anglesey.[1]

By PROF. GRENVILLE A. J. COLE, F.R.S.

THE thoughts of travellers across Anglesey in the Irish mail-train are usually controlled by a previous vision of the breakers rolling in on Colwyn Bay; yet many must have been attracted by glimpses of grey homesteads set on elongated mounds, farmlands alternating with strips of marsh and moor, and here and there the "desert scenery" of some sunlit groove, bounded by low terraces of ancient rock, along which the sand has drifted inwards from the sea. In 1895 Mr. Edward Greenly retired from the staff of the Geological Survey to devote himself to the geology of the island. For twenty-four years he pursued his investigations, recording his results line by line upon the six-inch maps. The antique complex, offering problems similar to those faced by him in the Scottish highlands, was his first object of research; but nothing in Anglesey proved foreign to his aim as he carried out his work. The result is a memoir presented by its author to the Geological Survey, and thus to the general public, accompanied by a map reproduced on the scale of one inch to one mile. Mr. Greenly's generosity has led him even to provide much of the cost of publishing these two handsome volumes. Geologists in many countries will associate themselves warmly with the thanks so well expressed by Sir Aubrey Strahan in his preface. May we be allowed to join also in the author's gratitude to Mrs. Greenly for her co-operation in long years of preparation?

FIG. 1.—The folding of the Mona complex, from the South Stack, Holyhead. Height seen 445 ft. From "The Geology of Anglesey," by permission of His Majesty's Stationery Office.

A comparison of the map, which is so clearly produced, in spite of all its detail, with the hand-coloured sheets issued in 1852 will best reveal the changes of view that studies in other areas have brought about. When J. F. Blake, in 1888, read his memorable paper on "The Monian System of Rocks," we were still in the grip of what may be called the pre-cambrian controversy. Lapworth had recently published his work on the north-western highlands of Scotland; the Geo-

[1] (1) "The Geology of Anglesey." By Edward Greenly. (Memoirs of the Geological Survey.) Vol. i., pp. xl+388+plates i–xxvi; Vol ii., pp 389–980+plates xxviB–lx+16 folding plates. (Southampton: Ordnance Survey Office; London: E. Stanford, Ltd., 1919.) Price, two vols., 3 guineas net.

(2) Geological Survey of England and Wales "Anglesey." Colour-printed map, one inch to one mile. (Southampton: Ordnance Survey Office, 1920.) Price 2s. 6*d*.

logical Survey, after a natural hesitation, had frankly accepted and developed his conclusions; but many felt that to surrender large areas of "altered Lower Silurian" on our maps to combatant claimants was a first step in the disintegration of the British Empire. On the other hand, the word "mica-schist" was reserved by others for a type of sediment that had not been repeated since pre-cambrian times. Mr. Greenly came into the field without any of these predilections, and his memoir on Anglesey represents the reasoning of an absolutely unhampered mind.

His first volume is devoted to the "Mona complex," which is regarded as probably pre-cambrian (p. 142). The details of folding and of foliation in the successive divisions of the complex, and of the spilitic lavas, with their associated red jaspers, are finely illustrated in the author's plates. Two of his broader landscapes have been selected for the present notice. The word "encarsioblast" is introduced on p. 43 for a lenticular crystalline growth in a schist, in which the cleavages and planes of intergrowth are at a high angle to the general foliation, features indicating that such growths are among the latest features of reconstruction. When a term like this is written in international Greek, cannot we get rid of "hornfels" and "augen" from British usage? The

Fig. 2.—Typical scenery of the Mona complex; Amlwch Port Moor. From "The Geology of Anglesey," by permission of His Majesty's Stationery Office.

throughout. The green rocks, including the pillow-lavas of Newborough, are included in one of the earliest divisions—the Gwna "group." With J. F. Blake the author recognises (p. 896) this "group" in Howth, in eastern Ireland—a view that carries with it far wider suggestions. Gneisses underlie the Mona complex, but an unconformity has not been traced; the typical gneiss (p. 133) is composite, consisting of a granitoid element veining and permeating an originally sedimentary series, which includes even limestones. The resemblance with the gneiss of eastern Sutherlandshire and Forfarshire is close metamorphic rocks of Anglesey are admirably dealt with, and the glaucophane-schists are held (p. 120) to be modifications of the Gwna spilitic lavas.

The geological systems in Anglesey range up to the Coal Measures, in which the barren red strata of Malldraeth and the Menai Strait are now included (p. 668); but we must pass on to the features impressed on the island by denudation and deposition since Cretaceous times. Mr. Greenly (p. 777) shows the probability of a large outlier of Chalk, resting on Jurassic beds, remaining in the sea between the Isle of Man and

Lancashire. The Cretaceous sea lay over Anglesey, and Cainozoic folding has carried its base (p. 895) to some 700 or 800 ft. above the present sea-level. No great warping is needed to prolong this base over Snowdon, and the excavation of the deep valleys of the highland is ascribed, like the levelling of the "Menaian platform" (p. 783), to Pliocene denudation. The contrast between Snowdonia and the lowland of Anglesey is not due to differential erosion, but to the curve of the Cainozoic anticline, rising to the east.

The details of the glaciation of the island are now for the first time adequately dealt with, and with this last hint of the additions made by Mr. Greenly to British geology, our notice must, ever gratefully, conclude.

Food Requirements and the Minimum Wage.

A WELL-KNOWN and trusted Labour leader remarked, not very long age, to the writer of the present article, *apropos* the scientific assessment of food requirements, that "Science leaves me cold." Labour, in common with other parties in the community, has to learn that, unpalatable or no, scientific truth must be faced squarely. Unless the conduct of affairs be laid securely on a sound, scientific basis, and not on sentimentalism, the social edifice will collapse. It is constantly forgotten that the scientific dictum of to-day usually becomes the hackneyed commonplace of to-morrow.

Much as the recent proposal to base wages on a sliding scale, rising and falling with the cost of living, is resented, it is an absolutely sound doctrine, and probably the only practicable base to work from without inflicting undue hardship upon the community at large. Many workers seem to resent the utilisation of this base on the ground that it would reduce them, in their opinion, to the level of animals. This is a perfectly unsound deduction, and not only is it unsound; it is unwarranted. The introduction of such a scientific assessment of wages does not reduce the status of the worker.

We all have a right to live, and life is maintained by an adequate ingestion of food. The only practicable basis for the fixation of the level of the minimum wage would seem to be the cost of living. It has been contested by many people who are unacquainted with the methods of science that as all humanity is neither of the same sex nor of equal age and size, and as the work performed by various classes of the community varies within wide limits, as regards both severity and duration, it is impossible to lay down standards which will be uniformly applicable. So far as the *minimum* wage is concerned, there is absolutely no difficulty.

It may be well to state briefly, in the first place, the methods by which science has reached its definite conclusions, as the whole question is dependent on the fact that food is consumed as a source of energy for internal and external work. The demands for internal work are fairly definitely known, and are a function of the mass of the active tissue (mainly muscle) of the body. This fraction will be considered under the terms of basal or standard metabolism—*i.e.* the energy requirements when the body is in a state of complete repose. In order to assess the amount of work done, both internal and external, and the amount of food which must be consumed in order to cover this, it is obvious that there must be some common unit to which everything is reduced. The unit most generally utilised is the large calorie, as all forms of energy may finally be reduced to terms of heat. The large calorie is the amount of heat required to raise 1 kilo. of water from 15° to 16° C.

The number of Calories contained in a unit mass of food can be determined directly by burning the food in a special small steel chamber (the bomb calorimeter) where the heat liberated by the combustion of the food material is taken up by water contained in a water-jacket, the rise of the temperature of the water being measured by a sensitive thermometer. The amount of energy given off by the body can also be determined, either directly by measuring the amount of heat given off as heat and estimating the external work done in work units, which, in turn, can also be stated in terms of heat, or indirectly by means of the exact analysis of the expired air, where each litre of oxygen consumed can be calculated in terms of Calories.

The cost of the internal work, the basal metabolism, is, as already mentioned, a function of the amount of active metabolic tissue present in the organism. It is obvious that the actual amount of such tissue cannot be directly determined in the living subject. Formerly it was assumed that the weight of the individual gave a good approximation, and that therefore the Calorie output per kilogram body weight—*i.e.* including active tissue like muscle and inactive tissue like fat—would be the measure of the cost of internal work. Recent research has shown that such a value is an approximation only; that much more uniform values can be obtained if the weight-factor is correlated with the age and the height of the individual. The basal metabolism by the use of suitable formulæ can now be stated in terms of Calories per square metre surface of the body. The mean of a large number of determinations has shown that the basal metabolism of a man between the ages of twenty and fifty on an ordinary diet is 39·7 Calories per square metre surface per hour. It is generally accepted that the "average" man has a surface of about 1·77 square metres, and, therefore, a daily basal metabolism of approximately 1700 Calories—*i.e.* as cost of internal work.

This method of assessing the basal metabolism enables us to deal with the fact that workers vary markedly in physical condition. An objection to the use of a general average for all workers in all trades is that it is frequently found in practice that a certain type of man tends to drift into one type of occupation and a different type into another. It is a case, in the majority of instances, of the survival of the fittest; if a worker is not suited to the trade he has selected he eventually seeks another. But, in spite of this possible segregation—and nothing could be more simple than to make definite allowances if these were required—it is found that the general law of averages can be applied with success.

In order to determine the total daily output of energy by any individual, to the cost of the internal work must be added the increment due to the external work done. In spite of the widely expressed belief that it is quite impossible to correlate the daily work done by different types of workers, let us say that of a postman, a dock labourer, a bricklayer, and a trawler deck-hand, nothing is more easy, provided the appropriate tests are carried out. It is true that the amount of energy spent in the form of external work varies very markedly with the type of work performed and the conditions under which it is carried out. It may range from the low cost of sedentary work in a warm office or workshop, to the other extreme of hard manual labour under unfavourable conditions in the open air. One of the attempts at the classification of external work is given in the report on food requirements by the Food (War) Committee of the Royal Society. The figures given are net daily (eight-hour) figures to be added to the cost of the basal metabolism.

Sedentary	Less than 400 Calories	
Light work	400 to 700	„
Moderate	700 „ 1000	„
Heavy	1100 „ 2000	„

In certain types of work the 2000-Calorie limit may be exceeded.

Then, finally, there is the question of sex. Experimental work has definitely shown that the basal metabolism of women is about 7 per cent. below that of men, and, further, that, except in the lightest forms of manual work, the amount of external work performed is below that of men. It is generally held that the total energy output of women for the twenty-four hours is 17 per cent. below that of men. This divergence between the male and female metabolism can ultimately be referred back to two simple factors: (1) the relative weights, and (2) the relative proportion of muscle in the two sexes. As regards the first, it is common knowledge that the average woman weighs less than the average man; and, as regards the second, it is equally well known that the average woman is not so muscular as the average man—the average muscle in the case of man forms about 45 per cent. of the total weight, whereas in the woman it forms only about 38 per cent. It therefore follows that the expenditure of energy will be greater in the case of the male, making the assumption, of course, that each worker, male and female, is working at his or her optimum rate.

It is to be regretted that in this class of investigation, although a certain amount of work has been done, Britain has not played a prominent part. Compared with the work carried out both on the Continent and in the United States, the experimental work here has been almost negligible. The special apparatus and the facilities for such research have been lacking. The Inter-Allied Scientific Food Commission, which sat during the later stages of the war, did recommend that a special institute for such research should be founded in each country, but, so far, nothing has been done here.

As regards the practical aspect of the question, the investigations of Miss Lindsay and Miss Ferguson in Glasgow have thrown considerable light on the problem. Before the war, for example, it was found that the *average family* in receipt of 1*l*. per week could obtain, expending, it is true, about 73 per cent. of the total income on food, 3163 Calories per "man"[1] per day, roughly at the rate of 453 Calories per penny. Early in 1917 an income of 1*l*. 10*s*. did not suffice. At present, in a recent Government return (*Labour Gazette*, September, 1920), it is shown that the cost of food alone is 167 per cent. above pre-war level, and if the overall expenditure be taken there is an increase of 161 per cent. The following table, from data kindly supplied by Miss Ferguson, gives a good idea of the change in the cost of living during the past six years:—

Yield of Energy in Calories per 1d. Purchasable at Glasgow: Retail Prices.

Commodity	June, 1914	June, 1915	Nov., 1915	June, 1916	May, 1917	Nov., 1917	Feb., 1920	July, 1920	Oct., 1920

In view of the fact that, of the weekly wage of the workers earning 50*s*. a week or less, at any rate of those with families, 50 to 60 per cent. of the income is legitimately spent in the purchase of food, it is suggested that the total

[1] A family composed of father, mother, and children can be reduced to terms of "man" by the use of appropriate and well-established factors. Se Royal Society Food Requirements Report.

cost of living should be the dominant factor in the determination of the level of the minimum wage. Such a mode of assessment would also form an equitable basis for the determination of the wage of the skilled worker, in so far that the increment to be added in payment of (1) skill, (2) compensation for work carried out under unpleasant or unhygienic conditions, or (3) extra-heavy work, would be simply an addition to the minimum wage.

It is unquestionably true that there ought to be a statutory minimum wage. It is the unskilled worker who suffers most. No matter what the trade or occupation, it can be confidently asserted that, as a general rule, it will be found that the unskilled labourer is expending most energy and receiving least pay.

The assumption has been made that the purchase of food and the production of external muscular work are terms which are strictly interchangeable, and within the limits of the minimum-wage-earning class this is true. Objection to the proposal to use food consumption as the basis of wage fixation might legitimately be raised on the ground that, with the great majority of wage-earners, the purchase of food is not confined to the purchase for their own needs, but also for those of a family or other dependents. There is the further difficulty as to whether the minimum wage for men and women should be identical. There is absolutely no question about the fact that the average woman worker does not expend the same amount of energy as the average man, but this may be offset by another factor of wide application, that the majority of working women carry on at the same time housework in their own homes, where the expenditure in energy may easily compete in severity with the work done outside.

Science may seem at times to be cold and unsympathetic, even harsh, but, nevertheless, it is only when the facts are observed in a clear and unimpassioned manner that the truth can be found. Far from viewing man as a mere machine for the conversion of the latent energy of food into the potential energy of work, science is fully alive to the fact that this is only one aspect of vital activity, that there is a psychic side of life —everything that makes up the environment— which plays an equally important part in the life-history.

The purely energy side of the subject cannot be the sole criterion for the determining of wages. Food alone will not suffice to keep men going; it must be consumed under conditions which are satisfactory—conditions, it is true, which vary, at present, with the social status of the individual. There must be a sufficiency of money for a reasonable expenditure on various small luxuries, for entertainment, and for the various amenities of life, the absence of which makes life for the majority of people scarcely worth living. There is no question, then, as many Labour leaders seem to imagine, that an attempt is being made to reduce the manual worker to the level of serfdom.[2]

E. P. C.

[2] The Editor has very kindly directed the writer's attention to a footnote in Mr. H. G. Wells's "Outline of History" (p. 519; Cassell and Co., 1920) with reference to an experiment of the Oneida Silver Co. In the assessment of the weekly wage reference is made to the cost of staple commodities and common necessities, and the worker receives his wages *plus* a percentage representing the advance of the cost of food, etc., from a standard value.

Obituary.

DR. MAX MARGULES.

THE news of the death of Dr. Max Margules on October 4, which reached this country a fortnight ago, is rendered particularly sad by the announcement in Tuesday's *Times* that "his death was due to starvation. He had been living on a pension of 400 crowns a month (which is equivalent to 8s.), and he was too proud to beg for assistance." Dr. Margules was born in 1856 at Brody, in Galicia. After studying at Vienna and Berlin, he entered the Austrian Meteorological Service in 1880, and became secretary of the Institute at Vienna in 1890.

In 1882 Lord Kelvin suggested that the explanation of the regular semi-diurnal variation of the barometer, which has a range of more than two millibars in equatorial regions, might be found in the coincidence of a free period of oscillation of the atmosphere with the period of the solar gravitational tide. Lord Rayleigh in 1890 showed that *if the rotation of the earth were neglected*, a rough computation of the free periods led to values of 23·8 and 13·7 hours, so that Kelvin's hypothesis became at any rate a possibility, although the actual values obtained by Rayleigh would have indicated a bigger diurnal and a smaller semi-diurnal barometer variation. Margules, in the same year, attacked the problem of computing the pressure oscillations of the atmosphere on a *rotating* globe, and found that for an atmosphere with a temperature of 268° absolute (−5° C.) the free period was exactly twelve hours.

In 1892 and 1893 Margules contributed to the *Sitzungsberichte* of the Vienna Academy a series of masterly papers on the motion of the air on a rotating spheroid. These papers are little known to English meteorologists, as they were not included in the collection of papers and translations issued by the Smithsonian Institution in the volumes of "Mechanics of the Earth's Atmosphere."

Margules contributed to the Year Book of the Meteorological Institute of Vienna for 1903 a comprehensive discussion of the energy of storms. He showed that the atmospheric phenomena associated with storms would arise if two masses of air of different temperatures were in juxtaposition. The situation would be unstable, and in passing from this unstable situation to a stable one the potential energy would be reduced, part of it being converted into the kinetic energy of the ensuing "storm." This paper contains the germ of the theory of line squalls, of the development of cyclones, of polar fronts, and so forth. It includes computations of the horizontal velocities which would result from various distributions of pressure and temperature, and shows that actual distributions would lead to velocities of 50 miles an hour. Margules summed up his conclusions in the sentence: "So far as I can see, the source of storms is to be sought only in the potential energy of position."

Margules retired from active participation in the work of the Austrian Meteorological Service during the directorship of the late Prof. Pernter, and applied himself to the study of chemistry. He fitted up a small laboratory in his own house, where he lived in comparative retirement. The present writer was saddened to see him there in 1909 entirely divorced from the subject of which he had made himself a master. Meteorology lost him some fifteen years ago, and is for ever the poorer for a loss which one feels might and ought to have been prevented. E. GOLD.

THE *Engineer* for October 22 records the death of MR. C. J. BOWEN COOKE on October 18 in his sixty-second year. Mr. Bowen Cooke was educated at King's College School, London, and on the Continent, and thereafter spent the whole of his life in the service of the London and North-Western Railway. After serving a pupilage under the late Mr. F. W. Webb, he was appointed assistant in the running department, and rose to be its superintendent. In 1909 he was appointed chief mechanical engineer, and thereafter was responsible for the design of several important types of locomotive engines. The chief of these was a non-compound superheater engine weighing 116 tons and having four cylinders; this engine was fitted with Walschaert's valve gear. Mr. Bowen Cooke took a very active part in the development of the manufacture of munitions of war in railway workshops, and was made C.B.E. in 1918. He was a member of both the Institutions of Civil and Mechanical Engineers, a Justice of the Peace and County Councillor for Cheshire, and a major in the Engineer and Railway Staff Corps. He was the author of two books on locomotives, and also of a paper on the mechanical handling of coal for British locomotives, read at the Institution of Civil Engineers in 1912.

PROF. HANS PEDR. STEENSBY, whose death at the early age of forty-five is announced by the *Times*, was professor of geography in the University of Copenhagen. He was chiefly known for his researches on the Eskimo in relation to their environment, most of which appeared in *Meddelelser om Grønland*, and included "Contributions to the Ethnology and Anthropogeography of the Polar Eskimos" (1910) and "An Anthropogeographical Study of the Origin of Eskimo Culture" (1917). Prof. Steensby came to the conclusion that the Eskimo were originally an inland people dwelling in the tundra, probably in the vicinity of the Great Slave Land and Coronation Gulf, and that their culture was originally an Indian hunting culture adapted later to the conditions of the Arctic shores. He also wrote on the early voyages of the Norsemen, and was returning from America, where he had been in connection with his investigations into this subject, when his sudden death at sea occurred.

Science announces that PROF. SAMUEL MILLS TRACY, agronomist of the United States Department of Agriculture, died at Laurel, Miss., on September 5, aged seventy-three years. Prof. Tracy was born at Hartford, Vermont, and graduated from Michigan State Agricultural College in 1868. From 1877 to 1887 he was professor of botany and agriculture at the University of Missouri, and from 1887 to 1897 director of the Mississippi Agricultural Experiment Station. Since that time he had been attached to the United States Department of Agriculture. He was a fellow of the American Association for the Advancement of Science, in the work of which he took an active part, and a member of the New Orleans Academy of Science and of the Botanical Society of America. Among Prof. Tracy's works are "The Flora of Missouri," "The Flora of Southern United States," and numerous bulletins issued by the Mississippi Experiment Station and the United States Department of Agriculture.

SIR CORNELIUS NEALE DALTON, whose death occurred on October 19 at seventy-eight years of age, was Comptroller-General of Patents from 1897 to 1909. When, in 1901, the Committee appointed by the Board of Trade to inquire into the working of the Patent Acts reported in favour of an examination for novelty, within certain limits, being undertaken by the office, Sir C. N. Dalton laid down the lines on which the examination has since been conducted, and recommended and carried out the necessary scheme of reorganisation. His strength lay in his tact, energy, and power of organisation, and these enabled him to carry out alterations in the law and practice of patents, though it may be doubted whether the changes were to the advantage of the inventor. He was hon. D.C.L. of Oxford, was created K.C.M.G. in 1908, and was chairman of the council of the East London College.

THE death of DR. ANTON WEICHSELBAUM, professor of pathological anatomy at Vienna University, at the age of seventy-five years, occurred on Friday, October 22.

Notes.

IMPORTANT changes are announced at the Ministry of Agriculture, the effect of which is the promotion of Mr. F. C. L. Floud to be Permanent Secretary and the liberation of Sir Daniel Hall from office work so that he will be able to keep in close personal touch with agricultural developments in this country as well as abroad, and devote his whole time to the organisation of agricultural education and research. Sir Daniel has been associated with this work throughout his whole official career. The scheme now in operation comprises four essential parts:—(1) Research institutions, where knowledge is gained and agricultural science systematically developed and put into such form that teachers and experts can use it. At first this work was distributed among a number of university departments, but of recent years there has been a tendency to concentrate it at a few institutions owing to the necessity for bringing individual workers into closer personal contact with each other and with the large-scale problems of the farmer. (2) Agricultural colleges, where experts and large farmers will be trained, receiving a three years' course of instruction of university character. Most of these colleges are associated with universities which award degrees in agriculture; for students who do not wish to take degrees there is a diploma course requiring a high standard of technical work. (3) Farm institutes for small farmers and farm-workers who cannot spare three years for college, but have some practical knowledge and are unable or unwilling to go through the ordinary college course. These institutes aim at giving sound courses of instruction on soil, manure, crops, animal husbandry, etc., but it is usually presumed that the student will take up farming in the area served by the institution, and for which the instruction is specially appropriate. (4) Advisory officers. In each county arrangements are made whereby farmers, smallholders, and others may consult the agricultural expert appointed by the county authority in regard to any difficulties they may meet with in their work. The expert is in a position somewhat similar to that of the general medical practitioner, and usually finds that he can deal with a large number of the cases presented to him. He is, however, in touch with the colleges, research institutions, etc., and can always obtain expert advice in any particular problem of special difficulty.

PROF. T. H. PEAR has been elected an honorary secretary of the Manchester Literary and Philosophical Society in succession to Prof. C. A. Edwards.

MR. J. A. BRODIE will deliver an inaugural address at the opening meeting of the one hundred and second session of the Institution of Civil Engineers on Tuesday, November 2, at 5.30 p.m.

THE *British Medical Journal* announces that the fourth congress of the Far Eastern Association of Tropical Medicine will be held in August, 1921, at Batavia, the capital of the Dutch East Indies, under the presidency of Dr. W. T. de Vogel.

THE University and the Royal Academy of Sciences of Bologna will hold a joint commemoration service for the late Prof. Righi in the lecture hall of the University on November 1. This will be the fortieth anniversary of Righi's first association with the University, and an oration will be delivered by Prof. Luigi Donati, director of the Royal School of Engineering.

A JOINT meeting organised by the Faraday Society and the Sheffield Section of the Institute of Metals will be held at the University of Sheffield on Friday, November 19, to discuss papers dealing with various aspects of electro-plating. Communications are promised from representatives of the scientific side of the electro-plating industry in London, Birmingham, and Sheffield Anyone desirous of taking part is invited to communicate with the Sheffield local hon. secretary of the Faraday Society, Dr. F. C. Thompson, Department of Applied Science, University of Sheffield.

WE learn from the *British Medical Journal* that, through the gift of an anonymous fellow, the Royal Society of Medicine has been able to institute a triennial gold medal open to medical practitioners throughout the world. Sir Almroth Wright has been chosen as the first medallist, and the presentation will be made to him by the president of the society, Sir John Bland-Sutton, at 5 p.m., on Thursday, November 11, at 1 Wimpole Street, and Sir Almroth Wright will afterwards give an address on medical research.

AT the annual meeting of the Royal Society of Edinburgh, held on October 25, the following were elected as office-bearers and members of council:—*President:* Prof. F. O. Bower. *Vice-Presidents:* Prof. D. Noël Paton, Prof. A. Robinson, Sir G. A. Berry, Prof. W. Peddie, Sir J. A. Ewing, and Prof. J. W. Gregory. *General Secretary:* Dr. C. G. Knott. *Secretaries to Ordinary Meetings:* Prof. E. T. Whittaker and Prof. J. H. Ashworth. *Treasurer:* Dr. J. Currie. *Curator of Library and Museum:* Dr. A. Crichton Mitchell. *Councillors:* Prof. R. A. Sampson, Prof. J. Lorrain Smith, Dr. W. A. Tait, Surg.-Gen. W. B. Bannerman, Mr. H. M. Cadell, Prof. A. R. Cushny, Prof. F. G. Baily, Mr. G. J. Lidstone, Dr. R. Campbell, Prof. J. C. Irvine, the Hon. Lord Salvesen, and Prof. J. A. Thomson.

WE referred in our issue of September 2, p. 26, to a statement received from a correspondent in India that Sir Alfred Bourne was to be succeeded in the directorship of the Indian Institute of Science, Bangalore, by an administrator with no scientific experience, and we remarked that such an appointment would be greatly deprecated by scientific workers. By the statutes of the institute, the council appoints a committee at home to make nominations, and from the nominations sent out it selects a name for the approval of the Viceroy, who is patron of the institute. If the council sent home a nomination for the office, it apparently went beyond the spirit of the statutes, but, in any event, we understand that no director has yet been appointed to succeed Sir Alfred Bourne. We trust that the post will be filled by a man who combines administrative capacity with scientific knowledge.

One of the most valuable contributions to the study of magic in the Malay Peninsula was the description by Mr. W. W. Skeat in his "Malay Magic" of the methods by which the soul of the rice plant was evoked in the seed grain. Our knowledge of these practices has recently been advanced by the papers contributed by Mr. R. O. Winstedt to the *Journal of the Federated States Museums* (vol. ix., part 2, July, 1920) descriptive of similar rites in Upper Perak and Negri Sembilan. In the former region the seed is washed and cleansed with limes, and the farmer makes the invocation: "Greetings be to thee, God's prophet Solomon, King of all the earth! I would sow seed rice. I pray thee, cherish it from all danger and hazard!" At harvest he says: "Greetings be to you, gnomes of the latter days, gnomes of the beginning, gnomes one hundred and ninety! Get ye back and aside! If ye turn not aside, I will curse you!" After the regular invocation the soul of the rice will come in the form of a grasshopper or other insect with the sound of a breeze. When the rice-soul is invoked at harvest the magician must wave a white cloth, so that the rice-soul shall not fall on and crush one of the party at her coming. This valuable contribution supplies additional information on the subject fully discussed by Sir James Frazer in the last edition of his "Golden Bough."

The origin of cancer is discussed by Dr. Alexander Paine in a paper in the *Lancet* of October 2 last (p. 693). The conclusion Dr. Paine arrives at is that cancer is due, not to the action of a specific parasite, as has been suggested, but to a disordered growth of epithelium caused by various chemical or physical irritants, the most important being the toxins or poisons of micro-organisms. Dr. Paine considers that the origin of cancer lies in the degeneration of the "nobler" parts of the cell consequent on damage to its structure. The result of this damage is to disturb the balance of metabolism by impairing the special functions of the cell, thereby causing persistent overgrowth.

The Research Defence Society has published a pamphlet by Sir Leonard Rogers on "The Value of Experiments on Animals." No one is better qualified than Sir Leonard Rogers to speak with authority on this subject. Investigations on rinderpest in cattle and surra in horses are quoted as examples of the value of animal experiments in the elucidation and prevention of diseases affecting the lower animals, whereby much suffering to the animals themselves and pecuniary loss to their owners are diminished. The action of snake-venoms and the preparation of curative sera for snake-bites, the use of permanganates in the treatment of snake-bite and of cholera, work on the dysenteries, and experiments leading to improved treatments of leprosy, tuberculosis, and kala-azar are all summarised. It is shown how much we are indebted to experiments on animals for a better knowledge of these conditions and for improved methods of dealing with them.

Mr. E. H. Taylor gives (*Philippine Journ. Sci.*, vol. xvi., No. 3, March, 1920) an account of sixty-six species—seventeen being new—of Philippine Amphibia. These belong to the orders Apoda—represented by a new species of Ichthyophis—and Salientia, there being only one doubtful record in the order Caudata. The Salientia, which includes the frogs and toads, is represented by four families, Ranidæ, Engystomidæ, Bufonidæ, and Pelobatidæ, the first of which has by far the largest representation. A new genus of the Ranidæ—Hazelia—is described.

Messrs. Boving and Champlain (Proceedings of the U.S. National Museum, vol. lvii., No. 2323, 1920) describe the morphology and taxonomy of a number of North American species of beetle larvæ belonging to the family Cleridæ. With very few exceptions, these insects, both as larvæ and adults, prey upon destructive wood- and bark-boring beetles. This careful and very exact memoir should appeal to all coleopterists, and the classification of Clerid larvæ illustrates how much a taxonomic arrangement of the beetles can differ from that of their larvæ. A new appropriate classification of larvæ independent of the adults is necessary in this case. The second part of the paper deals with the biology and seasonal history of the Cleridæ. Information of this nature is obviously essential if the forester is ever to benefit by the preservation of the predators, and at the same time by the destruction of the injurious species upon which they prey. The authors state that, whenever practicable, the dissemination of Cleridæ, particularly of Thanasimus and Enoclerus, in quantities in badly infested regions would be a valuable additional aid to control measures.

A certain amount of romance is attached to the control of insect pests by parasites, and the Americans have specialised in this work. Those interested will find a very full illustrated account of the subject in the Monthly Bulletin of the Department of Agriculture for California (vol. ix., No. 4, April, 1920). Several parasites have been introduced as natural enemies of mealy-bugs in the hope that some might prove effective. One, a so-called mealy-bug destroyer, *Cryptolaemus Montrouzieri*, Muls., a ladybird beetle from Australia, was expected to solve the problem, but after the first few months seemed to die out except in particular localities. The reason is fairly obvious. The success of such a parasite means that its natural food becomes scarce, and therefore it starves. The problem has now, however, been solved by the Californian authorities, who found that they could feed the mealy-bug on potato-sprouts, and hence were enabled to keep the ladybird fed and breeding during the winter months. Special insectaries have been built for this purpose, and tubes of the ladybird can be supplied for release when and where necessary the following spring.

Many entomologists will welcome an important paper by Mr. A. C. Baker on the classification of Aphidæ which has been issued lately as Bulletin No. 826 of the U.S. Bureau of Entomology. Probably no group of insects has received more attention from the economic point of view than aphides or plant-lice. Unfortunately, the classification and synonymy of aphides are in a chaotic condition, and great difficulty is often experienced in securing correct naming of specimens. Mr. Baker's paper deals with their generic classification, and was undertaken with the object of remedying this defect, to some extent at least. He regards these insects as constituting the super-family Aphidoidea, and his efforts are confined to the genera and tribes of the family Aphididæ; Phylloxera and its allies he considers to be a separate family. The genus Mindarus is regarded in some respects as the most primitive of all forms, while the Hormaphidini are considered to be the most specialised. The last-named insects are gall-formers; they lack the cornicles or honey-tubes, and have curious aleyrodiform generations. The systematist who desires to make real progress with the specific determination of many aphides will have to rear each individual species and note carefully the characters of each generation for a given food-plant. The labour involved would be great and the time demanded lengthy, but the progress made would be sure, and substantial biological knowledge would result.

The problem of the toxic action of sulphur used as a fungicide is being investigated at the Agricultural and Horticultural Research Station, Long Ashton, Bristol, and a preliminary report on the subject by Messrs. B. T. P. Barker, C. T. Gimingham, and S. P. Wiltshire appears in the station's annual report for 1919, recently received. It has frequently been noticed that flowers of sulphur applied in paste form to the hot-water pipes in greenhouses will keep in check diseases of the mildew type on plants in the houses. Further, there are records of cases of unsprayed gooseberry bushes which have been defoliated as a result of the lime-sulphur spraying of adjacent plots of bushes. The results suggest that the toxicity of the spray is due to some gaseous compound, and if such a compound could be discovered it might be possible to surround plants with an atmosphere sufficiently antiseptic to prevent disease. The nature of the changes which follow the application of a sulphur spray were, therefore, studied, and the results showed that the active agent is the finely divided sulphur which is formed by the decomposition of the spray fluid. Several theories have been advanced to explain the action of this sulphur; the toxicity may be due to the gradual oxidation of the sulphur to sulphur dioxide, to the formation of sulphuretted hydrogen, to conversion into sulphuric acid, or, finally, the sulphur may act of itself by its own vapour. The experiments at Long Ashton show that under ordinary practical conditions none of these hypotheses meet the case. Further experiments have been made, and it is hoped that these will demonstrate the method by which sulphur at a distance from the plants under treatment is brought into contact with the fungus. It then remains to discover what happens when the sulphur comes into contact with the fungus, and for this purpose further researches must be made.

Prof. Jean Massart records (Bull. Acad. Roy. Belgique, Classe des Sciences, 1920, Nos. 4–5) the results of his observations on the movement of different species of littoral flagellates, and gives numerous figures of the organisms and of their paths of movement. Several of the genera and species observed are new, but the systematic descriptions will be published later. In Podomastix (a new genus) the pseudopodia—one to four in number—are long and slender, uniform in thickness, sometimes branched, and movable in an oar-like manner. They are retractile, and represent a transition between pseudopodia and flagella. The two flagella of *Cercobodo primitiva*, n.sp., are tapering prolongations of pseudopodia, but, contrary to those of Podomastix, they are permanent. One of the flagella is anterior and serves for swimming, the other is directed posteriorly. This organism can also move forward by lashing its anterior flagellum, its posterior flagellum and part of its body being applied to some object over which it is progressing, and, finally, it can move in amœboid fashion. The author remarks that many of the flagellates exhibit these three kinds of locomotion. *Clautriavia mobilis*, which has a single flagellum directed backwards, never swims freely; it becomes applied to some object by the flagellum, and pushes itself forwards obliquely, first right, then left. Dimastigamœba, n.g., forms pseudopodia while swimming freely and while creeping. In the latter condition the two flagella trail behind. The reaction —acid or alkaline—of the surrounding fluid was found to play an important part in determining change of form with Eugleninæ. In a slightly acid fluid these organisms swim in a state of extension and without modifying their contour, but if the medium is rendered alkaline the swimming is arrested and the organisms exhibit diverse changes of form.

The latest issue of the Journal of the Marine Biological Association (No. 2, vol. xii.) contains several papers dealing in considerable detail with the life-histories and food of Teleostean fishes. Particularly noticeable is a paper (promising further contributions to the subject) on the physical conditions influencing breeding in marine organisms, breeding being defined as "fertilisation resulting in subsequent development." There is much experimental and observational work in the literature of biology, and Dr. Orton collates and discusses some of this. The breeding of a marine animal is usually seasonal, and may occur during a very limited part of the year, or it may be continuous (in some tropical and abyssal organisms). It may begin at a very early period in the life of an animal, be repeated annually, or even be delayed until almost the end of life, and may occur only once. It is very difficult to correlate the nature and abundance of food with the occurrence and duration of the breeding period, and Dr. Orton inclines to disregard this factor, assigning little or no significance to it. Salinity variations may be so capricious in relation to the distribution and habits of some animals that these, too, are difficult to correlate with spawning cycles. On the other hand, temperature variations seem to explain many facts, and the discussion deals largely with these changes. There is a temperature constant which applies to most marine species, and breeding proceeds when this condition is satisfied. Growth (and absolute dimensions) will depend to some extent upon the fraction of the lifetime of the animal occupied in breeding. One might therefore expect that a semi-sedentary or sedentary animal at the extreme northerly limit of its distribution would be generally larger than one in which the temperature of the sea remained near the constant expressing the temperature optimum. It is suggested that the approximately uniform conditions obtaining in some polar, tropical, and abyssal marine areas may be connected with prolonged, or even continuous, breeding periods. The geographical distribution of a marine animal is obviously controlled by its physiological temperature constant, and deviations from the latter may be the mode of origin of sub-species or varieties.

AMONG a number of water-supply papers issued by the United States Geological Survey special attention may be directed to several series of river plans and profiles constructed in order to determine the location of undeveloped water powers. Recent volumes include "Profile Surveys of Rivers in Wisconsin" (Paper 417), "Profile Surveys of Skagit River Basin, Washington" (Paper 419), and "Profile Surveys along the Rio Grande, Pecos River, and Mora River, New Mexico" (Paper 421). The maps show the outlines of the river-banks, islands, the position of rapids, falls, shoals, and existing dams, and the crossings of all ferries and roads, in addition to the contours of the banks to an elevation high enough to indicate the possibility of using the streams. Data concerning the volume of the flow have been published in previous papers.

THE Monthly Bulletin of the Weather Bureau of the Manila Central Observatory issued by the Government of the Philippine Islands contains detailed observations for numerous stations situated in different parts of the group. The monthly results for August, 1919, are to hand, prepared under the direction of the Rev. José Algué, S.J. Rainfall at Manila during the month was 78·10 in., which breaks all records since the foundation of the observatory in 1865; the previous highest rainfall in August was 43·15 in. in 1877, and the highest for any month of the year was 57·88 in. in September, 1867.

THE exact relations between climate and the growth of crops, and the possibilities of accurate forecasts of production, is the subject of an article by Mr. T. A. Blair in the *Scientific Monthly* for October. Mr. Blair shows in the case of maize in Ohio that the United States Weather Bureau has found that a July rainfall of less than 3 in. means an average yield of 30 bushels per acre, and that a rainfall of 5 in. or more results in 38 bushels. When the July rainfall is 3½ in. the yield is 15,000,000 bushels greater than when it falls short of that amount by half an inch. In the four great maize-growing States of Indiana, Illinois, Iowa, and Missouri the addition of half an inch to a total of 2¾ in. adds 10 bushels per acre to the average yield. A more precise relationship is found in the idea of critical period—that is, certain short periods of time in the growth of any crop, during which its future prospects are largely determined. With some crops this is a single period; with some temperature, and with others rainfall or sunshine, are the most important factors. In the case of maize in Ohio it has been found that the first ten days of August are the critical period as regards rainfall. The application of this knowledge may be used to increase production in two ways. First, it will be possible to determine what crops are climatically suited to a particular district; and, secondly, by the use of early or late varieties and by the help of fertilisers or other means, the crop may be advanced or retarded so as to bring the critical period into coincidence with favourable weather.

Science Progress for October contains an article by Dr. Aston which summaries his work on the atomic weights of the elements as determined by his method of the "mass spectra." These spectra are obtained on a photographic plate placed *in vacuo* by deflecting positive rays on to it by passing them first through an electric, then through a magnetic, field in such a way that all the rays corresponding to an element of given mass are concentrated in a short line on the plate and those of different masses in other parallel lines. The separation of the lines is sufficient to fix the atomic weights to considerably less than a tenth of a unit. By this method it has been possible to demonstrate that boron consists of two, neon, silicon, and chlorine of two or three, bromine of two, krypton of six, and mercury of at least two isotopes—that is, elements of the same chemical properties but of different atomic weights. Dr. Aston concludes that the atoms have weights which are all integral numbers, and that observed fractional atomic weights are due to mixtures of two or more isotopes.

ELECTRIC furnaces in which the heating element consists of a metallic wire or strip are now extensively used both in the workshop and in the laboratory, and possess the advantages of cleanliness, accuracy of temperature control, and small working costs. A special form, possessing several new and useful features, and intended mainly for workshop use, is announced by Automatic and Electric Furnaces, Ltd. The furnace-chamber or muffle is flat on the top and bottom, while the sides are rounded, this shape being specially suited to secure complete contact with the heating coil wound on its exterior. In order to prevent destruction of the coil through inadvertent over-heating, a cut-out consisting of a loop of wire melting at 960° C. is inserted in the furnace. The heating current passes through the loop and is cut off by the melting of the latter, a red pilot-lamp being simultaneously lit up to serve as a warning. Several sizes are listed, ranging in power consumption from 700 to 9500 watts. The muffles are made of a new refractory material called "Ameroid," which is claimed to possess special advantages. We would suggest that intending purchasers of furnaces would prefer to know the composition of the refractory—to which the name given furnishes no clue—so as to judge of its suitability to their requirements.

Engineering for October 15 contains a description of a new 7½-ton six-wheel commercial vehicle made by Messrs. G. Scammell and Nephew, London. One obvious way of reducing costs of road transport is to increase the weight of the load which can be handled by one vehicle and one road crew, and this lorry appears to fulfil this condition admirably. It consists of a four-wheel chassis carrying the engine, and is arranged to draw a two-wheel body which pivots on a turntable at the rear of the chassis. The weight of the complete vehicle is 4½ tons, and it can carry a load of 7½ tons without exceeding an axle-load of 6 tons, which is the limit allowable for a vehicle travelling at 12 miles per hour. The vehicle is able, in addition, to draw a 6-ton trailer, so that a useful load of 13½ tons can be dealt with. Whilst the vehicle is not the first six-wheeler which has been produced, it possesses many points of novelty and interest which add to its usefulness and efficiency. The engine develops 47 brake-horse-power at 1000 revolutimes per minute.

THE presidential address to Section H (Anthropology) of the British Association, which was delivered by Prof. Karl Pearson at Cardiff in August last, has been re-issued as a separate publication by the Cambridge University Press, price 1s. 6d.

Our Astronomical Column.

BRILLIANT METEOR OF OCTOBER 19.—This fine object was observed at 8.15 G.M.T., and descriptions of its appearance have been received by Mr. Denning from Purley and Oxted, in Surrey, and from Stowmarket. Fortunately, the meteor was seen by two experienced observers, Miss A. Grace Cook and Mr. J. Edmund Clark. It was brighter than Venus and gave an intense flash, although the half-illuminated moon was in the same quarter of the sky. The motion was moderate, and a streak remained along one section of the path for about 10 seconds.

On the same date as that on which the meteor appeared the shower of Orionids is usually abundant, and the fireball from its direction of flight seems to have been a brilliant member of that system, though the radiant point was a few degrees below the horizon.

If we adopt a radiant at $88^\circ+17^\circ$, the observations of the object indicate a height from about 61 to 69 miles along a path of 110 miles, and a velocity of about 35 miles per second. In fact, the meteor seems to have been rising in the atmosphere instead of falling, as is usually the case.

The luminous flight occurred over the English Channel, from close to Beachy Head to about 40 miles south of Bournemouth.

Over the West of England the sky was cloudy, and it is important that further accounts should be sent to Mr. Denning from the eastern counties, as the computed heights are rather exceptional and require further investigation.

THE TOTAL SOLAR ECLIPSE OF SEPTEMBER, 1922.—The track of totality in this eclipse traverses the Maldive Archipelago and Christmas Island, south of Java. It then passes right across Australia, but reasonably accessible stations are confined to the eastern portion of its track. Mr. H. A. Hunt, the Commonwealth Meteorologist, acting under instructions from his Government, has prepared a map giving much meteorological information.

A shaded area runs across Australia parallel to, but somewhat south of, the eclipse track; it is stated that this shaded region has no single well-marked wet season, but is subject to both summer and winter rain-producing influences. The map also shows the periods in which most rain falls in each region, and it is noteworthy that the month of September occurs in the wet season on the south coast only, so that the month appears to be favourable on the eclipse track. The sun's altitude on the east coast of Queensland is only 18°, but 26° may be obtained by proceeding inland by rail to Cunnamulla or Coongoola. The directors of the leading Australian observatories have expressed their hope of occupying stations in Queensland, while plans are being formed for expeditions from England to the Maldives and Christmas Island. The scheme of observations will include further verification of the gravitational deflection of light, as it is desirable to strengthen the evidence for a result of such fundamental importance.

THE CAPTURE OF COMETS BY PLANETS.—Prof. H. N. Russell contributes a second article on this subject to *Astr. Journ.*, No. 775. He shows that out of a hundred million comets that approach within an astronomical unit of the sun, 90,000 would be made periodic by Jupiter's action and 2400 by that of Saturn, while the numbers in the case of Uranus and Neptune are only 14 and 8 respectively. Hence he concludes that the two outermost planets have not played any part in such capture, with the possible exception of the comet of the November meteors by Uranus. Prof. Russell admits the curious relationship of the orbits of the comets with periods less than a century, which fall into four groups, the aphelia of which are somewhat outside the orbits of the giant planets. This point gives strong grounds for assuming some connection between these cometary groups and the corresponding planets; further, the point made by Prof. Russell, that many of the cometary orbits considered do not pass within several astronomical units of the planet with which they are associated, may be explained by the slow alteration in the cometary orbit through planetary perturbations.

Many of the facts now pointed out were noted by Mr. R. A. Proctor half a century ago. His explanation was that the origin of the comets in question took place, not by capture, but by expulsion from the giant planets. It is surprising that this suggestion has met with so little support from other astronomers; the phenomena observed in the atmospheres of Jupiter and Saturn testify to the existence of very powerful forces. Even on the earth such explosions as that of Krakatoa occur, in which cubic miles of matter are flung to a great height. Moreover, retrograde orbits would occur more readily if the motion of the parent planet were slower and its gravitation weaker, which would explain their restriction to the comet-families of Uranus and Neptune. Hence it would seem to be premature to accept the non-connection of Neptune with the comet-family that bears his name, as finally demonstrated.

Intensive Cultivation.*

By PROF. FREDERICK KEEBLE, C.B.E., Sc.D., F.R.S.

I PROPOSE to devote my address entirely to horticulture—to speak of its performance during the war and of its immediate prospects. Although that which intensive cultivators accomplished during the war is small in comparison with the great work performed by British agriculturists, nevertheless it is in itself by no means inconsiderable, and is, moreover, significant, and deserves a brief record. That work may have turned, and probably did turn, the scale between scarcity and sufficiency; for, as I am informed, a difference of 10 per cent. in food supplies is enough to convert plenty into dearth. Seen from this point of view, the war-work accomplished by the professional horticulturist—the nurseryman, the florist, the glasshouse cultivator, the fruit-grower and market gardener—and by the professional and amateur gardener and allotment holder assumes a real importance, albeit the sum total of the acres they cultivated is but a fraction of the land which agriculturists put under the plough. As a set-off against the relative smallness of the acreage brought under intensive cultivation for food purposes during the war, it is to be remembered that the yields per acre obtained by intensive cultivators are remarkably high.

The reduction of the acreage under soft fruits—strawberries, raspberries, currants, and gooseberries—which took place during the war gives some measure of the sacrifices—partly voluntary, partly involuntary—made by fruit-growers to the cause of war-food production. The total area under soft fruits was 55,560 acres in 1913, by 1918 it had become 42,415—a decrease of 13,145 acres, or about 24 per cent. But though the public lost in one direction it gained in another, and the reduction of the soft-fruit acreage meant—reckoned in terms of potatoes—an augmentation of supplies to the extent of more than 100,000 tons. Equally notable was the contribution to food production made by the florists and nurserymen in response to our appeals. An indication of their effort is supplied by figures which, as president of the British Florists' Federation, Mr. George Munro—whose invaluable work for food production deserves public recognition—caused to be collected. They relate to the amount of food production undertaken by 100 leading florists and nurserymen. These men put 1075 acres, out of a total of 1775 acres used previously for flower-growing, to the purpose of food production, and they put 142 acres of glass out of a total of 218 acres to like use. I compute that their contribution amounted to considerably more than 12,000 tons of potatoes and 5000 tons of tomatoes.

In this connection the yields of potatoes secured by Germany and this country during the war period are worthy of scrutiny. The pre-war averages were: Germany 42,450,000 tons, United Kingdom 6,950,000 tons; and the figures for 1914 were Germany 41,850,000 tons, United Kingdom 7,476,000 tons. Germany's supreme effort was made in 1915 with a yield of 49,570,000 tons, or about 17 per cent. above the average. In that year our improvement was only half as good as that of Germany, our crop of 7,540,000 tons bettering our average by only 8 per cent. In 1916 weather played havoc with the crops in both countries, but Germany suffered most. The yield fell to 20,550,000 tons, a decrease of more than 50 per cent., whilst our yield was down to 5,469,000 tons, a falling off of only 20 per cent. In the following year Germany could produce no more than 39,500,000 tons, or a 90 per cent. crop, whereas the United Kingdom raised 8,604,000 tons, or about 24 per cent. better than the average. Finally, whereas with respect to the 1918 crop in Germany no figures are available, those for the United Kingdom indicate that the 1917 crop actually exceeded that of 1918. There is much food for thought in these figures, but my immediate purpose in citing them is to claim that of the million and three-quarter tons increase in 1917 and 1918 a goodly proportion must be put to the credit of the intensive cultivator.

I regret that no statistics are available to illustrate the war-time food production by professional and amateur gardeners. That it was great I know, but how great I am unable to say. This, however, I can state: that from the day before the outbreak of hostilities, when, with the late secretary of the Royal Horticultural Society, I started the intensive food-production campaign by urging publicly the autumn sowing of vegetables—a practice both then and now insufficiently followed—the amateur and professional gardeners addressed themselves to the work of producing food with remarkable energy and success. No less remarkable and successful was the work of the old and new allotment holders, so much so indeed that at the time of the armistice there were nearly a million and a half allotment holders cultivating upwards of 125,000 acres of land—an allotment for every five households in England and Wales. It is a pathetic commentary on the Peace that Vienna should find itself obliged to do now what was done here during the war, namely, convert its parks and open spaces into allotments in order to supplement a meagre food-supply.

This brief review of war-time intensive cultivation would be incomplete were it to contain no reference to intensive cultivation by the armies at home and abroad. In 1918 the armies at home cultivated 5869 acres of vegetables. In the summer of that year the camp and other gardens of our armies in France were producing 100 tons of vegetables a day. These gardens yielded in 1918 14,000 tons of vegetables, worth, according to my estimate, a quarter of a million pounds sterling, but worth infinitely more if measured in terms of benefit to the health of the troops.

As the result of Gen. Maude's initiative, the Forces in Mesopotamia became great gardeners, and in 1918 produced 800 tons of vegetables, apart altogether from the large cultivations carried out by his Majesty's Forces in that wonderfully fertile land. In the same year the Forces at Salonika had about 7000 acres under agricultural and horticultural crops, and raised produce which effected a saving of more than 50,000 shipping tons.

Even from this brief record it will, I believe, be conceded that intensive cultivation played a useful and significant part in the war. What, it may be asked, is the part which it is destined to play in the future? So far as I am able to learn, there exist in this country two schools of thought or opinion on the subject of the prospects of intensive cultivation, the optimistic and the pessimistic schools. The former sees visions of large communities of small cultivators colonising the countryside of England, increasing and multiplying both production and themselves, a numerous, prosperous, and happy people and

* From the opening address of the President of Section M (Agriculture) delivered at the Cardiff meeting of the British Association on August 24.

a sure shield in time of war against the menace of submarines and starvation. Those, on the other hand, who take the pessimistic view point to the many examples of smallholders who "plough with pain their native lea and reap the labour of their hands" with remarkably small profit to themselves or to the community.

Before making any attempt to estimate the worth of these rival opinions, it may be observed that the war has brought a large reinforcement of strength to the ranks of the optimists. A contrast of personal experiences illustrates this fact. When in the early days of the war I felt it my duty to consult certain important county officials with the object of securing their support for schemes of intensive food production, I carried away from the conference one conclusion only: that the counties of England were of two kinds, those which were already doing much and were unable therefore to do more, and those which were doing little because there was no more to be done. In spite of this close application of the doctrine of Candide—that all is for the best in the best of all possible worlds—I was able to set up some sort of county horticultural organisation, scrappy, amateurish, but enthusiastic, and the work done by that organisation was, on the average, good; so much so, indeed, that when after the armistice I sought to build up a permanent county horticultural organisation I was met by a changed temper. The schemes which the staff of the Horticultural Division had elaborated as the result of experience during the war were received and adopted with a cordiality which I like to think was evoked no less by the excellence of the schemes themselves than by the promise of liberal financial assistance in their execution. Thus it came about that when the time arrived for me to hand over the Controllership of Horticulture to my successor, almost every county had established a strong county horticultural committee, and the chief counties from the point of view of intensive cultivation had provided themselves with a staff competent to demonstrate not only to cottagers and allotment holders, but also to smallholders and commercial growers, the best methods of intensive cultivation.

By means of county stations the local cultivator may learn how to plant and maintain his fruit plantation and how to crop his vegetable quarters, what stock to run, and what varieties to grow. Farm stations—with the research stations established previously by the Ministry: Long Ashton and East Malling for fruit investigations; the Lea Valley Growers' Association and Rothamsted for investigation of soil problems and pathology; the Imperial College of Science for research in plant physiology, together with a couple of stations, contemplated before the war, for local investigation of vegetable cultivation; an alliance with the Royal Horticultural Society's Research Station at Wisley, and with the John Innes Horticultural Institute for research in genetics; the Ormskirk Potato Trial Station; a Poultry Institute; and, most important of all from the point of view of education, the establishment at Cambridge of a School of Horticulture—constitute a horticultural organisation which, if properly co-ordinated and (dare I say it?) directed, should prove of supreme value to all classes of intensive cultivators. To achieve that result, however, something more than a permissive attitude on the part of the Ministry is required, and in completing the design of it I had hoped also to remain a part of that organisation long enough to assist in securing its functioning as a living, plastic, resourceful, directive force—a horticultural cerebrum. Thus developed, it is my conviction that this instrument is capable of bringing horticulture to a pitch of perfection undreamed of at the present time either in this country or elsewhere.

In my view, horticulture has suffered in the past because the fostering of it was only incidental to the work of the Ministry. In spite of the fact that it had not a little to be grateful for—as, for example, the research stations to which I have referred—horticulture had been regarded rather as an agricultural sideshow than as a thing in itself. My intention, in which I was encouraged by Lord Ernle, Lord Lee, and Sir Daniel Hall, was to peg out on behalf of horticulture a large and valid claim and to work that claim. The conception of horticulture which I entertained was that comprised in the "petite culture" of the French. It included crops and stock, fruit and vegetables, flower and bulb and seed crops, potatoes, and pigs and poultry and bees. I held the view, and still hold it, that the small man's interests cannot be fostered by the big man's care; that horticulture is a thing in itself, and requires constant consideration by horticulturists and not occasional help from agriculturally minded people, however distinguished and capable. I hold that education—sympathetic and systematic—is an instrument the power of which, for our purpose, is scarcely yet tried; is, in fact, of almost infinite potency.

The truth is that great skill and sure knowledge exist among small cultivators side by side with much ignorance and moderate practical ability. Herein lies the opportunity of the kind of education which I have in mind. But for any such intensive system of education to prevail the isolation both of cultivators and of Government Departments must be abolished. There is only one way to prepare the ground for the intensive cultivation of education, and that is to secure the full co-operation of officials and cultivators. If this be not done, the official must continue to bear with resignation the unconcealed hostility of those he wishes to assist. That a state of confidence and co-operation may be established is proved by the record of the Horticultural Advisory Committee which was set up by Lord Ernle during my Controllership. The Committee consisted of representatives of all the many branches of horticulture—fruit-growers, nurserymen, market gardeners, growers under glass, salesmen, researchers, and so forth. That Committee became, as it were, the Deputy-Controller of Horticulture. To it all large questions of policy were referred, and to its disinterested service horticulture owes a great debt. That its existence has been rendered permanent by Lord Lee is of good augury for the future of intensive cultivation.

It may be asked: What are the subjects in which growers require education? To answer that question fully would require an address in itself. Among those subjects, however, mention may be made of a few: the extermination or top-grafting of unthrifty fruit, the proper spacing and pruning of fruit-trees, the use of suitable stocks, systematic orchard-spraying, the use of thrifty varieties of bush fruit and the proper manuring thereof, the choice of varieties suitable to given soils and districts and for early cropping, the better grading and packing of fruit. Of all methods of instruction in this last subject the best is that provided by fruit exhibitions. Those interested in the promotion of British fruit-growing will well remember the object-lesson in good and bad packing provided by the first Eastern Counties Fruit Show, held at Cambridge in 1919. That exhibition, organised by the East Anglian fruit-growers with the assistance of the Horticultural Division of the Ministry of Agriculture, demonstrated three things—first, that fruit of the finest quality is being grown in East Anglia;

secondly, that this district may perhaps become the largest fruit-growing region in England; and, thirdly, that among many growers profound ignorance exists with respect to the preparation of fruit for market.

I believe that no administrator, save the rare genius, can direct the expert, whereas the expert with trained scientific mind and possessed of a fair measure of administrative ability can direct any but a genius for administration. If the work of a Government office is to be and remain purely administrative, no creative capacity is required, and it may be left in the sure and safe and able hands of the trained administrator; but if the work is to be creative it must be under the direction of minds turned as only research can turn them—in the direction of creativeness. To the technically initiated initiation is easy and attractive, to the uninitiated it is difficult and repugnant. The useful work that such a staff as I have indicated would find to do is well-nigh endless. It would become a bureau of information in national horticulture, and the knowledge which it acquired would be of no less use to investigators than to the industry. Diseases ravage our orchards and gardens; some are known to be remediable and yet persist, others require immediate and vigorous team-wise investigation, and yet continue to be investigated by solitary workers or single research institutions. Certain new varieties of some soft fruits are known to be better than the older varieties, and yet the latter continue to be widely cultivated. The transport and distribution of perishable fruit are often inadequate—"making a famine where abundance lies." The information gathered in during the constant survey of the progress of horticulture would serve not only to direct educational effort into useful channels, but to stimulate and assist research.

The tacit assumption which has so far underlain my address is that an extension of intensive cultivation in this country is desirable. I have indicated that areas are to be discovered where soil and climate are favourable to this form of husbandry, and that by the establishment of a proper form of research—administrative—and educational organisation the already high standard reached by intensive cultivators may be surpassed. It remains to inquire whether any large increase in the area under intensive cultivation is, in fact, either desirable or probable.

The dispassionate inquirer will find his task by no means easy. He should, as a preliminary, endeavour to discern in the present welter of cosmic disturbance what are likely to be the economic conditions of the politician's promised land—the new world which was to be created from the travail of war. In the first place, and no matter how academic he may be, he cannot fail to recognise the fact that costs of production, including labour, are at least twice, and probably two and a half times, those of pre-war days, and he must assume that the increase is permanent and not unlikely to augment. What this means to the different forms of cultivation may be judged from the following estimates of capital costs of cultivation of different kinds:

Labour and Capital for Farming and Intensive Cultivation.

—	Labour per 100 acres. Men.	Capital per acre. Pre-war. £	Capital per acre. Present. £
Mixed Farming	3–5	10	20–25
Fruit and vegetable growing	20–30	50	100–125
Intensive cultivation in the open (French gardening)	200	750	1,500–1,875
Cultivation under glass ...	200–300	2,000	4,000–5,000

In the second place, the inquirer is bound to assume that the intensive cultivator of the future, like his predecessor in the past, will have to be prepared to face the competition of the world.

But, on the other hand, he may find some comfort in the fact that both immediately before and, still more, after the war, the standard of living both in this country and throughout the world was, and is still, rising. Hence he may perhaps expect a less severe competition from foreign growers, and also a better market at home. He may also derive comfort from the reflection that the increased cost of production which he must bear must also, perhaps in no less measure, be borne by his foreign competitors. Even before the war the cost of production of one of the chief horticultural crops—apples—was no higher in this country than in that of our main competitors. There are also certain other apparently minor, but really important, reasons for optimism with regard to the prospects of intensive cultivation. Among these is the increasing use of road in lieu of rail transport for the marketing of horticultural produce. The advantages of motor over rail transport for the carriage of perishable produce for relatively short distances—say up to 75 miles from market—lie in its greater punctuality, economy of handling, and elasticity. Fruit crops ripen rapidly and more or less simultaneously throughout a given district. They must be put on the market forthwith or are useless. A train service, no matter how well organised, does not seem able to cope with gluts, and hence it arises that a season of abundance in the country rarely means a like plenty to the consumer. Increasing knowledge of food values, together with the general rise in the standard of living, also present features of good augury to the intensive cultivator. Jam and tomatoes and primeurs may be taken as texts.

In 1914 the consumption of jam in the United Kingdom amounted to about a spoonful a day per person. The more exact figures are 2 oz. per week, or 126,000 tons per annum. It is difficult to estimate the area under jam-fruit—plums, strawberry, raspberry, currants, etc.—required to produce this tonnage, but it may be put at between 10,000 and 20,000 acres. By 1918, thanks to the wisdom of the Army authorities in insisting on a large ration of jam for the troops, and thanks also to the scarcity and quality of margarine, the consumption of jam had more than doubled. From 126,000 tons in 1914 it reached 340,000 tons in 1918. To supply this ration would require the produce of from 25,000 to 50,000 acres of orchard, which in turn would directly employ the labour of, say, from 5000 to 10,000 men. Yet even the tonnage consumed in 1918 allows only a meagre ration of little more than a couple of spoonsful a day. It may therefore be anticipated that if, as is probable, albeit only because of the immanence of margarine, the new-found public taste for jam endures, fruit-growers in this country will find a considerable and profitable extension in supplying this demand.

The remarkable increase in consumption which the tomato has achieved would seem to support this conclusion. Fifty years ago, as Mr. Robbins has mentioned in his paper on "Intensive Cultivation" (*Journal of the Board of Agriculture*, vol. xxv., No. 12, March, 1919), this fruit was all but unused as a food. To-day the production in this country amounts to upwards of 45,000 tons. Yet the demand for tomatoes has increased so rapidly—the appetite growing by what it feeds upon—that the imports in 1913 from the Channel Islands, Holland, France, Portugal, Spain, Canary Islands, and Italy amounted to nearly double the home crop, viz. 80,000 tons, making the total annual consumption not less than 1¼ tons, or about 2 lb. per week per head of population. Is it too fanciful to discern in this rapidly growing increase in the consumption of such accessory foodstuffs as jam and tomatoes, not merely an indication of a general rise in the standard of living and a desire on the part of the community as a whole to share in the luxuries of the rich, but also a sign that in a practical, instinctive, unconscious way the public has discovered simultaneously with the physiologists that a monotonous diet means malnutrition, and that even in a dietetic sense man cannot live by bread alone? If, as I think, the increasing consumption of the accessory foods which intensive cultivation provides represents not merely a craving for luxuries, but an instinctive demand for the so-called accessory food-bodies which are essential to health, then it may be expected that, as has been illustrated in the case of jam and potatoes, consumption will continue to increase. If this be so, the demand both for fresh fruit and also for "primeurs"—early vegetables—should grow, and should be supplied, at least in part, by the intensive cultivators of this country.

If the home producer can place his wares on the market at a price that can compete with imported produce—and it is not improbable that he will be able to do so—he need not, even with increased production, apprehend more loss from lack of demand than he has had to face in the past. Seasonal and other occasional gluts he must, of course, expect.

Even when judged by pre-war values, his market, as indicated by imports, is a capacious one. Thus in 1913 the imports into the United Kingdom of products from small holdings were of the value of about 50,000,000*l.* sterling. To-day it is safe to compute them at more than 100,000,000*l.* To that sum—of 50,000,00*l.*—imported vegetables contributed 5,500,000*l.* sterling, apples 2,250,000*l.*, other fruits nearly 3,000,000*l.*, eggs and poultry more than 10,000,000*l.*, rabbits and rabbit-skins 1,500,000*l.*, and bacon and pork more than 22,000,000*l.* No one whose enthusiasm did not altogether outrun both his discretion and knowledge would suggest that the home producer could supply the whole, or even the greater part, of these commodities. But, on the other hand, few of those who have knowledge of the skill and resources of our intensive cultivators, and of the suitability of favoured parts of this country for intensive cultivation, will doubt that a modest proportion, say, for example, one-fifth, might be produced at home. This on a post-war basis would amount in value to more than 20,000,000*l.*, would require the use of several hundred thousand acres of land, and would provide employment for about 100,000 men.

The estimated acreage under fruit in England and Wales is:

	Acres.
Apples	170,000
Pears	10,000
Plums	17,000
Cherries	10,000
Strawberries	13,000
Raspberries	6,000
Currants and gooseberries ...	22,000
	248,000

exclusive of mixed orchards and plantations.

These figures are, however, well-nigh useless as indicating the areas devoted to the intensive cultivation of fruit for direct consumption. Of the 170,000 acres of apples, cider-fruit probably occupies not less than 100,000, and of this area much ground is cumbered with old and neglected trees. Of the 10,000 acres in pears some 8000 are devoted to perry production, and hence lie outside our immediate preoccupation. Having regard, however, to the reduction of acreage under fruit, to the increasing consumption of fruit and jam, and to the success which has attended intelligent planting in the past, it may be concluded that a good many thousand acres of fruit might be planted in this country with good prospects of success.

Lastly, it remains to consider what results are likely to occur if intensive cultivation comes to be more generally practised in this country.

It may, of course, be true that a chance word, a common soldier, a girl at the door of an inn, have changed, or almost changed, the fate of nations, but it is probable that the genius of peoples and the pressure of economic and social forces are more potent. Is there then, it may be asked, any indication that the people of this country will seek in intensive cultivation a means of colonising their own land rather than continue to export their surplus man-power? The problem is too complex and too subtle for me to solve, but I will conclude by citing a curious fact which may have real significance in indicating that if a nation so wills it may retain its surplus population on the land by adjusting the intensity of its cultivation to the density of its population. If a diagram be made combining the intensity of production of a given crop, *e.g.* the potato, as grown in the chief industrial countries of the world, it will be found that the curve of production coincides closely with that of density of population.

Density of Population and Intensity of Production. Potatoes.

	Density of population square mile.	Percentage of population.	Percentage of yield	Yield in tons per acre less seed. Average 1911–13.
United States	31	10	33	1·3
France	193	62	56	2·2
Germany	311	100	100	3·9
U.K.	374	120	110	4·3
England and Wales ...	550	177	128	5
Belgium	658	212	155	6·04

From these facts we may take comfort, for they indicate that as a population increases so does the intensity of its cultivation: the tide which flows into the towns may be made to ebb again into the country. The rate of return, however, must depend on many factors: the proclivities of peoples, the relative attractiveness of urban and rural life and of life at home and abroad, but ultimately the settlement or non-settlement of the countryside must be determined by the degree of success of the average intensive cultivator. The abler man can command success; whether the man of average ability and industry can achieve it will, I believe, depend ultimately on education. He can look for no assistance in the form of restricted imports. He must be prepared to face open competition. Wherefore he should receive all the help which the State can render; and the measure of success which he, and hence the State, achieves will be determined ultimately by the quality and kind of education which he is able to obtain.

Studies in Animal Inheritance.

ALL students of modern advances in our knowledge of heredity are familiar with Prof. W. E. Castle's experiments in modifying the hooded pattern of piebald rats by continued selection. In a recent Publication of the Carnegie Institution, No. 288, "Studies of Heredity in Rabbits, Rats, and Mice," Prof. Castle describes the results of crossing his selected races with unmodified wild rats, in continuation of his previous work, and announces the conclusion to which he has come. "The same wild race, when its residual heredity is made fully effective by repeated crosses, brings both the *plus*-selected and the *minus*-selected hooded lines to a phenotype of common grade. This shows, contrary to my earlier opinion, that what has really happened in the case of the selected races was more largely due to residual heredity than to any change in the gene for the hooded character itself." In this paper further experiments on the breeding of English and Dutch white-spotted rabbits are also described, the results of which are generally comparable with those obtained from the hooded rats.

The magpie moth (*Abraxas grossulariata*) has been a favourite subject for breeding experiments since Doncaster's memorable demonstration of the sex-linked inheritance of the *lacticolor* colour-aberration. In a recent paper (*Journal of Genetics*, vol. viii., No. 4, 1919) H. Onslow describes the result of crossing with the type the variety *lutea*, in which the ground-colour of the wings is yellow or orange instead of creamy-white, the difference being due to a general deepening of the pigment of the scales. The *lutea* ground-colour is incompletely dominant over that of typical *grossulariata*, so that in the first hybrid generation the colours form a continuous series from white to deep orange, and a plotting of the frequency distribution gives an approximately even "chance" curve. "But the F_2 generation, etc., are at once seen to give curves having more than one maximum caused by the tendency of the colour factors to segregate according to the ordinary Mendelian laws."

In the same number of the *Journal of Genetics* Dr. J. W. W. Harrison continues his series of papers on the hybrid Bistonine moths, dealing especially with what he calls the "stimulus of heterozygosis." His experiments strongly confirm the general belief maintained by Darwin that "cross-fertilisation is a source of strength or of stimulus to metabolic activity"; for he found that among the moths the inheritance of which he studied "the hybrid larvæ were not only emphatically more robust than those of the weaker parent, but they also surpassed in strength and vitality those of the stronger form." Hybrid caterpillars had a very low mortality rate, and they often completed their transformations in an "amazingly short period." Besides discussing the possible intra-cellular causes of these stimuli, Dr. Harrison points out how they may affect the results of breeding experiments on the size and weight factors of such animals as poultry or rabbits. "Any attempted genetic analyses for size purposes which fail to allow for heterozygotic impulses are vitiated and useless."

On the fascinating subject of sex-linked inheritance some new light may come from an extension of Dr. E. Hindle's records of the sexes of series of families of body-lice (*Pediculus humanus corporis*) published in the same number of the *Journal of Genetics*. Three types of family occur, all males, all females, or mixed in which one sex or the other may predominate. The author believes that these results suggest the existence of two types of female and two types of male. The puzzling facts, first noted by Doncaster, respecting coat-colour and sex-inheritance in cats receive further attention and a suggested explanation in a short paper by C. C. Little (*l.c.*, pp. 279–90).

G. H. C.

The Site of the University of London.

WE note with pleasure the decision arrived at by the Senate of the University of London regarding the Government's offer of a site at Bloomsbury. At the meeting of the Senate held on October 20 the report of the Site and Accommodation Committee was adopted, as was also, after a long discussion, the resolution of which we give the full text below. The provisos attached to the acceptance of the offer evince a capacity for keen bargaining and a business mentality not conventionally associated with an academic body. It is to be hoped that they will not in the eyes of the Government constitute an obstacle to the completion of the matter, though it is obvious that some of the conditions will prove difficult in practice. It would be a matter of keen regret if a scheme which has advanced so far should come to grief over any points of detail.

The text of the resolution is as follows:

"That his Majesty's Government be informed that the Senate are prepared to accept the offer made in Mr. Fisher's letter of April 7, 1920, to the Chancellor of the site therein described, gratis and in perpetuity, on the terms as regards the maintenance, rates, etc., of the University headquarters buildings laid down in the Treasury Minutes of February 16 and July 13, 1899, and in Mr. Fisher's letters of June 26, September 24, and October 6, 1920, to the Vice-Chancellor, provided:

"(1) That such grant for maintenance, rates, etc., shall not be counted as a portion of the grants made to universities for educational purposes.

"(2) That the allocation of the site between the various buildings to be erected thereon shall be at the sole discretion of the Senate of the University.

"(3) That the University shall retain and King's College shall retain full possession of their present sites and buildings under the conditions under which they now hold them until such time as the new buildings are ready for occupation and are free from debt.

"(4) That the buildings to be erected for the University headquarters shall be, as regards dimensions and design, in accordance with plans to be agreed upon between the Senate and his Majesty's Treasury, and shall afford not less than 50 per cent. more floor-space than is now allocated in the buildings at South Kensington for the separate use of the University.

"(5) That the terms of the removal of King's College from the Strand to the Bloomsbury site shall be a matter of subsequent negotiation between his Majesty's Government, the Council of King's College, and the Senate of the University, and that an agreement shall be concluded between the said parties.

"And that the Senate, in accepting, subject to the above conditions, the Government's offer of a site in Bloomsbury, assume that the offer does not incidentally involve a policy of curtailing the development of the work of those colleges and schools of the University which are not now, nor in the future will be, situated in the neighbourhood of the Bloomsbury site, and that these institutions will not receive less favourable consideration at the hands of the Government than would otherwise have been the case."

University and Educational Intelligence.

BIRMINGHAM.—At the last meeting of the council profound regret was expressed at the death of Mr. Arthur Godlee, who since 1914 had filled the office of treasurer of the University, and whose death at the present juncture was greatly to be deplored.

The Worcestershire County Council has increased its grant to the University for the current year from 300*l.* to 500*l.*

The following appointments have recently been made:—Mr. T. G. Madgwick, assistant professor in petroleum technology; Mr. Kenneth Neville Moss, assistant professor in coal-mining; Mr. T. Spencer, demonstrator and instructor in petroleum drilling; Miss Nora I. Calderwood and Mr. T. A. Lumsden, assistant lecturers in mathematics; Mr. F. H. Boden, lecturer in machine design; Mr. T. G. Bamford, lecturer in metallurgy; Mr. H. Baker, assistant lecturer in machine design; and Mr. Harold Harris, demonstrator and instructor of assaying.

BRISTOL.—Mr. H. G. Hughes has been appointed assistant lecturer in physics, and Miss G. Gilchrist demonstrator in botany.

The number of full-time day students who have already entered the faculty of engineering this term is 223, as compared with 207 last session.

CAMBRIDGE.—Mr. W. G. Dixon, Downing College, has been re-appointed reader in pharmacology and Mr. S. W. Cole, Trinity College, lecturer in medical chemistry. Mr. T. R. Parsons, Sidney Sussex College, has been re-elected to the Michael Foster research studentship. Field-Marshal Viscount Allenby is to receive an honorary degree on October 29.

Dr. L. E. Shore, St. John's College, and Mr. W. B. Hardy, Gonville and Caius College, have been re-appointed University lecturers in physiology.

The Gedge prize has been awarded to G. E. Briggs, St. John's College, for an essay on "Photosynthesis in Plants."

The Board of Research Studies has recommended to the Senate that degrees of M.Litt. and M.Sc. be established in the University on a two years' post-graduate research course.

EDINBURGH.—The University Court has approved of the minute of the order of the proceedings at the laying of the foundation-stone of the first of the "King's Buildings" by his Majesty the King and the Laureation of her Majesty the Queen on Tuesday, July 6, and directed that it be printed and circulated among the graduates and alumni of the University throughout the Empire and elsewhere, and that an appeal be made for the financial assistance necessary to further the schemes now in progress.

The following appointments have been made to the newly instituted office of reader:—Dr. Cargill G. Knott (applied mathematics), Mr. George G. Chisholm (geography), and Dr. R. Stewart Macdougall (entomology).

The War Office has authorised the utilisation of the estate of Stobs as a forest area in connection with the department of forestry.

LONDON.—A course of three public lectures on "Present Tendencies of Philosophy in America" commences to-day at King's College with a lecture on "New Realism: Its Background and Origin," by Prof. W. P. Montague, professor of philosophy in Columbia University, New York City. The two other lectures will be "New Realism: Its Implication and Promise" (October 29), also by Prof. Montague; and on Monday, November 1, "Pragmatism: Its Right and Left Wings," by Prof. J. E. Boodin, professor in Carleton College, Minnesota. The lectures are at 5.30 p.m., and admission is free without ticket.

Dr. Edwin Deller, assistant secretary of the Royal Society, has been appointed academic registrar of the University in succession to Mr. P. J. Hartog, now Vice-Chancellor of the University of Dacca.

DR. N. MORRIS, assistant to the professor of physiology in the University of Glasgow, has been appointed to the chair of physiology at the Anderson College of Medicine, Glasgow.

A LECTURE on "Eugenics and Religion" is to be delivered at the Wigmore Hall at 5.30 on Tuesday, November 16, by Dean Inge, under the auspices of the Eugenics Education Society.

MR. F. J. HARLOW, head of the department of mathematics and physics at the Sir John Cass Technical Institute, Aldgate, has been appointed principal of the Municipal Technical College, Blackburn, in succession to Dr. R. H. Pickard, now principal of Battersea Polytechnic.

A LECTURE on "Rare Gases in the Atmosphere" will be given by Prof. J. Norman Collie at University College, Gower Street, W.C.1, on Friday, November 19, at 6 p.m., as one of the London County Council's lectures for teachers. The chair will be taken by Mr. A. Chaston Chapman.

A COURSE of twelve free Swiney lectures on geology is announced for delivery by Dr. J. D. Falconer in the geology lecture theatre, Royal School of Mines, South Kensington, on Mondays, Wednesdays, and Fridays, at 5.30, beginning on Monday, November 8. The subject will be "The Modelling of the Earth's Crust."

Societies and Academies.

PARIS.

Academy of Sciences, October 4.—M. Henri Deslandres in the chair.—E. **Picard**: The International Congress of Mathematics at Strasbourg.—The President announced the death of Sir Norman Lockyer, and described the main lines of the scientific work carried out by this distinguished astronomer and correspondant of the Academy.—A. **Lacroix**: A series of alkaline syenitic potassic rocks in sodium minerals from Madagascar.—G. **Bigourdan**: Corrections of the normal time-signals sent out by the Bureau international de l'Heure from January 1 to March 19, 1920. Two types of signal are sent out: ordinary signals for the purposes of navigation, railways, etc., and scientific or rhythmic signals for use in observatories. The corrections for the directing clock are tabulated; those for the time-signals will be given later.—C. **Sauvageau**: The membranes of some algæ (Florideæ) and the setting of the gelosic hydrosol.—M. **Gevrey**: The determination of Green's functions.—T. **Varopoulos**: Some theorems of M. Rémoundos.—J. **Soula**: Generalisation of a theorem of M. Leau relating to the determination of the singular points of a function defined by a Taylor's series.—A. **Bilimovitch**: The intrinsic equations of motion of a solid body.—V. **Vâlcovici**: The hydrodynamical forces in movements differing between themselves by a uniform rotation of space.—J. **Andrade**: The problem of the spiral cylinder.—A. **Vela**: Observations of Nova Cygni. An account of work done on the new star at the Madrid Observatory. Maximum brightness, about 1·4 magnitude, was attained on August 24. A number of spectroscopic observations were made.—J. **Bergengren**: The absorption spectrum of phosphorus for the X-rays.

The substances employed included ammonium phosphate, Bridgemann's black phosphorus, phosphoric acid, and commercial red phosphorus. It was found that the wave-lengths of the limits of absorption were different for the various kinds of phosphorus. This is the first time that the chemical state of an element has been found to have an influence on its X-ray spectrum.—M. **de Broglie** and A. **Dauvillier**: The fine structure of the absorption discontinuities in X-ray spectra. A discussion of some phenomena having a bearing on the results described in the preceding paper by M. Bergengren.—A. **Dauvillier**: The mechanism of the chemical reactions caused by the X-rays. The only mineral substances sensible to the action of the X-rays are crystals for which I. Langmuir, Born and Landé, and Debye and Sherrer have supposed and proved the existence of an ionic structure. All other sensitive substances, colloids, electrolytes, glass, etc., also contain ions. The cause of the chemical actions would thus be due to the destruction of the negative ions, which would lose their electrons under the impact of the rapid electrons constituting the corpuscular radiation. The violet coloration of alkaline glasses, the photo-electric properties of crystals, and the colour-changes in platinocyanide screens are considered from this point of view.—H. **Copaux** and C. **Philips**: The heat of oxidation of beryllium. Direct combustion of the metal in compressed oxygen in the calorimetric bomb gave unsatisfactory results; the combustion of the metal was never complete. The figure required was hence derived indirectly by measuring the heats of solution of the metal and its oxide in dilute hydrofluoric acid. The heat of oxidation, 151·5 calories, was high, and ranges beryllium with calcium (160 calories), lanthanum (148 calories), and magnesium (144 calories).—G. **Denigès**: The microchemical reactions of radium: its differentiation from barium by iodic acid. The usual reagents employed in the microchemical reactions of barium, hydrofluosilicic, oxalic, and tartaric acids, tartar emetic, potassium ferrocyanide, and tartrate give identical results with barium and radium salts. Ammonium cyanurate, ammonium phosphomolybdate in ammonia solution, and potassium bromate, which are also good reagents for barium, give similar crystals with radium compounds. Iodic acid, on the other hand, shows clear differences between the two metals, and reproductions of two microscope-slides are given to prove this. As showing the delicacy of the microchemical method, it is mentioned that all experiments on the reactions of radium were carried out with 0·2 milligram of metallic radium added as the bromide.—R. **Fosse**: The qualitative analysis of cyanic acid.—A. **Lumière** and F. **Perrin**: A new class of hypnotics: the dialkylhomophthalimides. Starting with naphthalene, this is oxidised to phthalonic acid, which reduced by hydriodic acid leads to homophthalic acid, $(CO.OH).C_6H_4.CH_2.CO.OH$, the ammonium salt of which, evaporated to dryness and gently fused, gives the homophthalimide. From this dialkyl derivatives are readily obtained. Used as hypnotics, they possess the advantages of very slight toxic power, and are practically free from unfavourable secondary reactions.—F. **Kerforne**: The tectonic of the Armorican massif.

Diary of Societies.

THURSDAY, OCTOBER 28.

CHEMICAL SOCIETY (at Institution of Mechanical Engineers), at 8.—Dr. M. O. Forster: The Emil Fischer Memorial Lecture.

ABERNETHIAN SOCIETY (at St. Bartholomew's Hospital), at 8.30.—Sir St. Clair Thomson: Recollections of Joseph Lister by one of his House-surgeons.

ROYAL SOCIETY OF MEDICINE (Urology Section), at 8.30.—Sir Thomas Horder: The Treatment of Sub-acute Nephritis by Decapsulation; with an Account of Four Cases.—V. Booney: A New Operation for Nephroptosis.

FRIDAY, OCTOBER 29.

ROYAL GEOGRAPHICAL SOCIETY (at the Æolian Hall), at 5.—T. A. Barns: In the Land of the Okapi and the Gorilla.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Prof. A. Keith: Demonstration on the Contents of the Museum.

INSTITUTION OF MECHANICAL ENGINEERS (Informal Meeting), at 7.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—H. W. Bennett: Winchester: The Cathedral, the School, and the Hospital of St. Cross.

CHEMICAL INDUSTRY CLUB (at 2 Whitehall Court), at 8.—Annual Meeting.

ROYAL SOCIETY OF MEDICINE (Epidemiology and State Medicine Section), at 8.30.—Dr. A. K. Chalmers: The Function of the Isolation Hospital in a General Scheme of Hospital Provision.

MONDAY, NOVEMBER 1.

ROYAL INSTITUTION OF GREAT BRITAIN, at 5.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Prof. S. G. Shattock: Demonstration of Pathological Specimens in the Museum.

ROYAL INSTITUTE OF BRITISH ARCHITECTS, at 8.

INSTITUTE OF BREWING (at Imperial Hotel, Russell Square), at 8.—A. F. Baillie: The Use of Oil Fuel in Breweries.

SOCIETY OF CHEMICAL INDUSTRY (at Institution of Mechanical Engineers), at 8.—Sir William J. Pope: The Photography of Coloured and of Distant Objects.

TUESDAY, NOVEMBER 2.

ROYAL HORTICULTURAL SOCIETY, at 3.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, at 5.—Sir William B. Leishman: An Experimental Investigation of the Parasite of Tick Fever, *Spirochaeta Duttoni* (Horace Dobell Lecture).

INSTITUTION OF CIVIL ENGINEERS, at 5.30.—J. A. Brodie: Presidential Address.

ZOOLOGICAL SOCIETY OF LONDON, at 5.30.—J. H. Lloyd: Some Observations on the Structure and Life-history of the Common Nematode of the Dogfish (*Scyllium canicula*).—Mrs. O. A. Merritt Hawkes: Observations on the Life-history, Biology, and Genetics of the Lady-bird Beetle, *Adalia bipunctata*, Mulsant.—Hara Ram Mehra: The Sexual Phase in certain Indian Naididæ (Oligochæta).—E. A. Barnes: In the Land of the Gorilla and Okapi.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—Capt. C. W. R. Knight: Heronry.

RÖNTGEN SOCIETY, at 8.15.

WEDNESDAY, NOVEMBER 3.

GEOLOGICAL SOCIETY OF LONDON, at 5.30.—Miss M. E. J. Chandler: The Arctic Flora of the Cam Valley at Barnwell, Cambridge.

SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS (at Chemical Society), at 8.—Dr. W. R. Schoeller and E. F. Waterhouse: The Gravimetric Estimation of Bismuth as Phosphate and its applications in Ore Analysis.—P. J. Fryer: The Time Factor in Saponification.—V. Cofman: The Position of Analytical Chemistry in France.—W. T. Burgess: Apparatus for collecting Samples of Water at Great Depths.

THURSDAY, NOVEMBER 4.

ROYAL SOCIETY, at 4.30.—*Probable Papers:* Prof. H. Lamb: The Vibrations of an Elastic Plate in Contact with Water.—Prof. H. M. Macdonald: The Transmission of Electric Waves around the Earth's Surface.—Lord Rayleigh: A Re-examination of the Light scattered by Gases in respect of Polarisation. II. Experiments on Helium and Argon.—Prof. C. F. Jenkin: Dilatation and Compressibility of Liquid Carbonic Acid.—W. T. David: Radiation in Explosions of Hydrogen and Air.—Dr. R. E. Slade and G. I. Higson: Photochemical Investigations of the Photographic Plate.—Dr. E. H. Chapman: The Relationship between Pressure and Temperature at the same Level in the Free Atmosphere.—Prof. J. C. McLennan: Note on Vacuum Grating Spectroscopy.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, at 5.—Dr. R. C. B. Wall: Chorea (Bradshaw Lecture).

LINNEAN SOCIETY, at 5.

ROYAL AERONAUTICAL SOCIETY (at Royal Society of Arts), at 5.30.—Wing-Comdr. Flack: The Human Machine in Relation to Flying.

CHILD-STUDY SOCIETY (at Royal Sanitary Institute), at 6.—Mrs. S. S. Brierley: Discussion on Vocational Tests.

CHEMICAL SOCIETY, at 8.—L. Higginbotham and H. Stephen: The Preparation of 4-, 5-, and 6-Methyl-coumarin-2-ones, and some Derivatives of *o*-, *m*-, and *p*-Tolyloxyacetic Acids.—H. Stephen: A New Method for the Preparation of 2:4-Dihydroxy- and 2:4:4′-Trihydroxy-benzophenone, and some Observations relating to the Hoesch Reaction.—W. J. Pope and E. E. Turner: Triphenylarsine and Diphenylarsenous Salts.—R. H. Atkinson, C. T. Heycock, and W. J. Pope: The Preparation and Physical Properties of Carbonyl Chloride.—H. W. Bausor, C. S. Gibson, and W. J. Pope: Interaction of Ethylene and Selenium Monochloride.—G. Van B. Gilmour: A Study of the Reactions of Sugars and Polyatomic Alcohols in Boric Acid and Borate Solutions, with Some Analytical Applications.—F. L. Pyman and L. A. Ravald: The Sulphonation of Glyoxalines.—F. L. Pyman and L. A. Ravald; *o*- and *p*-Tolueneazoglyoxalines.—M. E. Laing and J. W. McBain: Investigation of Sodium Oleate Solutions in the Three Physical States of Curd, Gel, and Sol.—J. C. Irvine and E. S. Steele: The Constitution of Polysaccharides. Part I. The Relationship of Inulin to Fructose.—B. E. Hunt: The Preparation of Ethyl Iodide.—R. C. Menzies: Action of Sulphur Trioxide on Aromatic Ethers.—G. T. Morgan and H. D. K. Drew: Researches on Residual Affinity and Co-ordination. Part II. Acetylacetones of Selenium and Tellurium.—R. R. Drew: The Formation of 2:3:6-Trinitrotoluene in the Nitration of Toluene.—J. N. E. Day and J. F. Thorpe: The Formation and Reactions of Imino-compounds. Part XX. The Condensation of Aldehydes with Cyanoacetamide.—O. Becker and J. F. Thorpe: The Formation and Stability of Spiro-compounds. Part III. Spiro-compounds from Cyclopentane.—H. Chattopadhyaya and P. C. Ghosh: Condensation of Dimethyldihydroresorcin with Aromatic Aldehydes.—E. B. Maxted: The Influence of Lead on the Catalytic Activity of Platinum.

FRIDAY, NOVEMBER 5.

ASSOCIATION OF ECONOMIC BIOLOGISTS (in Botanical Lecture Theatre, Imperial College of Science), at 2.30.—Prof. F. W. Oliver: The Reclamation of Waste Land by Botanical Means.—Dr. E. J. Russell: The Reclamation of Waste Land by Agricultural Means.

GEOPHYSICAL COMMITTEE (Royal Astronomical Society), at 5.—Discussion on the African Arc and Meridian, to be opened by Col. H. G. Lyons, and continued by Sir Charles Close, Col. E. M. Jack, A. R. Hinks, C. G. T. McCaw, and others.

INSTITUTION OF MECHANICAL ENGINEERS, at 6.—Sir Richard T. Glazebrook: Limit Gauging (Thomas Hawksley Lecture).

Symbolic Language of Science.

WE have received from Prof. McAdie, of Blue Hill Observatory, an off-print of a note on the subject of uniformity in aerographic notation, which occupies nine pages (169-177) of the Blue Hill Meteorological Observations, forming vol. lxxxiii., part 4, of the Annals of the Harvard Observatory. It invites agreement with regard to the symbolic representation of the quantities and operations required for the discussion of problems in the dynamics and physics of the atmosphere in pursuance of a suggestion of Dr. Otto Klotz in *Science*, vol. xlvi., p. 360, 1917.

There can scarcely be any difference of opinion as to the desirability of arriving at an agreed practice in the use of symbols by different workers in the same subject. So far as the atmosphere is concerned, Prof. Bigelow held a very comprehensive review of the rank and file of the analysis of atmospheric operations in his discussion of cloud observations which forms the second volume of the Report of the Chief of the Weather Bureau for 1898-99; the first volume of the work on "Dynamic Meteorology and Hydrography," by V. Bjerknes and others (Carnegie Institution of Washington, 1910), sets out the representation of the physical quantities to be employed in a systematic manner, and a book by Mr. L. F. Richardson, now in the printer's hands, ranges over the same field. Ideas of uniformity are naturally developed to some extent in the various parts of the Computer's Handbook of the Meteorological Office, which endeavours to provide the worker in atmospheric dynamics and physics with the necessary material and forms for numerical computation arranged upon a systematic basis, and aspires to attach to each quantity its appropriate symbol.

But the subject bristles with difficulties of many kinds. We have available in practice, let us say, five alphabets ("lower case" roman and italic, "upper case" roman and italic, "lower case" Greek), a few letters taken from other alphabets, and a few additional symbols for units or operations. With these we have to represent the items of a considerable number of quite separate categories; for example, we want to represent: (1) defined quantities for specific units, as m for metre, g for gram; (2) quantities undefined as to unit, as ϕ for latitude and λ for longitude, which may be in radians or degrees, and u, v, w for velocity irrespective of unit; and (3) symbols of operation, as of multiplication, division, summation, and differentiation of various kinds.

In the absence of a sufficiency of letters or alphabets, we are accustomed to make out with suffixes and indices, but here we are liable to get into vexatious difficulties with the printer, and more particularly with the typist, who must be reckoned with in these days, and is apt to display a misguided ingenuity in substituting for a carefully selected symbol the nearest thing to it that can be got out of the keys; and, in any case, if the symbolism could be so arranged as to allow the print to "run on," it would be useful for both reader and publisher.

No adequate account can be given of the details of Prof. McAdie's scheme without reproducing it *in extenso*. With three alphabets and some suffixes and indices (apparently without making any use of the discrimination between roman and italic type), he represents ninety-four quantities, including such modern conceptions as electron, Planck's element of action, Taylor's eddy conductivity and viscosity, and Richardson's turbulivity. He uses them in five pages of fundamental relations. But the allocation is not altogether successful; the letters are all gone, and some very ordinary quantities, such as area and vapour-pressure, have no symbol. N means Avogadro's constant, S entropy, E energy, and W external work; but somehow or other, definition or no definition, N—S and W—E are written down as representing wind components. If it be agreed that kb means kilobar and s means space, there is a certain depravity in using kbs, as Prof. McAdie does, to mean simply a plural of kb.

Furthermore, it is not really possible with our limited number of letters to allocate so many of them for purely arithmetical purposes. Very many of them are wanted for algebra; in fact, many more than are actually available before any allocation takes place. Prof. McAdie allows only x, y, z, and t for co-ordinates, but we must be permitted to change our co-ordinates. In the past, polar co-ordinates, co-ordinates referred to moving axes, and direction cosines have claimed letters which Prof. McAdie proposes to hand over for fixation.

The fact is that the allocation of a letter in common use to one specific and conventional meaning is a very awkward policy. It is not unfair to argue that if we want a symbol to be allocated definitely to a new quantity, and taboo for everything else, we ought to invent a new figure and get it canonised by a sufficient authority to induce printers to stock it. It sounds impracticable, but is at least worth consideration, for meteorologists have already done it in the case of symbols for atmospheric phenomena. Otherwise workers in sciences which are adjacent and not altogether independent are likely to select the same letters for different quantities, and there must be confusion. Perhaps the language of science ought to expand its notation as ordinary language has done by proceeding from single letters to syllables, and that would certainly be an easy and effective way of dealing with the question if we could do away with the convention that multiplication needs no symbol of operation, and require that every operation should be represented by a suitable sign.

Indeed, all ideas of allocating symbols for special quantities lead up to the suggestion that the study of the effectiveness of the language of science ought no longer to be left to the casual play of forces of individual workers. An Academy of Science might with advantage have a literary side, and there might even be lectures on the art of expression, symbolically or otherwise, of scientific truths, with examples, some good and some bad, taken from scientific literature. Scientific institutions tend to separate themselves from the study of the classical languages and become independent centres of learning, and as they do so they ought to make adequate provision for the study of the history and literature of science in order to make sure that the literary form of the results which the institutions will present to the world will not be entirely neglected, as apparently it is now in some contributions to science. Scientific achievement is not really complete when only the author is satisfied with the results. It might be useful to make out how much scientific literature is neglected because its form is crabbed, repulsive, or even unintelligible.

These are quite natural expansions of the idea of economising the effort of the writer and reader by an agreement as to the use of symbols. That is an obvious and essential step, but we ought first to come to an agreement upon some general principles whether, to begin with, there is, or shall be, any difference in meaning between a symbol in roman and the same letter in italic. The Computer's Handbook draws a distinction. It reserves roman for units or symbols of operation. It uses italic to indicate varying quantities, and sometimes capitals for defined quantities. Thus g is gram, but g is gravitational acceleration; θ is temperature, but T is temperature on the absolute scale. Another general question is whether operations should be consistently indicated by letters or by signs, or either mode of indication be allowed as the writer finds convenient.

The difficulty in the way of getting agreement on these questions is not so much unwillingness on the part of workers as lack of authoritative reference to recognised classics. After carrying on an elaborate series of computations with the improvised symbolism that suggests itself as one goes along, it is too laborious to go over it again to bring it into agreement with someone else's notions; and as one is naturally led on gradually in the course of a research to take in more quantities, one can scarcely begin it by selecting a system of notation. It grows of itself as the work progresses. But if the Royal Society were to alternate the list of publications as an advertisement in the lining of its Transactions with a list of recognised symbols, or if in some other way some convention were made quite easy of reference, we should have little difficulty in adhering to it.

NAPIER SHAW.

The History of a Mind.

Pasteur: The History of a Mind. By Prof. Emile Duclaux. Translated by Erwin F. Smith and Florence Hedges. Pp. xxxii+363. (Philadelphia and London: W. B. Saunders Company, 1920.) Price *21s.* net.

PASTEUR has been fortunate in his biographers. There is the well-known life by René Vallery-Radot, which describes for us the man himself, his noble, impulsive character, his thirst for knowledge and zeal for humanity, and gives a general account of his researches and discoveries; an essay by Sir George Newman, which appeared some twenty years ago and deserves republication, expresses in eloquent terms an appreciation of Pasteur's life-work from the English point of view; while, for the purpose of scrutiny of the details of the discoveries themselves, we possess studies by two of the master's disciples, Duclaux and Roux. The volume now under review is a translation by two American pathologists of Emile Duclaux's "Histoire d'un Esprit." In French it is the volume which every serious student of Pasteur's work has read, and it is a little surprising to find, not only that twenty-four years have apparently elapsed before the appearance of an English translation, but also that the original work appears to be almost unknown outside France, according to the senior translator.

The introduction to the book takes mainly the form of a brief memoir of the author. As Boswell derives his fame from Dr. Johnson, and Lockhart is known as the biographer of Scott, so Duclaux will live chiefly in the shadow of Pasteur and by this book. As a chemist, he was first closely associated with Pasteur in 1862 at the École Normale; separated from him for a short time on becoming professor of chemistry at Tours, he was soon transferred to Clermont-Ferrand, where a portion of his time could be given to Pasteur's work; subsequently he went to Lyons as professor of physics for five years, and in 1878 he came to Paris as professor of meteorology in the Agronomic Institute. In 1888, when the Pasteur Institute was founded, Duclaux joined the staff assembled under the command of Pasteur, numbering such illustrious names as Chamberland, Roux, Nocard, Grancher, Metchnikoff, and Yersen among his colleagues. Duclaux's function was the intelligence department, the dissemination of discoveries to the world—not the actual research work. He founded *Les Annales de l'Institut Pasteur*, and in so doing created the channel through which the wealth of the discoveries made by Pasteur and his co-workers poured to the open sea of scientific knowledge. Duclaux was an organiser. He wrote well, with all the vivacity and picturesque style of which a master of the French language is capable; there is not a dull page in his scientific treatises. He found his *métier* as an editor and an interpreter of the labours of others. An ardent toiler, who early adopted Pasteur's motto, "*il faut travailler toujours*," Duclaux himself did little original work. His books, "Ferments et Maladies" (1882) and "Le Microbe et la Maladie" (1885) were records of Pasteur's labours; he collated and co-ordinated the scattered facts on enzymes, classed them into groups according to their reactions, and proposed a scheme of terminology for them. In a word, he was one of the earliest administrators in science. On the death of Pasteur, in 1895, he succeeded him as director of the Institute, and died himself in 1904.

In the book before us, Duclaux traces in detail the steps by which Pasteur was led to make his famous discoveries. "*Que peut bien être l'histoire d'un esprit?*" is the first sentence of the original work, and then the author proceeds to show how, in the hands of Duclaux, the task is possible. Guided by him, we follow Pasteur through the thicket of truth and error. We observe how, amid the storm of criticism and controversy, Pasteur advanced unshaken, and if ever he missed his way for a moment, as in the earlier days of the conflict on spontaneous generation, how speedily and surely he retraced his steps. Duclaux tells us the fascinating story of the first work on crystallography, when the foundations of stereochemistry were well and truly laid. As a chemist, Duclaux lingers over this early work; we can readily understand how great a pure chemist was lost in Pasteur when he chose to become the first bacteriologist. Yet, as Duclaux reveals to us, all Pasteur's life-work pursued an orderly sequence: the study of crystals led to the researches on ferments. "If one of the salts of racemic acid, paratartrate or acetate of ammonia, for instance, is placed in the ordinary conditions of fermentation, the dextro-tartaric acid remains in the liquor, the reason being that the ferment of that fermentation feeds more easily on the right than on the left molecules." Pasteur found then that molecular dissymmetry appeared as a modifying agent on chemical affinities in a physiological phenomenon, and it was a mere step for his mighty intellect to proceed to solve the problems of lactic and alcoholic fermentations, of spontaneous generations, and of the diseases of wines and silkworms. Short, too, was the step again for Pasteur from these studies towards the etiology of microbial diseases, the wonderful work on anthrax and on chicken cholera, the problems of immunity, virulence, and attenuation, and the crowning work on rabies.

All this we read with the avidity of a child for a twice-told tale, and the pen of Duclaux transports us back to the days when these discoveries were revolutionising the realms of medicine and surgery. Sir Rickman Godlee's "Life of Lord Lister" has reminded us afresh of the influence that Pasteur exercised on that great surgeon's work, a debt which Lister acknowledged from the inception of his own researches. Duclaux deals more briefly with the later discoveries of Pasteur, possibly because his own studies had lain more in the direction of the researches on crystallography and fermentations; this, however, is no blemish upon the book, which must always remain a classic in the history of science.

The translation has been faithfully done; at times too faithfully. Thus, on p. 7, "The general law, just now stated, that a science progresses above all by changing its point of view, explains the aid which it always derives from kindred sciences," is too literal a rendering of "La loi générale énoncée tout à l'heure, qu'une science progresse surtout en changeant ses points de vue, explique le secours qu'elle tire toujours des emprunts faits aux sciences ses voisines."

The book is well printed, and illustrated by several portraits of Pasteur at different ages and by two portraits of Duclaux. A good index has been prepared by the translators, who are also responsible for an innovation in a scientific work in respect of a "Who's Who" of persons mentioned in the book. Lister's knighthood is given, but not his peerage.

Duclaux's work thus presented should find new readers both in Great Britain and America.

A. S. M.

Applied Plant Ecology.

Plant Indicators: The Relation of Plant Communities to Process and Practice. By Frederic E. Clements. (Publication No. 290.) Pp. xvi+388+92 plates. (Washington: The Carnegie Institution of Washington, 1920.) Price 7 dollars.

DR. CLEMENTS'S enthusiastic and prolific researches in pure ecology are well known to botanists. In his latest publication he endeavours to apply his principles and methods to the practical problems of agriculture, stock-raising, and forestry, with special reference to the Western United States. According to his view, every plant is an indicator of "conditions, processes, or uses," because it is the product of the conditions under which it grows. The individual, the species, or the community may serve as an indicator, and the choice of the unit to be employed in a given case will depend partly upon the practical end in view, and partly upon the ecological data available. To give a concrete instance: the *species* *Mertensia sibirica* indicates the *condition* "deep shade" in the montane forest of Colorado. In using plant-communities as indicators Dr. Clements relies mainly upon the dominant species, so that in practice there appears to be no sharp distinction between specific and community indicators. His general classification of types of grazing-land, however, is based upon plant-communities, inasmuch as a uniform community of grass, weed, or browse is held to indicate suitability for cattle, sheep, or goats respectively, while a prairie or a grass-scrub mictium [*i.e.* a mixed community containing dominants both from grass- and from scrub-associations] [1] or savannah denotes the advisability of mixed grazing by two or three kinds of animals. As an example of "individual" indicator-criteria, it is stated that ten "water-ecads" [*i.e.* habitat-forms corresponding to ten different degrees of water-supply] of *Ranunculus sceleratus* have been produced experimentally; plate 11 further shows photographs of [natural] shade, alpine, and "normal" ecads of *Campanula rotundifolia, Gentiana amarella,* and *Androsace septentrionalis.*

The nature of plant-indicators, briefly explained above, forms the principal topic of the first section (chaps. i.–iii.), which also deals with the determination and application of indicators, and includes a short historical *résumé* of the indicator concept. Chap. iv. gives a summary review of the climax [*i.e.* climatic] formations of western North America, and, judged by the account of Chapparal-formations—which the reviewer is best able to appreciate from personal knowledge of analogous Mediterranean formations—is adequate on the descriptive side; some useful information regarding rainfall and other environmental factors is included, and the dominant species are recorded for each formation. Altogether this chapter, already outlined in a former paper [F. E. Clements, "Plant Succession," Carnegie Institution, No. 242, 1916], is a very useful addition to the literature of plant geography.

The most interesting portion of the book is the last—roughly one-third of the whole—in which Dr. Clements discusses in detail the practical employment of indicators in the interests of farmers, stock-raisers, and foresters. A striking feature

[1] Words in square brackets are the reviewer's.

of the agricultural section (chap. v.) is the proposal to base the legal classification of land upon indicator communities. The bearing of the study of climatic cycles on agricultural practice is dealt with in the light of facts already for the most part summarised in "Plant Succession." The large amount of space devoted to grazing-indicators (chap. vi., 66 pages) is accounted for partly by the very full discussion of over-grazing, in the detection of which condition indicator-species appear to be specially helpful, and partly by a digression on the general principles of range [ranch] improvement. As regards the forestry section (chap. vii.), the very scant attention paid to afforestation is disappointing to the European reader, though comprehensible in view of the relatively large area of natural forest growth still preserved intact in North America.

In order properly to appreciate Dr. Clements's arguments, it is above all necessary to understand his point of view, which is that of a thorough-going adaptationist who regards every feature in the behaviour or structure of an organism as a response to environment. His utmost concession to the influence of heredity is the admission that "structure also possesses a well-known inertia, as the result of which it may register the impact of factors but partially or slightly." Probably few biologists will be satisfied with so meagre an allowance for the factor of inherited constitution. Further, for Dr. Clements, "ecology is the central and vital part of botany," and other lines of botanical research are, or ought to be, subordinated thereto. One need not, therefore, be surprised to meet with sweeping proposals for the radical reform of taxonomy, involving the institution of a trinomial nomenclature [!] and the virtual abolition of the use of herbarium type-specimens. Unless we are prepared to jettison the taxonomic work of the past centuries in its entirety, it is to be feared that a hasty acceptance of such revolutionary suggestions would increase rather than diminish the difficulties that already beset the taxonomist and all who depend upon him. Doubtless "the practical man is [or would like to be] concerned primarily with real species rather than with the many varieties and forms into which some of them fall"; but the problem of what are "real species" remains to be solved, and surely this desirable end is more likely to be attained through a healthy co-operation among workers in the various branches of biology than by a *tour de force* in any one of them.

Apart from such debatable matter, "Plant Indicators" is a record of a large quantity of solid observation and experiment, and a stimulating book with a wider appeal than that of the average ecological memoir. Judgment as to the practical value of the indicator method must be suspended until it has undergone the test of extensive application under varied conditions and on an economic footing.

Dr. Clements properly lays stress on the special value of ecological research in new or partly settled regions. Oddly enough, no mention is made of those tropical countries which in every respect offer the most promising field to the ecologist, and to which American botanists have unrivalled facility of access. M. D.

The Food Problem of the United States.

The Nation's Food: A Statistical Study of a Physiological and Social Problem. By Prof. Raymond Pearl. Pp. 274. (Philadelphia and London: W. B. Saunders Co., 1920.) Price 16s. net.

ONE result of the Great War has been to bring into unusual prominence the problem of the world's food supply. Each civilised nation contains two great divisions, which in many ways are somewhat antagonistic, dependent respectively on food production and on industrial work. The problem differs in urgency for the two groups: for the food producer, living in the country, it is one of greater or smaller profits, but not of daily bread, of which he is certain; for the industrial town-dweller the problem is more serious, because the intricate social machine is easily thrown out of gear by a few disaffected spirits, and food is forthcoming only so long as the machine turns out sufficient goods to induce the production of more food than the countryman needs for his own consumption.

Prof. Raymond Pearl has given in this book a statistical study of the food problem of the United States, and with his usual thoroughness and breadth of view he has included in his inquiry so many ramifications that his investigation covers Europe also. It thus possesses extraordinary interest at the present time. His tables contain a wealth of material of which only a few indications can be given here. The contribution made by the United States to the food supply of the Allies during the war was remarkable. The pre-war average export of wheat and flour was 122·7 million bushels, of which 43·3 million went to the Western Allies; during the war, but before America's entry, it rose to 262·9 million bushels, of which 151·2 million went to the Allies; even in the first year of the war the Allies still received

114·8 million bushels. This astonishing change is a remarkable achievement for which the Allies may well be grateful and of which America may justly be proud. The total production of food naturally did not increase to the same extent. The data are:—

Total Food Production in the United States: Metric Tons, Millions.

	Total food	Protein	Fat	Carbohydrates	Total Calories, million millions
Average for 7 years, 1911–18	90·2	4·1	5·7	16·3	137·2
,, ,, 3 pre-war years	85·0	3·8	15·5	15·3	129·3
,, ,, war period ..	93·7	4·2	5·9	17·1	143·0

Animals contributed 58 per cent. of the total food, 50 per cent. of the protein, and 83 per cent. of the fat.

The table further shows what a vast amount of food has to be grown in order to produce a sufficiency of nutrients; only 29 per cent. of the total tonnage of human food is net nutrients; the remainder is water, ash, and inedible refuse.

Comparing the annual increases in the production of food with the growth of the population, Prof. Pearl arrives at the comforting conclusion that the food supplies of the United States are increasing more rapidly than the population, so that there is "as yet no occasion for worry along Malthusian lines in this country so far as subsistence is concerned."

Study of the details of Prof. Pearl's tables brings out a number of points of importance to administrators. The very small part played—and playable—by the so-called "home garden" movement is shown by the fact that the *total* vegetable production of farm and garden amounts to only 2 per cent. of the total Calorie production in human food, and of this 2 per cent. a large proportion is contributed by commercial concerns. Similarly, poultry contributes less than 2 per cent. of the Calories. Cows, pigs, and wheat are the great reservoirs, contributing together 62 per cent. of all the protein and carbohydrate used as human food, 69 per cent. of all the fat, and 65 per cent. of all the Calories. Obviously, if there is to be an increase in human food we must concentrate on these (and in England on the sheep as well), and not lose ourselves in less important items, although, on the other hand, we must not fail to develop even a 1 per cent. item.

The distribution of this enormous production is elaborately dealt with. The high-water mark of exports was reached in the year 1914–15; thereafter they fell, and in 1917–18 were down almost to pre-war level; but, of course, the exported food was all going to the Allies instead of being distributed over the world. The 1914–15 result is explained by supposing that all reserves were then cleared out—a process obviously possible once only. In spite of the high exports, more food remained in the United States than in the pre-war period, which may be connected with the larger and more prosperous domestic population.

Finally, a table is given showing the average daily consumption per "adult man." For convenience the British data are also given. The figures are as follows:—

	United States			United Kingdom	Physiologica minimum
	Corrected for waste Grams per day	Not corrected for waste Grams per day		Not corrected for waste Grams per day	Grams per day
Protein ...	114	120	...	113	100
Fat	127	169	...	130	100
Carbobydrate	433	541	...	571	500
Calories ...	3424	4288		4009	3400

The United Kingdom figures are taken from the Royal Society's Report (Cd. 8421), and show that we eat less than our cousins across the water, unless, indeed, we waste less.

E. J. RUSSELL.

Theory of Electric Cables.

The Theory of Electric Cables and Networks. By Dr. Alexander Russell. Second edition. Pp. x+348. (London: Constable and Co., Ltd., 1920.) Price 24*s*. net.

DR. RUSSELL'S well-known book on the theory of electric cables and networks is one which should be increasingly studied as the complex networks, which are now required in connection with large power stations, are constructed. The book is already well known to electrical engineers. It lays down those fundamental principles on which all designs of cable networks must be built up. The kilowatt capacity of central stations for generating electrical energy is now three times as large as it was when the first edition of Dr. Russell's book was published, and the importance of economical design in cables and networks is much more clearly recognised than it was twelve years ago.

The chief difference between the first edition and the second is the introduction of new chapters on alternating current theory and systems of supply, and in the inclusion of numerical examples which will make the book more useful for beginners. Some further extensions of Kelvin's law have been made, and an account is given of recent developments in cable construction. The scope of the work is so well known that it is not necessary to review it in detail. It deals with the properties of conductors and of insulating materials, methods of testing them, and the economy of the various systems of supply. It includes a number of important theorems relating to distributing networks, with the measurement of their insulation resistances and with the determination of the positions of faults.

The subject of dielectric strength is one on which Dr. Russell is a well-known authority, and the chapter on this subject is exceedingly good; it includes a number of useful tables for sparking voltages in air. There is a chapter on the grading and the heating of cables, and another on electrical safety valves, the book concluding with a chapter on lightning conductors. If the theories here given and their practical application were more clearly understood by all central station men, there would be a considerable reduction in the weight of copper which is now laid down in cable systems. It is to be hoped that an increasing amount of consideration will be given to the design of cables and distribution networks, and for this purpose the new edition of Dr. Russell's book will be of great value.

The Carbon Compounds.

A Text-book of Organic Chemistry. By E. de Barry Barnett. Pp. xii + 380. (London: J. and A. Churchill, 1920.) Price 15s. net.

SINCE almost all lecture courses on organic chemistry follow certain main lines, it is to be expected from financial reasons that new text-books on the subject will not diverge far from the older books in their general treatment of the material. All that can be expected from the authors is the infusion of fresh interest by a variation in the scope of the books and in the handling of details. This is to be regretted; but it is apparently almost inevitable.

Within these limitations Mr. Barnett has written an excellent book. It is clearly put, very well illustrated, furnished with formulæ much superior to those usually found in text-books, and in addition possesses certain features distinguishing it from the ordinary run of its class. The most original of these is the guide to the literature of organic chemistry which terminates the introduction, and this is supplemented by references to books at the end of those chapters where further information may be required. By these means the student will gain a truer perspective of the subject, and will not be inclined to assume that his text-book has made him a past-master in the field.

If there is any fault in the book, it lies in the fact that the author appears to over-estimate the mental quickness of the ordinary student. The theoretical side of the subject is dealt with as a whole at the beginning of the volume, and it seems probable that the book would gain considerably if this part of it were extended. Also, cross-references to this section in the body of the text would improve the work.

The commercial applications of organic chemistry are emphasised more frequently than in most text-books, and enough information is given about the heterocyclic section to enable the student to appreciate its importance from the point of view of naturally occurring materials. In a new edition some description of indicators other than phenolphthalein might be given, and possibly a brief reference to the flavones and anthocyanins included in the heterocyclic section.

The book is laudably free from errors, and no misprint in it is likely to give any trouble to a careful reader. The only important slip appears to be the erroneous formula for chloropicrin given on p. 150.

As a whole the book is marked by its fresh treatment of the material, and is to be welcomed. Its main drawback lies in its price.

Anthropology and History: Being the Twenty-second Robert Boyle Lecture, delivered before the Oxford University Junior Scientific Club on June 9, 1920. By Dr. W. McDougall. Pp. 25. (London: Humphrey Milford; Oxford University Press, 1920.) Price 2s. net.

THE object of this instructive lecture is to illustrate the importance of the study of anthropology as an adjunct to the study of history. Anthropology is not exclusively concerned with the measuring of skulls, or with the study of primitive man, save for the sake of cultured man. Without it, it is impossible to understand the causes of the rise and fall of nations, to forecast their future, or to guide the statesman from the experience of the past. An alien culture can rarely be imposed upon a people by external power and authority. As examples of the effect of race upon culture, the lecturer points to the disappearance of Buddhism from India and its progress in Tibet and China; the relative distribution of the Roman Catholic and Protestant forms of Christianity in Europe; and the power of expansion as illustrated by the success of Great Britain and the failure of France to create a colonial empire. These last, capacity and incapacity, were evolved in the prehistoric period, because no adequate explanation of them in the historical period can be postulated, and similar diverse qualities are assigned by the earliest historians to the ancestral stocks of both peoples.

The races capable of producing and sustaining civilisation at a high level are generally formed from the blending of several peoples of superior natural endowments, when social institutions are free from the feeling of caste. This last condition is important, because the concentration of natural endowments in a privileged order inevitably leads to atrophy and decline. Men and nations are both free to choose and pursue their course towards higher ends, and anthropology, studied as a branch of history, will suggest the means by which this progress can be attained.

The Journal of the Institute of Metals. Vol. xxiii., No. 1, 1920. Edited by G. Shaw Scott. Pp. xii + 644 + xxx plates. (London: The Institute of Metals, 1920.) Price 31*s*. 6*d*. net.

THE large size of this volume, as compared with that of previous issues, is an indication of the growing interest in the metallurgy of the non-ferrous metals. Sir George Goodwin's presidential address demonstrates the importance of those metals to the Navy, an importance which would in itself justify the existence of the institute. The fifth report to the Corrosion Committee carries this valuable investigation a stage further, and succeeds in throwing light on the problem of the corrosion of condenser tubes, the new facts concerning the skin on the surface of a drawn tube being of distinct value to the discussion of the possible methods of lessening corrosion. A similar subject is dealt with in a paper by Dr. Seligman and Mr. Williams on the action of hard waters on aluminium. Mr. Vivian's paper on the alloys of tin and phosphorus is an excellent piece of thermal analysis, dealing with a system of which one component is highly volatile, thus introducing great experimental difficulties. The alloys of zinc with less than 15 per cent. of aluminium and copper respectively are described in a paper from the National Physical Laboratory, and Dr. Haughton, of that laboratory, also contributes a preliminary account of the investigation of alloys by determination of the thermo-electromotive force. Some remarkable results obtained a few years ago by Mr. Alkins in the drawing of copper wire, which indicated a discontinuous change of properties at a certain stage of reduction, are now confirmed by very careful further experiments. The results contained in another paper in the same volume, on the properties of rolled copper, make it clear that rolling affects the metal much more irregularly than drawing, so that definite conclusions are not easily reached. Other subjects dealt with are the casting of brass of high tensile strength, and the production of idiomorphic crystals of copper.

C. H. D.

Dead Towns and Living Men: Being Pages from an Antiquary's Notebook. By C. L. Woolley. Pp. viii + 259. (London: Oxford University Press, 1920.) Price 12*s*. 6*d*. net.

THIS is a lively account of a digger's life on ancient sites, mainly describing hobnobbing with Kurds and other amiable ruffians, or bluffing Turkish officials, revolver in hand. The methods may have been effective, but could scarcely be a settled mode of living. The first half of the title is rather neglected, as there is but little archæology, and only five views of Carchemish, which is the bait of the book. A dozen pages give a welcome account of the remains of the Hittite capital, of which as yet only a small part has been opened. The complete clearance of this capital of a scarcely known civilisation will take years to finish. When done, there are several other cities one beneath another, and the clearance of each of them will mean the removal of everything of later age. Obviously there should be a museum to hold all the Hittite sculptures, and the site bared to study the cities beneath, which descend 30 ft. below the level of four thousand years ago.

A different point of interest is the sketch of Egyptian mentality (pp. 39–44) when natives imagine that fine buildings are known, and offer to show them. This is a painfully frequent failing; here the view is taken that this is auto-suggestion really believed in, and capable of being extended to the minds of other people, who all become convinced of what does not exist. If we can take this view it will, perhaps, explain the Indian conjuring feats as being such suggestion on the minds of spectators. Can it also be the true view of the sights well known in Egypt, of men holding red-hot iron in the hands or mouth, which show no trace of blistering or burning after it? Is there a power of suggestion to compel hallucination on cool English observers? It is at least as likely as a power of resisting burns.

A Manual of Practical Anatomy: A Guide to the Dissection of the Human Body. By Prof. Thomas Walmsley. With a Preface by Prof. Thomas H. Bryce. In three parts. Part i., *The Upper and Lower Limbs.* Pp. viii + 176. (London: Longmans, Green, and Co., 1920.) Price 9*s*. net.

PROF. WALMSLEY, in this manual, ranges himself with those teachers of anatomy who think that the subject should be studied almost exclusively in the dissecting-room, and that the student should be encouraged to build up his knowledge of the subject from personal observations. In his text, therefore, the author confines himself to the description of what any average student can readily discover for himself, and in his illustrations to simple line drawings such as any average student can easily reconstruct and supplement. The purely descriptive parts are also everywhere subordinate to the instructions which are given as to the manner of dissection and as to what may be observed in the actual process of dissection. The text is singularly accurate for a first edition, but certain of the diagrams are not quite so satisfactory. In Fig. 2 the cutaneous nerves of the back (cervical region) are in excess; in Fig. 4 the median part of the front of the leg is not shown supplied by cutaneous nerves; in Fig. 7 the formation of the median nerve takes place on the median side of the axillary artery; in Fig. 13 the coraco-brachialis muscle is shown on the median side of the musculo-cutaneous nerve; and in Fig. 51 the outer head of the musculus accessorius is omitted. These matters can be readily amended in any further edition, and scarcely detract from the value of the book, which in its length and simplicity is a not inadequate *riposte* to the larger and more elaborate manuals.

W. W.

Splendours of the Sky. By Isabel Martin Lewis. Pp. vii+343. (London: John Murray, 1920.) Price 8s. net.

THIS book can be warmly recommended to readers who desire to obtain a popular non-technical summary of the advances made in physical astronomy in the present century. The author's position as a computer for the American Nautical Almanac ensures an accurate knowledge of geometrical astronomy and of problems relating to distances and motions; and she writes in an enthusiastic tone that evinces a deep admiration for the "splendours of the sky."

The planets are reviewed in order. In discussing the vexed question of the rotation of Venus the author's judgment leans to the twenty-four-hour value, which implies a physical condition not unlike that on the earth. Prof. W. H. Pickering's explanation of the Martian canals as being due to the deposition of moisture by storms following fairly definite tracks is favoured as the most plausible one, but Lowell's irrigation theory is also described.

The remarkable solar work accomplished at Mount Wilson comes next, including the study of the sun's magnetic field, vortices round sunspots, and the recently named "hydrogen bombs." There is also mention of Einstein's prediction of the gravitational deflection of light, and the preparations made to test it at the eclipse of 1919. But the book went to press before the results were available.

The chapters on the stars include such recent work as Dr. Shapley's determination of the distances of clusters. It is necessary to criticise the suggestion on p. 247 that the M and N types are alternative routes to extinction. The galactic concentration of the N stars is proof of great distance and high luminosity; they are therefore giants, not dwarfs. A protest must be made against the use of the words "billion," "trillion," etc., in the American sense in a work published in London. An international agreement on the meaning of these terms would be welcome.

A. C. D. CROMMELIN.

Peetikay: An Essay towards the Abolition of Spelling: Being a Sequel to "Some Questions of Phonetic Theory," part i., 1916. By Dr. Wilfrid Perrett. Pp. 96. (Cambridge: W. Heffer and Sons, Ltd., 1920.) Price 6s. net.

IT is refreshing to find nowadays a scholarly essay written in a style so attractive as to engage the interest of even a casual reader. Dr. Perrett, in his quest for a land free from the horrors of orthography, is a hearty knight, who will merrily break a lance, if not a crown, with any pedant who comes along. He will have none of your "reformed" spelling, which is but one more shuffle of the historic pack of twenty-six letters among some forty sounds. He does not want to reform spelling indifferently well, so he creates a new alphabet, which is called "Peetikay," a word composed of his three first consonants and three first vowels. The basis of his vowel notation is the pitch of the whispered vowel, and he evolves a system of characters which are "real," giving at once some indication of both vowel quality and vowel length. His classification of consonant sounds starts from the voiceless mutes "p, t, k," being arranged finally in order of their place of formation. Particularly interesting, and frequently provocative of discussion, are his remarks upon the English sounds "h" and "r."

By means of his new notation Dr. Perrett aims at a just correspondence between signs visible and signs audible, so that English writing shall be English language in counterfeit. It is a book full of learning, well seasoned with humour, and brimming over with originality; it is a powerful blow at those who bleat about "vulgarity, degeneracy, and corruption of English," and an earnest appeal for "less professorism, and a little more shrewd insight and informed, constructive teaching."

A. LL. J.

A History of English Philosophy. By Prof. W. R. Sorley. Pp. xvi+380. (Cambridge: At the University Press, 1920.) Price 20s. net.

IN this very useful and handy volume we are given, in chronological order, a short record and brief epitome of the men of British birth who have a claim to be remembered on account of their philosophical writings. It begins with the medieval scholastics who wrote in Latin, and whose British birth is merely of biographical interest, and it ends with writers several of whom are still living, and among whom the author of this book is himself entitled to take rank. The attempt, however, to present this succession of British-born philosophers as a history of, or as material for a history of, English philosophy is not, and in the nature of the case cannot be, a success. In the history of philosophy English philosophy has denoted two distinct movements at definite periods. In the eighteenth century it denoted, throughout the intellectual world, the system of Newton and the principle of Locke. At the end of the nineteenth century English philosophy meant the evolution theory of Charles Darwin and the method of Herbert Spencer. In this book Newton and Darwin are mentioned as having given a direction to philosophy, but they are given no place among the philosophers. On the other hand, William Gilbert (quite rightly) is included, but this makes the omission of the two former only the more remarkable.

Light Produced by Rubbing Quartz Pebbles Together.

I HOPE that the letter from Lieut.-Comdr. Damant in NATURE of October 21 may induce some chemist to endeavour to ascertain the cause of the peculiar "empyreumatic" odour which accompanies the flashes of light produced by rubbing two quartz pebbles one against the other. My attention was first directed to the fact that the flashing could be obtained, as well when the pebbles are rubbed together submerged in a basin of water as in air, by the Rev. Reginald Gatty.

I have ascertained that careful chemical cleaning of the surface of the pebbles does not prevent the production of the peculiar smell—which might have been due to a deposit of organic matter from the sea—on pebbles picked up on the seashore. I also have ascertained that bits of quartz from inland quarries give out the peculiar smell when they are rubbed together so as to produce flashes of light, and the same smell accompanies the light production when large crystals of rock-crystal are used. Further, I found that the light flashes can be produced when the quartz or crystal is submerged in alcohol. Probably other liquids would not arrest it. Consequently it should be possible to obtain the volatile odoriferous matter in solution when produced and to subject it to chemical examination. It would not be difficult to devise a little mechanism for producing flashes of light by grinding two quartzite pebbles together beneath a small quantity of liquid for some minutes, or even hours, and so to obtain in the liquid such emanations from the triturated quartz as are soluble in suitable liquid reagents. (See pp. 60–61 of my "Diversions of a Naturalist," Methuen, 1915.)

E. RAY LANKESTER.

October 31.

Chemical Warfare, the Universities, and Scientific Workers.

I HAVE just received an invitation from the War Office "to become an associate member of the Committee now being constituted as part of the new peace organisation for chemical warfare research and experiment." The invitation was accompanied by what is stated to be the present list of associate members, containing more than sixty names well known in science. As it stands, this list is certainly a very powerful inducement to accept the invitation in the case of anyone content in this important matter to follow the lead of his more influential colleagues, for it comprises a very large proportion of the best known workers in the branch of science mainly involved. Unfortunately, however, it includes my own name, and I take it, therefore, that, in part at least, it is in reality a list of those to whom invitations are being issued rather than of those who have accepted the invitation.

The function of the Committee is stated to be "the development to the utmost extent of both the offensive and defensive aspects of chemical warfare." Its work is governed, as regards disclosures, by the terms of the Official Secrets Act, and every member of the Committee will be required to sign a statement that he has read the Act and is prepared to abide by its provisions. It is the intention to allocate, so far as practicable, research of a purely scientific nature in chemical warfare to universities and similar outside institutions.

Now, for my part, I think this is a very important matter which ought not to be left entirely to the personal choice of individuals, but should be most carefully considered by the universities and by scientific workers as corporate bodies. It was one thing for scientific men and the universities to be called upon in the stress of actual conflict to assist the fighting Services when they were forced by enemy action to protect themselves against, and in turn to develop, a mode of warfare until then proscribed by civilised nations, but it is surely quite another matter for them, in consequence, to be called upon without consultation to become a normal part of the peace organisation for developing it in secret, both in its offensive and defensive aspects, to the utmost possible extent.

I do not think there is any precedent for this departure. Universities train medical men indiscriminately for civil and military services, but the Army Medical Service is non-combatant, and is intended to ameliorate the horrors of war. Universities of late have recognised military subjects in their curricula for their diplomas, and lent their organisations for the purposes of what were in origin defensive military services, such as the Volunteer and Officers Training Corps.

Personally, I feel that universities and scientific men stand for something in the world higher than anything which has as yet found expression and representation in Governments, particularly in their international relations. In consequence, I fear that they will find themselves in a false position if they allow themselves by default to be depressed to the position of mere agents to develop this new and, as yet, still unlegalised mode of warfare. The uses likely to be made of their work are, in the present unsettled condition of the world, highly uncertain, except in so far as it is quite certain that the effective control over these uses is not the part in which they are invited to co-operate. No one can pretend that scientific organisations are strong enough to dictate, as in the case of the professional medical organisation, the purposes for which science shall be used in the community. My own individual view is against accepting this invitation until the question of the position of the universities and scientific men as corporate bodies, in the part of the organisation which they are not invited to join, has first been satisfactorily settled. I think the properly constituted unions of scientific workers should give the matter their consideration and lay down for the guidance of their members the conditions under which they should, if at all, accept the invitation. It would be most helpful to have the views of my colleagues, particularly of some of the sixty-four who are stated already to have joined the organisation as associate members, publicly expressed upon this very important matter.

FREDERICK SODDY.

British Laboratory and Scientific Glassware.

THE British glass industry is undoubtedly to be congratulated on attaining the excellent results described in Mr. Jenkinson's letter in NATURE of October 28, but I may venture to point out that it is little comfort to the user to know that good glass is made if no guidance is given him as to the particular brand referred to. Of the five samples tested it is true that the best was British, but the worst was also British. I gather from inquiries made that the faults complained of by laboratory workers are not so much defective resistance to alkalis, etc., but insufficient annealing and liability to break with changes of temperature. Table glass is well annealed, so that the defect in question is not insuperable, and a want of care in the manufacture is suggested. The increased loss by breakage has become a serious consideration in the running of practical classes since British glass has been in use. As pointed out in previous correspondence, the danger of restricting import lies in the lack of inducement to further improvement.

W. M. BAYLISS.

University College, London.

THE points raised by Mr. Jenkinson in his letter on the subject of laboratory and scientific glassware published in NATURE of October 28 should direct the attention of users of such glassware to the quality of the British-made product as compared with other well-know Continental brands.

No single type of glass can be superior to all others for all purposes. One glass may be superior as regards attack by water and acids, but inferior in respect to attack by alkaline solutions. As it would obviously be highly inconvenient in practice for chemists to use different types of glass for different reactions, a general average must be taken, and a study of the papers in the Journal of the Society of Glass Technology referred to by Mr. Jenkinson will convince any unbiassed person that the quality of British laboratory glass has been proved fully equal, if not superior, to that of any other laboratory glass from whatever source it may have been obtained.

In the earlier days of the war complaints were frequently heard as to the finish of British-made articles. Either they were too thin, too thick, uneven, or the colour and shape were unsatisfactory, etc. Whilst these complaints were frequently justified, they were chiefly due to lack of experience. The blowing of laboratory glassware of the desired thickness and even throughout requires considerable experience on the part of the glass-blower, and blowers trained in this branch of the industry were not available. The glass used in the manufacture of laboratory ware is much harder (less fusible and with a shorter viscosity range) than that to which the blowers were accustomed, and this militated against the rapid acquirement of the technical skill necessary to produce the best class of ware.

The hardness of the glass and the undesirability of using fining agents such as arsenic and antimony rendered it very difficult to obtain the molten glass homogeneous and free from small gas-bubbles, and necessitated increased furnace temperatures during melting, thus calling for alterations in the design of furnaces in use or the erection of new furnaces of special type.

The colour of British laboratory glass is admittedly inferior to that of the best foreign glass. This is due to the purity of the materials used, particularly the sand. British sands can be obtained with nearly the same degree of freedom from iron as the best Continental sands, but not in considerable quantity or of constant quality. For special purposes, where freedom from colour is essential—*e.g.* Nessler cylinders—specially selected qualities of British sands may be used, or even imported sands, but from the general point of view of the chemical and scientific glassware industry it is absolutely essential that we should be able to produce highly efficient laboratory ware without recourse to the importation of any material from outside the Empire, and so far as possible with only British materials.

Further experiment and experience both with materials and melting operations will undoubtedly lead to improvement in the appearance of the product, and we claim that as British manufacturers, with the aid of British men of science, we have mastered the difficulties attendant on the production of the necessary quality of glass so successfully. They will, given fair opportunity, master the less essential, but nevertheless desirable, property of pleasing appearance.

Scientific apparatus, particularly lamp-blown apparatus, has received a considerable amount of attention from manufacturers and men of science interested in the technology of the glass industry.

It is a fact, unfortunately, that in pre-war days the best work of this class was done by German and Austrian lamp-workers. This work is now carried on largely in this country (to a considerable extent by disabled soldiers and sailors), and great progress has been, and continues to be, made. Research work on the most suitable types of glass tubing for lamp-working purposes has been carried out with very successful results (Journal of the Society of Glass Technology, 1917, vol. i., p. 61; 1918, vol. ii., pp. 90, 154).

Manufacturers have followed up suggestions for possible improvement, sometimes with success and sometimes otherwise, but generally associated with considerable trouble and expense, and we may fairly claim that great improvement has been achieved in this direction, and that few grounds for legitimate complaint remain on the score of the annealing of British-made laboratory ware.

A further and most important section calls for mention, namely, the production of graduated apparatus. To some extent this is a factory operation, but the production of accurate and trustworthy graduated apparatus calls in addition for the most highly skilled, careful, and experienced work and supervision. The work entailed is much greater than appears on the surface. Experimental work has been carried out at the National Physical Laboratory and at Sheffield University, and the testing department of the National Physical Laboratory has drawn up stringent regulations for the certifying of first-class graduated apparatus, so that such apparatus with the National Physical Laboratory certificate of accuracy can be relied upon to be quite as trustworthy as the well-known German apparatus with the Reichsanstalt certificate.

Complaints and unfavourable comparisons have frequently been made in connection with British laboratory ware, and very few expressions of appreciation or gratitude to those manufacturers who stepped into the breach to supply an absolutely indispensable article, knowing that their productions were far from perfect, but striving, with the help of the best scientific aid in the country, to improve the quality of their ware. Very great progress has been made, but under the abnormal conditions ruling at present in this country it is essential that stability should be assured for some time to come until the industry has had time to settle down from what is practically an experimental stage to normal working conditions.

Is it conceivable that the research work done by Sir Herbert Jackson, Prof. Turner, the National Physical Laboratory, and others, and the patient and frequently thankless efforts of manufacturers to render this country independent in such an essentially key industry, should be wasted; and that the valuable experience already gained should be lost on account of the flooding of the English market with Continental productions—made so easy by the present rate of exchange between England and Germany—and the consequent transference of our energies to less essential, but certainly more lucrative, directions?

FRANK WOOD.

Crystal Growth and Recrystallisation in Metals.

THE effects of heat on certain cast and plastically deformed metals have been studied in considerable detail by Prof. H. C. H. Carpenter and Miss C. F. Elam in an investigation which was published and discussed at the autumn meeting of the Institute of Metals held at Barrow-in-Furness under the presidency of Vice-Admiral Sir George Goodwin.

At the outset the authors state that the terms "recrystallisation" and "crystal growth," which signify quite different phenomena, have previously been used for the most part indiscriminately and interchangeably, with the result that the discussion of this subject has necessarily been confused and unsatisfactory. By "recrystallisation" is meant the complete reorientation of a crystal or group of crystals. The new arrangement starts from new centres, and is quite independent of the old system of orientation. It is, in fact, the birth of new, differently oriented crystals in a crystal aggregate, and the gradual change of the old to conform with the new. This always gives, in the first instance, a refined structure. When all trace of the old arrangement has disappeared it is considered that recrystallisation is complete. By crystal growth is meant the rearrangement of certain crystals in a crystal aggregate to conform with the orientation of certain other crystals, during which process the latter increase in size by the addition of reoriented material at the same time as the former decrease in size by the same amount. This process necessarily leads to an increase in crystal size.

Many of the authors' experiments have been carried out with an alloy of tin and antimony containing about 1·5 per cent. of the latter metal. This alloy possesses a very peculiar property, which makes it of special value for investigating the above phenomena, and for the first time has enabled the stages of crystal growth in a metallic complex to be studied experimentally. It presented, however, some special difficulties in polishing and etching. Cutting, filing, and even grinding on the finer emery papers bring about spontaneous recrystallisation of the surface layer. This entirely obscures the genuine structure of the specimen, and can be removed only by alternate polishing and etching. Ammonium sulphide solution is the best reagent for developing the structure, and by alternately immersing the specimen in the solution and rubbing it on selvyt or chamois leather with magnesia moistened with ammonium sulphide a very beautiful surface is obtained. This reagent attacks different crystals to very different degrees, so that some appear white, and others black, under the microscope. This proved of considerable assistance in the experiments, as it made it easy to identify a particular area under examination. If a polished and etched specimen was heated at 150°–200° C., and growth of any of the crystals took place, the position of the new boundary was marked by a line which is really a difference of level almost as if the specimen had been etched; but there was no visible change in the surface of the reoriented area.

That these lines represent the position of the new boundaries after heating could be shown by (1) taking a photograph of an area which included some of them; (2) repolishing and re-etching the specimen and rephotographing the same area. On comparing the two photographs the boundaries of the crystals as shown by the etching in (2) correspond exactly with the new lines in (1). It was always a simple matter to distinguish between a growing crystal and one that was being grown into. The alloy tarnishes on heating, being first yellow, then orange, red, purple, blue, and green in turn. Just as the crystals etch differently, so they tarnish differently; but they tarnish first in accordance with the original etch. There is always a colour contrast between adjacent crystals, and the colour fixes the original boundaries. If new boundaries appear *inside* this colour boundary, it shows that the adjacent crystal is growing into it; if *outside*, it shows that the crystal is growing into its neighbour.

A very remarkable feature about these boundary markings is that they are formed only when the specimen is removed from the furnace and cooled. If a specimen is heated and cooled three times, there will be three new boundaries round some of the crystals; if four times, there will be four, and so on. But if another specimen be heated along with the first, and taken out only when the former was removed for the fourth time, one new boundary marking alone would be visible. It is, therefore, an arrest in the progress of growth which makes these markings on the surface, and further heating does not obliterate them. There is, however, no sign of them after polishing and etching, only the final and genuine crystal boundary being then visible.

The authors publish numerous photographs illustrating these phenomena, and the accompanying series revealing the gradual decrease in size and final disappearance of a crystal in four stages is taken from a plate in their paper. The crystals concerned are represented by letters in Fig. 1. Fig. 2 shows the effect of heating once. The crystal A has been invaded by crystals C, D, and E. Crystal C continues to grow on further heating, and also crystal B to a small extent (Figs. 3 and 4). The state of things after heating four times is shown in Fig. 5. All four crystals have invaded A, and C and E have met. Fig. 6 is of the same area repolished and re-etched, and shows that A no longer exists. The orientations of crystals B, C, and D as revealed by the etching are very different from that of A. It is possible that the orientations of A and E do not differ greatly, yet each crystal has taken a considerable share of A.

From a large number of observations the authors have drawn the following conclusions: (1) Crystal growth always took place by gradual

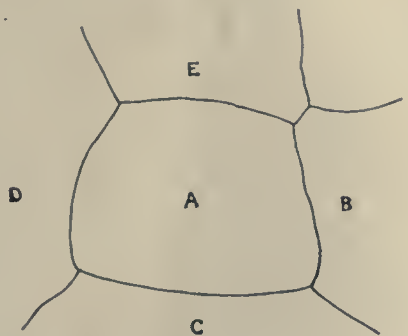

FIG. 1.

FIG. 2.—1st heat.

FIG. 3.—2nd heat.

FIG. 4.—3rd heat.

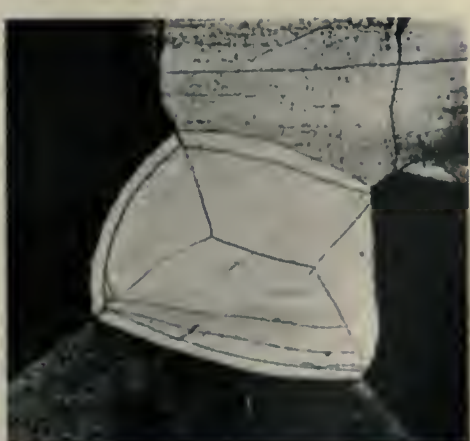

FIG. 5.—4th heat.

FIG. 6.—Same as Fig. 5, repolished and re-etched.

Magnification 100 diams. Reduced by one-sixth.

boundary migration, and not by coalescence; (2) growth may take place either of a large crystal into a small one, or of a small into a large—*i.e.* crystal growth does not depend on the relative size of crystals; (3) the relative orientations of the crystal which is being grown into and that which is growing do not appear to affect growth; (4) a crystal which is itself being invaded by one crystal may grow at the same time at the expense of another; (5) the change of orientation is accompanied by a difference in level of the surface which is the boundary usually observed; (6) the rate of growth is not constant for any given time at a particular temperature.

The authors tested the generally accepted view that the crystals of castings do not grow upon heating. This view, although widely held, does not rest upon adequate experimental evidence, and the difficulty of finding a suitable method of testing it is considerable. In the first place, all forms of strain in cutting, grinding, and polishing a specimen must be avoided, because it is known that work will produce recrystallisation of a metal on annealing. The ordinary methods of preparing a metal surface for microscopic examination are quite sufficient to cause recrystallisation of the surface layer on annealing, particularly in soft metals. After experimenting with various methods, the one finally adopted was suggested by the well-known fact that impurities tend to lie in the crystal boundaries of castings, whereas in the worked or annealed metal they either pass into solution or remain scattered throughout the crystals quite independent of the boundaries. It was reasoned that if it could be shown that after prolonged annealing the boundaries coincided with the impurities, it might be considered evidence that they were in the same position after annealing as before. The impurities must be such that they are insoluble in the metal and have a high melting point. Exhaustive tests were carried out with the metal aluminium, which, even in its purest form, contains the compound $FeAl_3$. In the cast metal some of this compound is always found existing in the boundaries. The authors publish a photograph showing that, even after annealing for ten weeks at 550° C., the boundaries of the crystals are still outlined by the impurities, and since the latter cannot have moved, it follows that neither have the boundaries. A specimen of rolled aluminium annealed for the same period showed that, except in a very few cases, the boundaries were quite free from impurities. The authors conclude, then, that the cast metal when free from strain showed neither crystal growth nor recrystallisation on subsequent heating.

The latter part of the investigation deals with an elaborate study of the quantitative effects of deformation on crystal growth and recrystallisation, and the structural changes produced in a crystal aggregate by deformation followed by heat may be summarised somewhat in the following way:—

The first effects are slight. They are revealed by slip bands, and in some cases by twins. The former are completely, and the latter to some extent, removed by heating. No change is observed in the shape of the crystals. The boundaries appear unaffected, and, apart from the twins, there is no change in orientation. Thus far only the interior of the crystals is affected. No identities are lost. Somewhat greater deformation, however, produces crystal growth, and at this stage the boundaries of the crystals become active. The activity is shown in the capacity of the growing crystal to push forward its boundary in certain directions, thereby invading other crystals, but even at this stage the orientation of the growing crystals is maintained. That of the crystals grown into is, of course, destroyed, unless it happens to be the same. The third stage, produced by still greater deformation, appears to take place exclusively in the boundaries of deformed crystals. It is here that the new crystals are born, indicating the destruction of the original crystals and a complete change of orientation. Whereas, therefore, the early effects of deformation are manifest in the interior of the crystals, the later ones appear to take place entirely at the boundaries.

The chief facts established by these experiments are: (1) The largest crystals are always formed after the minimum amount of stress sufficient to produce growth, which minimum is determined by the annealing temperature; (2) the lower the temperature the greater the stress required to produce the large crystals; (3) there is no gradual increase in size from the original-sized crystals up to the largest which form directly from them.

It is considered that all the evidence brought forward points to plastic deformation followed by heat as the true cause of crystal growth and recrystallisation followed by crystal growth. The only exception to this is where an alteration of crystal form occurs when a metal passes through a phase change. Apart from the direct evidence against any growth of crystals in castings, confirmatory evidence of the following nature has been obtained in this research: (1) Growth and recrystallisation can be induced by work; (2) the size of the crystals produced on heating at a given temperature after work is entirely dependent on the amount of deformation; (3) there is always in practice a limit to the crystal growth produced by work and heat in any metal as a result of which a single crystal has not yet been produced by prolonged heating. Such a result, however, is theoretically imaginable, provided that the degree of deformation and subsequent temperature of heating could be adjusted to certain very precise conditions.

Whatever forms of energy operate during the growth or recrystallisation of a crystal on heating, the authors' conclusion is that the energy is imparted to the metal when it is deformed. That energy cannot be stored in the amorphous vitreous films, which, according to Sir George Beilby, are the cause of work-hardening in metals, because, as the authors have shown, the growth of crystals in a worked metal proceeds after all mechanical softening has taken place. Hence all the amorphous metal must have recrystallised. It is, moreover, difficult to explain why the least deformation should produce the largest crystals on heating if growth depends on the presence of amorphous metal. Further, the energy cannot be stored in the amorphous cement around the crystals as conceived by Rosenhain, because (1) all the available evidence is against the view that the crystals of castings grow; (2) the greater the surface area of a crystal the more energy it should possess, and on this view a large crystal should absorb a small one. It has been shown that this is by no means always the case. It is considered that until much fuller knowledge of the structure and properties of crystals has been obtained, the true explanation of the effects of work upon metals will not be forthcoming.

The New Star in Cygnus.

By MAJOR W. J. S. LOCKYER.

THE new star in Cygnus, the third discovered in that constellation, and therefore designated Nova Cygni III., was of magnitude 3·5 when first observed by Mr. Denning on August 20, but is now very faint, being below 9th magnitude. It is still visible in small telescopes, but requires large instruments for spectroscopic investigation.

A summary of the earlier part of the star's history—*i.e.* previous to August 20—is brought together by Mr. Felix de Ray in the current issue of the *Observatory* (vol. xliii., No. 557, October), and is of great interest. Thus the object was not visible on June 3, 1905, when a plate taken of that region showed stars down to the 16th magnitude. On July 20 of the present year another plate taken there recorded stars down to magnitude 11; but still there was no trace of the nova. A photograph taken at Harvard on August 9, 1920, shows stars to the 9th magnitude, and no nova appears upon it; but the object was recorded there on August 19, and its magnitude was then 4·8. An earlier record than this is given on a plate taken by Nils Tamm in Sweden on August 16 of this year, when it was shown as a 7th-magnitude star.

The above records give an idea of the nature of the rise in magnitude of the nova, and these data (broken lines), combined with the excellent series of observations made at Greenwich (continuous lines), and published in the same number of the *Observatory* (p. 367), enable the light curve of the nova to be constructed. This curve is given in Fig. 1. It will be seen that, like all novæ, there is a very rapid rise to maximum brilliancy, followed for a short period by an almost as rapid decrease. After that the decrease is more gradual, but at a quicker rate than is generally the case in later stages of novæ.

It should be remarked that the Greenwich values here recorded are "smoothed" values—that is, a mean curve has been drawn through the original observed values. This process has the drawback of eliminating any small oscillations of magnitude which may occur in the original curve. Thus on the descending side of the curve there are undoubtedly instances where the nova not merely retained the same magnitude for two consecutive nights, but actually increased in brightness. Such fluctuations were, however, on a very small scale, and nothing like the pronounced regular variations which Nova Persei presented after it had reached the 4th magnitude, the amplitude of this fluctuation amounting to about one and a half magnitudes in periods of three or four days.

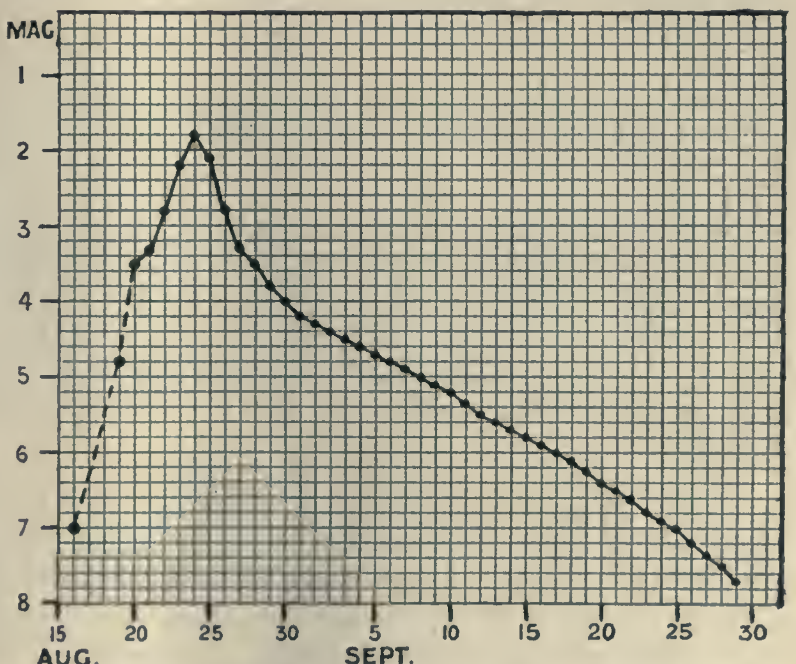

FIG. 1.—The light curve of Nova Cygni III., illustrating the rapid rise to maximum and the comparatively slow descent. The unbroken line is from observations made at Greenwich Observatory.

No less interesting has been the spectroscopic study of this nova. Up to the present time very little has been published on the subject, but no doubt several communications upon it will be made at the November meeting of the Royal Astronomical Society. In Section A of the British Association at the recent meeting Prof. Fowler showed some slides taken from negatives secured at the Hill Observatory, Sidmouth, on the night of August 22, when the nova was approaching its maximum.

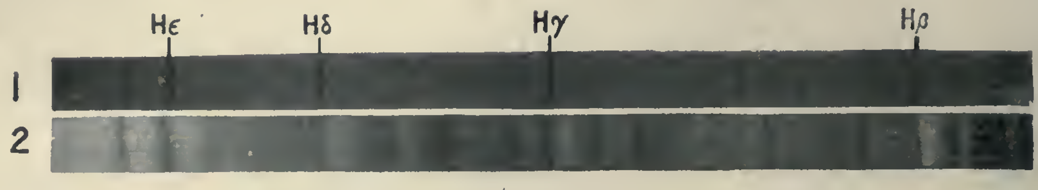
These photographs showed that the spectrum was practically identical with that of the star α Cygni—that is, it was practically an absorption spectrum. This star is noted for exhibiting fine, sharp lines representing metals at a very high temperature, these lines being enhanced when passing from the temperature of the arc to that of the spark. Two nights afterwards, when the nova attained its maximum brilliancy, all the lines became broad and fuzzy, and bright components to the lines began to show up at the red end of the spectrum. More recent work at the Hill Observatory has shown that at later stages all lines became more diffuse, a larger number of bright components appeared, and the continuous spectrum began to dim.

The stage when the nova showed a *typical* nova spectrum is illustrated in Fig. 2. It will be noticed that amongst others all the dark hydrogen lines have bright components on the right-hand side. For the sake of comparison, a spectrum of the star α Cygni is placed above the nova spectrum, and the line Hβ is made to fit the dark Hβ in the nova.

The reason why the other hydrogen lines in α Cygni do not fit those in the nova is that, owing to the great velocity in the nova, these lines are displaced towards the left—*i.e.* towards the violet. From measurements made, the velocity in the line of sight works out at about 400 to 900 km. per sec., depending on the date on which the photograph was taken. In this particular case—namely, August 26—the velocity was about 900 km. per sec., and was actually the maximum velocity attained.

At a late stage in their career novæ begin to exhibit the nebular lines. The first indication of this stage having been reached in the present nova was recorded on a photograph taken at the Hill Observatory, Sidmouth, on October 22. The stage might have been reached at possibly an earlier date, but no records were available between October 2 and the date mentioned above.

As a rule, new stars are far more scarce than comets, but Mr. Felix de Ray points out the interesting fact that for a couple of years novæ have been more plentiful than comets, and that at the present time no fewer than four novæ, including Nova Aquilæ III., Nova Lyræ, and Nova Ophiuchi IV., can be observed with small apertures.



1. α Cygni. 2. Nova Cygni, August 26.

FIG. 2.—The spectrum of Nova Cygni on August 26, showing the *typical* nova spectrum. The comparison spectrum is that of α Cygni, which the nova closely resembled on August 22.

Obituary.

DR. HERMANN STRUVE.

DR. KARL HERMANN STRUVE, who died on August 12 at the age of sixty-six, belonged to a family famous in astronomy, being the son of Otto Struve, and the grandson of F. G. W. Struve. All three were gold medallists of the Royal Astronomical Society, this being a unique case of hereditary distinction in the annals of that body.

K. H. Struve was born at Pulkova in 1854, being the third of the four sons of Otto Struve, who was then director of Pulkova Observatory. He studied at Dorpat University, where he showed special aptitude in physics and optics. Apparently it was the acquisition of the 30-in. refractor at Pulkova that tempted him to devote his life to astronomy. It was with this instrument that he made the splendid series of observations of Saturn's satellites for which his name will be chiefly remembered. He adopted the plan of comparing the satellites with each other, instead of with Saturn, which led to a great increase in accuracy. His discussion of the observations gave greatly improved values of the masses of primary, ring, and satellites, and of the positions of Saturn's equator and the orbit planes; it also revealed some interesting librations in longitude. For this work Struve was awarded the R.A.S. medal and the Damoiseau prize of the Paris Academy. A similar investigation on the system of Mars gave the position of Mars's equator, the amount of its oblateness, and the rate of motion of the nodes.

Other astronomical work included double-star measures, star parallaxes, micrometer measures of Eros, and drawings of Jupiter; moreover, in 1874 Struve took part in the Russian expedition to Port Possiet, Eastern Asia, to observe the transit of Venus.

In 1895 Struve became professor of astronomy at Königsberg, and director of the observatory, for which he obtained a 32·5-cm. refractor. In 1904 he succeeded Dr. W. Foerster as director of the Berlin-Babelsberg Observatory, retaining this post until his death. So late as 1916 he made further observations on Saturn's satellites with the 26-in. refractor there. He suffered for some time from heart trouble, and his death was probably accelerated by a bad fall last spring. He married in 1885, and leaves a son and daughter.

ALFRED LIONEL LEWIS.

WE regret to record the death of Mr. Alfred Lionel Lewis on October 22. Mr. Lewis, who was in his seventy-ninth year, joined the Anthropological Society of London in 1866, and was elected a member of its council in 1869. When the society was absorbed by the foundation of the Anthropological Institute in 1871, Mr. Lewis became a member of this body, of which at the time of his death he was one of the oldest members. He was elected a member of the council in 1876, and in 1886 he became treasurer, an office which he continued to hold for seventeen years. From 1905 to 1907 he served as vice-president. Mr. Lewis's interests were directed almost exclusively to archæology, and in particular to megalithic monuments, a subject on which he was for many years recognised, especially in France, as one of the foremost authorities. The great accuracy of his measured plans and drawings was not the least valuable feature in the numerous papers on this subject which he contributed to the Proceedings of the Anthropological Institute, the Prehistoric Congresses of France, the International Congresses on Prehistoric Archæology, the International Congress of Religions, and the British Association. He had already attained the fiftieth year of his membership of the last-named body, and had looked forward eagerly to taking part in 1921 in the celebration of the jubilee of the Royal Anthropological Institute.

THE death is announced, at the age of seventy-five, of DR. ANTON WEICHSELBAUM, emeritus professor of pathological anatomy in the University of Vienna. Soon after graduation, Weichselbaum became interested in pathology, and published work on the nature of rheumatoid arthritis. Before long he turned his attention to the then young science of bacteriology, and investigated the cause of pneumonia. About 1886, after a detailed investigation of a number of cases of this disease, he published a paper in which he described a coccus, the *Diplococcus pneumoniae*, as the causative organism, which corresponded with the organism previously described by Fraenkel. In 1887 his *magnum opus* appeared, on the discovery and description of the causal organism of cerebrospinal fever, the *Diplococcus intracellularis*, which is now almost universally accepted as the causative organism of this disease. In 1885 Weichselbaum succeeded Rokitansky in the chair of pathological anatomy, remaining on the active staff of the university until last year, when he was appointed emeritus professor. In 1912 he was installed as Rector Magnificus for the year, the highest honour in the gift of the university. Weichselbaum was a great investigator and a teacher of repute. In addition to numerous original papers and communications, he was the author of "Elements of Pathological Histology," which was translated into English.

THE death of MR. WILLIAM MELVILLE is recorded in *Engineering* for October 29 as having occurred on October 21. Mr. Melville was born in 1850, and served his pupilage with the North British Railway Co., under Mr. James Bell. He joined the Glasgow and South-Western Railway in 1874, and rose to be engineer-in-chief of the company, a position from which he retired in 1916. Mr. Melville was responsible for a large number of extensions and improvements on the railways and docks in Scotland, among which may be mentioned the widening of the City Union lines, Glasgow, which comprised the demolition of the old viaduct carrying the railway over the Clyde, and the substitution therefor of a new viaduct carrying four lines on the site of the old viaduct. He also extended St. Enoch Station, Glasgow, adding six new platforms to the six of the original station.

Notes.

WE are glad to note that a movement is on foot to establish a memorial to the late Mr. W. Duddell, whose early death in November, 1917, deprived many of a valued friend and cut short a career of scientific research of great brilliance. Mr. Duddell's work on the recording of the wave-form of alternating currents, including the development of the oscillograph, had great influence on alternating current theory as well as on telephony, while his well-known researches on the electric arc led up to a large field of development in wireless telegraphy. The memorial is to take the form of a medal to be awarded periodically by the council of the Physical Society at its discretion to those who have advanced physical knowledge by the invention or design of scientific instruments or of materials used in their construction. If sufficient funds are available, it is also proposed to form a fund to be devoted to the foundation of scholarships or prizes to be awarded to students of the Physical Society under conditions to be determined by the council. We are sure that the many friends whom Mr. Duddell made among the members of the Institution of Electrical Engineers and of the Röntgen Society, of both of which he had been president, and of the Physical Society, of which he was for some years the treasurer, will be glad of the opportunity to support the scheme. An influential committee has been formed under the chairmanship of Sir William Bragg (president of the Physical Society). Mr. R. S. Whipple (president of the Optical Society) is acting as hon. secretary to the Duddell Memorial Fund, and subscriptions may be sent to him at 15 Creighton Avenue, Muswell Hill, N.10.

WITH the advice and assistance of the National Research Council of the United States, a co-operating group of scientific investigators of insect pests and plant diseases, together with representatives of leading industrial concerns engaged in the manufacture of chemicals and appliances used in fighting these enemies of crops, has been organised under the name of the Crop Protection Institute. This institute will undertake and support a series of thorough scientific studies of the crop pests themselves and of the means for improving and standardising the materials and appliances used in fighting them. The Board of Trustees of the institute is composed of nine scientific men representing leading organisations interested in crop protection and four representatives of the manufacturing and commercial interests. The temporary secretary is Mr. Harrison E. Howe, chairman of the Division of Research Extension of the National Research Council. The annual losses as a result of the attacks on growing and stored crops by insect pests and plant diseases are enormous, despite all that has been done to lessen them. A conservative estimate of the loss of wheat in the United States in a single recent year on account of the black-stem rust is 180,000,000 bushels, and this pest is but one of many that attack the wheat every year.

THE Federal Government of Australia, acting in response to representations which have been made to it, has taken steps for the preservation of the aborigines who are under its jurisdiction. It has been decided to set aside part of the State lands in the Northern Territories as a reservation for the tribes. This aboriginal reserve will include the Mann and Petersen Ranges and practically the whole of Lake Amadeus. Areas have also been set aside by the Governments of South and Western Australia in the adjoining districts for the purpose of this reserve. No intimation has been received that medical attention will be provided, but it is to be hoped that, if no step in this direction has been taken, some form of medical service may be instituted, as it is essential to the success of any scheme to preserve the aboriginal from extinction.

THE presidential address delivered by Sir Robert Hadfield to the ninth annual conference of the British Commercial Gas Association at Sheffield on October 19 has now been published. The address deals with a number of problems connected with increased production and with the economy of natural resources. True economy does not consist in the mere cutting down of expenditure; wise expenditure on improved working conditions, on modern plant, on research, and on education is more than ever necessary. Increased production demands economy of fuel, diminished cost per unit of production, and the better organisation and training of labour by scientific planning and direction of the details of operations. This would be accompanied by a decrease of strain on the workers rather than by an increase, owing to the elimination of unnecessarily fatiguing methods and the extension of the use of labour-saving machinery. The universal adoption of modern methods of obtaining heat and power would result in cheaper factory construction, economy of space, increased speed and trustworthiness of output, and decreased consumption of fuel. Tables are given to show the present state of the national industries, and also to compare gas, coal, and electric heating from the point of view of cost and consumption of coal in the heating and melting of steel. It is evident that for heating to moderate temperatures coal is the cheapest fuel; whilst for melting, producer gas is by far the most economical. Electric energy cannot compete with gas in cost, except for certain classes of work at very high temperatures. The author again directs attention to the necessity of applying scientific principles more thoroughly to the design of furnaces, and urges the desirability of a study of the important researches of Groume-Grjimailo on the flow of heated gases through a furnace.

THE Carnegie Corporation of New York some time ago made a gift of five million dollars to the American National Research Council and National Academy of Sciences, of which about one million dollars is to be devoted to the erection of a building in Washington to serve as the home of these two closely related scientific organisations. The remainder of the total sum is to serve as an endowment for the maintenance of the Council. A site for the building, comprising an entire block of land near the present Lincoln Memorial in Potomac Park, has just been obtained at a cost of about 200,000 dollars through gifts from about a score of generous individuals, most of whom are business men associated with great industrial concerns or generally interested in the promotion of American science. The National Research Council, which was organised during the war to aid the Government in mobilising the scientific resources of America, in both *personnel* and material, for attack on scientific problems connected with America's war-time activities, has now been reorganised on a peace-time basis as a permanent institution for the promotion of scientific research and the dissemination of scientific information. It is not a Government Department or Bureau, but is privately supported and wholly controlled by the co-operating scientific men of the country. The major part of its membership is composed of appointed representatives of about forty American major scientific and technical societies. Dr. George E. Hale, director of the Mount Wilson Solar Observatory, is the honorary chairman, and Dr. H. A. Bumstead, professor of physics at Yale University, is the active chairman for the present year. Dr. Vernon Kellogg, formerly of Stanford University, is the permanent secretary.

THE Institut International d'Anthropologie has been formally constituted, with a provisional council of direction, consisting of representatives of seventeen nationalities.

MR. ALAN A. CAMPBELL SWINTON, chairman of the council of the Royal Society of Arts, will deliver the inaugural address of the 167th session on Wednesday, November 17, at 8 p.m. His subject will be "Wireless Telegraphy and Telephony."

THE annual general meeting of the National Union of Scientific Workers is to be held at King's College, Strand, on Saturday, November 13, at 2.30. An invitation to attend is extended to all scientific workers. The annual dinner of the union will take place in the evening of the same day.

THE Stockholm correspondent of the *Morning Post* announces that the Nobel prize in medicine for 1919 has been awarded to Dr. Jules Bordet, chief of the Pasteur Institute, Brussels, and the same prize for 1920 to Prof. August Krogh, professor of physiology in the University of Copenhagen.

THE PRINCE OF MONACO has summoned a meeting of representatives of the Oceanographic Section of the International Union of Geodesy and Geophysics for January 25, 1921, at Paris. An extensive programme of the work to be undertaken by the Section will be submitted to this meeting.

A DISCUSSION on the African arc and meridian will be held in the rooms of the Royal Astronomical Society on Friday, November 5, at 5 p.m. The chair will be taken by Col. E. H. Hills. Col. H. G. Lyons will open the discussion, which will be continued by Sir Charles Close, Col. E. M. Jack, Mr. A. R. Hinks, Mr. C. G. T. McCaw, and probably Sir S. G. Burrard and Sir G. Lenox-Conyngham.

THE British Motor Cycle and Cycle-car Research Association has been approved by the Department of Scientific and Industrial Research as complying with the conditions laid down in the Government scheme for the encouragement of industrial research. The association may be approached through Major H. R. Watling, "The Towers," Warwick Road, Coventry.

THE Civil Service Commission of Canada announces the promotion of Mr. Arthur Gibson to the position of Dominion Entomologist and head of the Entomological Branch of the Dominion Department of Agriculture. Mr. Gibson has been Acting Dominion Entomologist since the death of Dr. C. Gordon Hewitt in February last.

THE Institute of Industrial Administration, 110 Victoria Street, London, S.W.1, has among its objects "the general advancement of knowledge relative to the principles of industrial administration and their applications." The inaugural meeting was held on October 23, when an address on the industrial question was given by Viscount Haldane. Other meetings to be held are as follows:—November 9, The Influence of Exposed Records on Output, F. M. Lawson; November 23, Staff Selection and Promotion, E. W. Cousins; December 7, Road Transport as an Aid to Industrial Management, R. Twelvetrees; December 21, Standardisation of Rate-fixing Methods, J. E. Powell; January 11, 1921, The Measure of Output in Agriculture, W. J. Malden; and January 25, News and its Influence on Output, H. S. Rylands.

MR. F. S. SPIERS, secretary of the Faraday Society, was recently appointed by the King an Officer of the British Empire (O.B.E.), and reference was made to this honour at the opening of the joint meeting on the physics and chemistry of colloids described elsewhere in this issue. Mr. Spiers has been responsible for the organisation of the many valuable joint conferences arranged by the Faraday Society during Sir Robert Hadfield's presidency, and everyone who has attended any of them will be glad to know that his work has met with official recognition. He was secretary of the two British Scientific Products Exhibitions organised in 1918 and 1919 by the British Science Guild, and is secretary of the Institute of Physics, which there is every reason to believe will eventually occupy a very strong position among scientific bodies.

IN recent notes in the *Astr. Nachr.* (No. 5047) and the Paris *Comptes rendus* (vol. clxxi., p. 520) Prof. Carl Störmer describes most interesting results from photographic observations made at seven stations in Norway on the height of a very brilliant aurora seen on the night of March 22–23 last. More than six hundred photographs were taken. Only some of the plates have been fully studied, but these give for the summits of some of the auroral rays heights *of the order of* 500 *km.* Prof. Störmer describes a unique corona, seen on March 23 about 3h. 45m. a.m. G.M.T., of "long blue rays of indescribable beauty." Of this he himself, at his station at Bygdo, near Christiania, obtained several photographs, but unfortunately by that time all his other stations had run out of plates. He is anxious to know whether anyone else obtained a photograph of the blue rays, as he thinks their height was probably quite exceptional.

THE second reading of the British Empire Exhibition (Guarantee) Bill was carried in the House of Commons on November 1. The exhibition is to be held in London in 1923, and to be representative of the industries and resources of the British Empire. It will be privately organised, but has received official recognition and support. The King has given it his patronage, and the Prince of Wales is to be president of the General Committee. Under the Bill the Government proposes to guarantee the sum of 100,000*l.*, subject to private guarantees amounting to 500,000*l.* being forthcoming. As a condition of the guarantee, the Board of Trade is to approve the manager of the exhibition, the executive committee, and the general conditions under which the exhibition will be run, so that the Government may be in a position to secure that the exhibition is conducted with proper regard to economy and on lines which will ensure a success worthy of the object in view.

THE usual winter courses of the Ecole d'Anthropologie began at Paris on November 3. Prof. Manouvrier's subject is the anthropological problems of heredity; Prof. Hervé's the regional ethnology of France and the conclusion of a study of crossings; Prof. Mahoudeau's the naturalists and philosophers of the eighteenth century, and the struggle against creationism; Prof. de Mortillet's labour, industry, and commerce among primitive peoples; Prof. Capitan's the most recent observations upon the megaliths of Brittany, upon Alsatian and Belgian prehistorics, and, generally, upon the architecture and art of prehistoric times; Prof. Schrader continues his teaching on the normal and abnormal relations of modern civilisation with natural laws; Prof. Papillault lectures on the psycho-sociology of art; Prof. Zaborowski on the ancient and modern peoples of Europe and America; Prof. Anthony on morphological determinism in biology; and Prof. Vinson on the languages of Europe. We miss the usual announcement of conferences.

PROF. ROGET in his third Chadwick lecture, delivered on Friday, October 29, dealt with the future activities in the civil community of the public health department of the League of Red Cross Societies. The work to be undertaken has been divided up among seven sections. The first is concerned with social diseases. The lecturer pointed out the difficulty of including these affections in Red Cross work; nevertheless, he is of opinion that science is bound to do its utmost to stamp out the "social evil." At the same time every moral and religious influence must also be brought to bear on the subject. The second section will deal with the prevention of tuberculosis. Prof. Roget stated that both preventive methods and the segregation of tuberculous persons must be employed in this work. The third section will be devoted to the prevention of malaria, chiefly by carrying out scientific changes which have been proved to be effective in the administration of areas in which the disease is rife. Child welfare and nursing will be the work of the fourth section. With the collaboration of the visiting nurse with the mother work can be done which is peculiarly suited to Red Cross organisations. Another section is concerned with preventive medicine; preventive service could be efficient only when a large number of Red Cross laboratories had been placed at the disposal of the medical practitioner. The seventh section would have the greatest task of all, that of education. Museums, lectureships, health libraries, and literature were all necessary, particularly in those countries in which hygiene, sanitation, and clean housing are neglected.

IN an important paper by Mr. A. L. Kroeber on "California Culture Provinces" (University of California Publications in Ethnology, vol. xvii., No. 27) the author dismisses the theory held by American ethnologists that California represents a well-defined culture area. This region falls more properly into three areas: northern, central, and southern. Of these the northern is part of the culture of the North Pacific coast, with its centre in British Columbia. In the south the foundation of everything is Mexican, but the culture has taken its peculiar shape and colour on the spot. What the author says of the south-west may be generally applied to the other regions: "The truth is that the south-west is too insuperably complex to be condensed into a formula or surrounded with a line on the map."

OBSERVERS of social life in India have long been aware that certain varieties of the sári or sheet are distinctive marks of caste. In the October issue of *Man* Mr. R. S. Nicholson describes some remarkable methods of ornamentation of the sári which prevail in the Cuddapa district of the Madras Presidency. New cloths, though they may have been previously procured, are assumed in the eighth month of the Telugu year, corresponding with October–November. Each type of cloth has a special border, indicating the god in whose honour the cloth is worn—a special colour for the Nága or snake god, the Mother goddesses, and so on. These special marks on women's cloths seem to be peculiar to Southern India, and, so far as has hitherto been observed, do not prevail in the north.

MUCH interest has lately been excited by the attempted breeding of a pair of bee-eaters in Scotland. These birds took up their quarters on a sandbank of the River Esk at Musselburgh, and it seemed at one time probable that they would succeed in rearing young. A full account of this attempt and its lamentable ending is given by Dr. Eagle Clarke in the September–October issue of the *Scottish Naturalist*.

THE *Philippine Journal of Science* (vol. xvi., No. 4) is devoted to an interesting and valuable survey of the avifauna and flora of the Philippines. The author, Mr. R. C. McGregor, gives a condensed but vividly written account of the various types of forest of this region in relation, on one hand, to their economic value, and, on the other, to the problems they present to the ecologist. He then proceeds to give a lively review of the birds of this area and their distribution in regard to the different types of forest, supplementing his observations by comparisons with other types of tropical forests in Africa and America. To naturalists at large this essay will prove supremely interesting and helpful. Furthermore, it is illustrated by a number of beautiful plates.

MEMOIRS of the Agricultural Department of India, Entomological Series, vol. v., No. 5 (May, 1920), deals with two destructive species of rice-leaf hoppers. This well-illustrated brochure by C. S. Misra emphasises the great damage done by these insects. In the Chhattisgarh Division of the Central Provinces in 1914 they were reported to have damaged 3,000,000 acres, causing a loss approximately of 14,000,000 rupees. From observations conducted on the habits of these insects it was ascertained that they have a strong predilection for light. In order to apply the use of light traps satisfactorily it was necessary that the cultivators should co-operate in the work, but the Chhattisgarhi ryot is both superstitious and lethargic. No amount of persuasion could induce him to go to his fields at night and light the lamps, owing to his innate dread of evil spirits. Among other methods the necessity for clean cultivation and the elimination of all grassy areas in the immediate vicinity of the paddy fields is emphasised. The use of large field-bags, 6 ft. long, 4 ft. broad, and 4 ft. deep, attached to a light bamboo frame is also advised. Each bag can be carried by two men at a walking pace and drawn through the fields when the plants are small. The inside of the bags should be smeared with kerosene in order to prevent the leaf-hoppers from escaping when once they are caught. The possibility of selecting immune varieties of paddy is a subject worth consideration, together with the relation of the ripening period to the incidence of the pests.

SEALING operations at the Pribilof Islands closed for the season on August 10, and the United States Bureau of Fisheries reports that telegraphic information has been received stating that a total of 25,978 pelts had been taken during this calendar year (*Science*, October 8). Of this number 21,936 were taken on St. Paul Island and the remainder on St. George Island; 721 of the pelts were from seals seven years of age or older. A by-products plant was in operation on St. Paul Island which produced some 1800 gallons of oil and 29,000 lb. of meat or fertiliser. These figures could have been exceeded if the Bureau had been able to obtain more labourers from the Aleutian Islands. Comments are made on the rumour that the United States Government intends to remove restrictions on pelagic sealing in the North Pacific Ocean and Bering Sea. North of the thirtieth parallel of north latitude, and in the seas of Bering, Kamchatka, Okhotsk, and Japan, pelagic seal-fishing is prohibited by an agreement entered into in 1911 by the United States, Great Britain, Russia, and Japan, which is in perpetuity unless one or more of the signatories dissent from it. This agreement has never been rescinded, and in face of the benefits which have been shown to accrue from the proper management of fur-seal herds—in the fiscal year 1920 the United States revenue from the sale of skins was 1,457,790 dollars, and Great Britain and Japan take shares of 15 per cent. each of the annual catch—there is no likelihood of the re-introduction of pelagic seal-fishing. The Alaskan herd is protected by the patrolling vessels of the United States and Canada working in co-operation.

THE *Lancet* of October 23 contains an interesting account of an outbreak of Senecio disease, or cirrhosis of the liver due to Senecio poisoning, which occurred in the George district of Cape Province, Union of South Africa, in 1918. Dr. F. C. Willmot and Mr. G. W. Robertson, the authors of the article, state that the disease has been traced to the presence of the toxic seeds of *Senecio ilicifolius* and *Senecio Burchelli* in wheat harvested from fields in which these weeds were prevalent. They mention that precisely similar diseases (Molteno disease in South Africa, Winton's disease in New Zealand, and Pictou disease in Nova Scotia) have long been known in farm animals, especially horses, but they appear to be unaware that so long ago as 1911 Dr. H. E. Watt, working in the Imperial Institute laboratories, isolated from *Senecio latifolius*, the plant chiefly suspected of causing the disease in horses in South Africa, two toxic alkaloids, senecifoline and senecifolidine. These alkaloids were afterwards examined pharmacologically by Prof. Cushny, and found to produce hepatic cirrhosis in the animals used, the symptoms and post-mortem findings being identical in all respects with those recorded by the veterinary surgeons who have dealt with cases of Molteno, Winton's, or Pictou disease in South Africa, New Zealand, and Canada respectively. The outbreak now recorded by Dr. Willmot and Mr. Robertson is, however, probably the first instance of Senecio poisoning in human beings, and it raises the interesting question of the possible occurrence of cases in Europe, since *Senecio jacobaea*, the source of the disease in sheep in Nova Scotia, is a common weed in the United Kingdom and throughout Europe. In this country, however, the cleaning of wheat prior to its conversion into flour is probably so efficiently done that the risk is negligible.

WANDERING storms form the subject of an article by Prof. A. McAdie, of Harvard University, in the *Geographical Review* for July last. The communication is for the most part based on Sir Napier Shaw's "Manual of Meteorology," part iv., published during the war, which discusses the relation of the wind to barometric pressure and the travel of cyclones. Prof. McAdie instances three unusual storm tracks dealt with by Sir Napier Shaw, and alludes to the need in forecasting of knowledge of recurving storms, with especial reference to the aviator and his long-distance flights. A remarkable instance is given by the author of the erratic travel of a disturbance from May 8 to June 6, 1910. This is tracked from the Strait of Juan de Fuca to the Grand Banks, when it is said to have recurved again and again, and to have come back to the Continent on May 26. It then merged with a storm that was moving north from Texas, and after meandering about to the east and north-east of Nova Scotia for ten days, until June 6, the disturbance dissipated.

THE October issue of the *Abstracts and Papers* published by the Institution of Civil Engineers contains 300 abstracts occupying more than 200 pages, and an index of 12 pages. The necessity for such a publication if the results of foreign investigations are to be made available in the engineering industries of this country will be apparent to every reader. Taking the abstracts which deal with the uses and properties of concrete for structural purposes, we find that a five years' experience in Germany of the use of furnace-slag as a substitute for gravel and sand in concrete has shown that slag-concrete is stronger than concrete made of Rhine sand. The conditions under which Portland cement can be stored for a couple of years without the strength of the concrete made from it suffering have been investigated in America. In Germany a saving of 17 per cent. has been effected by the substitution of concrete for brick in workmen's dwellings. In South Africa the manufacture of large pipes of concrete by the centrifugal process has proved successful. In Belgium the best way of driving concrete piles without injury to them has been investigated; while the American Railway Engineers' Association has found concrete road-beds uniformly successful.

IN the *Journal de Physique* for August last MM. H. Abraham, E. Bloch, and L. Bloch describe their direct-reading thermionic voltmeter which is manufactured by Carpentier. The invention of this instrument is a notable step in the development of the science of electrical measurement. Hitherto it has been impossible to get a direct-reading voltmeter which would read one volt of alternating pressure accurately. This instrument gives a direct reading for the ten-millionth part of an alternating volt. It consists of two thermionic amplifiers, followed by two thermionic valves in parallel, the "plate" current of which is measured by an ordinary direct-current milliammeter. With the help of this instrument the measurement of very minute alternating currents and pressures is as simple as everyday measurements with ordinary voltmeters and ammeters. By its use absolute measurements of inductances and capacities are made in a few minutes with a maximum inaccuracy of about 1 in 1000. By the use of suitable electrical "filters" very approximately sine-shaped waves are obtained by blocking out the disturbing harmonics. The authors have shown recently in the same journal how the frequency of the alternating currents can be determined with high accuracy. Its sensitiveness is shown by the fact that it can measure, by means of a direct reading of the pointer, the capacity of a sphere one millimetre in radius. The instrument has very many useful applications.

SOME comments on the statistics just issued by *Lloyd's Register* for the quarter ending on September 30 appear in *Engineering* for October 22. Before the war the merchant tonnage under construction in this country usually exceeded the total building in all other countries in the world; at present the tonnage building abroad exceeds our tonnage under construction by about 103,000 tons. At the end of September the vessels building in this country numbered 961 with a total gross tonnage of 3,731,098, an increase during the year of more than 32 per cent.; in comparison with the figure for September, 1913, the increase is more than 90 per cent. The individual tonnage in no case exceeds 25,000. With regard to the tonnage building abroad, the most noticeable feature is the decline in the tonnage building in the United States, where there are now only 312 vessels with an aggregate gross tonnage of 1,772,193 in hand, as compared with 767 vessels and a gross tonnage of 3,470,748 for the corresponding quarter of last year. Of the vessels now under construction, 114 with a total gross tonnage of 796,060 are intended for carrying oil in bulk. The United States is building 79 of these ships, and there are 32 building in the United Kingdom. Only five small steamers are being constructed of reinforced concrete in the United Kingdom, their total tonnage amounting to 2354; eleven vessels of this type are being built abroad, having a total tonnage of 24,069.

THE miscellaneous catalogue (No. 2, 1920) of second-hand books just issued by Mr. W. H. Robinson, 4 Nelson Street, Newcastle-upon-Tyne, contains nearly a thousand items, about two hundred of which deal with scientific subjects. The prices asked for the works appear very reasonable. The catalogue can be obtained upon application.

WE have received from the firm of Scientific Appliances, Southampton Row, W.C.1, a copy of its illustrated catalogue, which shows the apparatus available in two sections of the establishment. Section E contains electrical and magnetic apparatus, and fittings such as telephone sets, lighting sets, Wimshurst machines, accumulators, etc. Section O comprises optical appliances and drawing materials.

Our Astronomical Column.

COMETS.—Dr. Kudara, who rediscovered Tempel's second comet last May, gives the following revised elements for it in *Popular Astronomy* for October. He also gives the corrected R.A. for the observation on May 25 last as 22h. 55m. 43·7s.:

$$T = 1920 \text{ June } 16{\cdot}196 \text{ G.M.T.}$$
$$\left.\begin{aligned}\omega &= 186^\circ\ 39'\ \ 0''\\ \Omega &= 120^\circ\ 46'\ \ 5''\\ i &= 12^\circ\ 45'\ 14''\\ \phi &= 33^\circ\ 54'\ 21''\end{aligned}\right\}1920{\cdot}0$$
$$\mu = 687{\cdot}51''$$
$$\log a = 0{\cdot}47515$$

The period is the shortest of any known comet with the exception of that of Encke.

Popular Astronomy also contains the following elements of Borrelly's comet (1905 II.) deduced by Mr. F. E. Seagrave from observations on 1918 October 9 and December 6 and 1919 February 4:

$T = 1918$ Nov. 16·8632 G.M.T.	$\phi = 37^\circ\ 57'\ 11''$
$\omega = 352^\circ\ 23'\ 32''$	$\mu = 514{\cdot}023''$
$\Omega = 76^\circ\ 57'\ \ 2''$	$\log a = 0{\cdot}559350$
$i = 30^\circ\ 29'\ 14''$	

MOUNT WILSON OBSERVATIONS OF CAPELLA.—Some account of the remarkable observations of Capella as a double star at Mount Wilson, using interferometer methods on the 100-in. equatorial, was given in NATURE last April. The *Astrophysical Journal* for June contains further details; the theory of the interferometer is described by Mr. A. A. Michelson, while Mr. J. A. Anderson discusses the observations of Capella, and finds the orbit from observations on six days ranging from 1919 December 30 to 1920 April 23, combined with the spectroscopic data. The following are the adopted elements: Period = 104·006 days; periastron = Julian day 2422387·9; $a = 0{\cdot}05249'' = 130{,}924{,}000$ km.; $e = 0{\cdot}016$; $i = 140^\circ\ 30'$; $\omega = 117{\cdot}3^\circ$; parallax = 0·0600″; masses of components in terms of sun, 4·62 and 3·65. These elements satisfy the observations with no error exceeding 0·00004″ in distance and 0·9° in position-angle, but the author points out that a longer series would probably show much larger residuals, since the interferometer multiplies the theoretical resolving power by $2\frac{1}{2}$ only.

From the close resemblance of the spectrum of one of the components with that of the sun it is probable that the surface brilliancy is much the same as the sun's, in which case the diameter of each star would be of the order of ten times that of the sun, or one-tenth of the distance between them. It is noted that the visual magnitudes of the two components must be very nearly the same, since the interference fringes completely vanished on superposition.

VARIATION IN THE LIGHT OF JUPITER.—A novel use of the photo-electric cell was made by Herr P. Guthnick at the Berlin-Babelsberg Observatory in an investigation as to whether the light of Jupiter showed any variation in the course of the planet's rotation owing to different markings being presented to us. In fact, last December and January there was a distinct variation having an amplitude of 0·14 magnitude. However, this rapidly diminished, and by February was only 0·04 magnitude. The author remarks that this rapid change gives support to the temporary variability in the light of Neptune in a period of eight hours observed by Prof. Hall and discussed in Monthly Notices, vols. xliv. and lxxv. Unfortunately, Neptune is too faint for observation with the photo-electric cell, otherwise a determination of its rotation-period might result.

Educational Science.*

By SIR ROBERT BLAIR, LL.D.

THE value to education of science and the scientific method has hitherto been for the most part indirect and incidental. It has consisted very largely in deductions from another branch of study, namely, psychology, and has resulted for the most part from the invasion into education of those who were not themselves educationists. A moment has now been reached when education itself should be made the subject of a distinct department of science, when teachers themselves should become men of science.

There is in this respect a close analogy between education and medicine. Training the mind implies a knowledge of the mind, just as healing the body implies a knowledge of the body. Thus, logically, education is based upon psychology, as medicine is based on anatomy and physiology. And there the text-books of educational method are usually content to leave it. But medicine is much more than applied physiology. It constitutes an independent system of facts, gathered and analysed, not by physiologists in the laboratory, but by physicians working in the hospital or by the bedside. In the same way, then, education as a science should be something more than mere applied psychology. It must be built up not out of the speculations of theorists, or from the deductions of psychologists, but by direct, definite, *ad hoc* inquiries concentrated upon the problems of the class-room by teachers themselves. When by their own researches teachers have demonstrated that their art is, in fact, a science, then, and not until then, will the public allow them the moral, social, and economic status which it already accords to other professions. The engineer and the doctor are duly recognised as scientific experts. The educationist should see to it that his science also becomes recognised, no longer as a general topic upon which any cultured layman may dogmatise, but as a technical branch of science, in which the educationist alone, in virtue of his special knowledge, his special training, his special experience, is the acknowledged expert.

Educational science has hitherto followed two main lines of investigation: first, the evaluation and improvement of teachers' methods, and, secondly, the diagnosis and treatment of children's individual capacities.

I. THE PSYCHOLOGY OF THE INDIVIDUAL CHILD.

It is upon the latter problem, or group of problems, that experimental work has in the past been chiefly directed, and in the immediate future is likely to be concentrated with the most fruitful results. The recent advances in "individual psychology"—the youngest branch of that infant science—have greatly emphasised the need, and assisted the development, of individual teaching. The keynote of successful instruction is to adapt that instruction to the individual child. But before instruction can be so adapted the needs and the capacities of the individual child must first be discovered.

A. *Diagnosis*.

Such discovery (as in all sciences) may proceed by two methods: by observation and by experiment.

(1) The former method is, in education, the older. At one time, in the hands of Stanley Hall and his followers—the pioneers of the child-study movement—observation yielded fruitful results. And it is perhaps to be regretted that of late simple observation and description have been neglected for the more ambitious method of experimental tests. There is much that a vigilant teacher can do without using any special apparatus and without conducting any special experiment. Conscientious records of the behaviour and responses of individual children, accurately described without any admixture of inference or hypothesis, would lay broad foundations upon which subsequent investigators could build. The study of children's temperament and character, for example—factors which have not yet been accorded their due weight in education—must for the present proceed upon these simpler lines.

(2) With experimental tests the progress made during the last decade has been enormous. The intelligence scale devised by Binet for the diagnosis of mental deficiency, the mental tests employed by the American Army, the vocational tests now coming into use for the selection of employees—these have done much to familiarise, not school teachers and school doctors only, but also the general public, with the aims and possibilities of psychological measurement. More recently an endeavour has been made to assess directly the results of school instruction, and to record in quantitative terms the course of progress from year to year, by means of standardised tests for educational attainments. In this country research committees of the British Association and of the Child-Study Society have already commenced the standardisation of normal performances in such subjects as reading and arithmetic. In America attempts have been made to standardise even more elusive subjects, such as drawing, handwork, English composition, and the subjects of the curriculum of the secondary school.

B. *Treatment*.

This work of diagnosis has done much to foster individual and differential teaching—the adaptation of education to individual children, or at least to special groups and types. It has not only assisted the machinery of segregation—of selecting the mentally deficient child at one end of the scale and the scholarship child at the other—but it has also provided a method for assessing the results of different teaching methods as applied to these segregated groups. Progress has been most pronounced in the case of the sub-normal. The mentally defective are now taught in special schools, and receive an instruction of a specially adapted type. Some advance has more recently been made in differentiating the various grades and kinds of so-called deficiency, and in discriminating between the deficient and the merely backward and dull. With regard to the morally defective and delinquent little scientific work has been attempted in this country, with the sole exception of the new experiment initiated by the Birmingham justices. In the United States some twenty centres or clinics have been established for the psychological examination of exceptional children; and in England school medical officers and others have urged the need for "intermediate" classes or schools not only to accommodate backward and borderline cases and cases of limited or special defect (*e.g.* "number-defect" and so-called "word-blindness"), but also to act as clearing-houses.

In Germany and elsewhere special interest has been aroused in super-normal children. The few investigations already made show clearly that additional attention, expenditure, study, and provision will yield

* From the opening address of the President of Section L (Educational Science) delivered at the Cardiff Meeting of the British Association on August 24.

for the community a far richer return in the case of the super-normal than in the sub-normal.

At Harvard and elsewhere psychologists have for some time been elaborating psychological tests to select those who are best fitted for different types of vocation. The investigation is still only in its initial stages, but it is clear that if vocational guidance were based, in part at least, upon observations and records made at school instead of being based upon the limited interests and knowledge of the child and his parents, then not only employers, but also employees, their work, and the community as a whole, would profit. A large proportion of the vast wastage involved in the current system of indiscriminate engagement on probation would be saved.

The influence of sex, social status, and race upon individual differences in educational abilities has been studied upon a small scale. The differences are marked; and differences in sex and social status, when better understood, might well be taken into account both in diagnosing mental deficiency and in awarding scholarships. As a rule, however, those due to sex and race are smaller than is popularly supposed. How far these differences, and those associated with social status, are inborn and ineradicable, and how far they are due to differences in training and in tradition can scarcely be determined without a vast array of data.

II. TEACHING METHODS.

The subjects taught and the methods of teaching have considerably changed during recent years. In the more progressive types of schools several broad tendencies may be discerned. All owe their acceptance in part to the results of scientific investigators.

(1) Far less emphasis is now laid upon the *disciplinary value of subjects*, and upon subjects the value of which is almost solely disciplinary. Following in the steps of a series of American investigators, Winch and Sleight in this country have shown very clearly that practice in one kind of activity produces improvements in other kinds of activities only under very limited and special conditions. The whole conception of transfer of training is thus changed, or (some maintain) destroyed; and the earlier notion of education as the strengthening, through exercise, of certain general faculties has consequently been revolutionised. There is a tendency to select subjects and methods of teaching rather for their material than for their general value.

(2) Far less emphasis is now laid upon an advance according to strict *logical sequence* in teaching a given subject of the curriculum to children of successive ages. The steps and methods are being adapted rather to the natural capacities and interests of the child of each age. This genetic point of view has received great help and encouragement from experimental psychology. Binet's own scale of intelligence was intended largely as a study in the mental development of the normal child. The developmental phases of particular characteristics (*e.g.* children's ideals) and special characteristics of particular developmental phases (*e.g.* adolescence) have been elaborately studied by Stanley Hall and his followers. Psychology, indeed, has done much to emphasise the importance of the post-pubertal period—the school-leaving age, and the years that follow. Such studies have an obvious bearing upon the curriculum and methods for our new continuation schools. But it is, perhaps, in the revolutionary changes in the teaching methods of the infants' schools—changes that are already profoundly influencing the methods of the senior department—that the influence of scientific study has been most strongly at work.

(3) Increasing emphasis is now being laid upon *mental and motor activities*. Early educational practice, like early psychology, was excessively intellectualistic. Recent child-study, however, has emphasised the importance of the motor and of the emotional aspects the child's mental life. As a consequence, the theory and practice of education have assumed more of the pragmatic character which has characterised contemporary philosophy.

The progressive introduction of manual and practical subjects, both in and for themselves, and as aspects of other subjects, forms the most notable instance of this tendency. The educational process is assumed to start not from the child's sensations (as nineteenth-century theory was so apt to maintain), but rather from his motor reactions to certain perceptual objects—objects of vital importance to him and to his species under primitive conditions, and therefore appealing to certain instinctive impulses. Further, the child's activities in the school should be not, indeed, identical, but continuous, with the activities of his subsequent profession or trade. Upon these grounds handicraft should now find a place in every school curriculum. It will be inserted both for its own sake and for the sake of its connections with other subjects, whether they be subjects of school life, of after life, or of human life generally.

(4) As a result of recent psychological work, more attention is now being paid to the *emotional, moral, and aesthetic* activities. This is a second instance of the same reaction from excessive intellectualism. Education in this country has ever claimed to form character as well as to impart knowledge. Formerly this aim characterised the public schools rather than the public elementary schools. Recently, however, much has been done to infuse into the latter something of the spirit of the public schools. The principle of self-government, for example, has been applied with success not only in certain elementary schools, but also in several colonies for juvenile delinquents. And in the latter case its success has been attributed by the initiators directly to the fact that it is corollary of sound child-psychology.

Bearing closely upon the subject of moral and emotional training is the work of the psycho-analysts. Freud has shown that many forms of mental inefficiency in later life—both major (such as hysteria, neurosis, certain kinds of "shell-shock," etc.) and minor (such as lapses of memory, of action, slips of tongue and pen)—are traceable to the repression of emotional experiences in earlier life. The principles themselves may, perhaps, still be regarded as, in part, a matter of controversy. But the discoveries upon which they are based vividly illustrate the enormous importance of the natural instincts, interests, and activities inherited by the child as part of his biological equipment; and, together with the work done by English psychologists such as Shand and McDougall upon the emotional basis of character, have already had a considerable influence upon educational theory in this country.

(5) Increasing emphasis is now being laid upon *freedom* for individual effort and initiative. Here, again, the corollaries drawn from the psycho-analytic doctrines as to the dangers of repression are most suggestive. Already a better understanding of child-nature has led to the substitution of "internal" for "external" discipline; and the predetermined routine demanded of entire classes is giving way to the growing recognition of the educational value of spontaneous efforts initiated by the individual, alone or in social co-operation with his fellows.

In appealing for greater freedom still, the new psychology is in line with the more advanced educational experiments, such as the work done by Madame Montessori and the founders of the Little Commonwealth.

(6) The *hygiene and technique of mental work* is itself being based upon scientific investigation. Of the numerous problems in the conditions and character of mental work generally, two deserve special mention—fatigue and the economy and technique of learning.

But of all the results of educational psychology, perhaps the most valuable is the slow but progressive inculcation of the whole teaching profession with a scientific spirit in their work, and a scientific attitude towards their pupils and their problems. Matter taught and teaching methods are no longer exclusively determined by mere tradition or mere opinion. They are being based more and more upon impartial observation, careful records, and statistical analysis—often assisted by laboratory technique—of the actual behaviour of individual children.

Popular Relativity and the Velocity of Light.[1]

By Sir Oliver Lodge, F.R.S.

In using the phrase "popular relativity" I indicate that what I am criticising is not Einstein's equations—which seem to have justified themselves by results—but some of the modes of interpreting them in ordinary language. Especially do I attack that proposition which asserts that to every observer the velocity of light will not only be constant in reality, but will also superficially appear constant even when he ignores his own motion through the light-conveying medium—a proposition or postulate or axiom which has been shown to lead to curious and, as I think, illegitimate complications, threatening to land physicists in regions to which they have no right of entry, and tempting them to interfere with metaphysical abstractions beyond their proper ken.

Not that a physicist's proper ken is limited to what he immediately observes; he is entitled, and indeed required, to interpret appearances rationally by taking into account every relevant adventitious circumstance, including complications due to his own unobserved, and perhaps unobservable, travel through space.

In a relativity discussion at the Physical Society recently a member is reported to have asked the pertinent question: "Does an observer merely observe, or does he think as well?" If he thinks, I urge that he can allow for changes in his measuring instruments and any other consequences of possible motion, and can refrain from making deductions about space and time on the strength of experiments on matter.

He will know that his senses are material senses, and that all his experiments are made ultimately by their aid. He will know that he can only experiment even on the æther of space indirectly by means of matter, for he has no other means of getting a grip on it. Possibly he may be unable to grip it even thus, but matter gives him his only chance; he certainly cannot experiment on abstractions like space and time.

On the basis of material experiments he may be able to make deductions or draw inferences about the æther, because that certainly has some inter-relations with matter; but it is probably illegitimate, on the basis of material experiments, to make deductions about space and time at all; they are not likely to be affected by anything that matter can do, and it is only matter with which we can directly deal.

The relation between space and time that represents the velocity of light gives us directly one property of the æther, viz. the product of its electric and magnetic constants, both of which separately are at present unknown. Every student who accepts the æther of space as a reality is probably ready to admit that the velocity of light through free æther is an absolute constant, not dependent on anything that either the observer or the source is doing, has done, or may do.

But this admission has been erected into a fetish by the theory of relativity, at least when expressed in ordinary words, and is interpreted as requiring that to every observer, whatever he may be doing, the velocity of light in every direction will *appear* the same.

That is not only a different, it is a contradictory, proposition. Given the constancy of the real velocity of light—if an observer travel to meet it, it must appear to arrive more quickly than if he travel away from it, provided he has any means of making the observation at all. He may be unable to make the observation, but suppose he can make it, say by the aid of Jupiter's satellites, and detected a discrepancy, he need not infer any real change in the velocity of light; because, if he thinks, he can attribute any observed difference to his own motion, and thereby emerge with clear and simple views. If he sets out with the gratuitous notion that he can never become aware of his own motion, or that his own motion has no meaning, he will indeed encounter a puzzling universe, and will presently long for a Copernicus to unravel the subjective complexities of observation.

But it may well be extremely difficult for an observer to measure the velocity of light through the æther except with the aid of some return signal which the æther likewise has to transmit in the opposite direction; and in that case he may find that the to-and-fro pair of journeys take exactly the same time in every direction.

This, as everyone knows, has been done for a to-and-fro journey of a beam of light. And the timing is exact, not only to the first order of small quantities, as might readily be expected, but to the second order also—an exactitude which, if rigid unchangeable materials could be used, would not be expected, and ought not to occur. But if the dimensions of the material object used as the foundation-stone of his apparatus are subject to change by reason of motion, and if the changes are in accordance with the electrical theory of matter, as suggested by FitzGerald and elaborated by Lorentz, then everything becomes clear again until we come to astronomical and gravitational applications, and the precisely negative result of Michelson and Morley is precisely explained.

A mathematical doctrine of relativity may be based upon this experimental result, and may be convenient for reasoning purposes, but no such doctrine is required by the facts. The facts are patient of the doctrine; they do not compel it, nor do they justify it. Any comprehensive mathematical expression is liable to permit other modes of interpretation, as well as the simplest and truest or the one most directly applicable to the problem in hand. It is devised to cover one set of facts, but in its generality it is apt

[1] The substance of this controversial note was communicated to Section A of the British Association at the Cardiff meeting on August 27.

to cover more. Why, then, proceed to build up on an equation an elaborate metaphysical structure? And, especially, why imagine that the success of the Einstein equation proves the observed velocity of light to be the same whatever the motion of the observer? If the observer thinks, and if he is aware of the FitzGerald-Lorentz contraction, he will know that such a proposition is not true; he will know that the velocity of light is not equal in all directions in a relatively drifting medium, that the wave-front is not concentric to the observer, and that the Michelson experiment gives no proof of anything of the kind.

The uniformity of the æther makes the obtaining of positive results difficult; there seem to be always compensations. Some day we may be able to evade this experimental difficulty, but meanwhile, if we choose to make the supposition that motion of the observer can never have any directly observable effect, or that one set of axes of reference is necessarily equivalent to every other and indistinguishable by any kind of superficial observation, then we seem to be in accord with present experience. From that supposition definite consequences can, with adequate skill, be deduced, and the deductions have been subjected to successful verification.

But if on the strength of that remarkable achievement some enthusiasts proceed to formulate propositions which by ignoring the motion of the observer and all its consequences complicate the rest of the universe unduly, then, however much we may admire their skill and ability, I ask whether they ought not to be regarded as Bolsheviks and pulled up.

Emil Fischer's Contributions to Organic Chemistry.[1]

By DR. M. O. FORSTER, F.R.S.

EMIL FISCHER was born on October 9, 1852, at Euskirchen, and his death on July 14, 1919, occurred at a time when every element of constructive and harmonising influence was most sorely needed. Since 1892, when he succeeded von Hofmann, he had fulfilled the duties of professor and director of the chemical institute in the University of Berlin with increasing distinction. Physically commanding, his authority rested on the solid foundation of natural dignity. The brisk, upright carriage marked the man of action; the glowing eyes revealed his attitude of constant, keen inquiry; it was impossible to escape his contagious enthusiasm.

Fischer addressed himself to organic chemical research at the opening of its brightest epoch. Having described the preparation of phenylhydrazine in 1875, he devoted many succeeding years to developing the transformations of that remarkable substance. During this period he also collaborated with his cousin, Otto Fischer, in elucidating the constitution of rosaniline bases, their first joint paper appearing in 1876. It is noteworthy that, in spite of his early interest in the chemistry of these and other colouring matters, and notwithstanding his association with von Baeyer, beginning in Strasbourg and continuing until he left Munich to occupy the chair of chemistry at Erlangen in 1882, he nevertheless resisted the temptation to succeed Caro as director of research in the Badische factory, although at this time (1883) the colour industry was in the early flush of its active growth.

When reviewed as a chapter which is closed, Fischer's work must be regarded as having established upon a firm basis the fundamental science of biochemistry. The assimilation of carbon dioxide and water by plants, the variety and complexity of saccharide molecules proceeding therefrom, the degradation of the proteins, the probable course of their synthesis from amino-acids, and the power of assemblage or of disruption exerted by enzymes on all these building materials of the animal and vegetable kingdoms are subjects which Fischer not merely illuminated, but was the first to place in coherent arrangement and intelligible sequence. Recognition of the fact that all this was accomplished, not by revolutionary processes or theories, but by skilful development of the thoughts and operations expanded by Liebig, von Hofmann, Pasteur, and von Baeyer, is perhaps the highest tribute which can be paid to his genius.

Fischer's association with the branch of chemistry which first brought him fame began in 1884, when he discovered phenylglucosazone, produced from glucose, fructose, and mannose by the action of phenylhydrazine. At that time only two aldohexoses (glucose and galactose) and two ketohexoses (fructose and sorbose) were known and recognised as straight-chain pentahydroxy-derivatives. According to the requirements of van't Hoff's theory, a pentahydroxy-aldehyde of this class, in which five carbon atoms are each associated with one hydroxyl group, should appear in sixteen stereoisomeric forms, eight of these being enantiomorphs of the remainder. The bare statement that Fischer and his collaborators elucidated the configuration of twelve such isomerides, most of which they synthesised for that purpose, although perhaps an accurate summary of his opening achievement, conveys but a nebulous impression of the character and amount of the labour involved. Moreover, his discovery of γ-methylglucoside in 1914, and the consequent recognition of cyclic relations distinct from that occurring in α- and β-glucose, have opened the way to a multitude of contingent isomerides, those of *d*-glucose alone numbering ten. Thus Fischer not only elaborated his own sugar chemistry, but also added to this the foundation of a new carbohydrate classification.

The directive influence on Fischer's work in this field was the discovery, in association with Tafel in 1887, of α- and β-acrose. The former sugar he identified with *dl*-fructose, whilst β-acrose is now recognised as *dl*-sorbose. The above-mentioned synthetical operations, and many others connected with pentoses, tetroses, and artificial sugars containing more than six atoms of carbon, were effected by means of the cyanohydrin reaction, Pasteur's method of separating optical antipodes, and the discovery that when a monobasic sugar-acid is heated with quinoline at 140° C. the configuration of the carbon atom adjacent to the carboxyl group becomes epimerised (1890).

One of the most remarkable achievements in a series unsurpassed by any organic chemist was Fischer's synthesis of the principal constituent of Chinese tannin. In 1852 Strecker had shown that gall-nut tannin is a compound of grape-sugar and gallic acid, but latterly the conclusion had become discredited, and tannin was regarded as consisting mainly of digallic acid. This was synthesised in 1908 by Fischer and found to be crystalline, although astringent, and in 1912 he showed that the principal constituent of Chinese tannin does give glucose on hydrolysis. By a series of complex synthetical opera-

[1] Synopsis of the Emil Fischer Memorial Lecture delivered before the Chemical Society on October 28.

tions in association with Bergmann he prepared in 1918 the penta-(*m*-digalloyl)-derivatives of α- and β-glucose, and found them to be indistinguishable from the principle of Chinese tannin excepting for a slight difference in optical activity.

Fischer is entitled to a high place amongst the notable figures in chemical history associated with problems arising from the structure of uric acid and its derivatives. This work, begun in 1881, when he resolved caffeine into methylcarbamide and dimethylalloxan, reached its climax in 1898, when he derived purine from uric acid by means of indirect deoxidation. It has now passed into the text-books, and the classification of all such materials, many of which are important products of animal and vegetable metabolism, is based on his notation of 1897.

In view of their extent and the far-reaching biochemical conclusions based upon them, the labours of Fischer in the region of proteins make the same appeal to the imagination and evoke the same delight in craftsmanship as his activities amongst carbohydrates. Recognising amino-acids as the building materials of albuminoid molecules, he devised an unrivalled practical method for isolating them from the complex mixtures which follow the hydrolytic disruption of the proteins. Accumulating a large number of such units in their optically active forms, he proceeded to reassemble them as anhydrides, and thus elaborated molecules which, although much simpler than natural proteins, nevertheless approach them in physical properties. These were called polypeptides, and one of them, an octadecapeptide described in 1907, attained a molecular weight of 1213. The experimental methods developed in the course of these investigations are too complex for summary description, but they represent an extraordinary technical feat, and establish a connecting link between laboratory syntheses and the peptones arising from incomplete disruption of protein molecules. The investigation is limited only by material considerations, for a calculation made by Fischer in 1916 showed that the octadecapeptide has 816 possible isomerides, whilst a polypeptide involving thirty amino-acid molecules differing widely, but not entirely, amongst themselves may have isomerides reaching $1 \cdot 28 \times 10^{27}$ in number.

Throughout these inquiries Fischer made frequent and skilful use of enzymes, developing a technique which will offer substantial guidance to later investigators of vital changes. In 1894, having assembled a variety of artificial carbohydrates, he studied their behaviour towards different families of yeast, drawing the fundamental conclusion that the fermentative enzyme is an asymmetric agent attacking only those molecules of which the configuration does not differ too widely from that of *d*-glucose. Applying this principle to the natural and artificial *d*-glucosides, he ranged these in two groups, the α-*d*-glucosides being hydrolysed by maltase and indifferent towards emulsin, the β-*d*-glucosides exhibiting converse behaviour. The *l*-glucosides, *d*-galactosides, arabinosides, xylosides, rhamnosides, and glucoheptosides were not affected by either enzyme, and the glucosidic relation of sucrose, maltose, and lactose was determined by similar means. It was the knowledge thus gained which led Fischer to represent enzyme-action by the analogy of a lock-and-key, and to conclude that disaccharides are fermented only as a consequence of preliminary hydrolysis. Turning his attention to secretions of animal origin (1896), he studied the behaviour of carbohydrates and glucosides towards a great variety of tissue extracts and juices, but it was when these were applied by him, in association with Abderhalden (1903), to the proteins and polypeptides that the most fruitful results arose, from which it followed very clearly that the synthetic polypeptides are susceptible to zymolysis only when constructed of those amino-acids which occur in the natural proteins themselves.

Although the subjects to which Fischer mainly devoted his attention were not related directly to problems of manufacture, he quickly made contact with the chemical industry, and many of the processes in use at the Bayer, Höchst, and Böhringer factories were based upon principles developed in his laboratory; the improvement which he effected in the production of diethylbarbituric acid led to this compound becoming one of the most valuable hypnotics in pharmacy under the name "veronal." Whilst shunning publicity in its grosser forms, he played an active part in the German chemical world, and the reliance placed on his judgment by leaders of the German chemical industry ultimately grew into an attitude of trust which was quite exceptional. It was this which enabled him to become instrumental in establishing the Kaiser-Wilhelm-Institut für Chemie, a research foundation independent of teaching duties inaugurated in 1912. A pronounced individualist, he trusted personalities more than organisations and wisdom more than learning, his own kindling personality and clear wisdom being freely applied to the furtherance of scientific method, both industrial and academic.

It is not difficult to imagine the demands which were made upon him during the war period, the five years which were destined to be his last. In a directive capacity he was associated with many of the commissions charged with solving chemical problems connected with the great conflict, but it was the food shortage which engrossed his attention most urgently. There is no doubt that these labours and their fruitless issue preyed too heavily upon a constitution undermined by lifelong over-application to exhausting labour, and in view of the great age attained by his father, who passed the ninety-fourth year, his own demise was premature in every sense.

Even when due allowance has been made for the storehouse of accumulated facts upon which the chemists of his era were empowered to draw and for the variety of technique which was at their command, it can scarcely be claimed that in wealth of revelation and manipulative skill Emil Fischer is eclipsed by any of his predecessors. It is difficult to imagine that he can be surpassed by any of his successors, but whether this be so or not, his achievement will remain for all time a monument of industry, a masterpiece of symmetry, and a gospel of inspiration.

The Physics and Chemistry of Colloids and their Bearing on Industrial Questions.

THE Faraday and Physical Societies held a joint discussion on "The Physics and Chemistry of Colloids and their Bearing on Industrial Questions" on October 25 in the spacious lecture theatre of the Institution of Mechanical Engineers. The societies were extremely fortunate in having the subject introduced by Prof. Theodor Svedberg, of the University of Upsala, who gave an excellent *résumé*, mainly from the physical point of view, of the present state of knowledge of the subject of colloids on the theoretical side. Prof. Svedberg's written contribution included an excellent bibliography of the subject, which will be found most helpful to physicists and others who wish to become acquainted with modern theoretical developments. The ensuing discussion was divided into the following five sections: (1) "Emulsions and Emulsification," opened by Prof. F. G. Donnan; (2) "The Physical Properties of Elastic Gels," opened by Mr. E. Hatschek and Prof. H. R. Procter; (3) "Glass and Pyrosols," opened by Sir Herbert Jackson; (4) "Non-aqueous Systems," opened by Sir Robert Robertson; and (5) "Precipitation in Disperse Systems: Cataphoresis and Electro-endosmose," opened by Prof. A. W. Porter.

In section (1) the discussion centred mainly around the important problem of the reversal of phases in emulsions produced by electrolytes. The results of experiments on soap emulsions carried out by Mr. S. S. Bhatnagar at University College, London, were given by the author, who concluded that there was a strict parallel between the reversal of phases in emulsions and the precipitation of suspensions by electrolytes. Apart from the considerable theoretical interest attaching to the subject, the matter is of practical importance in that it is closely associated with the action of soaps as protective colloids, to which property it appears probable their detergent nature is due. The speakers were unanimous in affirming the efficiency of the electrical method, first suggested by Clayton (Brit. Assoc. Colloid Reports, No. 2, p. 114, 1918), of ascertaining the point at which phase reversal takes place. A matter of considerable importance referred to by Prof. W. C. McC. Lewis, and agreed to by other speakers, was the necessity when studying the effects of electrolytes on colloids of employing solutions possessing the same conductivity rather than those of identical molar concentrations.

The discussion on the physical properties of elastic gels revealed how scanty is the present state of our knowledge of the mechanism of gel formation and the importance of further research in this direction. Mr. Hatschek emphasised the importance of an extended study of the mechanical properties of gels, which hitherto had been confined precticallv to gelatin, in which chemical complications may arise. A much more promising field presented itself in non-aqueous systems, *e.g.* vulcanised rubber in benzene. In an investigation into the mechanical properties of gelatin Mr. Hatschek had obtained the astonishing result that, after straining a rectangular prism of 10 per cent. gelatin gel for five days, not only had the stress practically disappeared, so that on removing the constraint the strain remained, but the optical anisotropy remained after removal of the stress.

Prof. Procter, in advocating his well-known solid-solution theory—which, he explained, differed from the sponge-like structure theory mainly on the question of size—pointed out that the difference was not unimportant, since microscopic size of network excludes or complicates the simple chemical causes which are sufficient for the solid-solution view. The opposite view involves a mechanical structure which itself demands explanation. Critics of the solid-solution theory, however, found it difficult to believe that a 1 per cent. agar gel is a solid solution, and Prof. Procter admitted that the case of agar presented great difficulties.

Some very important work relating to gel structure has been carried out in the laboratories of Prof. McBain at Bristol on soap solutions, which in Prof. McBain's opinion excludes the cellular-structure theory. It has been shown in his laboratory that a half-normal solution of sodium oleate could be made to exist in any one of three forms: (*a*) Transparent liquid (sol), (*b*) a jelly (gel), and (*c*) a curd. The sol and gel are absolutely identical in every respect except in mechanical properties. They display identity of Na-ion content, refractive index, osmotic pressure, and conductivity, so that it appears that the particles present are identical in the sol and gel. On the contrary, in the curd form some of the soap separates out into fibrils and the conductivity disappears, this process being analogous to crystallisation. Prof. McBain considered these results to bear out the view of Zsigmondy and others that the particles in both sol and gel exist in micellar form and are linked together in some way analogous to the structure of liquid crystals. An example of the extraordinary character of the sol-gel transformation was brought to notice by Prof. Svedberg. A non-aqueous gel was formed of cadmium in alcohol having a cadmium concentration of only 0·1 per cent., in which the slightest vibration was sufficient to break down the whole structure and change it to the sol state.

Sir Herbert Jackson, in opening up the subject of glass and pyrosols, expressed doubt, except perhaps in some cases of colouring, as to whether glass came within the domain of colloids. With good glasses ordinary methods of illumination failed to reveal the Tyndall phenomenon, this being visible only with very strong illumination. The figures obtained by etching glasses he considered to be merely surface-tension effects, and afforded no evidence whatever of the colloidal nature of glass. In regard to the colouring of glasses much research is needed into the conditions under which various colours are produced. Evidence was adduced by Sir Herbert which makes it appear probable that the colouring substances have specific effects, although pure diffraction effects depending on the sizes of particles undoubtedly exist.

Non-aqueous colloid systems were dealt with under three headings: (*a*) Nitro-cellulose, (*b*) Celluloid, and (*c*) Rubber. Sir Robert Robertson dealt with the colloidal properties of nitro-cellulose gelatinised by means of suitable solvents, which properties have an important bearing on the manufacture of propellants. Useful relationships had been established between the viscosities of solutions of cellulose, those of the resulting solutions of nitro-cellulose, and the mechanical properties of the final dried material. By controlling the viscosities of the solutions the required mechanical properties of the resultant dried nitro-cellulose mixtures were assured. In connection with celluloid the discussion centred largely around the solvent property of binary mixtures, such as ether-alcohol, which is very different from that of the constituents separately. The ether-alcohol complex theory originally put forward by Baker was largely criticised. The discussion on the colloidal properties of rubber was confined practically to a communication by Mr. B. D. Porritt, who, in describing the effects of light on rubber, emphasised the important part played in rubber deterioration by oxygen, both as a catalyst and by direct chemical action. The inclusion of a dye to absorb ultra-violet light helps to prevent the deterioration. Experiments on the sol-gel transformation produced in rubber solutions by light and oxygen were described.

Perhaps the most important paper of the whole discussion, in that it represented a distinct advance in theory, was that by Mr. J. N. Mukherjee in section (5). Starting with the view that the charge on a suspensoid particle is due to adsorption, arising from chemical forces, of the ion the particle has in common with the peptising or stabilising electrolyte, Mr. Mukherjee has deduced a relation between the "electrical adsorbability" of the oppositely charged ion of the precipitating electrolyte and its valency and mobility. This theory not only results in the same series of cations arranged in order of adsorbability as that for the precipitation of negatively charged suspensoids, but also agrees extremely well with the most trustworthy experimental results on electro-endosmose.

On the whole, it may be said that the discussion centred around the physical properties of colloids rather than around their industrial applications, which are complex. Advancement in our knowledge of colloids can be made only by simplifying experimental conditions as much as possible, and thence building up step by step to the more complex cases. The full report of the discussion will be published in due course by the Department of Scientific and Industrial Research, and should be read by all those who are interested in this fascinating subject.

University and Educational Intelligence.

BRISTOL.—At Congregation held on October 22 the honorary degree of M.A. was conferred on Mr. Avery Adams, who has held the office of secretary to the Bristol Education Committee for thirty-three years; Mr. G. H. Burkhardt, head of the North Wilts Secondary School and Technical Institution; and Mr. W. A. Knight, head of Sexey's School at Bruton, Somerset.

CAMBRIDGE.—The trustees of the Capt. Scott Memorial Polar Research Trust have offered the University a sum of 6000*l.* towards the provision of a suitable wing or annexe to a proposed new school of geography, the special wing to serve as a Polar research institute. There is a prospect of financial help towards the maintenance and upkeep of the institute from the same source. The institute is to act as a centre both for information on Polar matters and for the working up of results, and it is to include a Polar library, a museum of Polar equipment, a collection of biological and geological specimens, and a set of rooms for research work. Cambridge University is chosen for the site of the institute as a centre which has already proved itself friendly to such research; it contains a nucleus of Polar men able to use and take a keen interest in the department, and is likely to continue to produce men equipped with the necessary knowledge and spirit for further work in Polar regions. An appeal will shortly be issued for funds to endow the larger building required for geographical studies.

A committee at Cambridge has collected a fund to commemorate Sir James Frazer's great services to learning. It is proposed to endow a Frazer lectureship in social anthropology, the lecture to be given annually in rotation at Oxford, Cambridge, Glasgow, and Liverpool.

It is proposed to make Dr. Duckworth, of Jesus College, reader in human anatomy. Dr. T. J. I'A. Bromwich, of St. John's College, has been re-appointed University lecturer in mathematics. Prof. J. T. Wilson has been elected a fellow of St. John's College.

The vote on the proposed statute admitting women to membership of the University has been fixed for December 8.

MAJOR DAVID DAVIES, M.P., has given 12,500*l.* to found a chair of tuberculosis at the Welsh National Medical School, University of Wales.

FOUR free lectures on "Four Great Geometers" (Archimedes, Galileo, Newton, and Clerk Maxwell) are announced for delivery by Mr. W. D. Eggar at Gresham College, Basinghall Street, E.C.2, on November 16–19. The lecture hour is 6 o'clock.

THE sum of 425,000*l.* has been stated by Mr. H. A. L. Fisher, President of the Board of Education, in reply to a question in Parliament, to be the price which the Duke of Bedford and his trustees have agreed to accept for the Bloomsbury site offered by the Government to the Senate of the University of London.

NOTICE is given by the University of London of the award in 1921 of the 100*l.* Rogers prize, the subject for which is "Hyperthyroidism and its Surgical Treatment." Copies of the regulations governing the competition and information as to the date on which the essays must be received can be obtained from the Academic Registrar, University of London, South Kensington, S.W.7.

VISCOUNT HALDANE will deliver an address entitled "The Nationalisation of Universities" at a reunion of old students of the Royal College of Science on Tuesday next, November 9, at the Imperial College Union, Prince Consort Road, South Kensington, London, S.W.7. The president of the Old Students' Association, Sir Richard Gregory, will take the chair at 8 p.m. The address will be followed by discussion.

THE prospectus of the courses to be held at the Municipal College of Technology, Manchester, during the year 1920–21 has been issued. Full-time courses extending over three years, which lead to certificates and degrees, are provided in mechanical, electrical, and sanitary engineering, and in the chemical and textile industries. Another feature of the college is the provision of part-time day courses for engineers' and other apprentices whose employers allow them to devote one whole day per week to study. Part-time evening courses which extend over five years are also given for the purpose of training men for responsible posts in industrial affairs. Research and advanced study receive attention, and students are prepared in part-time classes for degrees at Manchester and London in natural and technological sciences. A new degree of Doctor of Philosophy has been instituted with the object of encouraging research; candidates for this degree must be graduates of a university who have pursued an approved course of advanced study or research in Manchester University for a period of at least two years, of which not more than one year may be spent in another approved institution. Details of the full-time courses are given, but for particulars of the part-time classes application should be made to the Registrar for the prospectus of the department concerned.

ON September 29 the executive of the Engineering Training Association met, by authority of the council of that body, to consider the transference of the work of the association to the Federation of British Industries or to the Engineering and National Employers' Federations. Representatives of these different bodies were present, and outlined the motives which induced their respective organisations to make the offer. Mr. Richmond, on behalf of the Engineering and National Employers' Federations, stated that the chief reason for his society's offer was the increasing frequency and the greater importance of training questions which occur in the agenda of the federation's conferences with Labour. Until now they had been satisfied with the work of the Engineering Training Association, but they felt that as the latter body was about to cease to be an independent unit they were in the best position to carry on its work without interfering with that of other organisations. Mr. Prescott, speaking for the Federation of British Industries, said that they were prepared to carry on the work of the Engineering Training Association if they were asked to do so, or to stand aside if they felt satisfied that the work would be done properly by someone else. The co-ordination of industrial education was part of the work of his body, but if he could receive assurances that the Engineering and National Employers' Federations would keep the educational section of the Federation of British Industries fully informed, and that the two societies would co-operate in the fullest possible way, he would be glad to withdraw the offer of the latter in favour of the Employers' Federation. After a discussion the executive of the Engineering Training Association decided to accept the offer of the Engineering and National Employers' Federations, and details of the transfer were delegated to the honorary organiser, Mr. A. E. Berriman.

Societies and Academies.

PARIS.

Academy of Sciences, October 11.—M. Henri Deslandres in the chair.—The president announced the death of Prof. Yves Delage.—G. **Bigourdan**: Corrections of the normal time-signals emitted by the Bureau international de l'Heure from January 1 to March 19, 1920. Two tables give corrections of the ordinary partly automatic signals and of the beats 1 and 300 of the scientific signals.—Y. **Delage**: The application of the Pitot tube to the determination of the velocity of ships and to the registration of the distances traversed. The Pitot tube has been much used for the determination of fluid velocities with respect to immersed solid objects; it can also be utilised to determine the velocity of an object moving in still water, and its application to the measurement of the speed of a vessel is described in the present communication. Various devices are given for working the indicator at a distance from the Pitot tube, for rendering the indications independent of the variations of the load of the vessel, and for arranging that the movements of the needle shall be proportional to V and not to V^2, so that from the continuous curve the total distance traversed can be estimated.—C. **Moureu** and G. **Mignonac**: The dehydrogenation of alcohols by catalytic oxidation under reduced pressure. The general method described in a previous paper for the preparation of aldehydes and ketones by the catalytic oxidation of the corresponding alcohols by air in presence of reduced silver gives excellent results for the alcohols of low molecular weight, but the yield diminishes as the molecular weight of the alcohol increases. By working under reduced pressure (20 mm. to 40 mm.) this difficulty is removed.—P. **Termier**: The mylonites of the fourth Briançon *écaille*.—The secretary announced the death of M. Daniel Pauline Œhlert, correspondant for the section of mineralogy.—A. **Chatelet**: The enumeration and constitution of any Abelian body whatever.—L. **Antoine**: The possibility of extending the homœomorphy of two figures to their vicinity.—J. **Andrade**: Friction and isochronism.—Ch. **Déné**: Waves of shock. The results of the study of a series of photographs of a stationary projectile placed in a stream of air moving at the rate of 450 metres per second. As the secondary waves are stationary, they can be more easily photographed and studied.—W. A. **Loth**: A new method of navigation, permitting any vessel to enter and leave our (French) ports without risk when the usual means of determining the route are missing. An armoured cable traversed by an alternating current with a musical frequency is laid on the sea-floor along the track to be followed, and a telephonic receiving apparatus of special design is carried by the entering vessel. One person without specialised knowledge can bring in a ship, as has been shown by practical trials at Brest.—R. **Dubrisay**: The application of a new method of physico-chemical volumetry. The solutions under examination are mixed with an equal volume of phenol and the temperature of miscibility is determined. The method has been applied to the study of mixtures of solutions of sulphuric acid and sodium hydroxide, and two angular points are shown on the experimental curve corresponding to the formation of $NaHSO_4$ and Na_2SO_4. It is noteworthy that when the neutralisation curve of sulphuric acid is followed by electrical conductivity or by cryoscopy no point corresponding to the formation of $NaHSO_4$ is detected.—P. **Bugnon**: Causes of the transversal course of the libero-ligneous bundles at the nodes of the Gramineæ.—C. **Beau**: The trophic *rôle* of the endophytes of orchids.—G. **Astre**: The biology of the molluscs in the French coast dunes and its relations with botanical geography. A discussion of the distribution of molluscs as affected by varying conditions of dryness. Apart from some secondary modifications of minor importance, the malacological fauna of the dunes is not one which has evolved in view of adaptation to a special medium, but a fauna already preadapted on the Mediterranean coasts, and which has simply extended its area of distribution.—P. **Wintrebert**: The aneural conduction of the ectoderm in the embryos of Amphibians.—M. **Caullery** and F. **Mesnil**: The existence of asexual multiplication in certain Sabellians (*Potamilla Torelli* and *Myxicola dinardensis*).—L. **Besson**: Relations between the meteorological elements and the number of deaths through inflammatory diseases of the respiratory organs in Paris. The data covered 522 weeks, and showed a clear relation between the number of deaths and the mean temperature three weeks before. From 0° C. to 14° C. the fall in the number of deaths was proportional to the rise in temperature. Above 20° C. the deaths remained constant and independent of the temperature.

HOBART.

Royal Society of Tasmania, September 13.—Mr. L. Rodway, vice-president, in the chair.—Dr. W. L. **Crowther**: The Tasmanian aborigines. The general habits of the race were traced and the osteology of the aborigines was described.—H. H. **Scott** and C. **Lord**: *Nototherium Mitchelli.* The apendicular skeleton, including the mamus and pes (hitherto unknown). The paper dealt in detail with the osteological formations of the feet of the Nototheria. After describing in detail the various characteristics of these and other portions of the specimen under review, the authors append various recapitulative notes on their studies to date. In the course of these they point out that their aim has been to show that the rhinoceros type was not absent from the fauna of Australia in ages past. True to the structural type of the country, the animals retained the marsupial habit, simply grafting on to it the results of that evolutionary trend that has culminated in other lands in the Perissodactylan lengulates. For the scientific use of the skeleton of *Nototherium Mitchelli* the authors are indebted to Mr. K. M. Harrisson, of Smithton, who generously placed the specimens at their disposal for the purpose named. Mr. Harrisson has also presented the whole of the remains to the Tasmanian Museum, Hobart, with a view to their future exhibition in that institution.—W. L. **Crowther** and C. **Lord**: A descriptive catalogue of the osteological specimens relating to *Homo tasmanensis* contained in the Tasmanian Museum. For their introductory remarks the authors state that during the course of the preparation of a paper dealing with certain recent valuable additions to the Tasmanian Museum it became necessary to revise the complete collection of the osteological specimens relating to the Tasmanian aboriginals. The present list forms a record of the largest single collection of osteological remains of the extinct Tasmanian aboriginals. The main portion of the paper deals with 361 osteological specimens relating to the Tasmanian aboriginals, each bone being described.
